On some displays, the ribbon cable is fastened to the display by a heat activated adhesive, called a "heat seal" for obvious reasons. Once you take the old one off it must be replaced with a new one. In my experience you cannot try and reattach it never works. There is a special tool made for doing this (attaching cable to display) that consists of an iron with a bar on the end (like a T), once seal is lined up you press bar onto tape for a second or two and its done, but its a one shot deal. I used to do quite a few when I worked for a company that repaired pocket organizers, lots of fun!!

Comments on soldered flex cables

(From: Ken Bouchard (bouchard@ime.net).)

These are the leading cause of problems for me! I repair camcorders for a living, and all too often have seen these flex cables fall off the PCB, or are so delicate in construction that they fall away from the PCB.

In many cases during repair stage, I often touch up the soldering with a low heat iron, while pressing down on the soldered to PCB area of the cable, with a flat plastic blade, enough to re-flow the connection. Then I take and apply some general purpose glue around the cable to get it to adhere better to the PCB and prevent tearing. Of course the consumer never should encounter a problem unless the camcorder is dropped, and the case splits open and rips the connectors away from the PCB.

Sony is infamous for having connectors fall off the boards. Many brands of camcorders are infamous for having connectors that mate 2 boards together break away from the PCB. It is a very bad situation because the boards they work with are very expensive to replace. For the cost of a simple piece of flex cable and 2 insertion force sockets, it is amazing they are cheap and choose to mate the boards together directly, knowing that failure is just around the corner!

Most commonly the CCD board or camera assembly is mated to the video (main) PCB in this fashion and it is very sad when they break due to stress. This is one reason that the consumer should never ever attempt to repair delicate items like this.

The best you can hope for in dealing with these is to never attempt to repair the flex cable by soldering to it, etc. That is asking for future problems at best...

Don't 'tin' the ends of the cable either, you simply melt and distort it so that it will no longer get a good connection into the socket. Only clean it possibly with denatured alcohol if needed - otherwise replace it.

Also do not stress them, you soon discover how easily they rip!

About elastomer ('zebra stripe') connectors

Remember that first (or last) digital watch you took apart? Remember how a little piece of rubber fell on the shag carpet and you thought: "What the heck, that can't be anything important". Remember how the watch's display never worked again? Well, you lost the connector that linked the LCD panel to the logic board.

Elastomer or 'zebra stripe' connectors are used to attach LCD panels to the logic board and interconnect multiple boards on digital watches, calculators, pocket computers, and many other modern gizmos. It seems as if every cheap and many not so cheap gadgets now uses this connector technology.

They can shift position, become dirty, and lose pressure due to warpage or damage to the plastic retainers. Very often, a weak display or missing segments can be traced to a problem with these 'zebra stripe' connectors. Equally often, disassembling, cleaning all parts with alcohol, drying, and reassembling will return the device to (better than) new condition. When installing, make sure the striped edges are against the circuit traces if there is any ambiguity.

Of course, it isn't that the zebra stripe shifts position a small amount - by its nature this should not matter. However, if the display shifts with respect to the circuit board contacts or the zebra stripe material becomes twisted or angled, poor and/or erratic connections will result.

(From: Spehro Pefhany (speff@gold.interlog.com).)

These are conductive elastomer connectors made from alternating layers of conductive (carbon filled) and insulating silicone rubber.

There are also lower resistance versions with embedded wires, but they are not used for LCD displays because the series resistance doesn't matter for LCD's.

Alignment to the PCB is critical as is even pressure, so they tend to be used only in high volume applications where a metal stamping or plastic molding is used to hold all the parts in place.

Identifying wiring on an auto radio/cassette

So you want to use your old car stereo as a boombox but don't have the connection information. Here is what I would do:

Locate the power - there will be a +12 switched and possibly a +12 unswitched for channel memory. At least one may be obvious if has an in-line fuse. Use an ohmmeter if necessary. Once you have found the power connections, power it from your 12 V power supply. Keep the volume way down and use the balance and fader controls to identify the speaker connections. There will be either 2 pairs of wires or more likely 4 pairs for front and rear speakers.

Ray's notes on plastic part repair

(From: Raymond Carlsen (rrcc@u.washington.edu).)

I recently had to repair a power supply for a camcorder. It was dropped. Parts of the case were broken, and the circuit board inside was cracked. Board repair was easy. I glued the PC back together with superglue and soldered across the broken traces with jumper wires.

The plastic case presented me with more of a challenge. Two little "ears" held the front end cap on the unit with small screws. The ears were broken into several pieces and could be heard rattling around inside the case. I could glue them back together, but the results have, in the past, been unreliable at best.

I decided to try and reinforce the plastic. I often melt solid hookup wire across a break (on the inside, where it doesn't show) with a soldering iron to strengthen a glued area, but these tabs were so small, any heat would warp them and the case would not fit back together. What to do?

I noticed once that when Superglue gets on ordinary notebook paper, it gets hard as a rock. It is difficult to tear, but is flexible enough to bend a little without breaking. Since one side of the little plastic ears were essentially flat, I superglued a strip of paper on each ear. The glue partially melted the plastic and made a good strong bond. After the glue set up, I trimmed the edges with an Xacto knife and poked holes in the paper for the mounting screws. The finished repair is stronger than the original product. The paper reinforcement is thin enough that there was no problem fitting the front back on the case.

Putting equipment into long term storage (Self-Stor, etc.)

Electronic equipment is happiest if kept in the same type of environment that humans like - moderate temperatures, low humidity. What if you are forced to store equipment for months or longer in a non-environmentally controlled space like a public storage facility?

Recommendations:

1. Find some long lost relatives who will store the electronics for you in a heated space.

If this is not possible:

2. Seal each piece of equipment in a thick plastic bag along with a pack of dessicant to keep it dry (that silica gel stuff you always throw away). This will preferably be in the original packing box (and include all cables, accessories, and manuals, so they won't get lost.)

Moisture is more of a problem than the absolute temperature (within reason) or temperature fluctuations. Therefore, avoiding the totally damp and dingy dungeon of a medieval castle is definitely desirable.

Dealing with a kit that was assembled by someone else a long long time ago

When you purchase a commercial piece of equipment, it is assumed that the construction has been done properly. This may not always be the case but it is more likely when a million of something is manufactured than a hand soldered kit possibly assembled by someone who barely knew which end of the soldering iron to hold!

I picked up a Heathkit DMM at a garage sale for next to nothing that had apparently never been quite completed. The problem turned out to be a defective rectifier in the power supply. However, everything else including the soldering was perfect. For kits, this may be the exception :-(. The original owner must have given up when the DMM didn't power up properly - and had no DMM to debug it with!

(Portions from: jmccarty@sun1307.spd.dsccc.com (Mike McCarty)

1. Look for improperly soldered joints. Kits often are soldered by people with, shall we say, less than completely optimal soldering skills. I have looked at kits I assembled when I was a teenager, and can't believe the joints were really that bad.

2. Clean any switches or other moving contacts with some good TV tuner cleaner.

3. Vacuum out any dust which may have accumulated. I prefer that to using compressed air, but you may use that also; be careful of compressed air which may come out with a high static charge.

4. Reseat socketed components and any boards with edge connectors. If the contacts look oxidized, clean them with a soft pencil eraser and/or contact cleaner. Look for loose spade connectors as well.

5. Check for loose screws or other fasteners and tighten if necessary.

6. Jiggle wires and look for corrosion/fatigued wires especially where flat ribbon type cables are used

7. Where something is more than 10 years old (in particular), it may be a good idea to check and/or just replace any electrolytic capacitors which may be drying out.

8. Replace any primary batteries after thoroughly cleaning the battery contacts. Depending on age and previous use types may also be bad as well. Discharged lead-acid types more than a year or two old are likely hopeless. However, I have found some NiCds that were quite old and perfectly fine.

9. Finally, if the equipment had possibly never been operational (i.e., you found the cover still in its protective plastic bag!), check ALL components for proper location and direction before applying power. Of course, it may already be too late if there was a part installed incorrectly and the original owner attempted to power it up.

Cleaning exterior surfaces

I usually start with soap and water or mild detergent. If this does not work, rubbing or 91% medicinal alcohol, 'Windex', and then, WD40 are tried. All of these are usually safe for plastics though some paints or printing may be affected - test on an inconspicuous area first. Scouring powder and/or sandpaper is only used as a last resort! :-) However, in some cases, where there is serious discoloration due to heat and ozone, these may prove somewhat effective...

One or more of the following will probably work even for tough tobacco smoke/tar buildup (also more in the next section, below):

(From: Terry DeWick (dewickt@esper.com).)

I have found plain household ammonia works well especially since it is cheap, if not available I use '409' or 'Fantastic' cleaners.

(From: Ralph Wade Phillips (ralphp@gcstation.net).)

'Scrubbing Bubbles' bathroom cleaner (Dow is the brand I use) works better than anything else I've found yet, besides chucking the case.

Be sure to follow with a decent Windex-like cleaner - the residue from the Dow cleaner will cause you to gasp every so often for the next six months!

(From: Joe (joeb@viaduct.custom.net).)

Go to SAM'S and get a jug of 'ENTNT'. Mix it in a spray bottle with water (I like about one part ENTNT to four parts water) and enjoy watching the nasty brown yuck drip off the monitor. Finish the job with windex to remove the residue from the ENTNT. The ENTNT is safe on plastic, but test it on painted surfaces first.

Eliminating tobacco smoke smell from electronic equipment

Of course, the best way to avoid this hassle is to not subject your equipment to second-hand smoke. However, where you picked up something at a garage sale or flea market, you its previous habits may have been out of your control!

CAUTION: Where an oven is suggested for drying, make sure it's temperature can be set low enough to avoid melting plastic and damaging sensitive electronic components!

(From: Hapticz (hapticz@email.msn.com).)

First, unplug it. then open it up as much as possible. get a spray bottle of Fantastic and cut the strength in half with water.

Put the thing over the kitchen sink and spray away. let it sit for a minute and watch the yellow nicotine crud slither out. repeat if necessary you shouldn't even have to do any scrubbing.

Avoid getting the stuff into inaccessible dial spaces, water spots are inevitable.

Then, and this is very important, use the sink spray to thoroughly, very thoroughly, rinse any hint of cleaner out. (it is NaOH, most all cleaners are)

Shake it off, spin it around, whatever, to remove excess water.

Heat your oven to 140 degrees F. put in oven for 2 to 3 hours. use some kind of metal cookie sheet between it and the oven elements to avoid radiant melting.

If it's got a lot of plastic, lower the heat to 120 and leave for 4 to 5 hours.

Hair dryers work well if you're willing to stand around for 2 hours.

It sounds weird, but it has worked very well for me on many items.

(From: Jerry Greeberg (jerryg50@hotmail.com).)

In the high end service industry boards are washed when serviced if the need arises.

You can use a mild soap. At home Fantastic will do the job for getting rid of cigarette stains and grimy dirt on boards. You will have to rinse them very well with water afterwords.

You can dry your boards in an oven at about 120 to 150 degrees F. But your home oven may be a bit too intense for this. The upper element tends to come on too strong at times because your oven was really made to work much higher.

You can shake off the boards and let them dry under some 60 watt lamps for a few days. Make sure they are not too hot on the boards. Do not exceed about 160 degrees F. average, or you can cause some damage.

It is very important that you let these boards be properly dried before putting the power back on them.

As for the case and non electronic pieces, you can also wash these... These must also be very dry before assembling. A drop of water on the electronics will cause you a lot of grief, and possible damage, if the power is turned on with wetness present.

I would say that you can do a mild cleanup by just blowing the boards off with forced air, and then gently cleaning things with Q-Tips, paper towels, and isopropyl alcohol.

It is extremely important that you do not disturb any trimmer adjustments, or devices that effect the alignment of the boards. you will never be able to get these adjustments back to their proper positions yourself without the proper test gear and facility setup.

You can take the case apart and wash all the non electrical parts with dish soap and water. Also these parts must be properly dried before assembling.

(From: John (jberenyi@tacisp.com).)

Well I tried it. Took the radio completely apart and soaked the boards with Scrubbing Bubble foam spray. Wow does it make aluminum shine and strip that nasty crap off the boards. A final clean with Windex and a clean rinse with distilled water is the final touch. Then I used compressed air to get most of the water removed. Next I got a cardboard box to put all the equipment in to and hooked up a 100 watt bulb and thermometer. I baked everything for 2 days at 130 degrees. Sure looks nice and works great!

When glue is more than glue

(From: Jim Leone (jim.leone@paonline.com).)

I have two words (no they are not plastics --- sam): Resistor Glue.

A lot of today's electronics manufacturers, before the printed circuit board goes through the flow solder machine, use a certain type of glue to hold down large components like heatsinks, electrolytic capacitors, and resistors. After 2 to 3+ years of life, bonded to a high temperature component, this glue turns conductive!!!!!!!

One blatant example of this is the Viewsonic (however many other manufacturers use the same type of stuff) 4e Model 7033 computer monitor where the 86VDC main rectifier on the switching supply has it's pins coated with this 'Resistor Glue'. When the monitor was new the glue has a tan color and kind of feels like really dried up chewing gum. You know, the kind that has been under a desk for 1 year. After about 2 years, the color has changed to a darker brown; it could be almond to dark walnut colored. Now you should be able to easily remove it by scraping it away with an Xacto knife, and it will crumble away.

However, in equipment left on 24 hours a day in moderate to high heat environments this glue takes on a more carbon hue. Typical units have holes burned right through the circuit board and others are left with carbon scarred 'divits' on the board that must be gouged out to keep the supply from arcing across.

On one hand, an optimist might say that this is a result of engineers who's goal was to get the product out before the deadline at the end of the month.

But on the other hand, a pessimist could say that this is a result of blatant planned obsolescence

Grounding of computer equipment:

While electronic equipment with 3 prong plugs will generally operate properly without an earth ground (you know, using those 3-2 prong adapters without attaching the ground wire/lug), there are 3 reasons why this is a bad idea:

1. Safety. The metal cases of computer equipment should be grounded so that it will trip a breaker or GFCI should an internal power supply short occur.

   The result can be a serious risk of shock that will go undetected until the wrong set of circumstances occur.

2. Line noise suppression. There are RLC filters in the power supplies of computer and peripheral equipment which bypass power supply noise to ground. Without a proper ground, these are largely ineffective.

   The result may be an increased number of crashes and lockups or just plain erratic wierd behavior.

3. Effectiveness of surge suppressors. There are surge suppression components inside PC power supplies and surge suppression outlet strips. Without a proper ground, H-G and N-G surge protection devices are not effective.

   The result may be increased hard failures due to line spikes and overvoltage events.

Specific Problems and Repairs

Classic ATT Touch Tone phone will not dial properly

Most electronic equipment over 20 years old would be history but many of these are still around and in service for a couple good reasons: They are very reliable, almost indestructible, and still have a solid feel rarely duplicated in modern phones. Typical symptoms are: Everything works fine except erratic or no dialing. For some buttons, dial tone would not go away. For others, tones would be accepted but will be erratic and result in incorrect digits. Certain digits may sound weak, wavery, or single frequency (rather than the proper DTMF dual tones).

(Note that this is not the same as the situation where the phone does not dial at all - there are no tones of any kind generated. In this case, the wires to the phone may simply be reversed - old ATT touch tone phones will not dial out if they are but will work in all other respects. Modern phones generally don't care about phone line polarity.)

While the internal wiring of these old phones is intimidating, the basic tone dialing circuitry is an amazing example of simplicity. About the only things that fail yet still permit some tone generation are the pot core coils that determine tone frequency. Therefore, this is the first thing to check.

There are two cores which each consist of two halves glued together. Breaks seem to be a common problem due to both the age and the brittle cement used on some revs of this model phone, and probably, as a result of rough treatment when hanging up the handset, or dropping or throwing of the desk phone.

These cores must be aligned before being glued back together. In addition, there is an adjustment plug which may need to be tweaked. I align by ear as follows: Put a known good tone dialing phone and the bad phone on the same phone line. Momentarily depress the hook switches to silence the dial tone. You will now have about 25 seconds before the nice polite operator recording tells you how to make a call. Depending on which core is bad, depress either an entire (same) row or column of buttons on both phones. (Adhesive tape is handy to hold down the buttons unless you have four hands.) By depressing the entire set of buttons, you are disabling the other tone generator so you hear a pure tone. Without turning the fine adjustment plug (assuming it was not disturbed; if it was, set it mid-range or the same as the one in the other core), rotate the loose core top until a zero beat is obtained. As your rotate the core, you will hear the pitch change. As it approaches the correct setting, you will hear the tones beat against each other. When you are set correctly, the pitches will be equal and the beat frequency will go to zero. Mark the position of the core with a pen or pencil and then glue with Epoxy or other general purpose adhesive (around the outside - not on the mating surfaces as this will affect the tone frequencies). After the glue sets, confirm and adjust the plug core if needed. These cores use a strange triangular core tool - I made mine by filing down an aluminum roofing nail (do not use a ferrous material).

These classic ATT Touch Tone phones are virtually indestructible. However, broken cores (or actually, just broken joints on the cores) are common but easily repaired once you know what to look for. Setting the tones by referencing a known good phone seems to be a very reliable technique as the zero beat permits an adjustment to better than .1%. Note that if the reference phone is a more modern (and flimsy digital one), then pushing multiple buttons may not work as it does with the old analog models. Setting the frequency using the normal dual tones will work - it is just not as easy.

ATT classic dial phone will not dial

I know, you haven't seen one of these in years, but I just had to throw this in.

Most likely it was dropped - these phones simply do not seem to fail any other way. When dropped, assuming there is no obvious damage, a little plastic stop inside the dial mechanism which is on a pivot flips the wrong way. This normally prevents dialing pulses from being generated when the dial returns to its home position but when flipped, prevents dialing totally. It is real easy to flip it back into place.

About those old battlewagon phones

(From: Author Unknown)

I got a hold of a couple of old rotary dial AT&T 500 sets with the old non-modular cords for both the coiled cord and wall cord. Man, I love these old clunkers because no one likes to steal them and they last just about forever. The reason they work well is that where I put them the people mostly just answer the phone so the dial doesn't make any diff. And since they are so big and clunky they tend to stay in one place.

I took the wall cord off and cut a hole in the back for the modular jack that I got over at Fry's for under a buck. They make it a whole lot easier to change the cord. But I haven't been able to find the same kind of jack for the four pin coiled handset cord. I also got some of the rubber ducky shoulder rest thingies over at Radio Shock, and before I put them on I decided to clean off the handle of the handset with rubbing alcohol. Man was I in for a surprise.

I started rubbing on the handle with a cotton ball and some alcohol, and all the paint started coming off. What a MESS. After I used a lot of cotton balls and rubbing alcohol on the whole handset, I got off most of the paint, but the screw on covers for the receiver and transmitters were different colors than the original beige, one was PINK! Weird. So now I have an even uglier rainbow phone! Cleanest phone in the neighborhood, though.

One of the phones looked like someone dropped something really heavy on it and the dial was loose from the base. So I had to drill out the rivets on the base and replace them with screws. Feels a whole lot better now. On another 2500 set, I had to take the touch tone pad apart and go in the bathroom and wash out all the dried up coke sugar goop that was in it, so now the buttons don't stick anymore. I had to take the keys out, but I couldn't remember which side the * and # went, so I had to cheat and peek at another phone. I also found out that the weird screws that hold the base to the cover are some odd screw thread like a #7 - 18 tpi.

One interesting thing is that the 500 and 2500 sets are made to compensate for the loop length. They have varistors inside, and they do a decent job. But it seems to me that the newer electronic phones don't do such a good job of this.

One thing I thought was really strange was the sticker on the bottom of the 2500 set. This is a AT&T 2500MMG set, and the sticker on the bottom says:

"WARNING: USE FOR BUSINESS SYSTEMS ONLY OR YOU RISK AN ELECTRICAL SHORT CIRCUIT"

I kind of think this is a put-on, since the phone works okay on a POTS line.

Jerrold 400 Cable Converter Problems

The following may also apply to other models of similar vintage (e..g, 440).

The most common symptoms for these cable boxes relate to their not staying on or acting erratically when the buttons are pressed. The causes are usually quite simple:

1. Cold solder joints around the power supply regulator ICs (on chassis heat sink).

2. Dried up main filter capacitors - two large electrolytics in power supply on main board.

Be careful disassembling the main board from the chassis as at least one of the regulator ICs clipped to the side of the chassis is insulated from this heatsink and the insulation is easily damaged.

One cause of a totally dead converter is a blown thermal fuse in the primary of the power transformer. It will be buried under the outer wrap inside the transformer, between the bobbin and core, or molded into the bobbin, but may be repairable. Test by jumpering around it. But for safety, install a replacement.

Original Nintendo console erratic or dead

While the original Nintendo game machine is a couple of generations out of date, many are still in use. And, hey, kids usually don't care.

The most common problem with these units is a worn or dirty cartridge connector. In this case, the red power/status light will continue to flash even after the RESET button is pressed with a game cartridge in place. Replacements are available for about $9 from the sources listed at the end of this document.

First, try another game cartridge - the one that is not working may just have dirty contacts or may be defective. Clean the contacts with a Qtip moistened with water followed by isopropyl alcohol. (The water will remove the sugar from the candy that may have made its way onto the connector.)

To get inside, you first remove the 6 screws on the bottom and then about 12 screws which fasten the circuit board and shield to the bottom of the case. (Note: there are two screws which are longer and silver colored - make sure they get back to their original location when you put everything back together.) Once all these screws are removed, the black connector can be slid off the edge finger on the circuit board Inspect these connections - they just may be a bit corroded or dirty. Use contact cleaner and/or a pencil eraser and see if that makes any difference. Use contact cleaner on the dual rows of fingers that connect to the game cartridge as well. A dental pick can be used to gently spread the fingers apart ever so slightly and thus improve the connection when the cartridge is inserted.

Even if this only makes a slight improvement - you can press down on the cartridge and the machine will respond to the RESET button - you have confirmed that the connector is indeed the problem. In many cases, just this cleaning will result in reliable operation for a long time to come.

Replacement connectors are under $10 from places like MCM Electronics and Dalbani.

Repairing Texas Instruments TI-5X calculators

I have them up through TI-57 so I don't know if the following applies to models higher than this (TI-58 and TI-59).

If it hasn't been used for a while (like 15 years?) then the NiCds are likely deader than a door nail and will not accept a charge since they are totally shorted. Bad NiCds is very likely all that is wrong with the calculator.

If your calculator has a pack that plugs in inside the back with 2 AA NiCds and some circuitry, then it is the same.

First crack open the pack by using a butter knife or similar instrument at the catches along the seam. You will see a pair of AA NiCds and a small circuit board. This is a DC-DC convertor which boosts the 2.4 V of the NiCds to about 10 V to operate the logic of the calculator.

Inspect the circuit board for corrosion and other obvious damage. Unless the calculator was stored in a damp area, it should be fine. The batteries will probably have crusty white stuff on the positive ends. They are bad. Don't even bother trying to zap them.

As a test, you can do either or both of the following:

1. Get a large electrolytic capacitor (e.g., 10,000 uF at 10 V) and put it in in place of the batteries. Observe polarity. Try out the calculator using the TI charger/adapter. Operations will be a bit flakey but should basically work (the capacitor, no matter how large, apparently will not substitute for the NiCds).

2. Unplug the TI battery pack and set it aside. Find a 9 V power supply or a 9V battery. Connect this to the red and black wires coming from the logic board connector which went to the battery pack. NOTE: the wire color coding is backwards on at least some of these. Black is positive for some reason. However, nothing disasterous happens if you connect it backwards as far as I can tell since I was testing it backwards for quite a while until I caught on. And, I thought TI was a real company!

If these tests are successful, the calculator is likely fine and you just need a new set of AA NiCds with solder tabs to make it as good as new.

Or, if you don't need the authenticity of a genuine TI form-and-function rechargeable battery pack, use a 9V AC adapter, 9V Alkaline, or 9V NiCd battery and charge it externally.

Some information (with photos) on battery packs for various TI calculators can be found at Datamath.org - Battery Packs. You'll find what you just read there as well. :)

Service Information

Determining belt type and size

Belts are normally specified by their cross section - square, flat, round, and their inside circumference (IC). The IC is used since it is virtually impossible to accurately measure the diameter of a belt.

Assuming you cannot locate an actual part number, determine the type of belt; square, flat, or round. If you do not have the old belt, this is usually obvious from the pulleys. Most small belts (as opposed to V-belts on 1 HP shop motors!) used in consumer electronic equipment are of square cross section though flat types are sometimes found in the main drives of VCRs, cassette/tape decks, and turntables (remember those?). Measure or estimate the thickness.

The IC is always specified with the belt fully relaxed. This can be measured by hooking the old belt on one end of a ruler and pulling it just tight enough so that it more or less flattens out. Read off the length, then double it for the IC. Get a new belt that is 5% or so smaller to account for the old one be somewhat stretched out. Of course, if the belt broke, measurement is real easy. Or, if you do not care about the old belt, just cut it and measure the total length.

If the old belt decomposed into a slimy glob of jellatinous black goop or is missing, you will need to use a string or fine wire around the appropriate pulleys to determine the IC. Reduce this by 10-25% for the replacement. Very often the match does not need to be exact in either thickness or length - particularly for long thin belts. A common rubber band may in fact work just as well for something like a tape counter!

However, there are cases where an exact match is critical - some VCRs and belt driven turntables or tape decks do require an exact replacement for certain drive belts but this is rare.

Some parts suppliers make determining replacement belts very easy with the PRB system in which the part number fully codes the shape, size, and thickness.

Making custom length rubber belts

The following will probably work for most drive belts except for those which are critical for accurate speed control in devices like cassette decks and turntables.

(From: Melissa & Jim (mgkepner@facstaff.wisc.edu).)

3M and Eastman make cyanoacrylate adhesives (super glue) that are specially made for making custom O-rings from linear stock. This seems to be exactly the same problem you are approaching. These glues work very well and produce a joint as strong as the base material, but without the need for the needle and thread. The joint can be made almost invisible. The only hard part is holding the pieces aligned while the glue cures, but in this case that is only seconds.

I have used a machinists steel V-block for this, but one of the O-ring manufacturers sells a plastic tool for exactly this purpose. In the US, I would check at a bearing supply house; they often carry O-ring supplies as well.

Rubber or elastic bands as drive belts?

It is 3 AM, you have finally removed the last of the 38 screws to access the tape transport in your Suprex Never-Forget model X4123 answering machine and what do you fine? A broken belt, of course! What to do?

As a test at least, a common elastic band may work. The recordings will likely have terrible wow and flutter but this will at least confirm that there is nothing else broken. In a pinch, this free solution can be left in place until a proper replacement arrives. This should work for many types of devices - CD players, VCRs, tape decks, etc. - where grooved pulleys are used and the belt is not called on to provide a great deal of power.

Identifying and replacing SMT devices

See the document: Surface Mount (SMD) Transistor/Diode Cross-reference. If this does not list your device or it is so fried that no markings survive, you can usually use some educated guesswork to select a suitable replacement. SMD types can usually be replaced with normal devices since there is usually sufficient space. If there are any other SMD parts with the identical marking, you should be able to determine pinout (e.g., BCE for transistors - see the document: Basic Testing of Semiconductor Devices) and replace with a general purpose non-SMD type. I doubt that the specifications of parts used in telephones or modems are critical. Even if there are no identical device, if you can determine the voltages on the pins, you may be able to guess the type. The worst that will likely happen if you are wrong is to blow your replacement device - anything that this will do the rest of the circuitry has already been done.

Interchangeability of components

The question often arises: If I cannot obtain an exact replacement or if I have a VCR, tape deck, or other equipment carcass gathering dust, or I just have some extra parts left over from a previous project, can I substitute a part that is not a precise match? Sometimes, this is simply desired to confirm a diagnosis and avoid the risk of ordering an expensive replacement and/or having to wait until it arrives.

For safety related items, the answer is generally NO - an exact replacement part is needed to maintain the specifications within acceptable limits with respect to line isolation, X-ray protection and to minimize fire hazards. However, these components are not very common in audio equipment or other consumer devices (other than TVs, monitors, and microwave ovens) except for possibly in their power supply.

For other components, whether a not quite identical substitute will work reliably or at all depends on many factors. Some designs are so carefully optimized for a particular part's specifications that an identical replacement is the way to return performance to factory new levels.

Here are some guidelines:

1. Fuses - exact same current rating and at least equal voltage rating. I have often soldered a normal 3AG size fuse onto a smaller blown 20 mm long fuse as a substitute. Also, they should be the same type - slow blow only if originally specified. A fuse with a faster response time may be used but it may blow when no faults actually exist.

2. Resistors, capacitors, inductors, diodes, switches, trimpots, lamps and LEDs, and other common parts - except for those specifically marked as safety-critical - substitution as long as the replacement part fits and specifications are met should be fine. It is best to use the same type - metal film resistor, for example. But for testing, even this is not a hard and fast rule and a carbon resistor should work just fine.

3. Potentiometers - user knobs usually control one or more of these. There are four considerations in

locating a suitable replacement: resistance, and taper, power rating, configuration, and mechanical fit. Configuration refers to the number of ganged pots, concentric knobs, etc. Matching this from your junk box may prove to be the toughest challenge! Many of the controls for audio equipment use what is known as an 'audio taper'. This means that the resistance change with knob rotation is not linear but is designed to produce a uniform incremental change in perceived volume, for example. Replacement with a linear taper pot will squish all of the effect towards one end of the range but it will still work. If measuring the resistance of a (good) potentiometer with its wiper set in the middle results in significantly different readings from center to each end, it is most likely an audio taper pot (though some other weird taper or other peculiarity is possible).

4. Rectifiers - many are of these are high efficiency and/or fast recovery types. Replacements should have equal or better PRV, If, and Tr specifications. For line rectifiers, 1N400x types can usually be used.

5. Transistors and thyristors (except power supply choppers) - substitutes will generally work as long as their specifications meet or exceed those of the original. For testing, it is usually ok to use types that do not quite meet all of these as long as the breakdown voltage and maximum current ratings are not exceeded. However, performance may not be quite as good. For power types, make sure to use a heatsink.

6. Switching power supply transistors - exact replacement is generally best but switchmode transistors that have specifications that are at least as good will work in many cases. See the documents: "Notes on the Troubleshooting and Repair of Television Sets", "Notes on the Troubleshooting and Repair of Computer and Video Monitors", and "Notes on the Troubleshooting and Repair of Small Switchmode Power Supplies" for more info.

7. Audio and erase heads - may be possible if the mountings are reasonably compatible. However, there could be other unknowns like coil impedance and drive requirements. The connectors are not likely to be similar either. There are usually significant differences in head configuration and mounting arrangement between 2 head, 3 head, and autoreverse cassette or open reel tape decks.

8. Motors - small PM motors may be substituted if they fit physically. Make sure you install for the correct direction of rotation (determined by polarity). Capstan motors - especially the direct drive type - are probably not interchangeable. However, generic speed regulated cassette drive motors are available.

9. Sensors - many are sufficiently similar to permit substitution.

10. Power transformers - in some cases, these may be sufficiently similar that a substitute will work. However, make sure you test for compatible output voltages to avoid damage to the regulator(s) and rest of the circuitry. Transformer current ratings as well as the current requirements of the equipment are often unknown, however.

11. Belts, tires, and pinch rollers - a close match may be good enough at least to confirm a problem or to use until the replacements arrives.

12. Mechanical parts like screws, flat and split washers, C- and E-clips, and springs - these can often be salvaged from another unit.

The following are usually custom parts and substitution of something from your junk box is unlikely to be successful even for testing: SMPS (power supply) transformers, interstage coils or transformers, microcontrollers, other custom programmed chips, display modules, and entire power supplies unless identical.

Why are there parts missing from my equipment?

It is not uncommon for parts to be missing from production equipment due to design changes or field mods. Thus, it may not mean anything. Inspect the solder pads - if they look the same as all the others, it was probably never installed in the first place. Of course, that could have been a manufacturing omission as well. Parts just don' jump ship without leaving evidence behind!

Don't be tempted to add a part just because there is an empty spot. In some cases, like the RCA TV that would tend to blow HOTs if the power failed, that would be a really bad idea and complicate your troubleshooting.

Whole blocks of circuitry are often left unpopulated on lower priced models. You didn't pay for those features. Sometimes, this can work to your advantage enabling you to upgrade to a fancier model for the cost of the parts.

Web resources

Radio Shack has a nice web resource and fax-back service. This is mostly for their equipment but some of it applies to other brands and there are diagrams which may be useful for other manufacturers' VCRs, TVs, CD players, camcorders, remote controls, and other devices:

- Radio Shack Product Support

Since Radio Shack does not manufacture its own equipment (I can tell this doesn't particularly surprise you!) - they are other brands with Realistic, Optimus, or other Radio Shack logos - your model may actually be covered. It may just take a little searching to find it.

Some general references

Here are some suggested titles that might be found in your local public library or a technical bookstore.

11. All Thumbs Guide to Telephones and Answering Machines
Gene B. Williams
TAB Books, Inc., 1993
Blue Ridge Summit, PA 17294-0214
ISBN 0-8306-4435-0 (paperback)

This one is very basic but does cover the most common problems and has illustrated instructions for general telephone wiring, adding extensions, answering machine cleaning, rubber parts, simple electronic problems, etc.

And, for that older audio equipment (including record changers):

12. Repairing Home Audio Systems
 E. Eugene Eckland
 McGraw-Hill Book Company, 1962
 Library of congress catalog number: 61-18021

Recommended parts suppliers

For general electronic components like resistors and capacitors, most electronics distributors will have a sufficient variety at reasonable cost. Even Radio Shack can be considered in a pinch.

However, for consumer electronic equipment repairs, places like Digikey, Allied, and Newark do not have the a variety of Japanese semiconductors like ICs and transistors or any components like tape heads or belts.

See the document: Major Service Parts Suppliers for some companies that I have used in the past and others that have been recommended. Also see the documents: Troubleshooting of Consumer Electronic Equipment.

DISCLAIMER

Working on VCRs entails a number of personal risks: electrical, mechanical, as well as the possibility of irreversible damage to the equipment and loss of irreplaceable recordings due to improper repair or adjustment.

We will not be responsible for damage to equipment, your ego, county wide power outages, spontaneously generated mini (or larger) black holes, planetary disruptions, or personal injury or worse that may result from the use of this material.

- Back to VCR Repair FAQ Table of Contents.

Introduction

Entertainment - then and now

Think back past 25 years. You went to the theater to see a movie. You watched TV programs when they were broadcast (there was no cable, remember?) or you missed them. TV studios and industry had video recording equipment but it was expensive and cumbersome. Little did you realize at the time, but after some false starts, the modern video revolution was about to be born. Are we better off? Whatever you decide, there is no going back. You may be able to leave your VCR's clock flashing 12:00 but you cannot escape the impact that this technology has had on so many aspects of your life.

The video cassette recorder is a wonderful example of extremely complex precision technology that has been made affordable through mass production. In general, it is usually quite reliable. Treat a modern VCR with a bit of respect and it will provide trouble free service for a long time. Unlike a TV where the power circuits take their toll on circuit components, the electronics in VCR are generally quite reliable and rarely fail. Most VCR problems are mechanical - dirt and dust in the tape path, deteriorated rubber parts, dried lubrication, wear of precision parts including the spinning video heads, and abuse caused by rocks, toys, and peanut butter and jelly sandwiches.

Scope of this document

This document was developed specifically for the troubleshooting and repair of VCRs using the VHS format. However, most of it also applies to Beta, 8 mm, 4 mm (DAT), and the industrial U-Matic formats as well. The basic tape related problems found in camcorders are also likely to be similar to those for full size VCRs. However, due to the miniaturization and difficulty in accessing internal parts of these units, troubleshooting and repair are generally much more difficult.

Note: Links to all the diagrams and photographs referenced from this document can be found in Sam's VCR FAQ Files.

VCR repair

Note: for VCR emergencies that just cannot wait, the solution may be found in the document: VCR First Aid and you may not need to read further. VCR First Aid deals with the half dozen or so acute VCR problems that may tempt you to throw something through the window - or worse.

Even if you are a technoklutz who lets your kids change the light bulbs in your house and would never consider tackling any actual repair or internal maintenance of your VCR, some basic awareness of the principles of video recording and the likely causes for common problems will enable you to intelligently deal with the service technician. You will be more likely to be able to recognize if you are being taken for a ride by a dishonest or just plain incompetent repair center. For example, did you know that one of the most dreaded of problems - the tape eating VCR - can often be remedied by a thorough cleaning and a 50 cent rubber tire?

This document will provide you with the knowledge to deal with over 85% of the problems you are likely to encounter with your VCRs. It will enable you to diagnose problems and in most cases, correct them as well. First and foremost are the techniques for cleaning of the tape path and replacement of rubber parts like belts, tires, and the pinch roller - the solution to many common problems with VCRs. With minor exceptions, specific manufacturers and models will not be covered as there are so many variations that such a treatment would require a huge and very detailed text. Rather, the most common problems will be addressed and enough basic principles of operation will be provided to enable you to narrow the problem down and likely determine a course of action for repair. In many cases, you will be able to do what is required for a fraction of the cost that would be charged by a repair center.

Should you still not be able to find a solution, you will have learned a great deal and be able to ask appropriate questions and supply relevant information if you decide to post to sci.electronics.repair. It will also be easier to do further research using a repair text such as the ones listed at the end of this document. In any case, you will have the satisfaction of knowing you did as much as you could before taking it in for professional repair. With your new-found knowledge, you will have the upper hand and will not easily be snowed by a dishonest or incompetent technician.

Repair or replace

While VCRs with new convenience features are constantly introduced, the basic function of playing a tape has not changed significantly in 25 years. Even the introduction of HQ about 15 years ago does not represent a dramatic improvement. Therefore, unless you really do need a quick start transport, a real-time counter, index search, or the like, repair may not be a bad idea. The older VCRs are built much more solidly than the $100 models of today. Even high-end VCRs may be built around a poorly designed transport and flimsy chassis. Many older VCRs - for example 10 year old Panasonic models (and their clones) can be kept functional - nearly indefinitely, it would seem - at minimal cost. The consensus of those in the business is generally that most newer VCRs are built to last through the warranty and then either be too expensive to repair or simply impossible to repair. However, there are still millions of middle age to older VCRs out there whose life could be greatly extended with a little tender loving care. If you buy a $79 K-Mart special, you get what you pay for. Don't expect it to last more than a year or so. However, if you have something that is a few years old, it may be well worth the effort to keep it going. As already noted, newer VCRs don't have significant picture or sound quality - they are just more cheaply made to optimize the manufacturer's bottom line.

If you need to send or take the VCR to a service center, even a simple repair could easily exceed half the cost of a new VCR. Service centers may charge up to $50 or more for providing an initial estimate of repair costs but this will usually be credited toward the total cost of the repair (of course, they may just jack this up to compensate for their bench time).

If you can do the repairs yourself, the equation changes dramatically as your parts costs will be 1/2 to 1/4 of what a professional will charge and of course your time is free. The educational aspects may also be appealing. You will learn a lot in the process. Thus, it may make sense to repair that old clunker so the kids will have their own VCR or you will have a convenient means of copying tapes (legally, of course).

BTW, if you ARE one of those individuals (and there are bucket loads) who doesn't bother (or doesn't know how) to set the clock on your VCR, there is a solution - at least the next time you need to purchase a new VCR. These machines search for a TV station that includes the time code in its transmission format (it is in the vertical blanking interval should you care) and automagically sets the VCR's clock from that information. There - no more flashing 12:00! Many VCRs have this feature nowadays.

- Back to VCR Repair FAQ Table of Contents.

Video Recording Technology

Helical scan video recording

Modern VCRs - both consumer and professional - are based on what is known as helical scan recording. The main technological challenge that confronted the designers of early video recording machines was achieving the necessary bandwidth - several MHz - to faithfully capture the high frequency video signal. The first such machines ran normal audio tape past stationary recording heads at high speed - 10s of feet per second - in an attempt to solve this problem. Needless to say, the mechanisms were complex, a finite length of tape could only record a few minutes of video, and the heads wore out almost as quickly. If anything - anything at all - went wrong with the tape transport, you were up to your eyeballs is spilled tape. An alternative technology was clearly needed.

Prior to practical video tape recording, the only way to preserve a TV show was to use special equipment that essentially made a film of it off of a video monitor. The quality of such recordings was not very good, editing was difficult, the film needed to be developed so playback was not immediate, and of course, the film could not be erased and reused.

The first successful commercial video tape recorder was introduced around 1956 with the Ampex Quadplex - a $50,000 machine using 2 inch open reel tape and a high speed spinning head with 4 pickups rotating across the tape. This event revolutionized commercial broadcasting. However, this technology was much too complex, cumbersome, and expensive for consumer use and has a number of technological disadvantages as well.

For a consumer video tape recorder to be successful it was felt that the following three major hurdles had to be overcome:

- Tape loading had to be simple and foolproof using a cassette - none of this open reel stuff.
- A cassette had to hold at least an hour of color video.
- The cost to the consumer had to be less than $1000 (1970's dollars!) for the machine and perhaps $20 per hour for the tape.

The rotating heads of the Quadplex machine provided the needed tape-head speed to achieve sufficient video bandwidth. However, the transport was much too complex for a consumer machine. Another disadvantage was that since a video frame consists of many adjacent tracks on the tape (16), special effects like stop motion as well as forward and reverse search were not possible without a frame store. While this would not be out of the question today, the cost of such a device in the 1950's would necessitate the consumer taking out a second mortgage to pay for it. Finally, the 2 inch wide format required too much tape for achieving a cost effective 1 hour program time and made the design of a manageable cassette an impossibility. A separate room would be needed to house a modest size video tape library!

Helical scan overcomes most of these problems. See: Helical Scan Video Head Assembly. Rather than scanning across the tape, the tape is wrapped a bit over 180 degrees around a rotating drum at a slight angle. Thus, successive tracks are written diagonally across the tape and can thus be much longer than the width of the tape as in the Quadplex. The tape, therefore can be rather narrow. The first helical scan tapes used a 1 inch format but narrower tape soon followed. The most common formats today are forms of VHS (and Beta) at 1/2", and 8 mm (mostly used for portable applications in camcorders and data storage.) 4 mm tape is used for high quality audio (DAT) as well as data storage.

VHS video

Most of the following discussion unless otherwise noted applies to the VHS format. Beta, which preceded VHS into the marketplace and which has all but disappeared for consumer VCRs is actually a somewhat better system technologically with superior picture quality. Physical tape format is similar to VHS but differs in the details. However, Sony's licensing practices with respect to Beta made it inevitable that VHS would triumph in the marketplace. Too bad in some ways. The 8 mm format, used mostly used nowadays in camcorders, is also helical scan but there are no separate audio and control tracks - they are part of the video track.

Each VHS track corresponds to 1 field of the interlaced video format. See: VHS Tape Format. Generally, two heads opposite each other on the rotating head drum are used. One rotation of the drum corresponds to a complete video frame with heads designated A and B for the even and odd fields respectively. What this also provides is the ability to easily implement a variety of special effects including freeze frame, and fully variable speed forward and reverse motion with a recognizable and in many cases, quite clear picture. With relatively minor restriction, this becomes as simple as moving the tape forward or backward or keeping it stationary.

For a not too terrible ASCII diagram and additional discussion, also see the section: VHS physical tape format

(Camcorders and other compact systems may use 2 pairs of identical heads where the opposing pairs are separated by 270 instead of 180 degrees. Physically, there are 4 heads spaced equally around a drum 2/3rds the size of the normal VHS drum. However, successive head in the sequence is 270 degrees apart. In other woeds, if the heads are numbered 1,2,3,4, they are used in the order: 1,4,3,2,1,4... This permits the use of a smaller, lighter video drum but the recorded format is identical.)

The A and B heads are not identical either. Their azimuth angle differs being +6 degrees for one and -6 degrees for the other. See: VHS Video Head Pair Azimuth Angles. This is one of several techniques used to minimize crosstalk between adjacent tracks. Azimuth angle is how far the head gap is from being perfectly perpendicular to the direction of tape-tape motion. For example, a head with an azimuth such as / will ignore most of the information recorded with an azimuth of \.

Note that the head gap - the distance between pole pieces - is on the order of 1 um - 1/25,000 of an inch. As a point of reference, a human red blood cell is about 7 um in diameter and an average sheet of typing paper is about 100 um in thickness. The gap is filled with a nonmagnetic material to prevent it from getting clogged and to force the magnetic flux out of the head structure and into the tape magnetic coating. This remarkably fine spacing is necessary to achieve the multimegahertz video bandwidth.

Actual tape motion for a VCR is remarkably slow. To someone familiar with audio decks, the tape in a VCR even at SP speed (the fastest) seems to be crawling along. Their first reaction is often one of: "there must be something wrong as the tape is moving sooo slooowly." Nope, just amazing technology. The SP speed of a VHS VCR corresponds to a linear tape speed of only 1-5/16 ips - slower than for an audio cassette deck (1-7/8" ips). EP speed is 1/3 of this - 7/16 ips. However, the effective tape speed as seen by the video heads is over 15 feet per second due to the spinning video head drum.

The luminance (Y) and color (C) components of the composite video signal are recorded differently. Luminance, which is in effect the black and white picture with all the high resolution components but no color, is frequency modulated on a carrier at around 3.4 MHz. The deviation is about 1 Mhz and the maximum frequency recorded on a VHS tape is a little over 5 Mhz (Beta is slightly different and S versions of Beta and VHS extend some of these to achieve higher bandwidths. The color signal is separated from the composite video and is amplitude modulated on a 629 kHz carrier. This is called the color under' system. The 'U' in U-Matic, a very popular industrial VCR 3/4" format (which predates Beta and VHS and is still in use) stands for this.

VHS audio

Sound for the VHS format is not merged into the video signal on the tape. For non-HiFi VHS VCRs, a separate stationary tape head is responsible for the audio signal. Due to the very slow tape speed, audio quality is not even comparable to a cheap audio cassette player even at the SP speed. VHS HiFi overcomes this by FM recording of the audio signal deep in the tape (recorded by a separate set of HiFi heads just before the video information), actually buried under the video information. The left and right audio channels are recorded in separate frequency bands - centered around 1.3 and 1.7 Mhz respectively. The azimuth angles for the HiFi audio heads are +/- 30 degrees which minimizes crosstalk between the recorded HiFi audio and video information.

Since the head-tape speed for the VHS audio track is the same high rate as for the video track and exceeds that of a typical audio cassette deck by a factor of more than 100, VHS HiFi audio reproduction - frequency response, signal to noise ratio, and dynamic range - is excellent and approaches that of a CD. In fact, using a T120 video cassette in EP (SLP, 6 hour) mode simply to record stereo music (with the video ignored or blanked) is extremely cost effective. What other media/technology will store a 6 hour concert with nearly perfect reproduction for under $2? (Note: if you do this, some VCRs will require some kind of video input to maintain stable tape speed. You can just ignore the video portion on audio playback.)

There are two disadvantages to VHS HiFi, however: (1) there may be some degradation of video quality due to unavoidable interactions with the buried audio, and (2) it is not possible to rerecord (dub) only the audio without disturbing the video. The only way to do this without copying the video to another tape would be to read out the video and hold it temperorily in a double buffered frame store for subsequent recording back onto the tape after the new video was laid down. However, this would put the video 1 frame behind where it was thus complicating the situation. So, audio dubbing simply isn't supported.

Beta and 8 mm audio

Like VHS, Beta has both linear and HiFi audio but in that system, the HiFi audio signal is actually recorded and played back via the video heads and uses a portion of the frequency spectrum to fit it in with the video information.

With 8 mm, there is no separate linear audio track - all audio is HiFi using the spinning video heads.

More information on video formats

See the following for additional information on these and other video formats.

- Tomi Engdali's Video Recording Formats Page.
- Leopold's Home Video Formats Page.

VCR servo systems

Linear tape motion and head drum rotation must be precisely synchronized during record, play, and special effects play modes. The general functioning is similar for all but the source of the basic reference signal differs for play and record. Some of the specific relationships may differ depending on the specific VCR design.

Record: reference signal is vertical sync pulse from video input:

- Head drum rotation is phase locked to vertical sync pulse so that appropriate head (of the A-B pair) is in contact with the tape during the appropriate video field.
- The speed of the capstan which moves the tape through the transport is also locked to the vertical sync pulses so that the selected linear tape speed (SP, LP, EP) is maintained.
- Control pulses (30 Hz for US NTSC) are recorded along the bottom edge of the tape by a stationary control head.

Play: reference signal is timing pulse derived from quartz oscillator:

- Capstan rotation speed is locked to a 30 Hz pulse derived from a precise quartz crystal oscillator. Head drum rotation is phase locked to the control pulses now being read off of the tape by the Control head.
- The tracking control is used to adjust the relative phase of the head drum with respect to the control pulses. This permits the head path across the tape to be aligned with the actual recorded tracks.

Video special effects

For CUE (fast play forward) and REV (fast play reverse), the capstan speed is phase locked to a multiple of the control track. Since the video heads are crossing multiple tracks during these modes, some noise bars are unavoidable. At SP speed, special wide or dual azimuth heads are required to minimize this degradation. Thus, only 4 head VCRs can play SP tapes at fast speeds with minimal noise. With EP speed, the tracks actually overlap and a normal video head is wide enough to pick up enough signal from adjacent tracks to produce a mostly noise free picture. Due to the way adjacent tracks line up with LP speed, most of these special effects cannot be used due to serious tearing of the picture. The sophisticated processing needed for proper support at LP speed is generally not included in modern VCRs due to the apparent lack of interest in the LP speed (recording support at LP speed seems to be absent in more and more newer VCRs though they will all play back LP tapes at normal playback speed).

Really slow speed is usually implemented as a variable frame advance with the tape fully stopping between frames. Special sets of video heads provide the best quality. Freeze frame (PAUSE) uses the same set of heads. As with CUE and REV, acceptable picture quality is provided even with a 2-head VCR for EP speed recorded tapes. In all cases, picture quality can be further improved through the use of a digital frame store.

Note that the servo systems in consumer VCRs are rarely precise enough to implement the kind of instantaneous forward or reverse frame advance that is present in high performance (and high cost) editing decks having jog shuttle knobs with instantaneous and precise response.

For more information on VCR and related technology

The books listed in the section: Popular books on VCR maintenance and repair include additional information on the theory and implementation of the technology of video recording and VCRs.

Philips/Magnavox used to have a very nice on-line introduction to a variety of consumer electronics technologies. Although their site has disappeared - and even people who work for them have no clue - I have now recovered several of the articles including those on TVs, VCRs, camcorders, satellite reception, and connections. See the Introductory Consumer Electronics Technology Series.

Also check out:

- The How Stuff Works Web site has some really nice introductory material (with graphics) on a variety of topics relating to technology in the modern world. Of relevance to this document are articles on VCRs (including the tape cassette), motors, remote controls, etc.
- The Video Cassette Recorder (U. Dayton CPS460 notes).
- An Introduction to VCRs is really only a summary but it does include some diagrams which may useful.
- EE498 Final Project: Disassembly and Inspection of a VCR includes some descriptions, photos, and diagrams which may be helpful, or at least amuzing!
- For some information on helical scan audio and data recording, see: Sprague's Technical Library.
- Tim Stoffel's Videotape Systems Theory includes history as well as some of the newest digital formats.

- NTSC Television Tutorials by Williamson Labs has many diagrams with a bit of text on their site. It looks like they are really trying to sell stuff including a CDROM but the graphics are worth checking out. While this is more of a TV site, there are some slides with VCR related information.

- Ronald's VCR Knowledge Page includes many nice diagrams of VCR basics and scope photos of video signals for normal, CUE/REV, and still frame operation.

On-line tech-tips databases

A number of organizations have compiled databases covering thousands of common problems with VCRs, TVs, computer monitors, and other electronic equipment. Most charge for their information but a few, accessible via the Internet, are either free or have a very minimal monthly or per-case fee. In other cases, a limited but still useful subset of the for-fee database is freely available.

A tech-tips database is a collection of problems and solutions accumulated by the organization providing the information or other sources based on actual repair experiences and case histories. Since the identical failures often occur at some point in a large percentage of a given model or product line, checking out a tech-tips database may quickly identify your problem and solution.

In that case, you can greatly simplify your troubleshooting or at least confirm a diagnosis before ordering parts. My only reservation with respect to tech-tips databases in general - this has nothing to do with any one in particular - is that symptoms can sometimes be deceiving and a solution that works in one instance may not apply to your specific problem. Therefore, an understanding of the hows and whys of the equipment along with some good old fashioned testing is highly desirable to minimize the risk of replacing parts that turn out not to be bad.

The other disadvantage - at least from one point of view - is that you do not learn much by just following a procedure developed by others. There is no explanation of how the original diagnosis was determined or what may have caused the failure in the first place. Nor is there likely to be any list of other components that may have been affected by overstress and may fail in the future. Replacing Q701 and C725 may get your equipment going again but this will not help you to repair a different model in the future.

Please see the document: On-Line Tech-Tips Databases for the most up to date compilation of these resources for TVs, VCRs, computer monitors, and other consumer electronic equipment.

A site to rival this one - but WITH a tech-tips database and nice graphics

Check out:

- http://www.fixer.com/ (Fixer.com - VCR Repair and Tech-Tips Database)

This site includes a relatively short but fairly complete VCR repair guide that covers most of the common classes of problems - with nice diagrams to help with the explanations.

The VCR-only tech-tips database is clearly indexed by manufacturer and model number. Every repair includes a level-of-difficulty rating - which is handy! Many include layout and parts placement diagrams as well.

The developers of this site also sell a variety of generic VCR repair parts, tools, and TV remote controls.

My only real complaint is with respect to the annoying flipping banner at the top of their main pages! :-(

VCR Placement, Preventive Maintenance, and Rental Tapes

General VCR placement considerations

Proper care of a VCR does not require much. Following the recommendations below will assure long life and minimize repairs.

* Allow adequate ventilation - VCRs are not huge users of power but there is some heat buildup nonetheless. Leave at least 1-1.5 inches around all sides and top for air circulation. Try not to place the VCR near heat producing equipment.

* Do not put anything on top of the VCR that might block the ventilation grill. To be safe, don't put anything on top - period. Tapes are especially bad - for the tapes - as the heat and possible magnetic fields in the vicinity will tend to age them prematurely.

  In addition, modern VCRs are NOT built like the Brooklyn Bridge! The weight of a TV or stereo components could affect the VCR mechanically, messing up tape path alignment or worse.

* If possible, locate the VCR away from the TV. Some VCRs are particularly sensitive to interference from the TV's circuitry and while this won't usually damage anything, it may make for less than optimal performance.

* Don't locate VCRs in dusty areas if possible. Consider the use of a dust cover when not actually being used if you have no choice of location.

* Don't locate VCRs in areas of high (tobacco) smoke or cooking grease vapors. I cannot force you to quit smoking, but it is amazing how much disgusting difficult to remove brown grime is deposited on sensitive electronic equipment in short order from this habit.

* Make sure all input-output video and audio connections are tight and secure to minimize intermittent or noisy pictures and sound.

* Finally, store video cassettes well away from all electronic equipment including and especially loudspeakers. Heat and magnetic fields will rapidly turn your priceless video collection into so much trash. It is also recommended that you store the cassettes on edge so that the tape edges are not subject to pressing against the case and that you run them through a VCR or winder/rewinder from start to end and back on FF/REW at least once a year (another pair of recommendations that are rarely followed).

Video tape quality

> "What are the 'good' and 'bad' brands of videotapes (T-120)? Are the 'extra' or "high" grades really better?"

I would avoid brands you never heard of. K-mart brand, Recoton(sp), the street vendor from whom you buy Chinese food, whatever.

Higher grade tapes are not necessarily worth the expense but in my experience with some like Maxell and Scotch, going one level up from the cheapest is worthwhile and results in a noticeably better picture.

Only a few companies actually manufacture the raw tape stock. For what it's worth (FWIW), I have used Scotch in the past. It was inexpensive and the quality was good and consistent. I haven't purchased video tape in quite awhile now so I do not know if this is still true (Winter 2003).

The higher grade tapes may actually be harder on the video heads due to their formulation but this probably doesn't matter for the ordinary user.. You don't need HiFi grade tapes for HiFi - any tape will work. However, higher grade tapes may last longer with higher quality results in demanding situations like 24 hour a say security monitoring.

Consumer Reports does a review every so often, check back issues. I believe their conclusions were generally to buy name brands by price. Whether you believe in Consumer Reports or not, checking their ratings at least gives you an additional data point.

How long do video tapes last?

(From: Raymond Carlsen (rrcc@u.washington.edu).)

I have not seen any "official" guidelines on tape longevity for a long time, since the Beta days. Use of old tapes will not generally ruin video heads but may clog them. Proper manual cleaning restores normal operation.

Your mileage really depends on several factors, the most important being the conditions under which it's used. I've seen VCRs that can chew up a tape in one or two passes and make it unusable. High humidity and heat will cause tapes to stick to the head drum and wear prematurely. Shuttling tapes back and forth and leaving them sit in pause (on one spot) can accelerate wear.

Under ideal conditions: clean machine in good alignment running a tape from beginning to end without stopping is as good as you're going to get. Alignment tape manufacturers used to indicate expected life as the "number of passes". No significant degradation in 50 passes, but after that, dropouts become obvious. Maximum life is 200 passes. At that point, the tape is starting to break down with oxide particles being shed onto the heads (actually happens with all tapes to some degree) causing head clogging. With tapes of any age, a liquid spill such as soda pop ends the game right there. It can be cleaned, but unless it's your precious home movies, forget it.

I would use a tape until the dropouts become annoying. Dropouts are places on the tape where the oxide is missing. You'll see them more at the beginning of a tape where it's mechanically stressed by loading and unloading. A lateral scratch on a tape (caused by buildup of gunk in a VCR) will show up as a 3 or 4 line continuous dropout somewhere on the screen. Look at some heavily used rental tapes and you'll get the idea. So, bottom line: use it until it shows it's age. :)

Preventive maintenance

You no doubt have heard that a VCR should be cleaned and checked periodically. This is basically good advice but few people actually do follow it. I cannot give a specific schedule to follow as many factors influence the amount of wear and tear on your VCR:

- If you mostly use new brand-name tapes to make your own recordings, rarely play rental tapes, and have the VCR located in a clean cool relatively dust free and smoke free location, you may be able to go 5 years with no problems. However, a more prudent interval would be 1-2 years between preventive maintenance and rubber replacement after 4-5 years. Obviously, if you time shift every evening or have frequent marathon viewing parties you should probably reduce the PM interval.

- If you play rental movies every weekend or older tapes and have chain smokers in the house, every 3 months may not be frequent enough. I would suggest 6 months to 1 year between preventive maintenance and rubber replacement after 3-4 years.

If you want some guidelines, see the next section: Sample VCR preventive maintenance schedule.

Realistically, you are not going to do any PM anyway. So, just be aware of the types of symptoms that would be indications of the need for cleaning or other preventive or corrective maintenance - erratic loading, need to convince the VCR to perform certain operations, whirring motors without completing cycle, VCR taking longer to go into or out of a particular mode than you recall, jittery or noisy picture, or wavering or muddy sound. If your inspection reveals deteriorated rubber parts, obviously these should be replaced regardless of their age.

Of course, acute symptoms like a tape jam or tape munching episode is a sign of the need for emergency treatment. This still may mean that a thorough cleaning is all that is needed.

I generally don't consider cleaning tapes to be of much value for preventive maintenance since they do not run long enough or with enough force to clean the rollers, stationary heads, and guide posts. Also, the dry type, in particular, are abrasive and frequent use may cause premature wear to the expensive video heads.

The following are some reasons to inspect and clean a VCR periodically:

- This will maintain performance at factory new levels. Dirt, dust, and shed tape oxide all contribute to a reduction in stable tape movement and possible problems with noisy or jumping pictures and muddy or wavering sound.

- Dirt, dust, and other crud can be deposited on the tapes you run through the VCR contaminating them and passing problems on to this or other VCRs in the future.

- Your inspection will reveal if service parts like belts, tires, the pinch roller, etc. are in good conditions so that future surprises will be minimized.

If you follow the instructions in the section: General guide to VCR cleaning and rubber parts replacement, there is minimal risk to the VCR. However, don't go overboard. If the belts are in good condition (by appearance and stretch test), just clean them or leave them alone. This is especially true in the (generally infrequent) designs of some models of VCR tape transports where significant disassembly is required to replace a belt. In this situation, you risk not being able to put everything back the way it was. Most belts can be replaced with little or no disassembly beyond removing the top and bottom covers and possibly any circuit boards that may be in the way, Sometimes one or two additional screws will need to be loosened or removed to move a bracket or shield.

Sample VCR preventive maintenance schedule

Here is an example of the recommended inspection, lubrication, and replacement schedule for a typical VCR as provided by the manufacturer. This is from the Sams VCRfact for a particular non-HiFi RCA VCR. I am providing this for information only and am not necessarily recommending these or other similar hard and fast rules for VCR preventive maintenance.

It is not clear here what a 'tape' is though the comments that go along with this table seem to indicate that it means a T120. However, parts that deal with tape loading are affected not by how long a tape is played but by the number of loading cycles. Wear on the video heads, on the other hand is strictly a function of play/record time. Wear of the A/C and erase heads depends on both time and tape speed. Thus, these are additional reasons not to take the numbers below too literally.

```
  After         What to do                       Which parts
------------------------------------------------------------------------------
250 tapes         Clean         A/C head, capstan, erase head, pinch roller,
                                 impedance roller, supply reel table, takeup
                                 reel table, video heads.

500 tapes        Replace        Video heads (upper cylinder).

750 tapes        Replace        Pinch roller

1000 tapes       Grease         Loading cam gears, impedance roller shaft,
                                 roller guide tracks.

                   Oil          Supply reel shaft, takeup reel shaft.

                 Replace        Reel belt, loading motor belt, main brake
                                 spring, main brake arms (left and right).

2000 tapes       Replace        A/C head, erase head, supply reel table,
                                 takeup reel table.

2500 tapes       Replace        Cylinder unit.
```

Rental tape considerations

It would be nice for your VCR if rental movies had never been invented. You have no idea of the history of any tape you bring home. The following may also apply to tapes in your video library or tapes given to you by friends or relatives:

- The tape may be old and old tapes shed a lot more oxide and crud than newer tapes. A single playing may clog your video heads.

- The tape may have been damaged by a prior viewing and one pass through may ruin your expensive video heads. A tape that has been seriously crinkled due to a VCR tape eating incident and then wound back into the cassette may be a ticking time bomb for your VCR. A tape with a partial break or one that has been improperly spliced is even more likely to cause serious damage. Do not splice tapes - see the section: Recovering damaged or broken tapes.

- The cassette mechanism itself may have been damaged (from being dropped or stored in a hot automobile) with unknown consequences for your VCR.

Note: if you should ever damage a rental tape as a result of a cranky VCR or for any other reason, don't just give it back to the video store. Please let them know. Also, if your VCR should jam with a tape inside, do not forcibly extract it - read the appropriate sections later in this document. If in doubt, let the video store know what happened and follow their recommendations.

Given that you are not likely to give up the movie couch potato addiction, some problems can be avoided by fast forwarding a couple of minutes into the tape before hitting PLAY. Damage to rental tapes often occurs near the start - and this will avoid some of the useless coming attractions as well!

If you notice the video breaking up or deteriorating while you are watching, immediately ejecting the tape may be the most prudent option since the worst may be yet to come!

While I cannot control your viewing habits, playing a lot of old, dirty, deteriorated tapes (rental or from your own tape library) will eventually take a toll on your VCR. At the very least, you should perform a general cleaning and inspection at more frequent intervals.

(From: Jim Lagerkvist (jlager@tir.com).)

Renting a video tape has all the same potential consequences as renting a hooker. That tape may pass to your machine anything from pizza grease to splices made from duct tape or staples. I keep two VCRs in my house. One for rental tapes and another for known trusted tapes.

VCR Maintenance and Troubleshooting Guide

Safety

Once you remove the cover(s) of a VCR (ignoring the warnings about no user serviceable parts, etc.), there are some risks to you and your VCR. You also, of course, void the warranty (at least in principle). Therefore, if the unit is still under warranty, having it serviced professionally may be your wisest option.

Stay away from the line side of the power supply - put electrical tape over the exposed connections. To be doubly sure, tape a piece of cardboard or thick plastic over the power supply section. Other than that, there is more danger of damaging the VCR by accidentally shorting something out or breaking a little plastic doodad than of you getting hurt.

- Don't wear any jewelry or other articles that could accidentally contact circuitry and conduct current, or get caught in moving parts (protect long hair as well).
- If circuit boards need to be removed from their mountings, put insulating material between the boards and anything they may short to. Hold them in place with string or electrical tape. Prop them up with insulation sticks - plastic or wood.
- Connect/disconnect any test leads with the equipment unpowered and unplugged. Use clip leads or solder temporary wires to reach cramped locations or difficult to access locations.
- If you must probe live, put electrical tape over all but the last 1/16" of the test probes to avoid the possibility of an accidental short which could cause damage to various components. Clip the reference end of the meter or scope to the appropriate ground return.

- Perform as many tests as possible with power off and the equipment unplugged. For example, the semiconductors in the switching power supply of a VCR can be tested for shorts and the fusable resistors can be tested for opens.

- If you need to probe, solder, or otherwise touch circuits in a switching power supply with the power off, discharge (across) large power supply filter capacitors with a 2 W or greater 20-100K resistor and then verify with your voltmeter.

- The use of GFCI (Ground Fault Circuit Interrupter) protected outlet is a good idea but will not protect you from shock from many points in a line connected power supply. A circuit breaker is too slow and insensitive to provide any protection for you or in many cases, your equipment. A GFCI may prevent your scope probe ground from melting should you accidentally connect it to a live circuit, however.

- Don't attempt repair work when you are tired. Not only will you be more careless, but your primary diagnostic tool - deductive reasoning - will not be operating at full capacity.

- Finally, never assume anything without checking it out for yourself! Don't take shortcuts!

Troubleshooting tips

Many problems have simple solutions. Don't immediately assume that your problem is some combination of esoteric complex convoluted failures. For a VCR, it may just be a bad belt or an experiment in rock placement by your 3-year old. Try to remember that the problems with the most catastrophic impact on operation (a VCR that eats tapes) usually have the simplest solutions (replace the idler tire). The kind of problems we would like to avoid at all costs are the ones that are intermittent or difficult to reproduce: the occasional interference or a VCR that sometimes will not record your favorite soaps on alternate Thursdays before a full moon.

If you get stuck, sleep on it. Sometimes, just letting the problem bounce around in your head will lead to a different more successful approach or solution. Don't work when you are really tired - it is both dangerous and mostly non-productive (or possibly destructive).

Whenever working on precision equipment, make copious notes and diagrams. You will be eternally grateful when the time comes to reassemble the unit. Most connectors are keyed against incorrect insertion or interchange of cables, but not always. Apparently identical screws may be of differing lengths or have slightly different thread types. Little parts may fit in more than one place or orientation. Etc. Etc.

Pill bottles, film canisters, and plastic ice cube trays come in handy for sorting and storing screws and other small parts after disassembly.

Select a work area which is well lighted and where dropped parts can be located - not on a deep pile shag rug. Something like a large plastic tray with a slight lip may come in handy as it prevents small parts from rolling off of the work table. The best location will also be relatively dust free and allow you to suspend your troubleshooting to eat or sleep or think without having to pile everything into a cardboard box for storage.

Another consideration is ESD - Electro-Static Discharge. The electronic components in a VCR are vulnerable to ESD. There is no need to go overboard but taking reasonable precautions such as getting into the habit of touching the chassis first before any of the electronic components is a good practice. The use of an antistatic wrist strap would be further insurance.

A basic set of precision hand tools will be all you need to disassemble a VCR and perform most adjustments. These do not need to be really expensive but poor quality tools are worse than useless and can cause damage. Needed tools include a selection of Philips and straight blade screwdrivers, needlenose pliers, wire cutters, tweezers, and dental picks. A jeweler's screwdriver set is a must particularly if you are working on a portable VCR or camcorder. For adjustments, a miniature (1/16" blade) screwdriver with a non-metallic tip is desirable both to prevent the presence of metal from altering the electrical properties of the circuit and to minimize the possibility of shorting something from accidental contact with the circuitry.

You should not need any VCR specific tools with the possible exception of a miniature metric hex key wrench set for loosening the set screws on the roller guides should you need to perform a tape path alignment. I have never needed a VCR head puller. You can make a tool for the special nut found on many A/C head assemblies for tracking adjustment by filing a slot in the blade of a straight blade screwdriver.

A low power fine tip soldering iron and fine rosin core solder will be needed if you should need to disconnect any soldered wires (on purpose or by accident) or replace soldered components.

CAUTION: You can easily turn a simple repair (e.g., bad solder connections) into an expensive mess if you don't have both a decent soldering iron and the soldering skills to go along with it. If in doubt, find someone else to do the soldering or at least practice soldering on a junk circuit board first! See the document: Troubleshooting and Repair of Consumer Electronics Equipment for additional info on soldering and rework techniques.

For thermal or warmup problems, a can of 'cold spray' or 'circuit chiller' (they are the same) and a heat gun or blow dryer come in handy to identify components whose characteristics may be drifting with temperature. Using the extension tube of the spray can or making a cardboard nozzle for the heat gun can provide very precise control of which components you are affecting.

Basic cleaning supplies include Q-tips (you may know them as cotton buds) for everything BUT video heads, chamois covered cleaning sticks (for video heads), lint free cloths or paper towels, water, and isopropyl alcohol (preferably 91 percent medicinal grade or better).

For info on useful chemicals, adhesives, and lubricants, see the document "Troubleshooting of Consumer Electronic Equipment".

If you have several VCRs or do repairs for friends (former friends?), there are inexpensive kits of VCR mechanical parts like washers and springs that come in handy. General belt or similar kits are not worthwhile unless you are in the service business - there is too much variety in the sizes and other characteristics of these types of parts to make an assortment a good investment.

Note: while working with the top off, you may need to put pieces of strategically located cardboard over the area of the cassette to block extraneous light from causing erratic behavior (modes aborting, not starting at all, etc.) with the start/end-of-tape sensors. Not all VCRs are sensitive to extraneous illumination but I have been bitten more than once by not doing this. Using overhead instead of direct illumination will probably help as well. In extreme cases, placing electrical tape over the end sensors may be needed but this will likely confuse the microcontroller under certain conditions into thinking that a non- existent tape is present - or if your troubleshooting will permit, leave a cassette in the transport. (I have heard of at least one case where this was a problem even for normal operation - apparently, light was falling on the VCR in just the wrong way where it happened to be located. The VCR would enter rewind mode regardless of what the helpless human wanted unless tipped on end!)

Test equipment

Don't start with the electronic test equipment, start with some analytical thinking. Many problems associated with consumer electronic equipment do not require a schematic (though one may be useful). The majority of problems with VCRs are mechanical and can be dealt with using nothing more than a good set of precision hand tools; some alcohol, degreaser, contact cleaner, light oil and grease; and your powers of observation (and a little experience). Your built in senses and that stuff between your ears represents the most important test equipment you have.

A DMM or VOM is necessary for checking of power supply voltages and testing of sensors, LEDs, switches, and other small components. Unless you get deep into the electronic repair of VCRs, an oscilloscope is not required.

There are two items of important test equipment that you probably already have:

- A video signal source - both RF and baseband (RCA jacks). Unless you are troubleshooting tuner or video/audio input problems, either one will suffice. RF sources include a pair of rabbit ears or an outdoor antenna, a cable connection, or a VCR with a working RF modulator. Similarly, a working VCR makes a handy baseband or RF signal source.

- A display device. A video monitor or TV makes an excellent video signal display. Many video problems can be diagnosed by just examining the picture. If you have an old TV with a vertical hold control, this is useful when adjusting backtension, should the need arise. A B/W TV is adequate for many of the tests you will be performing.

Why you should read the entire FAQ first

If you have no prior experience with precision electromechanical repair, don't just jump in as the following actual experience demonstrates:

(From: someone who would prefer not to be identified).

> "Ok, I did something dumb. I was given an old VCR (early 80s) a couple weeks ago (JVC-7100U). It stopped playing and recording, but FF and rewind worked fine. Reading the FAQ, I decided to check it out. I took the top off, and was trying to make the motor run so I could see the problem. There was an incandescent light, and I figured there was a light sensor, so I moved the lamp out of the way. The FAQ suggests electrical tape over the lamp, but I hadn't read it yet. My manipulation caused the lamp to fail. Until I could replace it, I just jumped the connection, which worked fine for awhile. I had just figured out the problem with play/record was a drive wheel not making contact with the take-up reel. It seemed to be a result of a weak spring, and I was trying to figure out which one, when the screwdriver I was manipulating the arm with slipped, and contacted the back side of a circuit board. Lesson number two: Use a chopstick for that purpose. I believe it was at this point I realized I got no reaction from any of the VCR control buttons, so maybe I shorted something out. All the buttons worked before. Even worse, as I was reinstalling the tape loading mechanism, the screwdriver slipped again, in a different place, and I did see a flash when it contacted the back of the circuit board. Whoops."

Don't let this happen to you. Or, at least start out with an old expendable VCR and accept the hits to your pride!

Cassette cheaters

When troubleshooting mechanical problems in a VCR, one of the handiest accessories is a cassette cheater - a frame to fool the VCR into thinking there is a cassette in place so that you have access to the reel spindles and idler.

You can buy these for $6-12 but you can make one that is almost as nice:

1. Take a discarded cassette, open it up and throw away everything but the top and bottom halves and the screws.

2. Punch out the plastic windows - and somewhat more of the top and bottom if you are so inclined - relatively little of the original structure is actually needed to fool the microbrain of the VCR! The more open the cheater is, the easier it will be to see and access guts of the VCR while running.

3. Reassemble the two halves of the cassette with the screws (you did save the screws, right?).

4. Put a bit of black tape over the sensor holes on the sides of the cassette (near where the hinge pins of the flap went).

These cheaters will load and 'play' just fine except that some machines actually sense that the supply reel is being turned by the tape movement during loading or always and will shut down if it isn't (among other peculiarities) so you may have to do this by hand.

There are several benefits to using one of these, one of which is that there is no chance of ruining a prized tape due to a hungry VCR. You will also be able to feel the spindles to get an idea whether they are turning properly and with enough torque in all modes. If you break out enough of the top and bottom, you will have access to the idler and other under-cassette parts at the same time. If you examine one of the commercial cassette cheaters, you will see that very little is needed beyond the outer frame as long as it sits properly on the indexing posts and doesn't jam the mechanism when loading/ejecting.

Test tapes

When aligning the tape path, a test tape will be needed as a reference. Actually, you want two - one recorded at the SP (2 hour) speed and another recorded at the EP (6 hour) speed. These do not need to be exorbitantly priced professional alignment tapes. A couple of recordings made on a known working VCR will get you close enough for most purposes. Do not use these same tapes for diagnosing or testing of mechanical problems, your VCR may be hungry and they may get eaten.

For general video diagnosis including mechanical and tape eating problems, a bunch of sacrificial tapes is handy - advertising, promos, feature shorts - anything you do not care about but have been recorded on working VCRs. Very often they get mangled and you do not want to continue to use mangled tapes which may damage the VCR - in particular the video heads. However, once you have the VCR basically working, you will want to test it start to finish on a T120 cassette. This is because the reel hub size on those short video cassettes is not the same as a standard (most commonly used) T120 cassette and may mask problems if the VCR is mechanically marginal in some respects.

Getting inside a VCR

You will void the warranty - at least in principle. There are usually no warranty seals on a VCR so unless you cause visible damage or mangle the screws, it is unlikely that this would be detected. You need to decide. A VCR still under warranty should probably be returned for warranty service for any covered problems except those with the most obvious and easy solutions.

It is usually very easy to remove the top and bottom covers on VCRs. For the top cover, there are usually some very obvious screws on the back or sides, and in rare cases on the top. There may be a couple of screws on the bottom as well that secure the top cover. For top loaders, you will probably need to remove the cassette holder lid - there will be two screws, perhaps hidden by rubber plugs.

Once all the screws are out, the top cover will lift up or slide back and then come off easily. If it still does not want to budge, recheck for screws you may have missed.

For the bottom cover, there are usually a half dozen or so screws around its perimeter and sometimes in the middle as well. There may be one or two grounding screws as well which are of different length and threads - these should go back in the same location from where they came. Bottom covers are usually simple sheet metal. In rare cases, you will need to remove the front panel to free the bottom cover (or vice-versa).

Circuit boards may prevent access to the top or bottom of the tape transport. Usually, removal of a few screws (often marked with red paint or arrows on the circuit board) and perhaps pressing of a couple of snaps will permit the board to be swung up on a hinge out of the way.

Front panels usually snap off, possibly requiring the removal of a few screws on top or bottom.

Make notes of screw location and type and store the screws away in a pill bottle, film canister, or ice cube tray.

When reassembling the equipment make sure to route cables and other wiring such that they will not get pinched or snagged and possibly broken or have their insulation nicked or pierced and that they will not get caught in moving parts. Replace any cable ties that were cut or removed during disassembly and add additional ones of your own if needed. Some electrical tape may sometimes come in handy to provide insulation insurance as well.

Why does my VCR shut down or behave strangely when I remove the cover?

There are various sensors in a VCR that are light sensitive - it is not a safety interlock (though it acts this way in some VCRs) but a result of the way the tape start and end sensors operate. VHS tapes have a clear leader and trailer. An LED or light bulb poking up near the center of the cassette shine towards sensors at either side of the cassette. When light is detected the VCR assumes that it is at the appropriate end of the tape and shuts off (or rewinds if in PLAY mode when it senses the end depending on model).

During servicing, a piece of opaque cardboard or other insulating material should be placed above the cassette basket if any strange behavior is detected that was not present with the cover in place. Not all VCRs are particularly sensitive external illumination.

Getting built up dust and dirt out of a VCR

This should be the first step in any inspection and cleaning procedure.

Do not be tempted to use compressed air!

I would quicker use a soft brush to carefully dust off the circuit boards and power supply. Work in such a way that the resulting dust does not fall on the mechanical parts.

For the deck itself, using compressed air could dislodge dirt and dust which may then settle on lubricated parts contaminating them. High pressure air could move oil or grease from where it is to where it should not be. If you are talking about a shop air line, the pressure may be much much too high and there may be contaminants as well.

A Q-tip (cotton swab) moistened with politically correct alcohol can be used to remove dust and dirt from various surfaces of the deck (in addition to the normal proper cleaning procedures for the guides, rollers, heads, wheels, belts, etc.)

What to do if a tiny tiny part falls into the VCR

We have all done this: a tiny washer or spring pops off and disappears from sight inside the guts of the unit. Don't panic. First - unplug the VCR if it is plugged into the AC. Remove the battery pack from a camcorder.

Try to locate the part with a bright light without moving the VCR. You may have gotten lucky (yeah, right). Next, over an area where a dropped part will be visible (not a shag carpet!), try any reasonable means to shake it loose - upside down, a little gently tapping and shaking, etc. A hard surface is better in some ways as you might hear the part drop. On the other hand it may bounce into the great beyond.

If this does not work, you have two options:

1. Assume that the part has landed in a place that will not cause future problems. There could be electrical problems if it is metallic and shorts out some circuitry or there could be mechanical problems if it jams some part of the mechanism. There is an excellent chance that the part will never cause any harm. What chance? I don't know, maybe 99%. It is not worth taking the unit to pieces to locate the part. You are more likely to damage something else in the process. Obtain a replacement and get on with your life. The exception is, of course, if you now begin experiencing problems you **know** were not there before.

2. Take the unit to pieces in an attempt to locate the part. For all you know, it may be clear across the room and you will never find it inside. If all the gymnastics have not knocked it loose, then it may be really wedged somewhere and will stay there - forever. If the VCR behaves normally, then in all likelihood it will continue to do so.

To prevent this sort of thing from happening in the future you will no doubt be much more careful. Sure you will! Some suggestions to prevent ejection of an E-clip, split washer, or spring into the great beyond:

- Construct a paper dam around the area.

- Tie a thread or fine wire around the part before attempting to remove it. Keep this 'safety line' on until after it has been reinstalled, then just pull it free.

- Keep one finger on the part as you attempt to pop it free.

- Hold onto the part with a pair of needlenose pliers or tweezers while prying with a small screwdriver.

(From: Paul Sagi (kamrok@tm.net.my).)

For finding a small part dropped on the floor, I darken the room, then shine a flashlight parallel to the floor, with the beam just touching the floor. the oblique (if that is the correct word?) beam shows up the part (and any dirt if the floor was not recently swept!) clearly. this works best on smooth floors or short-pile carpets. on shag carpets, if the part is on top of the pile, instead of having fallen into it (fat hope), the method works also. for shag carpets where the part has tried to hide, shine the light downwards at right angles and imagine how the part would look if seen against the background of the carpet, to prime the mind to recognize it when seen. a strong magnet (for steel parts like e-rings) can help when the above methods fail. sweeping or vacuuming the carpet or floor, then sorting through the debris can also help, especially for non-magnetic parts (sometimes cannot know if the part is magnetic or not until after it is found!)

I do not agree with the advice that a small part that cannot be located often can be left safely inside an electronic device. remember Murphy? he is ever-vigilant and delights in ensuring the part will have fallen where it can do harm when the power is switched on.

VCR Tape Transport Fundamentals

Parts of the tape transport in a VCR

Thanks to Brian Siler (bsiler@bigfoot.com) for using his Snappy(tm) rig to capture some of these original photos.

Please refer to the photo: Typical VHS VCR Tape Transport Components or Sharp VCR Transport with Major Parts Labeled for parts identification.

The following description applies to 99.9% of the VCRs in existence today. I have seen one that had a sideways loading mechanism - very weird.

Looking at the unit from above with the front toward you:

- Supply spindle - left hand side platform on which the supply tape reel (inside the cassette) sits. The edge which contacts the idler tire, and associated brake pad, should be cleaned.

- Takeup spindle - right hand side platform on which the takeup tape reel (inside the cassette) sits. The edge which contacts the idler tire, and associated brake pad, should be cleaned.

- Idler - assembly which swings between supply and takeup reels and transfers power to the appropriate reel to wind the tape up during play and record and often to drive FF and REW. This may use a rubber tire or a gear.

- Idler tire - the black rubber ring on the outside of one part of the idler which actually contacts the reel edges. This is single most likely part to need replacement after a few years of use. Some VCRs use a gear instead of a tire, but the tire is most common, especially in older units. Clean and inspect - replace if in doubt. See VCR with Idler Tire for a typical tire-type idler assembly.

  Some VCRs use gears in place of rubber (as is the case with the VCR shown in the photo: Typical VHS VCR Tape Transport Components. Teeth can break off but these are generally quite reliable. Some high-end decks may have separate motors for reel rotation.

- Roller guides - there are two, one on each side. These assemblies move from their retracted position toward front of machine to their loaded position for play and record. The white rollers should spin freely and be clean. When retracted, the roller guide assemblies will be slightly loose. However, when the tape is wound around the video head drum, they must be snug against the V-Stoppers - the brackets at the end of the tracks.

  Also on the same assembly are tilted metal guide posts - again one for each side. These sometimes fall out with obvious consequences.

Proper functioning and adjustment of the roller guides is the most critical requirement for proper tracking. (However, do not touch their settings without being really sure that they are at fault and not until you have read the sections relating to tape path alignment.) Clean and inspect.

- Roller guide tracks - combination of plastic and metal slots in which the roller guide assemblies slide during tape loading and unloading. Check to make sure there is still some healthy grease on the surfaces. If gummed up or excessively dirty, clean and relube with a dab of plastic-safe grease on each sliding surface.

- Video head drum or upper cylinder - approximately 2.45 inches in diameter by .75 inches high. This rotating assembly contains the video heads (and HiFi audio and flying erase heads, if present). Stay away from this unit. as video heads are very delicate. If you must clean it, refer to the specific instructions on cleaning video heads elsewhere in this document. Video heads do not normally require cleaning despite what the cleaning tape people will have you believe. If you are not having video noise problems, they should be left alone.

- Capstan - right side after tape exits from roller guide. The capstan is a shaft about 3/16" diameter which during play and record (and search) modes control tape movement forward or reverse when the pinch roller is pressed against it. Should be cleaned thoroughly to assure proper tape movement during play, record, and search modes.

- Pinch roller - black rubber roller about 1/2" diameter, 3/4" high which spins freely and is pressed against the capstan during play, record, and search modes. It is constructed as a molded rubber sleeve fused to a metal roller on a small ball bearing.

  A hard, shiny, dried out pinch roller can lead to tape edge munching and erratic sound, speed, and tracking. Clean thoroughly. Inspect for cracked, hard, shiny, or otherwise deteriorated rubber, and lack of free and smooth rotation. Replace if any of these are present.

  Even if you have no obvious record or playback symptoms, if the pinch roller appears concave or with a distinct worn ridge, replacement is recommended - erratic behavior will soon be the result. A tape which runs off center due to a bad pinch roller may result in tape edge damage and over time can also alter the wear pattern of the audio/control head and various guide posts.

  A quick test of the pinch roller is to put the VCR into PLAY and *carefully* try to stop it from turning between your thumb and forefinger - a good pinch roller will not be easy to stop.

  However, don't replace a pinch roller that is in good condition. The replacement may be inferior. (Apparently for at least some JVC VCRs, the original pinch roller is of very high quality and will last the life of the VCR if cleaned properly.)

- Audio/control Head Stack - between right roller guide (when tape is loaded around drum) and capstan. Includes magnetic heads for non-HiFi (linear) audio and synchronization control track. Should be cleaned since tracking and non-HiFi audio performance is critically dependent on its performance.

- Back tension arm - left side just as tape exits cassette - this is coupled to a felt Back Tension Band and serves to maintain a constant tension on the tape during play, record, and forward search. Retracts toward cassette when tape is unloaded. Back tension is somewhat critical and may need adjustment after long use.

- Various other fixed guide posts - vertical stationary metal posts which tape contacts. Should be cleaned but rarely need adjustment. The positions of these vary somewhat by manufacturer.

- Full erase head - left side towards rear which tape passes over just before going around roller guide, guide post, and drum. Rarely causes problems. Clean.

- Impedance roller - left side near full erase head. Freely rotating roller stabilizes tape movement. Some VCRs lack this component. Clean.

- Half loading arm - right side near capstan/pinch roller. On VCRs with 'rapid or instant access transports' this helps to position the tape in the intermediate (half loaded) position. A similar arm is usually present in other VCRs and helps to position the tape around the pinch roller. Check for free movement. Clean. Lubricate bearing if sluggish.

- Belts - various size black rubber bands - a typical VCR will have between 0 and 12 of these on top and bottom. Typical is 3 or 4. Most are of square cross section though an occasional belt may be flat or round. The belts will need replacement after a few years. Clean and inspect. Replace any belts that are hard, cracked, stretched, or flabby. A good belt will feel soft and rubbery without cracks or other signs of deterioration. It will return to its relaxed length instantly if stretched by hand about 25%. Belt kits are generally available by VCR model but individual belts can be ordered as well. In either case, this is very low cost maintenance which can make an absolutely huge difference in the happiness of your VCR. New belts can often restore a comatose VCR to perfect health.

For additional information on replacement rubber parts, see the section: Determining belt, tire, and pinch roller specifications.

Alex's quick tips

(From Alex (ramjam@globalserve.net).)

1. To confirm that a worn idler tire is causing a malfunction, without disassembly, I use a product called "Rubber Renue" (M.G.Chemicals Ltd. 13-80 Hale Road, Brampton, ON L6W 3M1 Canada 416 454-4178). First I clean the tire with isopropyl alcohol (99%) then using the other end of the Q-tip I apply Rubber Renue. You don't need much, I have had the same 100 ml (3.4 oz.) bottle for over 6 years. What the product does is rejuvenates and conditions the rubber (read: makes *sticky*) as to allow normal or near normal operation. I don't recommend this as a permanent fix, though it can be, it is a great diagnostic tool and the whole procedure takes about five minutes.

2. To fix squeaky pulley shafts and collars I use a pipe cleaner (most smoke shops sell them) to clean the collars, I then use transmission fluid (the same stuff you put in your car) as a lubricant on the shaft. It's lightweight, it doesn't gum up, it's cheap and can be bought just about anywhere. Just remember not to use too much as it spreads easily, which can be disastrous in a VCR.

Most common problems

- VCR refuses to FF or REW and shuts off.
- VCR shuts off entering PLAY or REC or at random during PLAY or REC.
- VCR eats tapes.
- VCR doesn't accept tapes or ejects them without cause.
- Sound is wavery, fluctuating, or muddy.

The cause for all of these is very often a bad idler tire or other dirty, worn, or tired rubber parts. See the section below: "General guide to VCR cleaning and rubber parts replacement". A VCR that just munched down your favorite tape is very likely only in need of a little tender loving care.

WARNING: Don't turn a simple repair into a full length double feature. Most tires and belts come off without extensive disassembly. However, if your VCR is the exception, DO NOT remove anything to get at the rubber part that may be part of a critical timing relationship - racks or gears, for example - before fully understanding the implications of this action. In some cases, if a gear is rotated even one tooth from where it should be, there can be unforeseen and catastrophic consequences. See the section: Mechanical relationships in VCRs for more information before proceeding any further!

General guide to VCR cleaning and rubber parts replacement

All the guideposts, wheels, and rubber parts of a VCR should be cleaned periodically - how often depends on usage. Of course, no one really does it unless something goes wrong.

Do not attempt to clean the video heads until you follow the proper procedure given elsewhere in this document, you can break them - very expensive lesson. In most cases, they do not need attention anyhow.

Q-tips and alcohol (91% medicinal is OK, pure isopropyl is better. Avoid rubbing alcohol especially if it contains any additives) can be used everywhere except the video heads. Just dry quickly to avoid leaving residue behind or damaging the rubber parts further.

Cleaning may get your machine going well enough to get by until any replacement rubber parts arrive and to confirm your diagnosis.

Things to clean:

1. Capstan and pinch roller. These collect a lot of crud mostly oxide which flakes off of (old rental) tapes. Use as many Q-tips (wet but not dripping with alcohol) as necessary to remove all foreign matter from the capstan (the shiny shaft that pulls the tape through the VCR for play and record). Just don't get impatient and use something sharp - the crud will come off with the Q-tips and maybe some help from a fingernail. For really hard encrusted crud, a scrap of soft metal like aluminum, brass, or copper may be of help if you're the impatient type. DON'T use iron or steel - you will be buying a new (expensive capstan assembly!

   Clean the pinch roller (presses against the capstan in Play, Record, and Search mode CUE and REVIEW) and until no more black stuff comes off. Use as many Q-tips as necessary until no more black gunk collects on Q-tip.

   If the pinch roller is still hard, shiny or cracked, it will probably need replacement. Many are available for about $6 from the sources listed at the end of this document. It is sometimes possible to put the pinch roller in an electric drill, drill press, or lathe, and carefully file off the hard shiny dried out rubber surface layer, but only use a last resort - and this fix is probably temporary at best. For a very detailed and complete step-by-step procedure, see: VCR crinkling tape, sound fading, speed flipping. (This is an archived sci.electronics.repair newsgroup posting.)

2. Various guideposts including the roller guides (the white rollers on metal posts which are near the video head drum when in play or record mode). When in FF or REW, or with no tape present, these move on tracks to a position toward the front of the VCR. Note that the roller guides with the white rollers and tilted metal posts will be fairly loose when in the unloaded position (but you should not be able to lift them off the tracks). When actually playing or recording a tape, they will be snug against the stoppers at the end of the tracks.

3. Idler tire (idler swings between reels and transfers motor power to reels - clean until no more black stuff comes off. A dirty or worn idler tire is probably the single most common VCR problem.

   If the idler tire appears cracked, glazed, or dried out, it will need to be replaced. About $.50 to $1.00. As a temporary measure, you can usually turn the tire inside-out and replace it. The protected inner (now outer) surface will grip well enough to restore functionality until a replacement tire arrives - and verify the diagnosis as to the cause of your problem.

   Also, the idler assembly includes a slip clutch. If this weakens, the idler may not have enough force to press on the reel table edges. If it becomes too tight, there may be audio, video, or crickled tape problems and/or excess wear of the idler tire. When in doubt, the entire idler assembly is often available as a replacement part. They can often be disassembled and adjusted if necessary.

4. Reel table edges - surface on the reel tables where the idler contacts.

5. Audio/control head (right side) and full erase head, (left side). Q-tips and alcohol are OK for these.

6. Anything else that the tape contacts on its exciting journey through your machine.

7. Rubber belts. Access to some of these will probably require the removal of the bottom cover. After noting where each belt goes, remove them individually (if possible) and clean with alcohol and Q-tips or lint free cloth. Dry quickly to avoid degrading the rubber from contact with the alcohol. If a belt is trapped by some assembly and not easy to remove, use the Q-tip on the belt and/or pulley in place. However, if it is stretched, flabby, or damaged, you will need to figure out how to free it.

   Make sure that there are no twists when a square cut belt or replacement is installed on its pulleys.

   On some models, you may need to unscrew circuit board(s) blocking access to either the top or bottom of the tape transport. Make notes of what went where - particularly different types of screws and routing of wires.

   Any belts that appear loose, flabby or do not return instantly to their relaxed size when stretched by 25% or so will need to be replaced and may be the cause of your problems. Belts cost about $.30 to $2.00 and complete replacement belt kits are often available by model for $3. to $12. Meanwhile, the belts will function better once they are cleaned, maybe just enough to get by until your replacements arrive.

8. Video heads: READ CAREFULLY. Improper cleaning can ruin the expensive video heads. DO NOT attempt to clean the video heads without reading and following the procedure described in the section: Video head cleaning technique.

   While VCRs should be cleaned periodically, the video heads themselves usually do not need cleaning unless you have been playing old or defective rental tapes which may leave oxide deposits on the tips of the delicate ferrite head chips. Unless you are experiencing video snow, intermittent color, or loss of or intermittent HiFi sound (HiFi VCRs only, the HiFi heads are located on the video head drum and for the purposes of cleaning, treated the same way) leave the video heads alone.

   If you really feel that video head cleaning is needed, refer to the sections on video head problem diagnosis and cleaning elsewhere in this document.

Polishing your tape path

(From: Gillraker (eternity@mcp.cybertron.com).)

I pride myself on the cleanings I do with all repairs, I like to keep my shop up to command performance and a cut above the rest I usually even clean up the chassis and deck of most equipment and relubricate and all the trim.

I have seen my share of broken heads come in from people after they use a Q-tip...or a store bought cleaning tape...

I use a few different size hemostats with a folded up lint free cloth. When folded, it really buffs the cylinder units and leaves a nice shine on the tape guide rollers, and audio and erase heads too. I have cleaned a head with chamois swabs and then gone over them with my own cloth and was horrified to see the residue that was left from ordinary swabs, when it was all collected on the cloth. It doesn't snag the video or stereo hi-fi heads either - I have cleaned a few thousand this way and never snagged any .

I use generation 2000 disk cleaner for heads and acetone to degrease the posts and capstan - just a dip - not too much.

(Editor's note: take care with strong solvents like acetone - both to protect your health and avoid damage to plastic parts. --- sam)

Tom's comments on approaches to cleaning

(From: Thomas L DeTogne (tdetogne@home.com).)

Pardon me while I trip over my long gray beard :-).

In the old days, we used to clean the platters in a disk drive using what were essentially tongue depressors wrapped with a Texwipe (Lint-free paper). We would first use 99% pure isopropyl alcohol and follow it with freon. (AAAAAh! the Ozone layer!) We would then manually run the heads out over the platters (while they were spinning) and listen for 'ticks'. If we heard any, we'd repeat the process. For those who smoked in the computer room, the residue could build up rather thick and evenly. Getting the whole mess off was a chore. If such was the case, I actually would use Soap and water, followed by water, then the alcohol and finally the freon. (This was more like R-22 and not the R-12 variety. That, we used do dump into the atmosphere freely trying to cool down components.)

I have resurrected many road-kill VCRs by using those cleaning techniques on them. I haven't as yet had to use soap, but using other than alcohol proves beneficial. Just don't get too liberal with any of the cleaning fluids. By the way, the freon was used to remove any residue left behind by the alcohol.

Lubrication of a VCR

The short recommendation is: Don't add any oil or grease unless you are positively sure it is needed. Most parts in a VCR are lubricated at the factory and do not need any further lubrication over their lifetime. Too much lubrication is worse then too little. It is easy to add a drop of oil but difficult and time consuming to restore a VCR that has taken a swim.

NEVER, ever, use WD40 in a VCR! WD40 is not a good lubricant despite the claims on the label. Legend has it that the WD stands for Water Displacer - which is one of the functions of WD40 when used to coat tools. WD40 is much too thin to do any good as a general lubricant and will quickly collect dirt and dry up. It is also quite flammable and a pretty good solvent - and there is no telling what will be affected by this:

(From: Matthew Fries (freeze@visi.com).)

> "I heard a horror story when I was in tech school about someone who heard a little squeaking inside the VCR when it was in PLAY mode, so he sprayed WD40 in through the tape door (front loading) and 'lubricated' the entire inside of the VCR. The students who were working on this took apart the entire mechanism, sprayed it clean with TF solvent (4 cans - there goes the ozone) and it still didn't work. No surprise."

A light machine oil like electric motor or sewing machine oil should be used for gear or wheel shafts. A plastic safe grease like silicone grease or Molylube is suitable for gear teeth, cams, and the roller guide tracks.

Unless the VCR was not properly lubricated at the factory (which is quite possible), the only likely areas needing lubrication are the roller guide tracks - clean and grease. Sometimes you will find a dry capstan, motor, lever, or gear shaft but this is less likely.

In general, do not lubricate anything unless you know there is a need. Never 'shotgun' a problem by lubricating everything in sight! You might as well literally use a shotgun on the VCR!

Head demagnetizing

With audio tape decks, demagnetizing is often recommended to improve sound quality and frequency response. There is some debate as to how much benefit there is to this practice but if done properly, there is little risk. Demagnetizing removes the residual magnetic fields that can build up on ferrous parts of the tape heads and various guideposts and other parts in the tape path which may affect frequency response.

For the following, do not go near the video head drum, only perform demagnetization of the stationary A/C head, erase head, and guide posts and rollers. In my opinion, the video heads should almost never need to be demagnetized. The ferrite material from which they are constructed is not prone to easily being magnetized like steel.

Use a small demagnetizer designed for a tape deck or cassette deck. Do not use anything homemade that might be too powerful or a bulk tape eraser which would certainly be too powerful.

Make sure the tip is covered with a soft material to prevent damage to the finely polished surfaces in your VCR.

Turn power on to the demagnetizer when a couple of feet away from the VCR. Then, slowly bring it in close and slowly go over all surfaces of anything that the tape contacts or comes close to in the tape transport. The key word here is **slowly**. Move fast, and you will make the magnetic fields stronger. When finished, slowly draw the demagnetizer away to a distance of a couple of feet before turning it off.

Homemade VCR head demagnetizer

Rather than trying to build something that plugs directly into the AC line, use an *AC* wall adapter. Typically something from an old modem with a rating of around 1 A at 12 VAC should be fine. There is no significant safety hazard to touch connections with power on and they are short circuit protected so no matter what you do, there will be no immediate damage to the adapter.

Use a large nail with its point filed down to a blunt tip covered with tape or a plastic or rubber boot to protect the polished surfaces of the heads. I have no idea of the exact number of turns but I'd say start with 100 turns of #20 to #26 AWG insulated wire. There should be a noticeable vibration when bringing the tip with 1/4 inch or so of a ferrous surface but not much beyond this.

CAUTION: This may be too strong for the video heads - stay away from them! In fact, it may be too strong at the full 12 VAC. A lower voltage adapter may be better or use on a Variac. If it pulls nails out of your drywall, it's too strong. :) Use at your own risk!

Building a bulk tape eraser

A variety of approaches work for this - all based on strong magnetic fields. These will erase floppy diskettes, audio and video tapes, and all your credit cards and Turnpike passes!

- Magnets removed from large loudspeakers (including the pole pieces where the voice coil went) and microwave oven magnetrons.

- Some motors, transformers, the butt-end of some soldering guns, etc.

(From: Steven L. Bender (buqu35d@prodigy.com).)

You need a Power Transformer about 3" in each direction, can be like a low voltage 12 volt / 3 Amp unit or rated higher. Remove end bells if any, remove all the metal laminations (break the first one, yank it, and the rest will come easier). Re-insert all the metal laminations facing in the same direction, with the "E" all pointed the same, re-glue, varnish, or whatever. Connect AC Plug to the Primary, then insulate the whole works with Plastic tape and outre layer of Duct tape. After insulating it with several layers of tape - Instant Bulk Eraser.

Warning - Do not apply power for more than 60 seconds at a time! (It will get hot and burn your hand after two minutes.)

I had one of those for some years, but accidentally left it plugged in, (pulled the wrong wire out of the 6 to 1 outlet box) and after a few minutes, it smelled and was too hot to touch, and made a nasty noise as the copper started to melt... (Sounds Effects of Liquid Krell Metal in the distance...., Forbidden Planet - Paramount, 1956).

Luckily I didn't walk out, another few minutes and it would have caught fire..

I am not liable for any personal, profession, or consequential damages from use of this information !!!

(From: Steve Walz (rstevew@armory.com).)

Use a transformer and remove the EI core pieces and replace all the E's only in the same direction. Current limit it with a wire-wound resistor so it doesn't overheat and put a momentary pushbutton on it and a power cord to wall AC and insulate it so you don't shock yourself. Then place it so the open face of the E core pieces faces the tape or disk or whatever to be erased and push the button. Run it all over both sides of the tape or disk and pull the tape or disk away before letting up on the button if you wish to erase it. If you wish to magnetize a tool or such, simply let up on the button while the object or tool is still in contact with it. That's how that works! (You may have to do it a couple times before you catch the AC cycle at the peak! --- Sam.)

(From: Pat Swayne (me@patswayne.com).)

Here's a safety tip for your homemade bulk tape eraser: Use a small length of very thin solder as a fusable link. Place this as close to, but insulated from, the primary windings as possible, and pass the current through it. If the thing gets too hot, it will melt the solder and break the connection.

(From: Sam.)

It would have to get mighty hot for that to be effective but it's cheap enough. Of course, a thermal fuse or thermostat would be a more well controlled alternative.

Cassette and Tape Loading Problems

Cassette loading and eject problems

Cassette loading places the cassette into proper position on the tape transport. In a front loader, pushing the cassette gently into the slot should cause a motor to take over and suck it in and down to rest on indexing pins. The mechanism that actually holds the cassette is called the cassette basket. Several types of problems are possible: the VCR may ignore you when you push the cassette in or press EJECT, or it may spit it out immediately or cycle back and forth. On a top loader, you do most of the cassette loading manually, so the only likely problem will be if EJECT does not work.

If attempting to load a cassette produces no response (though the VCR has power), then there could be a problem with the microswitch that senses the presence of a cassette, the cassette loading motor (if separate from the main motor), a slipping or broken belt, or a faulty driver or other electronic problem. Sometimes this could mean that the microcontroller is confused due to a faulty mode switch or because the mechanism somehow got into a peculiar state. Manual cycling of the cassette loading mechanism might reset it. Gently push a cassette in and turn the appropriate shaft or pulley by hand. First, try this with the VCR unplugged. If nothing happens or you feel resistance, try the other direction. Assuming you find no problems - there is no significant resistance to your turning and the cassette basket cycles from fully ejected to fully seated on the transport baseplate, leave the cassette basket in a partially loaded position and plug the VCR into the AC power and turn it on (this may not be necessary depending on the design of your VCR). It should now reset itself and either load or eject the cassette. If there are still no signs of a response, a power supply, motor, or electronic problem is likely.

Note: If this only happens with T160 (8 hour) tapes, it may be a problem with the thinner tape confusing the sensors. Avoiding these tapes is really the best thing to do since they can cause all sorts of problems (especially if they are an off-brand and of inferior quality to begin with).

If you hear a motor whirring but nothing happens, this is almost certainly a slipping or broken belt or something blocking the proper movement a mechanical part.

If pushing a cassette into the VCR results in it being ejected as though it tasted really bad (there may or may not be hesitation), or if the cassette cycles back and forth without stopping, there could be several possible causes.

If it stops part way during loading, does it pause as though the motor is straining or just abort with no warning? If the former, then check carefully for foreign objects, or lack of lubrication. A typical cause is a belt slipping, usually not the idler in this case. Help it out gently and see if that will complete the cycle. Sometimes it is helpful to cycle the mechanism by hand - turning the appropriate shaft or pulley and feeling and watching for any place where it binds. If the basket moves in the wrong way or you feel any significant resistance, try the other direction. Sometimes, the sticky cassette labels partially or totally peal off and clog the works. You may find a toy or rock inside carefully inserted by your 3 year-old! A bit of the cassette shell might have broken off and jammed the mechanism just to confuse you!

If the microcontroller were detecting an abnormality, then it would abort instantly but would most likely try to unload the tape before giving up but not in all designs. It is possible that if the expected behavior is not produced by the end/beginning-of-tape sensors during cassette loading, an abort could be initiated. Therefore, these sensors could be suspect. In some cases, the mode switch may be dirty or faulty. A gear may have broken some teeth or slipped a couple of teeth and the timing relationships may be incorrect. There may be a microswitch that is controlled by the cassette basket position and this may be defective or dirty.

Similarly, if the cassette seems to be cycling in and out in an apparently infinite loop, there may be an obstruction or the microcontroller is confused by a bad sensor or the basket is out of synchronization with the rest of the mechanism. A squirt of contact cleaner into the microswitch sensor and/or reflowing its bad solder connections may solve this type of problem.

Similar comments apply to cases where pressing the EJECT button produces no response. In particular, if the cassette was loaded successfully and you just finished a thoroughly enjoyable movie, the microcontroller may think the mechanism is not safe and is not ejecting to protect your valuable tape from possible damage should it not be fully retracted into the cassette. As with loading, EJECT may result in partial movement and shutdown or reloading the cassette into the down position. All the same causes apply.

There are even some poorly designed VCRs where extraneous light through the vent holes or tape door affect sensors and cause erratic operation. If a bright light is shining on the VCR, block and see if anything changes!

Ejecting a cassette from an uncooperative VCR

It is a common experience - the rental movie is due back at the video store **now** but no matter how you press the EJECT button, yell, scream, hold your breath, or jump up and down, the cassette refuses to be appear.

To remedy the underlying problem, see the sections on: "Cassette loading and eject problems" and other for appropriate information. This section only deals with getting the cassette out without damaging either your valuable recording or VCR.

Under no circumstances should you force anything - both your tape and your VCR will be history.

First, see if the VCR just got into a confused state - pull the plug and patiently wait a minute or two. This may reset the microcontroller and all will be well. These things happen.

If this is not successful, you will need to open up the VCR (unplug it first!) and attempt to cycle the mechanisms by hand. Probably both top and bottom covers will need to be removed. The following procedures assume that there are no broken parts, foreign objects, or other damage which might prevent manual cycling of the tape loading and cassette loading mechanism. (Inspect for toys and rocks.) Also note that some VCR designs use solenoids to engage various operations. This will complicate your task (to put it mildly) as locating and activating the proper ones at the appropriate time is, well, a treat.

1. Tape unloading: The first step is to determine if the tape has been unloaded from the video head drum back into the cassette. If the tape is fully retracted into the cassette - there is no tape showing, then go on to step (2). If not, you will need to figure out which shaft or pulley to turn to unload the tape. Trace the linkage or gears that move the roller guides back to their motor - it may be the main capstan motor or a separate small motor used only for this purpose. Rotate this in the direction which moves the roller guides back towards the cassette. It will take many revolutions - be persistent. If you feel any significant resistance or the roller guides move out toward the drum, turn the other way. The tape is fully unloaded when the roller guides are all the way into the cassette and the tape is straight across the cassette's stationary guideposts.

If a single motor performs both the tape loading and cassette loading functions, stop turning as soon as you see the cassette start to rise and read the next section before proceeding.

If you are not fully successful or if there is still a tape loop outside the cassette even once you have been turning for what seems to be an eternity, you can still try to eject the cassette but will need to be extra careful not to crinkle the tape as the cassette door closes with the tape sticking out. Before proceeding on in this case, try to find a way to turn one of the reels to pull that tape back in as this will make your task a lot easier. There may be an idler that swings between the two reels and this may be accessible from the bottom (the cassette will block it on top).

2. Cassette unloading. Once the tape is fully retracted into the cassette, the cassette can be ejected safely. If a tape loop is still sticking out of the cassette - and you care about the recording - you will need to be especially careful not to crinkle the tape as the cassette door closes. It is usually not possible to get the cassette fully out without its door closing, so the best you can do is to make sure when this happens, the tape is flat across the gap. With care, it should survive.

   On a top loader, there is usually a solenoid specifically for EJECT or a simple mechanical pushbutton. Once the appropriate lever is pressed, the cassette should pop up - hold the basket with one hand as you do this to prevent any exposed tape loop from being crinkled.

   On a front loader, locate the cassette loading motor and begin turning it in the appropriate direction - this will be fairly obvious assuming there are no broken gear teeth or other broken parts and that something isn't totally jammed. If this is the main capstan motor, then just continue turning as in (1). Eventually the cassette should raise up and out.

   As above, applying external low voltage power (6 to 12 VDC) to the motor *after* disconnecting it is an alternative if you cannot gain access to its shaft to turn it by hand.

   If you have a tape loop, be extra careful not to catch it on any guideposts or obstructions as you remove the cassette. Then, wind it back into the cassette by turning one of the reels (you may have to depress the release button on the bottom of the cassette with a pencil - this is the small hole in the center near the label side.)

   And in some cases, just turning the VCR upside-down and gently easing the cassette out will work. But as noted, don't force anything.

   Assuming the tape is not torn and not badly crinkled, it should be fine. If it is severely damaged, refer to the section: Recovering damaged or broken tapes.

VCR is confused - will not eject non-existent tape

If for some reason, the microcontroller gets confused and refuses to raise the basket and there is no tape in the VCR, first, try pulling the plug for a minute or two. This may reset the error condition. However, since the mechanism is in an illegal state, the microcontroller may refuse to do anything for fear of making things worse.

Assuming that the problem is still present, here are two suggestions:

- Manually turn the appropriate motor shaft with power off to put the mechanism through the eject cycle. In many VCRs, this is as simple as turning the EJECT motor or possibly the main motor. Be patient and gentle - it will take a while.

If there is some underlying problem which caused the basket to be lowered without a cassette in place, than the VCR may return to the illegal state, do nothing, or do something else that is peculiar once power is restored or any button is pressed.

- Convince the microcontroller that a tape really is present when there is none. You need to (1) cover the start/end sensor LED poking up in the center of the deck, (2) depress any other microswitches that sense tape present, press EJECT, and (3) possibly turn the non-driven reel by hand a bit while it is attempting to wind the tape loop back into the cassette. Three or four hands are a definite asset. Make sure you get your fingers out before they are caught! Again, an underlying problem may produce unexpected results.

For additional info on initialization problems, see the section: VCR is failing the power-up sequence.

---

3. Back to VCR Repair FAQ Table of Contents.

Fast Forward and Rewind Problems

VCR will not fast forward and/or rewind

Usually, the owner will admit that the machine is pre-Jurassic and has never been cleaned or serviced.

Anyway, rule out the idler tire as well as the idler clutch - if it weakens, then the idler wheel does not press against the appropriate reel with enough force to grip.

Is it s top or front loader? If a top loader, you should be able to trick it into playing a nonexistent tape by covering up the end-of-tape light (the one sticking up in the middle) so that it will think there is a tape inserted. (In some models, there might also be a microswitch.) This may permit you to see what is going on.

If a front loader, then it is tougher. You need a cassette cheater (see the section: Cassette cheaters). Then, with the cheater in place happily fooling the VCR, feel the spindles while the machine is operating. In FF or REW, you may find that they are not being driven or or being driven very weakly. Try to determine if the idler is even being pushed into position or is hung up on something.

If there is any chance that it is the idler tire, try turning it inside-out. The relatively protected inner (now outer) surface may grip well enough to confirm the diagnosis.

Has it been serviced in the last 15 years? The last 100 years?

VCR aborts fast forward or rewind

In this case, the tape starts to move - possibly at a reasonable speed - but then may shut down - possibly erratic or tape dependent.

Make sure the tape is not the problem - try another one.

If it starts the operation (as evidenced by whirring sounds and the tape counter changing numbers) but at some point - perhaps near the end of the tape - aborts and shuts down, then a worn idler tire, worn or broken idler clutch, bad belt, or lubrication problem is likely. See the section: VCR will not fast forward and/or rewind as well as Lubrication of a VCR.

With instant start transports - where the tape is maintained around the video head drum for all but the fastest rewind, there could be other control problems as well.

If the tape starts fast forwarding or rewinding properly (from a visual inspection with the cover off) but the tape counter does not change value and then the unit shuts down, a reel rotation sensor problem is likely. See the section: Reel rotation sensors.

If the operation aborts at the same location on only certain tapes, there could be pinholes in the tape oxide coating allowing light to pass through and confuse the sensors. This happens mostly with T160 or old well worn tapes. If you can locate the problem area, you can try indelible ink on the NON-oxide side of the tape but DO NOT use adhesive tape or glue. Else, discard the tape or live with its behavior.

Noisy REW or FF

While these operations are never exactly quiet, when grinding or squeaking noises are evident, it is time to at least consider the possibilities.

First confirm that the same thing happens with more than one cassette - it could be defective.

(Portions from: Alan McKinnon (alan.mck@pixie.co.za) and Oldguyteck (edward.croteau@the-spa.com).)

You get several types of noisy rewind:

- A high pitched squeak - dirt and/or dried or lost lubrication on reel spindles, remove both reel tables, clean and lubricate the shafts. On older machines you often find this as well on idler pulleys.
- Periodic 'eek-eek-eek' type noise, check for an out of round rotating part rubbing on something. No pat answers here, you have to get your eyes out and look.
- A grating metal on metal noise that sounds like car brake pads that should have been changed 5000 miles ago is always the capstan rubbing on its bearing. The only cure s a new motor. Ignore those that tell you to strip and clean the bearing. I've tried this trick at least 10 times on different machines - it won't last. If a capstan motor is worn enough to howl, the shaft and bearing are way beyond repair.

Miscellaneous causes:

- Cassette not seating properly and/or tape path alignment problems. Press down on the cassette during REW or FF and see if it shuts up.
- Brake levers not disengaging completely, pads worn, or misadjusted.
- Missing fiber washers (who worked on the VCR last?); worn, broken, or distorted gears; other lubrication or dirt problems, etc.
- Bad bearings in main motor (usually older VCRs).

The list goes on and on. In the end, the only way to narrow down the problem will be with your eyes and ears!

Tape rewinders

Should you buy a tape rewinder to save wear and tear on your VCR? Take it or leave it. I think they are good if your VCR is old and for whatever reason has trouble with FF or REW. However, sluggish FF or REW may be a precursor to tape eating and should be addressed to avoid an impending failure which may ruin a tape. Rubber parts deteriorate by just existing. The surface layer oxidizes and use may actually be good (don't quote me!).

I would not bother with a rewinder just to prevent wear and tear on the motors or heads.

- In many VCRs - particularly older VCRs without real-time tape counters, the tape is totally retracted into the cassette during high speed FF or REW and does not contact the heads at all.

- In newer VCRs with real-time counters, the tape will contact the control head lightly but wear should not be worth worrying about.

- Wear on the video heads where the tape remains in contact with them during rewind as in some high performance VCRs is not significant. This is due to the fact that the heads spin rapidly and wear isn't much different between normal play/record modes and fast rewind - it is the total time that matters for head wear - and rewind time is minimal. In addition, some VCRs reduce the tape tension during fast rewind as a further precaution.

  In more detail, assuming a 3 minute rewind time for a T120 tape (total tape length 240 m), the linear tape speed for REW or FF is 80 m/minute or 1.333 m/s. Relative video head-tape speed in normal play is about 4.83 m/s. So, the 1.333 m/s (actually, due to the slant of the tracks, it is very slightly less) gets added (REW) or subtracted (FF) from 4.83 m/s. So, assuming the machine is properly adjusted) this is similar to an equivalent length of time in normal play and is really is negligible. I wouldn't lose sleep over video head wear in this case or get a rewinder just to save wear on the video heads.

- Wear and tear on the motors is not a serious problem - and actually may be much less than when playing a tape.

If the convenience of being able to rewind off-line is important to you, then there may be no harm in using one. However, some rewinders can be hard on video tapes as they usually do not sense the clear leader but stop rewinding when the tape tension increases at the end of the tape. This may eventually damage the tape and/or pull the tape from the takeup reel hub. I have heard of some crinkling the tape edge and actually mangling tapes.

(From: Jim Lagerkvist (jlager@tir.com).)

There are dozens of fast rewinder units claiming to save wear on your VCR. The earliest ones snapped-off the clear leader from the hubs. The later ones with IR sensors simply made the real problem obvious:

Precious recordings are being damaged by a cheap transport screaming the tape at high speed. The tape is either creased or an edge is rippled (usually the control track).

I have a long list of heartbroken people that have lost their archives with these things; me included. If a customer complains about a tape suddenly not viewing well, ask if they use one of these things.

4. Back to VCR Repair FAQ Table of Contents.

Play and Record Mechanical Problems

Quick list of common mechanical problems

The following aren't in any serious order but those toward the top of the list are the most likely to occur:

0. Need for cleaning.
1. Dirty or deteriorated rubber belts and/or idler tire.
2. Idler clutch too weak or too strong from wear.
3. Need for lubrication of selected parts.
4. Worn brake pad or engagement problems.
5. Broken or misadjusted back tension band.
6. Dry or worn capstan motor bearing.
7. Gear timing incorrect due to forcing of mechanism of gear damage.
8. Other broken parts.

See Some Locations for VCR Mechnical Problems parts identification in a typical transport.

VCR refuses to record

If efforts to record (directly or via the timer) are totally ignored or cause the cassette to be ejected, then the record protect tab on the cassette may be broken off or the record protect sense switch in the VCR may be dirty or defective. This switch sits just under the cassette slot (on front loaders). Locate it by referencing the tab position on the loaded cassette. It can easily be tested with an ohmmeter - if you can get to it. To confirm, short out or disconnect (which you will need to do depends on the design of your VCR) the appropriate wires (maybe there is a connector - this could have bad contacts as well) and see if the VCR is more cooperative.

VCR aborts play or record during startup or shortly thereafter

This is a problem with the process called 'tape loading' - pulling the tape loop out of the cassette and wrapping it around the spinning video drum, engaging the capstan and pinch roller and reel rotation.

Check all the belts above and below the deck. Belts can appear to be firm but if they do not return immediately to their relaxed length when you stretch them 25%, they will need to be replaced.

With the cover off, observe the behavior when you hit play. (You may need to put a piece of cardboard over the cassette to block external light from interfering with the start/end tape sensors). Assuming this is a basic VCR (no instant start features), you should see:

1. The video head drum begins to spin.

2. the roller guides move smoothly on the tracks, wind the tape around the drum, and stop snuggly pressed against the 'V-Stopper' at the end of the tracks.

3. The pinch roller moves into position and presses the tape against the capstan.

4. The tape begins to move and is wound up by the takeup reel.

5. The picture and sound appear on the TV.

With a 'rapid or quick start' (or it may be called something else) transport, the tape moves to a half-loaded position when the cassette is inserted. This is at an intermediate position partially pulled out of the cassette but not wrapped around the drum. On VCRs with a real-time counter and/or index search capabilities, the tape will be in contact with the control head.

With an 'instant start' transport, the tape will fully load around the spinning drum when the cassette is inserted but the capstan will not engage and no tension will be applied to the tape until you press PLAY or REC. (After about 5 minutes, the drum will stop and it may unload to the half loaded or unloaded position.)

Note that for VCRs with a real-time counter and/or index search capabilities, the tape must be in contact with the control head (but not the video heads) for all relevant modes. These VCRs (which include many modern units) must therefore pull the tape at least partly out of the cassette.

In all cases, the completion of the sequence results in approximately the same mechanical configuration during PLAY.

Several likely possibilities when it shuts down:

1. Everything occurs as above, picture and sound appear for a few seconds, but then the VCR unloads the tape, ejects the cassette, goes into REW mode, stops, or shuts off. Two common causes:

   - The takeup reel does not turn and tape spills into the machine. This is sensed by the microcontroller which aborts record or play and attempts to save your valuable cassette. Most likely cause: old/dirty idler tire. As a test, turn the idler tire inside-out. The fresh surface will now work well enough to confirm this diagnosis and will continue working long enough for your replacement idler tire to arrive. See the section: General guide to VCR cleaning and rubber parts replacement.

   - The takeup reel is turning properly but one of the reel rotation sensors or its electronics is defective. As a test, check to see if the tape counter is changing at any time during the loading and abort process. Non-real-time tape counters usually get their pulses from this same sensor. (Real-time counters operate off of the A/C head control pulses and therefore would not be affected by a defective reel sensor). Some older VCRs used a belt driven counter - the belt may have broken or fallen off. Most newer VCRs use an optical sensor which may simply be dirty. See the section: Reel rotation sensors.

2. The roller guides are getting hung up and not fully loading the tape either as a result of an obstruction or dried up grease, or a slipping tape loading belt (often accompanied by an spine tingling squeal). Parts may have broken or fallen off of the roller guide assemblies preventing them from fully engaging the 'V-Stoppers'. A similar fault may prevent the capstan from fully engaging against the tape and pinch roller. A toy, candy, or a plastic bit of a cassette shell may be jamming something.

3. The mode switch sensor is dirty or defective and confusing the poor microcomputer as to the position of the loading mechanism. In this case, the loading process may stop half way, pause, and then unload as in

(1) or (2), above. Or, it may do almost anything. See the section on: "Erratic behavior in various modes".

4. Some other condition such as the end-of-tape sensor thinking that you are at the end of the tape is aborting the tape loading process. This might be indicated by a sudden reversal and shutdown rather than a pause (usually accompanied by the sound of a motor whirring) at some point attempting to complete part of the cycle. For problems with record in particular, the record protect tab switch may be dirty or worn resulting in random aborts.

5. Electronic problems like bad grounds or other bad connections are also possible. Since with some models, (a number of JVC manufactured VCRs, for example) ground integrity is via screws through the mainboard, should these loosen, erratic behavior may result. Tighten the screws.

6. A defective microcontroller or other logic could also be at fault but this is less likely than any of the preceding.

VCR aborts play or record at random times or near end of tape

In this case, the VCR starts to play or record but, say, an hour later, shuts down for no good reason - at least not as a result of a command you thought you issued.

Make sure the tape is not the problem - try another one. There may be spots on the tape where the oxide has come off resulting in pinhole (or larger) areas which are activating the end-sensors.

Confirm that you are using the proper play or record modes - not OTR (One Time Record) or other timed play or record modes which will likely operate in increments of 15 minutes depending on how many times you press the button. In addition, on certain VCRs, if the program timer is enabled with a program setting that has its stop time occur while you are using the VCR - even if the record operation has been aborted by pressing the stop button - the VCR will shut down.

If play or record aborts at the same location on only certain tapes, there could be pinholes in the tape oxide coating allowing light to pass through and confuse the sensors. This happens mostly with T160 or old well worn tapes. If you can locate the problem area, you can try indelible ink on the NON-oxide side of the tape but DO NOT use adhesive tape or glue. Else, discard the tape or live with its behavior.

Finally, make sure you are not using any 'insert editing' modes which require a previously laid down control track and would abort once blank tape was reached. See the section: Recording stops at random times on previously used tapes.

Once all the obvious problems and cockpit errors have been eliminated, mechanical problem still likely even though the VCR does not abort immediately. A worn idler tire, worn or defective idler clutch, bad belt, or improperly adjusted backtension, are all possibilities.

This is particularly likely if the problem is more likely to occur or only happens near the end of tapes as the required takeup reel torque is greater and any of the above mechanical problems will be exacerbated.

With instant start transports - where the tape is maintained around the video head drum for all but the fastest rewind, there could be other control problems as well.

If the operation starts properly (as indicated by a changing picture on the TV in play or from a visual inspection with the cover off) but the tape counter does not change value and then the unit shuts down, a reel rotation sensor problem is likely. See the section: Reel rotation sensors.

This could still be due to problems similar to those which cause an immediate abort if some components or connections are marginal. Also see the section: VCR aborts play or record during startup or shortly thereafter.

VCR eats tapes

The most common cause of a VCR eating tapes is a dirty/worn idler tire preventing the takeup reel from turning. See section: General guide to VCR cleaning and rubber parts replacement. The idler tire transfers motor power to the appropriate reel hub. If dirty, worn, dried out, glazed, cracked, or otherwise deteriorated, it will slip and cause the takeup reel (in play mode) to stop turning at some point. Hopefully, the microcomputer senses this and tries to wind the tape back into the cassette. But, you guessed it, this requires the idler tire so you end up with a mess of tape inside the machine. When you go to eject, you may get the cassette with a tape loop hanging out. If you are careful, you may be able to extract the tape without crinkling it too badly but don't just pull - it will break or be hopeless damaged. You will need to remove the top cover and carefully lift the tape loop out of the machine and wind it back into the cassette. If there is any significant crinkling or a partial break in the tape, discard the cassette. If it is priceless and irreplaceable, see the section: Recovering damaged or broken tapes. DO NOT try to use it or just return it to the video store without informing them of what happened - it is unfair the next renter as a badly crinkled or partially broken tape can destroy expensive video heads.

Tape loop hanging from cassette when ejected after play or record

(This may also apply to other modes for a VCR with a 'quick start' or 'instant start' transport.)

If your VCR aborts playing unexpectedly and shuts down and then, pushing EJECT results in a tape loop hanging out of the cassette when it is removed, this is considered tape eating - refer to the section: VCR eats tapes. However, if all other functions work normally but ejecting results in a tape loop, this section is for you.

Using a garbage cassette, try to observe exactly what is happening during EJECT. Specifically, is the operation terminating early or is there some problem with the appropriate reel not turning or not turning reliably or quickly enough? Is the tape getting hung up on the roller guides or on some other guideposts?

As with tape eating, the most common cause is dirty, old, deteriorated rubber parts - particularly the idler tire - preventing the tape from being fully wound back into the cassette. Therefore, the first step is to follow the procedures in the section "General guide to VCR cleaning and rubber parts replacement".

If this only started happening after you had the VCR apart for any reason, recheck your work - you may have neglected a connector, have the mode switch slightly out of position, or have gears which are improperly timed.

Many VCRs determine that the tape is completely wound back into the cassette by sensing rotation of the non-driven reel indicating that the tape is pulling on it as a result of being tight and pulled by the driven reel. If this sensor is defective, disconnected, the signal is noisy, or the associated electronics are faulty, the operation may be terminating early. As an experiment to confirm this, use a cassette cheater and while the VCR thinks it is winding the tape back into the cassette, turn the non-driven spindle by hand - this should stop the operation instantly. If it stops too quickly - before you turn the spindle, there could be a problem with this sensor. It is also possible for a failure of one of the reel brakes to allow one of the reels to continue spinning even after motor power has been shut off. Alternatively, a sticky brake band may increase the driven reel torque and fool the microcontroller into thinking that the tape slack has been taken up.

If the roller guides get hung up on the tracks while being retracted, even for an instant, the tape may become tight around the roller guides, pull on the non-driven reel, and stop the operation before the tape is fully wound back into the cassette. Check for obstructions and for adequate lubrication of the roller guide tracks.

If it is a late model Sony, the 'half loading arm' could need lubrication. See the section: Late model Sony VCR munches tape on eject.

Tape slows or stops (as though in pause or slow mode) while playing

What this means is that the tape continues to show a picture but it appears as it's struggling to pull the tape through the machine - which is basically what's happening. Once the picture freezes, it will probably abort due to the lack of reel motion.

With some VCRs, this may also result in periodic slowing or pausing. See the section: Sony capstan motor (bearing) problems.

There can be a variety of causes for this behavior but the most likely is related to a dry or worn capstan bearing or a defective capstan drive/servo circuit. The capstan rotation almost entirely determines tape movement during play and special effects modes. Only if for some reason the supply reel cannot rotate at all, could the capstan attempt to pull the tape across the video head drum unsuccessfully.

If you can catch the VCR in the act, then there are several tests that can be performed easily to localize the cause:

- If the capstan or its circuits are at fault, the tape tension on the supply side of the capstan will be normal. This is relatively loose if gently pressed side-ways or released by moving the back tension arm to the right. The picture will remain synced on the TV (though there may be noise bars due to incorrect tracking).

- Where a dry or worn capstan bearing is to blame, there may be an associated mechanical growning or grinding sound as well. Stop the VCR and immediately check to see if the capstan turns freely and smoothly.

  Cleaning and lubrication will help. Whether this is a permanent cure will depend on the severity of the damage.

- A magnetic sensor that is mounted too close to the perimeter of the capstan motor rotor can also rub as the rotor expands. As above, there will likely be noise - maybe a tick-tick sound with one tick per rotation of the capstan before it stops completely.

  Adjust the position of the sensor. It's hard to say from here how far away it can be but as a start, you should be able to slip a piece of letter paper between the sensor and the rotor without it rubbing at any position of the rotor.

- Where the capstan is belt driven (most nowadays are direct drive DC motors), a worn or flabby belt could be the cause. In this case, see if the belt is not successfully turning the capstan and check to see if the capstan itself is hard to turn - which would point to a bearing problem.

Inspect the belts and replace if necessary. In the meantime, clean the belts and pulleys which should result in some improvement and confirmation of the cause of the problem.

- If on the other hand, it is a supply reel brake that hasn't released, excessive back-tension, or something binding, the tension will be very high, causing the head drum to slow down and stop in extreme cases. Sync will be lost as this happens.

  You will have to determine what is preventing the tape from being fed properly. There could be a broken part, a problem with the supply reel or some other bearing, or something else like a defective brake release solenoid or its driver.

(From: Frank Fendley (frank.fendley@datacom.iglou.com).)

To see if the bearing is the problem, I usually remove the bottom cover of the VCR, play a tape for a fairly long time (or until the symptoms pop up), and then flip the VCR over and check the temperature of the IC on the capstan motor circuit board with my patented index-finger thermal probe. If the IC feels "hot", as opposed to warm or even very warm, I'm pretty confident that the bearing is at fault. (I define "hot" as too hot to leave my finger in place for more than a couple of seconds).

If the IC doesn't feel excessively warm after the symptoms start, I would suspect a heat problem in the servo section. This could be a tough repair, unless a can of freeze spray proves helpful in pinpointing the component.

Video head drum stops or slows during play or record

Check whether the backtension on the tape is applying so much pressure to the drum that it is slowing it down. Backtension should be just enough to keep the tape in good contact with the drum. If it is too tight, then you backtension felt may be worn or adjusted too high. There is a lever just as the tape exits the cassette - push this to the right to reduce tension. Someone may have attempted to repair a broken backtension band and reduced its length - I got a VCR for repair once where this was done.

If it is not the backtension, check free rotation of the drum when it stops - I bet it turns as freely as always. Could be a part in the motor driver that is faulty and failing when hot. However, the bearing could be worn or dry which would require disassembly and lubrication or replacement of the lower cylinder (assuming this is where the drum bearings are located).

Tape sticks to head drum

(From: Gary Woods (gwoods@albany.net).)

Usually under humid conditions, but not condensation of tape path, tape has excessive amount of drag around the scanner. S-tension is OK, or even a little light, but there is so much drag around scanner that the capstan skids.

- Reducing S-tension helps.
- Cleaning scanner helps.
- Cleaning capstan and treating pinch roller with PRB "conditioner" (smells like ether) helps.

None of these is a *real fix* and the problem recurs eventually. Somewhat dependent on the tape, but real problem appears to be drag around lower drum. Anyone know of a fix other than a new scanner?

(From: Daniel Schoo)

This seems to happen mostly on machines with a lot of play time. There is supposed to be an air film between the tape and drum to facilitate the reduction of friction. When the drum gets worn and polished the air is squeezed out and the tape sticks. Little can be done for this. You could replace the drum but this is expensive and not worth the effort for most machines. The other option is to try and rough up the drum surface by light sanding with 3M Scotchbrite(tm). I don't need to go into detail about how difficult this is to do correctly but what the heck you don't have anything to loose. Just be careful and stay clear of the heads. BTW I have seen "cleaning" tapes that rough up the drums very well!

Picture jittering vertically may be similar problem. Tape is not moving smoothly over the head drum.

---

5. Back to [VCR Repair FAQ Table of Contents](#).

General Control Problems

VCR is alive but will not do anything

Typical symptoms: front panel display is active, it may be possible to set the clock or timer and change channels, but all transport related buttons are totally inert. Perhaps there is no response to any button. The VCR may or may not refuse to accept or eject a cassette.

This could mean many things including motor problems as well as a general power supply or control system failure. However, here are a several things to try first:

0. Check for cockpit errors - Someone may have accidentally set it for 'timer record' or in 'parental lock mode'. Is there a little clock or key symbol, 'L', (or something else you don't understand) displayed? Inspect the position of any slide or push-push switches.

   - Timer mode may be set by a pushbutton, push-push, or slide switch, or from the remote control.
   - Parental lock is usually accessible only from the remote control. See the section: VCR shows LOCKED in the display.

     Consult your user manual if in doubt about how the thing is supposed to work!

1. Cycle power - unplug the VCR from the wall (don't just use its power switch) for a minute or two to see if the microcontroller simply got into a confused state. This is more common than you would think. A random power surge can do it. The VCR may have gotten into a bad (mechanical or electrical) state.

2. Unplug the VCR and remove the covers. Rotate the shafts of each of the motors (cassette loading and tape loading or main motors depending on your VCR) clockwise a couple of turns (assuming there is no resistance to turning). Plug it in and listen for initialization sounds - it should detect that the mechanism has been moved and then reset to a safe position. See if it is now behaving.

3. If (2) doesn't do anything, try several turns counterclockwise instead.

4. If still no improvement, there may be more serious power supply, motor, or control system problems.

If any of these appears to solve the problem, it is quite possible that you will never experience it again. However, a dirty mode switch (see the section: VCR mode (sensor) switches may have resulted in an overshootto a bad mechanical state and without cleaning or replacement, the same thing may happen again.

VCR clock does not run

The clock runs either off the power line (zero crossings of the 50 or 60 Hz waveform) or from a crystal (possibly a reference derived from one of the other frequencies used elsewhere in the VCR). Conceivably, a bad backup battery or supercap might result in the clock remaining in setup or power fail mode.

Unfortunately, this probably isn't much help since identifying and locating the relevant components will be next to impossible without a schematic :-(.

VCR attempts to play non-existent cassette

You turn power on or just plug in the VCR to the AC outlet and it goes through the whirring sounds of playing a cassette - but there is not cassette present.

However, first try unplugging it for 30 seconds or so and plugging it in again. The microcontroller may just have had a bad day and gotten confused - either a bad reset or a power glitch.

Assuming this doesn't help:

This could be due to a faulty end sensor or a bad LED or light bulb that provide illumination for the end sensors.

If either sensor's output is the same as when a cassette is present (blocked), it very likely that the microcontroller will be confused. In some designs, this is indistinguishable from a cassette actually being loaded.

If the 'cassette in' indicator is on, then this is likely.

BTW, if a VCR uses an actual light bulb for that central light source and it is not lit when you attempt to load a cassette, it is burnt out. The LEDs used in most modern VCRs are IR and invisible, however.

With somewhat similar symptoms, it is also possible that the VCR is not able to complete the startup initialization due to a slipping belt, gummed up lubrication, or other mechanical or motor problem.

The clincher would be if you manually load a cassette (by turning the appropriate pulleys, etc. with it unplugged) and it then plays the cassette properly and acts normally until you try to eject. However, don't try this unless you are sure of how the mechanism works as it is easy to cause damage.

Erratic behavior in various modes

You press PLAY and the VCR gets halfway through loading the tape and suddenly aborts and shuts down. Or, you put a cassette in and it is immediately spit out as though it tasted bad to the VCR. Or, you press PLAY and the VCR goes into REWIND mode. Or, you pressed REVIEW and it ejected or attempted to eject the cassette.

Before you break out the screwdriver or shotgun, cover up the IR remote sensor and cassette slot. Some types of electronic ballasted fluorescent lights may confuse the remote control receiver. Or, someone or something may be sitting on the remote hand unit or it may be defective and continuously issuing a REW command! Excessive general illumination may even make its way into the tape start and/or end sensors and trick the VCR into thinking the tape is at one end. (If you are working on the VCR with its cover removed, block any stray light from hitting the area of the tape transport to see if behavior returns to normal.)

Assuming neither of these is the source of the problem:

First, eliminate the possible mechanical causes such as slipping belts or a bad idler tire which could prevent the VCR from completing your requested action - it then shuts down or attempts to return to a 'safe' position.

Bad connections are a possibility but not as likely as in a TV or monitor, for example. However, some VCRs (certain JVCs and clones, for example) ground parts of the circuitry via the circuit board mounting screws and simply tightening these are all that is needed to affect a cure.

The microcomputer or its associated circuitry could be defective as well - but this is not as common most people fear.

Occasionally, a faulty power supply may result in similar behavior. Its output voltages may be marginal, drop under load, or have excessive ripple due to dried up filter capacitors.

However, a more likely possibility than any of the above is that a sensor assembly present on most VCRs called the 'Mode Switch' or 'Mode Sensor' is dirty or bad. See the section: VCR mode (sensor) switches. Failure of the Mode Switch is a very common problem with numerous VCRs of many makes and models.

VCR mode (sensor) switches

In order for the microcontroller in a VCR to confirm correct functioning and completion of various operations like cassette and tape loading and roller guide position, some mechanical sensor feedback is normally used. The most important sensor assembly in most VCRs is called the 'Mode Switch' or 'Mode Sensor'. The purpose of the Mode Switch is to inform the microcontroller of the gross position of the mechanism at all times. For example, the mode switch may have 5 positions:

1. Tape unloaded and cassette out.
2. Tape unloaded and cassette in.
3. Tape half loaded against A/C head but not around drum.
4. Tape fully loaded around drum and roller guides at V-Stoppers.
5. Pinch roller pressed against capstan - play/record position.

The microcomputer monitors the outputs of the Mode Switch continuously when it is executing a mechanical operation (some monitor it at all times even with power 'off'). If an operation takes too long to move from state to state or an incorrect state transition occurs, the operation will be aborted and an attempt - possibly several - will be made to return the transport to a 'safe' position - unloading the tape and possibly ejecting the cassette.

Most Mode Switches are actually mechanical rotary or linear switches with sliding contacts. However, some VCRs use optical Mode Switches - IR LEDs, a slotted wheel or sliding mask, and photosensors. These are much less common and failures are even less likely. Most of the specific comments on below on cleaning and so forth apply to the mechanical variety. See: Studio Sound's Mode Switches Page for some photos of typical units.

If the Mode Switch contacts are dirty or worn, or if it has somehow loosened on its mountings and shifted slightly, one or more of these positions will report back incorrectly or erratically signaling an error condition. For example, a transition from state 1 to state 4 directly would totally confuse the poor controller. A Mode Switch that shifted out of place (or where other timing relationships in the VCR are messed up) might result in certain operations stopping at the wrong position as well. For example, if the Mode Switch shifts one way, the pinch roller may never quite press against the capstan or the roller guides may not snuggle up to the V-Stoppers as they should in play mode. If it shifts the other way, operations may fail to complete and run against the mechanical stops - stripped or broken gears may even the result.

A dirty or worn mode switch can result in cassette or tape loading, or unloading or eject operations aborting and resetting or the VCR shutting down. For example, some Emerson VCRs will move part way when loading and then shut down. Repeated attempts may get them fully loaded and then PLAY or other tape movement operations will work properly. However, unloading will result in similar cranky behavior.

Note that erratic behavior that happens after the tape has been playing or recording for awhile is probably not mode switch related since nothing is changing in terms of mechanical relationships and the mode switch is probably happy. However, there can always be exceptions.

Mode Switches are usually linear or rotary slide switches with 4 or more output terminals. They may or may not be easily accessible. On some, they are visible once the bottom cover is removed. On others, they are buried beneath a bunch of mechanical doohickies (technical term). Some are removable with a screw or two and a connector. Others require desoldering and the removal of a whole lot of stuff - all of which must be carefully replaced with exactly the same timing relationships - just to gain access.

Once, you get at them, you can often snap apart the housing and use contact cleaner on the sliding contacts and surfaces. I usually do not use any kind of lubricant as it can gum up on the contact surfaces resulting in erratic outputs - possibly the cause of the original problems in the first place. Some may not come apart and replacement is the only option if squirting contact cleaner through any visible openings does not help. Note that without disassembly, there is no way of knowing if there is still dirt or gummed up grease inside or if the contacts are actually pitted. Conversely, if squirting in some contact cleaner does not help, the mode switch may still be the problem since you have no way of knowing how far the contact cleaner penetrated or whether it had any effect.

Sometimes, bad solder connections to the mode switch are the only problem.

However, be very careful about not moving anything and take careful notes on the position of any parts that you disconnect as critical timing relationships are controlled by the gear positions. Stripped gears or other broken parts may result when the mechanism cycles. Also, in certain positions, levers or sliders operated by the mechanism you remove may spring out of position and you will need to make sure they get put back into the correct slots in any cams when you are done. Mark all gear positions even if they do not seem to be critical. See the section below on how not to mess up your day by ignoring timing marks or more simply: "Mechanical relationships in VCRs".

Note that if you experience erratic behavior with a VCR manufactured by Sharp, the probability of a dirty mode switch is very close to 1. See the section: Erratic behavior of Sharp VCRs.

There are even some poorly designed VCRs where extraneous light through the vent holes or tape door affect sensors and cause erratic operation. If a bright light is shining on the VCR, block and see if anything changes!

Mechanical relationships in VCRs

The complexity of the mechanism in a VCR can be quite intimidating. To avoid total frustration and really messing up your day, before you remove anything mechanical, take careful notes of precise relationships of any gear, lever, switch, anything that might possibly get back together in an ambiguous way. Often there are 'timing' marks on the gears just as you would find in a lawnmower or automobile engine. These will be little arrows or holes which will line up with stationary marks or with each other on adjacent gears when the mechanism is in a particular position. Often, it is best to put the mechanism in the position where the timing marks line up because there may be fewer levers, cams, etc. which are under pressure or tension in this position and thus fewer things to pop out at you. If there are no apparent timing marks, make your own with a scribe or pen. Sometimes mechanisms that at first appear not to be critical are obscured in such a way that they really control critical timing. So, when in doubt, make more notes than necessary - with diagrams. In rare instances, there may even be a diagram showing the timing relationships pasted to the bottom cover or stamped on the chassis. What a concept!

Intermittent behavior

This may mean that pressing on a circuit board, flexing a cable, or operating the VCR in different orientation affects behavior. Sometimes this is affected by temperature as well.

Note: if this only happens while servicing, confirm that excessive light is not affecting the start/end sensors.

Do not confuse these sorts of symptoms with those indicating a faulty or dirty mode (sensor) switch. See the section: Erratic behavior in various modes.

6. Unlike TVs and monitors which have high power circuitry and are prone to cold solder joints from poor manufacturing or thermal cycling, most of the circuitry in a VCR is low voltage and low power. Although problems with bad connections to these components is relatively rare, visual inspection should still be performed where erratic behavior is noted.

   Exceptions include:

   - Power supply regulator(s) or switchmode power transistor (depending on type).
   - Motor driver (power) transistors or ICs - particularly those for the main (capstan/reel) drive and video head drum.
   - RF, video, and audio jacks since they may be stressed mechanically.

7. Internal multiconductor (crimp terminated) cable connectors. These may just deteriorate with age and use. Clean and reseat the connector(s).

8. Circuit board ground screws. One or more of the screws holding a circuit board may also be providing a ground connections. These can work loose or corrode. Remove screw, scrape corrosion, and/or tighten.

9. Hairline cracks in circuit boards. If the VCR has been dropped, this is very common. Sometimes, these are very difficult to locate visually but locate them you must! See the section: VCR was dropped.

10. Broken or shorted wires. Some of the individual wires in various signal cables are quite thin and fragile. Overzealous movement of circuit boards while replacing belts or other maintenance operations can easily pinch these resulting in immediate or delayed failure. This may also take place when replacing boards. It seems that the manufacturers seem to make it impossible to squeeze all the wires back in where they came from!

    CAUTION: Always try to avoid pulling on the wires when removing a connector. This will minimize stresses which could result in the wire conductor breaking off inside the insulation - this would be very difficult to locate.

VCR does not work after cassette was forcibly removed

You were watching your favorite tape and suddenly the VCR emits a mechanical eek and is now dead - or you press eject and the VCR shuts down without regurgitating your tape. Worse yet, someone (we will not point fingers) forcibly removed the tape to return it to the video store.

Assuming that 'forcibly' does not mean that permanent damage was done, then the first place, as always, to check is the idler tire and then all other rubber belts. At this point it is hard to say whether your problem was compounded by the removal of the tape. If any gears were shifted with respect to one another, parts bent, or springs sprung, then without a service manual, it would be difficult for a technician let alone someone not familiar with your VCR to repair it.

An error at power on usually means that the microcomputer thinks that it is unable to put the mechanism into a 'safe' position. This could be due to slipping belts, broken gears, a bad motor, shifted sensors, or faulty electronics. The original symptoms may have been a slipping idler preventing the takeup reel from rotating allowing tape to spill into the machine. Power on problems may be more serious. See the section: VCR is failing the power-up sequence.

If this is not enough for you to get the hint

Here is a true story of forced eviction of a tape and the consequences. :-(This teaches you two lessons: Don't use violence to remove a stuck cassette and mark all gear, lever, sliders, etc. timing relationships before you disturb anything!

(From: AL (kb8wcq@tir.com).)

"I have a Panasonic VCR (model PV-4820) that will not acknowledge tapes. The original problem I found was in the power supply. I replaced all the electrolytic caps, and the PS now works- all the outputs measure OK and the display and tuner controls seem to work OK.

But once the PS went bad, it would not take in tapes, so the owner decided to force one in. He sheared half the teeth off of the 'link gear', which I replaced, but it still will not accept a tape. I can manually push a tape all the way in, with some resistance, until it sits down on the reels, but it is not acknowledged in any way. If I don't hold it down, it springs back out."

It sounds like you possibly failed to retime the link gear in relation to the rack gear on the loader assembly.

If that's the one I think it is and you have not timed one (of course this is something the average person does, say once a week? :-) --- sam) before, you probably should get the manual. Or try this: Remove the carriage assembly, turn the VCR on its side, press and hold the little height change lever (bottom side, near the solenoid), manually turn (CCW) the large belt-driven pulley until the mechanism is in the full eject position, note the position of the link gear, turn the large belt-driven pulley in the opposite direction until the link gear makes exactly one revolution, re-install the carriage (in the eject position) making sure the carriage gear and the link gear mesh properly.

Other than that it's pretty simple... Assuming of course nothing was disturbed with the gears below the deck, and that the link gear, mode switch, pressure roller lift cam, etc', are in their proper position.

Sounds simple enough! --- sam :-)

VCR is failing the power-up sequence

This often means that the internal microcomputer found the mechanism in an unusual state and was unable to reset it. Some VCRs will actually move portions of the mechanism to make sure that everything is OK to accept a tape. Failure here may be the result of a slipping or broken belt or a belt that has popped off of its pulleys, gummed up lubrication, or some other mechanical fault. How old is it? Rubber parts tend to become smooth and lose their elastic properties ('rubberiness') after a few years. Does the VCR make any kind of whirring sounds before shutting down? This would mean that it is attempting to move something back into position. Is there a tape in the machine? How about a toy, peanut butter and jelly sandwich, or a little applesauce? It could be a sensor or other electronic problem, but check out the mechanical possibilities first.

On a VCR which has been cleaned and with good rubber parts:

VCRs have a light or LED (IR, infrared) in the middle of the mechanical assembly that detects the end of tape. When a tape is loaded the tape will cover the sensor. The controller can tell if the tape is at the beginning, middle, or end by the sensor. The is achieved by a clear leader at the beginning and end of the tape. The microcontroller will detect a problem if the sensors do not detect the light or LED (middle of tape) and the carriage assembly is up (no tape loaded). The VCR will shut down.

1. If you have an incandescent light and it is not lit, it is burned out. If you have the LED type you can buy an IR tester from an electronic parts supplier or construct one as described at the end of this document. Replacement LEDs are readily available.

2. The VCR might be in a confused state. Many VCRs have a belt that drives a loading motor. This is the motor that drives the tape around the heads. If those guides are not fully retracted, the VCR shuts down. Check the belt and replace if necessary.

3. Ensure the tape guide assembly is fully retracted by physically turning the appropriate gears.

4. Some obstruction is preventing part of the mechanism from resetting. Visually inspect for foreign objects or rough edges on something preventing full movement. Dried up grease can also cause this.

5. A gear has slipped a tooth and one part of the mechanism does not track another. This may happen if a tape was forcefully ejected after being eaten. You may find that a tooth has actually broken off.

6. If this occurred after having disassembled part of the mechanism, confirm the timing relationships. Make

sure belts are installed in the correct locations - and on the correct sides of any intermediate pulleys where belts link more than two pulleys.

Without a service manual, determining the correct relationships for all gears may be impossible, but if only one has slipped you may be able to locate timing marks near the edges of the gears which should line up - usually when the tape is unloaded. (portions from michael@marconi.nsc.com)

VCR displays DEW warning

Your VCR has worked fine for several years but now you get the 'DEW' warning in the display and no tape functions work.

The dew sensor is intended to prevent operation of the tape transport if the humidity is so high that moisture would build up and cause the video tape to stick to the rotating drum and damage the heads or get hopeless tangled as a result.

First, perhaps the dew warning is telling the truth. If you have just moved the VCR from a cold area to a warm one, let it sit for an hour or so and see if the dew warning goes away. If you just fished it out of the toilet or scraped stewed peaches from the interior, well, dew may be the least of your problems. Or, if you have just cleaned the inside of the VCR (or maybe even the outside if you were really overzealous!), some of the liquid may have gotten on the dew sensor (it is likely to be near the video head drum) so waiting a few minutes may be all that is needed to rectify the situation.

Assuming that there is no reason for a dew warning, the dew sensor may be bad or have changed value. There may or may not be an adjustment for this.

Before you go inside, try unplugging the VCR to clear any spontaneous fault condition - see the section: VCR has gone whacko.

The dew sensor is a resistor that changes value when there is condensation. If the sensor is bad, you should be able to replace it with a resistor and keep the VCR happy. You should be able to determine the appropriate resistance by trial and error. If it is the type where the resistance decreases with moisture and the controller does not care if the resistance is too high, then you can just remove it. Either way, you have now lost the protection that the dew sensor provides. Replacement is obviously best.

Don't overlook the possibility of a bad connection - it may be plugged in and just need to be reseated.

One type looks like a ceramic board, maybe 1/4" - 1/2" on a side with a silver/gray printed circuit pattern.

If the A/D or whatever is used to determine when there is dew is faulty, then you will most likely need a service manual to troubleshoot it.

Apparently, given the marginal value of the dew protection and the problems caused by it, newer VCRs may not even have a dew sensor.

The following pair of recommendations would seem to contradict one-another slightly but could still be a start:

(From: John R. Hepburn (jhepburn@recorder.ca).)

I use a 3.3K... No great technical justification other than 1 to 10K works on most machines and I ended up with a lot of 3.3K from an auction. Now if I could just get about 10,000 more old VCRs with a flashing dew light I could get rid of this darn box!!!

(From: Dan Sofie (sofie@olypen.com).)

The problem may not be the dew sensor but the support circuitry instead. In most circuit designs with dew sensors, it is ON (moisture detected) at about 450 ohms or higher and it is OFF (dry) at about 450 ohms or less. Try bridging a 100 ohm resistor across the terminals to see if the light goes out. If not, the problem is not the dew sensor, but the circuitry it interfaces with.

VCR shows LOCKED in the display

You go and try to play a tape and the VCR displays the word 'LOCKED' or perhaps just a flashing 'L' or 'PL' in the display.

This may mean that the VCR has somehow been programmed to prevent use by unauthorized kids (you are not reading this if you are a kid, right?) Even if your model does not have this feature, the same basic chassis is probably used for a range of models so it could have gotten into a confused state.

- Sometimes, just pressing the TV/VCR, PLAY, POWER, VCR1, VCR2, (or other much more obscure) button on the remote control (it may be designed not to work from the front panel) for 10 to 30 seconds will clear this mode. Some remotes have a little 'key' symbol. How logical! Press it.

- Unplugging the VCR for a minute or two may work. Unplugging for long enough to drain the backup battery will probably work but you may then need to reinitialize the clock, channel selection, and programming.

- Best bet is to check your instruction manual (you can locate your user manual, right???).

VCRs with Alzheimer's Disease

Suppose your just-out-warranty VCR is now acting up for no apparent reason - making strange sounds, forgetting its programming, refusing to cooperate, etc.

I don't know what kind of recourse you may have as an unsatisfied consumer, but I would try to get some resolution through your place of purchase. Such a VCR has all the symptoms of Alzheimer's disease - it should not be failing in these ways so early in life unless it is under penalty of hard labor in the damp snake infested dungeon of an English castle! Or it has been the depository for peanut-butter-and-jelly sandwiches, applesauce, or marbles!

All the usual recommendations of cleaning and checking rubber parts and so forth apply to units that have seen significant use or are a few years old or both. Something this new under normal use should not be causing this amount of grief. However, sometime I wonder whether using a machine very little contributes to problems.

First try your place of purchase - there may still be some degree of interest in maintaining customer satisfaction.

If you have given up on the store, start by checking the rubber parts for dust and deterioration (with that kind of use, dirt should not be a problem, but dust or smoke can accumulate), check for adequate lubrication (but don't add any unless it is definitely needed and then only the smallest amount - VCRs do not need much oil or grease and too much will just compound your problems - and check for foreign objects especially if there are small kids about.

VCR has gone whacko

You may think you are on the set of the latest sci-fi movie. The VCR displays are counting at random, pushing buttons produce unexpected results, motors may be spinning, or the VCR may be repeatedly loading and unloading a non-existent tape. I may be attempting to play a tape even without you pressing any buttons.

While these could be symptoms of a actual problem, first try unplugging the VCR from the wall outlet (don't just turn it off) for a minute or so.

If this does not help, try unplugging for a couple of hours - this will usually drain the backup battery and reset many other functions of the VCR.

If one of these techniques results in the universe returning to normal, there may have been a power surge or lightning strike nearby which threw the microcontroller into a confused state. It may never happen again. However, power surges can be the result of heavy appliances like air conditioners on the same circuit. If this is the case, you should consider using a different circuit for your electronic equipment.

If this behavior started when the VCR was just plugged in or following some other action requiring the mechanism to move or initialize, check for mechanical problems like a broken belt or one that has popped off its pulleys or an obstruction like a rock or toy that is preventing the VCR from completing the required motions. Also see the section: VCR is failing the power-up sequence.

Once you have ruled out mechanical problems, it is likely that the VCR has a microcontroller, power supply, or other electronic problem which may require professional service.

VCR forgets settings following power failure

Normally, the AC line provides power to retain the clock, active channels, and programming settings. During a power failure, the clock and programming is usually powered using a supercap or battery (usually rechargeable). Channel settings for older style varactor type tuners were often stored in some kind of non-volatile memory while active channels for quartz tuners generally use battery backup.

The clock and programming backup may be a supercap - a very high value special electrolytic capacitor - as much a 1 F (1,000,000 uF) at 5-12 V. Alternatively, it may use a rechargeable NiCd battery. In either case, these are easily replaceable with standard parts. A NiCd battery pack of similar ratings should be readily available. Supercaps are available from large electronics distributors.

NiCd batteries fail in two ways - loss of capacity or shorted cells. If memory is retained for a much shorter time than it used to, then the battery has probably lost most of its capacity. If you measure less than n x 1.2 V for an n cell NiCd battery pack after it has been charging for awhile, there is likely a shorted cell. In either case, the best solution is a replacement though the various common techniques for rejuvenating NiCd battery packs can be attempted (remove from VCR first!).

The non-volatile memory could use a special chip like EEPROM which does not require power or a battery backed SRAM or be internal to one of the VCR's microcontrollers. Channel memory may use a separate power source from the clock and programming, possibly a Lithium battery since it is undesirable for the channel settings to be forgotten even if the VCR is unplugged for a month or more as it is such a pain to reinitialize them. Rechargeable batteries have too high a self discharge rate.

Display is dim

Where the display works but is dim, there can be several causes:

- Some VCRs have a 'night mode' which dims the display after, say, 10:00 PM. Check that you don't have the clock AM and PM set incorrectly. There is usually a way to disable this 'feature'.

- If the VCR has been used in a location where there are heavy smokers, whatever tar and nicotine somehow avoided getting trapped in their lungs may have been deposited on the front and rear surfaces of the plastic display window and on the front of the display tube. Remove the front panel and use alcohol and a soft cloth to thoroughly clean all these surfaces.

- The VCR may have seen a long active life. Like CRTs and other vacuum tubes, cathode emission and/or phosphor brightness can degrade over time. There may be nothing much that can be easily done to remedy this but see the comments below.

- The filament or anode voltage may be low or faulty due to a bad connection, dried up electrolytic capacitor, or other power supply problem.

See the section: Display is dead but everything else works for more information.

Note that as a preventive measure, if your VCR has a dimming feature, use it. Operating the displays at lower brightness will prolong its life.

CAUTION: Try the following at your own risk - too much voltage on the filament will melt it.

(From: John Robertson (jrr@flippers.com).)

If these are the blue fluorescent displays then they might be able to be recharged. A bit of background first - a number of years ago people were finding that the blue fluorescent displays in Gottlieb pinball games would dim over the years until they were unusable. One clever fellow discovered that if you heated the filaments in these tubes until they glowed a dull red, by increasing the filament voltage, then the tube would work again at almost it's original brightness, plus this "recharge" would last for years in many cases. The normal filament voltage for some of these displays was in the order of 4 VAC and if the filament was then run at about 8 to 12 V (dull red to medium orange glow) for about ten seconds that the job was done.

So, if these tubes have a filament (several very fine horizontal wires inside between the front glass of the tube and the digit plane) - the connections would be the very first and the final pin of the tube, check the voltage there (AC or DC?) and then with the device turned of and a variable voltage source try increasing the filament voltage until you see the glow, then try the display out in normal operation.

(From: Andy Cuffe (baltimora@psu.edu).)

I've also had some success with increasing the negative bias to the filament by a few volts. I have an NEC VCR that had a very dim display even after replacing the bad caps in the power supply. Changing a zener diode to increase the negative bias by about 5 V did wonders.

Display is dead but everything else works

This usually means that one or more of the voltages to the vacuum fluorescent display (VFD) are missing or that the display controller is bad. If the front panel suffered physical damage, the display tube, circuit board, or other components could be damaged.

The VFD is usually designed to operate in a multiplexed mode to minimize pins and drivers at the expense of more complex logic - but that is all inside the system controller chip anyhow. Thus, there are 'segments' which correspond to the portions of each character and individual symbols, and 'grids' which are in effect, enables for each character or group of symbols. Compared to a multiplexed LED display, the segments correspond to rows and the 'grids' to columns. The filament, grid, and anodes operate in the same manner as in a vacuum tube (valve for those on the other side of the lake) or a CRT, for that matter. A typical VFD might have 9 segments and 7 grids for a total of 63 possible individually controlled displayed items.

The filament requires 2 to 6 VAC. Each of the segment lines are sequentially pulsed to about 30 V or more while the appropriate set of grids are pulsed positive to enable the desired combination of displayed items.

Here is the pinout for a typical VFD (from a Sharp VCR):

```
Pin 1: Filament 1A   Pin 2: Filament 1B (Tied together)

Pin 5: Grid 6        Pin 6:  Grid 5       Pin 7:  Grid 4     Pin 8: Grid 3,
Pin 9: Grid 2        Pin 10: Grid 1       Pin 11: Grid 0

Pin 12: Segment 8    Pin 34: Segment 7    Pin 35: Segment 6,
Pin 36: Segment 5    Pin 37: Segment 4    Pin 38: Segment 3,
Pin 39: Segment 2    Pin 40: Segment 1    Pin 41: Segment 0

Pin 44: Filament 2A  Pin 45: Filament 2B (Tied together)
```

All other pins are either not present or no-connects. While specific pinouts for each VFD device are likely to differ somewhat, the general arrangement appears to be similar - filaments on the ends, grids mostly on the low numbered pins, a gap with no pins or unconnected pins, then the segments on the high numbered pins.

Remove the front panel and with the VCR plugged in, turn out the lights and inspect the filament, several very fine wires running the length of the display. They should be glowing a very faint red-orange. If you see nothing, the filament voltage is likely missing. Filament voltage may come directly from the power transformer (if a non-switching type power supply) or be one of the DC outputs of the supply.

Check around the VFD for the +30 VDC (approximately) or if you have a scope, look for pulses on the pins of the VFD. If the +30 VDC is missing, there will be nothing displayed. In some VCRs like those manufactured by Hitachi, a separate DC-DC converter module provides power for the display only. See the section: Dead clock in Hitachi manufactured VCR.

Look for bad connections, open resistors, blown IC protectors or fuses, etc.

Of course, if the VCR has an on-screen display, you will be no worse off than many newer models that have done away with the front panel VFD entirely!

(From: Paul Grohe (grohe@galaxy.nsc.com).)

The fluorescent display in the VCR's I have seen require three sets of voltages:

1. The filament requires a floating 3 VAC (but see above --- sam).
2. The filament has to be biased at -12 V to -15 V
3. The segments need +20 V to +30 V to light.

The DC-DC converter usually provides a "floating" 3 VAC winding, a low current -12 VDC tap connected to one of the filament leads, and a +20 VDC to +30 VDC segment drive voltage.

If you look really, really closely at the display, you will see the faintly glowing filaments stretching across the length of the display.

It figures that the makers of VFD's would have a nice section on VFD displays. Here are some links to appnotes for driving VF displays. They have a few "tidbits" in them. AN-440 has a nice graphical depiction on page 2.

- AN-371
- AN-440

(From: Mark Zenier (mzenier@netcom.com).)

A DC filament supply can cause a brightness variation across the display depending on the design. And, as I remember it, some of them have lower filament voltages, like 2.5 VAC. A fatal thing to burn out.

The only one I've really messed with was a 32 character, 14 segment character display. It used a 6 volt filament, and 60 volts on the grids and segments/anodes. The filament/cathode was biased 6-9 volts positive, so that when the grids were grounded, they were negative relative to the cathode.

The power supply for this display was rather quirky, it used a H-bridge with emitter followers supplied by the system 12 volts, but the lower drivers of the H were clamped at 6 volts so that it supplied 6 vrms at a high (5-10 kHz) frequency to the filament, offset by the 9 volts, and a transformer, hooked up differentially, stepped that up to the 60 volts for the drivers. A real RFI pain in the ass.

---

11. Back to VCR Repair FAQ Table of Contents.

Play and Record Control Problems

VCR randomly switches speeds, tracking problems, and muddy sound

First, don't ignore the possibility that you are attempting to play an old, worn, or defective tape. This is especially true of rental tapes which have been through who knows what kind of VCR hell. The control and audio tracks - along the edges of the tape - are the first to wear. Weak muddy sound and erratic tracking are also common symptoms caused by old worn tapes. There have even been instances of new name brand tapes which were cut too wide - though this would be extremely rare.

To confirm that it is your VCR doing the dastardly deed, play or record for at least a minute on a tape known to be in good condition. The use REV to back of the tape for about 15 seconds. Eject and open the cassette door by releasing the latch and inspect for edge crinkling.

Any rippling along either edge of the tape is an symptom of a possible problem. It isn't only that the tape does not make good contact with the audio or control head (depending on which edge is damaged) but just an indication that the tape may not be moving through the transport precisely positioned.

Assuming you are having the same problem on multiple tapes and that using a known good (new) tape results in damage:

This is an indication that your tape path alignment is off or your rubber parts (probably the pinch roller) need replacing. The tape is wandering up and down as a result of unequal pull from the capstan due to a glazed/worn pinch roller. There could also be other aspects of tape path alignment like roller guide tilt (which is probably not adjustable), A/C head tilt, dirt, roller guide height (don't mess with it), etc. See the chapter: "Tape Path Alignment and Backtension Adjustment. It could also be worn feet on the roller guide assemblies causing the guides to not be perfectly vertical. Replacement of these parts may be the only cure. Other much less likely possibilities: excessive or varying backtension, tight idler clutch, electronic problems.

For a VCR with very high mileage, it is also possible that there has been a ridge worn in the surface of the control head preventing consistent contact between it and the tape:

(From: Phil Reed (100555.244@compuserve.com).)

> "One thing that can happen is that the control track head gets a ridge on it (due to wear) which prevents the tape making good contact with it. This can make the tracking go mad and sometimes even mute the video. Pausing the VCR overrides any muting, resulting in a clean still picture. Another clue is that some tapes will do it worse than others, this is due to slight variations in tape width or condition."

Other related symptoms include:

- Sound does not always appear at full volume or normal quality for a few seconds after the VCR starts playing. It may vary in loudness during play as well. Slightly changing backtension may make a big difference in audio.

- If your VCR has autotracking, its indicator may be flickering as the logic attempts to solve an impossible problem.

- On HiFi VCRs, there will likely be no HiFi sound as its tracking is even more critical than video tracking.

- Tape speed may be changing resulting in wavering sound or even running (usually) faster than normal. This may be due to the control head not reliably reading the control track.

If you look carefully, you should be able to see the tape wandering slightly producing the muddy sound and erratic tracking. The tape may not be perfectly smooth in passing over the various guides and rollers. Normally, you will almost not be able to tell the tape is moving at all except by examining the reel rotation - it is that mirror smooth.

First, clean the tape path properly, especially the capstan and pinch roller, tape guides, A/C head. Inspect the pinch roller for glazing, cracking, etc. and replace if necessary. See the sections: "General guide to VCR cleaning and rubber parts replacement" and if necessary, the chapter: "Tape Path Alignment and Backtension Adjustment".

Another possibility is that the control portion of the A/C head stack is dirty or defective or there are problems in the wiring or its circuitry. Double check that the tape is in solid contact with the bottom of the A/C head stack (where the control track is located), that the head is clean, its connector is clean and seated properly, and look for any broken wires or bad connections.

VCR plays but at fast forward speed (or beyond)

Normally, speed is controlled via phase locking the capstan to the 30 Hz control pulses read off of the tape via the stationary audio/control head.

On a VCR with autotracking, the autotracking light may be flickering as well.

Possible causes for loss of lock:

- Dirt or bits of tape or oxide on control head - clean and inspect.

- Defective control head. Try making a recording. If recording plays normally on another VCR, then control head is probably OK.

- Tape wandering up and down so that control track is not sensed properly (how is the sound - this would also cause fluctuating or missing sound.) See the section "VCR randomly switches speeds, tracking problems, and muddy sound".

- Mechanical fault preventing firm tape-control head contact such as a stuck movable guide post.

- Mechanical or mode switch problem preventing firm capstan-pinch roller contact. Under certain conditions - possibly at the beginning of a tape when takeup tension is greatest - the takeup reel may have enough torque to pull the tape past the video heads without the capstan controlling the speed as it should.

- Defect in servo or control circuitry or power supply (voltage out of tolerance).

- Bad tape. Don't overlook this possibility especially if it is a old or rental tape. The control track may have gotten erased or warn off - it is at the edge of the tape. Try another tape.

Inspect the tape path really really carefully to determine if there is some obstruction preventing tape-control head contact or other mechanical problems. Try cleaning the tape path and checking the rubber parts. Check power supply voltages if you can determine what they should be (see the section: VCR power supplies. If these procedures to not reveal anything amiss, you will need a service manual to pursue electronic faults.

Tape edge gets creased and/or random switching between speeds

As always, rule out the possibility that this is just a bad tape. There have even been instances of new name brand tapes which were cut too wide - though this would be extremely rare. It could have been creased by someone else's VCR. Try a tape you can afford to sacrifice (though it will still be safely usable) and run it through the VCR. Sometimes, there will be a problem only near one end so you will need to try it at various sections of tape. Record a few minutes and then back it up a bit and inspect for damage by opening the cassette door (press the release on the side). Both edges should be perfectly flat and smooth. If you get similar playback symptoms with this cassette and/or find that the tape is being creased along one or both edges, then it is your VCR doing the dirty work.

When the bottom of the tape gets creased, the control head may no longer align with the control track and you loose servo lock on the sync signal. Your audio may be fluctuating in intensity as well since the audio track is wandering also and the tape may be intermittently going in and out of correct tracking and/or changing speeds. Since the tape can no longer seat stably on the lower drum guide ridge, there could be other problems such as noise bars along the top or bottom of the picture, jumping, etc.

It could be the guide posts or other tape path components, but before you turn every screw you can find and make the problems hopelessly worse, replace all of the rubber parts - belts, idler tire, pinch roller. And while you are at it, give the machine a good cleaning.

A dirty, worn, hard, dried out pinch roller in particular can result in the tape wandering up and down causing tracking problems and creasing the tape in the process. This is probably the most common cause of tape damage assuming the VCR itself has not been abused (i.e., jammed cassette removed using a pair of Vice-Grips(tm).)

With a thorough cleaning of everything before buying the new rubber (which BTW should not be more than a total $10 to $15 from a place like MCM Electronics), you may at least see a temporary improvement in performance - and confirmation of the diagnosis.

You really need to determine exactly where the tape is being creased. Once you do this, you may be able to determine the cause and visually verify whether the problem is affected by any of your adjustments or probing.

Some other possibilities include:

- Worn feet on the roller guides causing them to not be precisely vertical. Sometimes there are adjustments for tilt; usually there are none. Sometimes replacements are readily available (especially if this is a common problem with your model).

- Cassette not seating properly. Press down on cassette while playing a known good tape. If it moves, then check for obstructions or foreign objects such as toys or peanut butter and jelly sandwiches! A dirty, oily, or just tired belt may not grip well enough for the mechanism to complete the cassette load cycle.

- Oil seal washer on bottom of capstan has worked its way up out of place. Carefully push it back down and then clean the capstan shaft.

- Various guides too high or too low but this is pretty unlikely unless they have loosened somehow. Don't adjust unless you have a service manual or are absolutely sure that they have changed height.

- Backtension misadjusted (usually too great). If the tape passes around the backtension lever at too straight an angle (it doesn't bend enough), in addition to the possible incorrect (excessive) backtension, it may simply not seat properly when passing around the subsequent guidepost or impedance roller (that white plastic wheel that doesn't seem to serve any purpose). One or more guide posts or roller guides may be binding.

(From: Raymond Carlsen (rrcc@u.washington.edu).)

There is a simple way to determine if the tape is skewing or has a tendency to do so... just reduce the back-tension by holding the arm so the tape is not as tight around the drum. If there is any tendency of a worn pinch roller to skew the tape, that will show it up quickly. I make my test tapes on an old linear stereo VCR and record two different tones on the two audio channels. When I play that tape back on a VCR with linear mono audio (all of them now), the two tones will play with equal volume if the audio head height is correct AND the tape is not skewing up or down. I can determine what's happening by ear, without even looking at the tape, and before the tape is damaged. Note: there are some machines that tend to skew even if the pinch roller is good. Those require more aggressive alignment procedures than the service manuals usually supply. Almost everything on the take-up side of the tape path can be "adjusted" for the really stubborn ones (even shims to tilt the capstan rotor), but in a few cases, there is just no way to get it perfect. With machines getting cheaper and cheaper, I don't spend any time on dogs unless it's a high end deck and the customer knows what it's worth.

(From: Vern (vgdeuel@ticnet.com).)

Tape damage along the top edge usually indicates too much back tension which, among other things, can be caused by the P2 roller not turning freely. Using a Tentelometer, check the back tension at the full erase head; it should be about 30 grams. Then check the tape tension just before the A/C head. If it's up around 80-100 grams or so, change the P2 roller and even the P3.

(From: Jerry G. (jerryg50@hotmail.com).)

Take a careful look at the capstan shaft and see if the capstan (where the pinch roller touches) is very clean. If it has black or brown markings (coating) on it, you must clean it off very well. Use alcohol and a Q-Tip. Take care to not scratch the shaft.

If the rubber pinch roller is shiny, or looks dried out and or cracked, change it. This area other than the reels is a prime cause of speed problems. The tape when under normal torque can be slipping between the pinch roller and the capstan shaft.

Recording stops at random times on previously used tapes

Symptoms may be that the tape counter stops moving and/or the VCR enters stop mode and shuts down. Assuming this is not a mechanical problem - bad idler, belt, etc., make sure you don't accidentally have an 'insert editing' mode enabled. Insert editing uses the previously laid down control track as the timing reference. This provides clean glitch-free transitions between scenes. Insert editing will not work at all on a new or bulk erased tape. If you routinely use your cassettes over and over, there will be varying amounts of previously recorded material - with control tracks - on the tapes. At some point your recording may start to use tape beyond the recorded sections and - presto, no more control track. Poor VCR is confused and aborts.

Record (or play) stops after 15 minutes (or 30 minutes, etc.)

Make sure you are using the proper record button. Most VCRs have a OTR (One Time Record) or 'quick record' feature which starts just like normal record stops after a multiple of (usually) 15 minutes depending on how many times you press the button. The (normally) red button should be used for unrestricted untimed recordings.

Some VCRs also have other timed modes - sort of like the timed off function of a clock radio. Pressing the 'Off-T' button adds time to record or play in 15 minute increments and then the VCR shuts off.

Tape counter is erratic

The result may be inconsistent positioning of the tape if you use the counts to locate programs. It might also result in the VCR aborting PLAY, REC, FF, REW, or search modes if it thinks that the counter is not changing as expected - missing pulses or skipped counts.

For real-time counters, this may mean a problem deep in the electronics requiring a service manual. However, if you are attempting to play a tape that has nothing on it, the real-time counter will not change. This is normal as there are no control pulses on the tape.

For non-real-time counters, if the display skips counts or 'free runs' - counts very quickly at certain times, this could be due to a defective sensor or hysteresis circuit. If it counts in the wrong direction, a logic problem is indicated as direction is determined by the microcontroller being aware of what mode the VCR is in - there is likely no actual direction sensing on the reel.

See the section: A HREF="#vcrrrotstst">Reel rotation sensor testing for further information.

Video Play and Record Problems

Video playback problems

If the VCR works in all respects when tuning broadcast or cable channels but playing a tape results in no picture, a very snowy picture, or just a blue screen, there may be problems with the video heads, the lower cylinder, head preamps, or other video electronics. Testing most of these is beyond the scope of this document and will require a service manual and test equipment. However, you can do a decent job of determining if the video heads are likely to be at fault.

Sometimes, when snow or serious video noise suddenly occurs while playing a rental, old, or damaged tape, it means the video heads have picked up some oxide and are no longer making good contact with the tape. Letting the VCR play a newer tape for a few minutes may clear this if it is minor. However, video head cleaning (using a cleaning tape or the manual procedure described in the section: Video head cleaning technique) will probably be needed. But, first start with the section: Snow on one or more speeds and NEVER NEVER attempt to clean the video heads without using one of the recommended techniques - you can easily destroy the heart of your VCR! Also, never attempt to play or record on a spliced or seriously damaged tape as this can also result in destruction of the video heads.

Video record problems

If attempting to record results in unexpected behavior, there could be a variety of causes depending on what you get for playback:

- Attempts to record are ignored by the VCR or cause the cassette to be ejected.

  This may mean that the record protect tab on the cassette is broken off or the record tab sense switch is dirty or bad.

- Record (either manual or timer) stops at random times - possibly with flashing display and/or ejects cassette.

  This could be the result of a dirty or defective record sense switch or misalignment preventing proper engagement with it. Some VCRs check for the record tab constantly while others just check when the REC button is pressed or the timer initiates record.

  It could also be a defective reel or tape end sensor halting record though these would likely affect playback as well.

- Playback results in video snow and whatever was on the tape, if anything, is gone.

  This means that the old recording is being erased (if there was one) but nothing or too weak a signal is being written by the video heads.

  This could be due to a variety of electronic faults as well as marginal or bad video heads.

- Playback results in a picture but it has a wiggling rainbow pattern running through it.

  This is normal at the start of a recording made on top of an old recording if your VCR does not have a flying erase head. However, it should wipe down the screen in a few seconds and disappear.

  If it does not go away, then your full width erase head is not working.

- Playback results in a flickering picture alternating between good video and snow at the frame rate (about 30 Hz for NTSC).

  This could mean that one of the two heads used for record is dirty or defective.

- Playback results in proper video but the previously recorded or no audio.

  The audio dub switch (if any) may be in the wrong position or the audio circuitry may be defective.

- Playback results in a picture which is cycling in brightness or flashing.

  This likely means that you are attempting to record (copy) a Macrovision(tm) or some other copy-protected tape or your cable or satellite company is transmitting copy-protected video.

  Info on Macrovision can be found at:

  - S.E.R FAQ Macrovision Page

  - Macrovision Web Site

  Some of the new digital DBS satellite receivers output a Macrovision copy protected TV signal so you can't tape the movies from them either.

Newer VCRs will generally not record successfully. Some older VCRs will record without problems. See the section: Why VCRs will not copy (Macrovision) copy protected tapes. (8mm VCRs may record the entire signal and therefore be able to playback successfully. However, attempting to copy the 8mm tape onto a VHS tape will result in the same problem.)

Problems with playback of self-made recordings

This someone unusual possibility deals with the case where a tape can't be viewed properly using the same VCR on which it was recorded.

For 2 head VCRs:

- Where playback of self-made recordings is bad or noisy (but they play fine on another VCR) and known good recordings made on another VCR play fine on this VCR, the video heads may be worn to the point of being marginal. Since the signal goes through the same heads twice (once for record and once for playback), any signal degradation will be worse.

For 4 (or more) head VCRs:

- In addition to the possibility, above, record and playback may use a different set of video heads and the playback set may be dirty, worn, or damaged. In this case, a recording made on a known good VCR *at the same speed* should also not play back properly.

Snow on one or more speeds

Did the problem happen suddenly? Or develop over time? If suddenly, what were you watching at the time? A (literally) dirty rental movie?

If this VCR has 4 or more heads, SP and EP may use a different set of heads, so certain heads may still be dirty or bad. If the machine tracks perfectly in EP, then alignment is probably fine - EP is more critical as to alignment as the EP track is 1/3 the width of the SP track.

Have the video heads been cleaned using the proper procedure (not just a cleaning tape - see the section: Video head cleaning technique).

New video heads may fix this, though it can be caused by other problems such as weak read electronics. See the chapter: "Video Heads and Upper Cylinders".

You should also check the backtension adjustment - if too loose, head to tape contact will be compromised. Try increasing it momentarily by pushing the backtension lever slightly to the left while the tape is playing. The usual way to adjust backtension without a backtension meter and service manual is to look at the image just before vertical retrace at the bottom of the screen - this is normally not visible unless you can reduce vertical size or play with vertical hold to get the vertical blanking bar to appear. Of course, most modern TVs don't have any such controls! This is the head switching point and when the backtension is properly set the image above and the bit of image below this break will be approximately aligned.

If increasing backtension helps, either the heads are marginal or the back- tension was low. However, low backtension will usually show up as a waving or flagging effect at the top of the picture.

Video turns to snow some time after vide head cleaning

What this means is that you are watching your favorite movie and in the middle of the most exciting scene, and your picture turns to snow or a blue screen. You performed what you thought was a thorough cleaning and then it happened again.

OK, well, if it is indeed your most watched tape, THAT may be the cause (especially if it happens during the same scene!) or it may be a problem with the VCR:

- Old, well worn, or dirty (the physical kind) tapes can result in oxide being deposited on the video heads even during normal play. After cleaning the video heads using the proper manual technique (see the chapter: "Video Heads and Upper Cylinders", play only newer tapes for awhile and see if the problem returns.

- Was your video head cleaning really done properly? One pass with a wet cleaning tape (assuming you believe in such things) is usually enough but not always. A manual head cleaning is best.

- If your VCR has an automatic head cleaner - remove it! The little foam wheel can just as easily put dirt back onto the video heads as remove it. Especially, after IT collects a fair amount of debris.

- Your video heads may be worn. Vides heads that clog up on their own is one possible indication that replacement is needed. See the chapter: "Video Heads and Upper Cylinders".

- The backtension may be too high. This can sometimes be remedied by a proper cleaning of the reel and felt band. See the section: Backtension adjustment.

The most likely cause if you rent movies or have a collection of older well used tapes is the first - your tapes are bad.

One or more lines at fixed locations in picture

This means that there is one or more horizontal lines during playback that are at fixed locations on the screen. These could be the result of electronic problems or marginal video heads but the possibility that should be explored first is that of tape damage.

If a prerecorded tape that plays properly on another VCR, shows the effect on the suspect VCR - AND - then shows the same thing on the other VCR, it is being damaged by something in the tape path.

Open the door of the cassette by releasing the catch on the side. Look carefully at the surface of the tape - it should be mirror smooth all across. If you see any evidence of hair fine (or larger) scratches running the length of the tape these are what are causing the line. This is likely a result of a bit of debris or a rough edge on one of the guide posts in the VCR. The effect on the picture is opposite of the vertical location on the tape - lines near the top of the tape affect the bottom of the picture and vice-versa.

Get a brand new tape or a known good tape (that you can afford to mess up) and test it on another VCR (at the tape speed that is worst, if this matters). Assuming playback is fine, play it on the suspect VCR for a couple of minutes. Pull the plug (DON'T hit STOP) so the transport remains in the fully loaded position. Now, carefully examine the surface of the tape all along the tape path (disturbing its position as little as possible) to identify the location where the damage begins. It may just be a bit of something stuck to a guide post. Has the VCR been cleaned in the last 10 years?

Note: This sort of damage to the tape does not represent a risk to your VCR's video heads so you can continue to use the tape if desired.

Jumpy picture in play

You have a VCR with known good heads that produces jumpy (vertically) video in play that cannot be stabilized with the tracking control. Perhaps you have attempted to adjust the mechanical tracking and maybe some other stuff. Some questions:

- Did you replace the heads? Could you have gotten them 180 degree rotated from the correct position? I don't know what the implications would be on your model VCR, but there is a definite right and wrong on this. It would certainly show up as tracking being way out when attempting to play back tapes recorded on this VCR on another machine.
- Exactly what adjustments did you touch?
- Have you verified that the roller guides are fully engaged against the stops?
- Have you checked backtension?
- Did you touch roller guide height?

This is probably a mechanical problem, most likely an adjustment or fault related to tape path alignment. However, it could also be due to electronic problems with the video or servo circuitry. The vertical sync could be corrupted or the head switching point not set correctly.

The head switching point is 6.5 lines before vertical sync. If this ends up moving into vertical sync for some reason, you will get unstable video. The supply side roller guide height adjustment is also critical and would be the first thing to check mechanical alignment problems are suspected.

However, don't overlook the obvious: your TV is marginal or misadjusted or you are attempting to play a bad tape.

Picture shakes or jumps or has snow in PAUSE/CUE/REV

Note that on a 2 head VCR, it is not possible to display a noise-free picture on a tape recorded at the SP or LP speeds. Therefore, for rental or pre-recorded tapes, what you are seeing may be normal. A 2 head machine should execute these special effects perfectly fine with EP(SLP) recorded tapes, however.

VCRs with 4 or more heads will usually have a V-Lock adjustment - either a knob on the front or rear panel, or sometimes 'conveniently' accessible from under the VCR. Sometimes, a special tool is needed to adjust this control. Where tracking is adjusted with a set of +/- buttons, these may also be used in PAUSE mode. There may be separate adjustments for SP and EP(SLP) speeds as well. In any case, these settings are made while viewing a tape recorded at the appropriate speed in PAUSE mode.

For LP speed - which is being phased out by many manufacturers, at least for record - these special effects usually do not work well if at all. This is basically due to the nature of the sync signal alignment on tapes recorded at LP speed and would require complex circuitry to handle properly at anything other than normal LP play speed. (If you care, the sync tips between adjacent tracks align on the tape in SP and EP recorded tapes but are off by 1/2 line with LP recorded tapes. This results in the tearing seen in search modes with LP recorded tapes.) Since this tape speed is of little true value - it is a compromise anyhow - the added expense has been found not to be justified except on professional machines.

Video search blanks out or doesn't work on recordings made at certain speeds

This may be a 'feature' of your VCR. On some older models, the designers in their infinite wisdom (or that of their marketing departments) decided that no picture or no search capability at all was preferable to a picture with serious noise bars or one which didn't sync properly. This was usually before the days of 4 head VCRs which directly addressed at least some of these issues.

Most 2 head VCRs will work fairly well on EP recordings but show noise bars over about 50 percent of the picture with SP recordings. For those made at LP speed, tearing will occur in addition to noise bars if they sync at all. Few VCRs deal properly with LP search as substantial additional circuitry is required.

In my opinion (IMO), any picture is better than a blank screen or no search capability.

VCR plays pre-recorded tapes but its own recordings are noisy or jumpy

Problems will be similar to the following:

> "I have a General Electric VCR model VG4217 that's displaying the most unusual problems. When I play back a pre-recorded tape from a video store it plays fine. When I play back a tape recorded on the machine I get video noise for 4 seconds then clear pix, then video noise for 4 seconds, then clear pix and so on.
>
> I also noticed that if I have the tape counter displayed on the screen, and when the counter progresses its count, the tape plays properly. Then all of a sudden the counter stops counting and the problem continues again.
>
> I have cleaned heads well, cleaned tape path, and even cleaned the underside of the takeup reel, all to no avail?"

First, make sure the tapes are in good condition. They may have been damaged (edge crinkled) before you serviced the VCR. This is now causing your erratic behavior and there is nothing wrong with the VCR.

Before considering drastic action, record on a brand new tape - from end-to-end if the initial results seem promising. You may have a non-problem.

Try recording you your VCR and playing back on another one. If this works, then bad tapes are the most likely explanation.

If this does not work, there could be electronic problems:

(From: Stephen Isaacs (stephen@myna.com).)

The normal playback of a pre-recorded tape suggests most things are working fine. The self recorded problems point to a faulty control track recording system. bad oscillator, or amp. It is also possible the erase head is not doing its job making it difficult to record a new control track over an old one.

(From: Richard (vcrtips@mail.vii.com).)

Almost all pre-recorded tapes are recorded at the SP speed. If you are like most people, you probably do your recordings at the EP speed (to get as much on the tape as possible). Do you have the same problem if you record at SP? Your VCR probably uses different heads for SP and EP. You may have dirty EP heads, defective EP heads, a head amp problem. Or, there could be a tape tension or other mechanical problem.

(From: Frank D. Ralston (fdr@continet.com).)

Check the following:

- Dirty (or worn) heads
- Low back tension (common problem)
- Tape path alignment (particularly input tape guide)

Incorrect frame alignment or bad video for part of frame

Symptoms like a picture which has a portion that is noisy or missing, or where the picture is split between top and bottom with the vertical blanking somewhere in between may indicate a problem with the PG sensor.

The rotational position reference for the video head drum is usually supplied by a pickup in close proximity to the edge of the lower cylinder (probably) which has a small magnet fastened to it. This generates the so called 'PG' pulse and is used by the servo circuitry to properly control the drum rotation and the head switching point.

If this sensor is moved or if there is a fault in the PG circuitry, a variety of record or playback problems can result. Without this reference, the servo circuitry has no way of knowing where the A and B heads are at any given time. During record, this may result in recording video which is not properly lined up with the video tape - a track may consist of the end of one field and the beginning of the next rather than an entire fields as it should. During playback, the head switching point may occur at the wrong time resulting in a partially snowy or missing picture since a head that is not even in contact with the tape may be active. Similar problems may make look like your TV's vertical hold control is set incorrectly with the vertical blanking bar visible at an arbitrary point on the screen.

The assembly on which the rotating magnet(s) are mounted and the upper cylinder may be secured with one or two set screws. If these loosen, the the precise relationship may be lost resulting in a shifted head switching point. It may even be random - changing location each time the drum starts up due to the inertia of the upper cylinder. If this is the case, you will need a service manual to properly adjust the angular location of the magnet assembly unless there are obvious 'timing' marks to guide you.

Beyond confirming that the pickup coil is in close proximity to the drum, the rotating magnet and sensor are secure, and that there are no bad connections or loose connectors, there is not much to be done for these problems without a service manual.

The definitions below are just For Your Information (FYI):

- **PG -** pulse generator. The pulse is derived from the rotation of a magnet on the video head drum past a sensing coil. I suppose this could be done optically as well.

- **FG** - frequency generator. This is a signal (sine or square) derived from the rotation of the video head drum. This may be phase locked to the PG pulse but can be a multiple of the frame rate. This could also refer to the capstan or reel rotation rather than the head drum.

Rainbow pattern in recordings made over previously recorded tapes

Unless your VCR has a flying erase head - located along with the normal video heads on the rotating drum - you will see a faint rainbow pattern near the start when recording over a previously used tape. The reason is that there is a separation of a few inches in the tape path between the video heads and the full width erase head. When you start recording at an arbitrary point, it takes several seconds (actual time depends on recording speed) totally erased tape to make it to the video heads. You are seeing an interference pattern between the old and new video signals. The pattern will slowly wipe from top to bottom as the diagonal tracks of new video intersect more and more of the erased tape.

This effect will not occur (except possibly at the very beginning of the tape) as long as you record from start to end without backing up the tape at any time.

If the rainbow pattern is present whenever recording over previously recorded tapes and does not go away, then your full width erase head is not working. This could be due to an electronic failure or simply a bad connection to the full width erase head. Alternatively, a mechanical problem such as a broken or popped spring or gummed up lubrication might prevent the pivoting full width erase head from contacting the tape properly.

Barber poling - bands of rainbow or color

Some rainbow patterns are normal for the first few seconds of recordings made on previously recorded tapes on non-flying erase head VCRs. See the section: Rainbow pattern in recordings made over previously recorded tapes. However, alternating bands of rainbow or color indicate a fault sometimesreferred to as 'barber poling'.

This is likely an electrical fault in the chroma playback circuitry buried deep in the bowels of your VCR. The chroma reference is not locking or is locking erratically with the chroma signal. Unless you can find some bad connections or other obvious problem, this will be difficult to troubleshoot without schematics. Don't be tempted to twiddle internal controls even if they appear to deal with color - you will just mess things up for whoever finally repairs your VCR!

Flag waving - top portion of picture wiggling back and forth

You have just loaded a videotape sent to you from your long lost cousin and you notice that the top of the picture is wiggling back and forth. This may be a VCR backtension problem but it could be much simpler.

First, if this wasn't the original complaint, make sure the flag waving problem exists with the TV that will actually be used with the VCR - it may just be your test TV or monitor that is unhappy. If the problem does exist on the relevant TV, all modern TVs have a dedicated video channel button(usually channel 0) which has a shorter flywheel line-timing duration allowing the TV timebase to lock up more effectively to unstable video sources such as VCRs. It may be that simple.

(Parts of the following from: Andrew Morphitis, Andrew@andrewsm.demon.co.uk).

This fault is sometimes known as flag-waving when associated with video recorders. If the tape back-tension provided by the tension arm and supply reel-table is not the same as the back-tension provided when the tape was recorded (possibly on another machine) then the field timing of the video tracks being played back will be inconsistent . Your back- tension can be checked using a back-tension cassette gauge (a typical reading would be about 35g-cm for VHS) or you could adjust the back tension using a known good test tape (or reliable pre-recorded tape) until the waving disappears. If your back-tension does turn out to be incorrect and you adjust it according to the manufacturers spec. then all of the tapes you have previously recorded will probably still exhibit this waving problem - adjust to spec. or to your tape library - take your pick.

That's the theory - now the practice. Back-tension refers to the tension of the tape over the head drum, this is provided by the felt covered metal band (tension band) which is wrapped around the supply reel (left-hand reel from the front), the friction providing the tension. There are usually two adjustments associated with back tension and these can be found near the opposite ends of of this tension band, the tension arm operating position and the anchor point of the band. Adjusting the latter position will increase or decrease back tension (you will want to increase your back tension which has dropped due to excessive wear on the belt). If you do give it a bash then be aware that poorly adjusted back-tension can, at worst, give rise to premature head wear. Because of the differences between the back tensions of different machines, all modern TV's have a dedicated video channel button (usually channel 0) which has a shorter flywheel line-timing duration allowing the TV timebase to lock up more effectively to unstable video sources such as video machines. Are you using the video channel? - try playing the video through different channels on your TV.

Why do newer VCRs seem to be worse with respect to flag waving?

(From: Jeroen H. Stessen (Jeroen.Stessen@philips.com).)

The head fault used to be specified +/- 10 us, then it became 16 us, 20 us and I think we have already seen 22 us. Sooner or later a TV will not be able to follow such large phase jumps before the picture begins. Some TVs can be modified and some can not. The problem is that the line deflection circuit CAN NOT instantly follow a large phase jump, the output transistor would be destroyed at once. It HAS to be distributed over a certain number of lines. You can only hope to distribute the phase jump evenly over as few lines as possible and that there is neither overshoot nor tail to the response. YMMV.

It is logical to see more problems on old tapes or on tapes that were recorded on another machine (especially rental tapes) because the phase jump has everything to do with mechanical tolerances and tape stretch. It should be much better on a new tape that has been recorded on your (his) new machine.

Macrovision anti-copy protection only makes matters worse !

I think I will buy me a nice new JVC S-VHS machine with built-in timebase corrector. Also, our new European Philips chassis has an input IC with built-in timebase corrector. That should help a lot.

---

13. Back to VCR Repair FAQ Table of Contents.

Audio Problems

Total lack of sound on playback from non-HiFi VCR

This assumes audio from the VCR's tuner is fine. If ALL audio is missing, check your external connections (particularly if you use the RCA jacks), try switching to the other channel (3/4) if you use the RF output, and adjust the fine tuning (if any) on your TV.

If this VCR also will not record audio, see the section: No (non-HiFi) sound on new recordings.

The following assumes this only happens when playing tapes:

While playing one that you know has good audio, carefully touch each of the terminals of the A/C head with the tip of a small screwdriver - if the audio circuits are working, the audio head terminal should produce a buzz from the speaker. CAUTION: Insulate all except the tip of the screwdriver to prevent shorts.

- If you get a buzz, the A/C head may be dirty. Try cleaning it with a Q-tip. DON'T touch the video heads.

  Other possible causes: Debris or problem with tape path alignment causing loss of contact with audio head in vicinity of audio tracks, bad audio head (but this would probably result in inability to record audio as well).

- If there is no buzz, something in the audio circuits is bad. Double check that there is no audio switch or mode select that might have changed its setting. For mechanical switches, flip them back and forth a couple times to clean the contacts. Beyond this, additional testing will be needed requiring a service manual with schematic.

Poor quality sound on non-HiFi VCR

There can be several non-electronic causes for poor quality sound on linear audio playback:

1. The audio head needs to be cleaned. A cleaning tape may not be effective. You can use Q-tips and medicinal or pure isopropyl alcohol or tape head cleaning solution. You might as well clean the tape guides as well while you are at it - a speck of dirt can cause the tape to wander and produce erratic sound.

2. The audio/control head needs to be aligned - particularly the azimuth adjustment which is the angle the head gap makes with respect to the direction of the tape's long axis (I hope this is clear). You can do this if you are so inclined. Before you adjust azimuth, a test for this would be to record and then play back a tape on this machine - regardless of how far off the azimuth adjustment is, the recording should sound good (at least as good as one can expect from the linear audio) track. See the chapter: "Tape path alignment and Backtension Adjustment".

3. The audio head (and other parts) needs to be demagnetized - use an audio tape head demagnetizer. Stay away from the video heads. Some demagnetizers are powerful enough to damage them. Make sure the demagnetizer you use has a no sharp ends to damage anything - cover with electrical tape if in doubt. Turn on the demagnetizer and move it slowly near all metallic parts that the tape contacts - guides, levers, erase and audio/control head. As mentioned, do not go near the video heads. See the section: Head demagnetizing.

4. The audio head is worn. If the poor sounds quality really bugs you, these can be easily replaced but they are not cheap since generic replacements are rarely available. Alignment will then be needed.

5. Tape path problem causing bad tape-head contact. See chapter: "Tape Path Alignment and Backtension Adjustment".

6. Your expectations for audio quality on the linear audio tracks on a non-HiFi VCR are unrealistic. The worst will be a stereo VCR in EP mode since the stereo tracks are less than half as wide as non-stereo tracks. Best will be SP non-stereo but even this is very poor for music. Once you get used to HiFi quality, linear audio sounds like crud.

Identifying source of one-channel (non-HiFi) low audio/hum/buzz

Perform the following 'screwdriver and short tests' to narrow down a one-channel low audio problem:

- While the VCR is playing a tape, CAREFULLY touch the tip of a screwdriver (or other metal tool) to each of the pins on the A/C head - you should be able to locate the L and R channels by the buzz resulting from signal pickup from the screwdriver. If the bad channel doesn't respond at about the same level as the good one, there is probably an electronics problem, not A/C head alignment (though a bad A/C head coil is still possible).

- If you can locate the signal ground for the A/C head, CAREFULLY short the output pin of the bad channel head to ground - the hum/buzz/whatever should disappear if there is a head or alignment problem. If it doesn't, there is an electronics problem for that channel.

Excessive flutter on VHS linear (non-HiFi) audio playback

While general quality of VHS linear audio is almost always mediocre, there should not be excessive flutter - wavering in pitch. Certainly it should not be noticeable for speech. How bad music sounds will depend on your expectations as well. Here are some possible causes:

- Dirty/gummed up stationary guides or A/C head.

- Lack of lubrication of the capstan or roller guides.

- Excessively tight idler or other clutch.

- Bad capstan motor, especially if direct drive type, or motor driver.

- Bad pinch roller/bearing. Sometimes aftermarket replacements may be inferior and result in the same or worse behavior. However, usually they are fine.

- Video head drum (upper cylinder) which is mounted off-center or which has excessive runout or wobble. This would most likely show up after the video heads are replaced. Sometimes, this may be detected by resting a dry finger very gently against the rotating drum - there should be NO detectable vibration.

- Servo system problems.

- Power supply problems.

- 'Stiction' between tape and lower cylinder.

- Unrealistic expectations of linear audio quality. Some VCRs are downright terrible, especially at EP speed. This is normal.

No (non-HiFi) sound on new recordings

Sound is fine on pre-recorded tapes or tapes recorded on this VCR prior to the problem developing. New recordings have no sound whatsoever.

Make sure your tape isn't bad. Yes, I know, this is unlikely, but very old tapes tend to lose oxide along the edges and that's where the linear audio goes.

If the previous audio is erased but you now have silence, the problem could be that erase is working but no new audio is being recorded on the tape. First, check any audio mode or dubbing switches for proper settings.

If you are using the RF input, see if the same problem exists with the RCA inputs. Sometimes, dirt/bad connections on the RCA inputs will trick the VCR into thinking you really want to use those instead of the RF. Pushing an RCA plug in and out a few times may clean these off.

If you are using the RCA inputs, make sure the the audio cable is plugged into the proper jack on the VCR and that there is audio from the source (plug it into an amplifier or another VCR to test).

(From: Raymond Carlsen (rrcc@u.washington.edu).)

I first saw this problem in Wards (Sharp) VCRs, then later in some Samsungs. The real problem is a bit of resistance in the connector on the full erase head. The FE head arm swings back and forth when loading and unloading the tape, causing the connections to weaken. That bit of resistance cause the bias/erase oscillator to fail to start up in record mode. If allowed to run that way, it can burn up that transistor and other components on the audio board. Just replacing the bad parts will not fix it for long. Cut off the plug and direct-solder the full erase head wires directly to the head.

End of problem. Done a bunch of 'em.

Audio not present through VCR

Tapes play fine but audio is missing to the TV and when making recordings using the VCR's tuner.

How is the TV connected? Through the RF/antenna input? If through the RCA jacks, of course, it could be a TV/cable problem. Bypass the VCR and check.

For the RF, this could be many things:

1. There may be an incorrect source select or dubbing mode setting or a dirty set of contacts on a related switch. Check your instruction manual and cycle and/or clean the contacts of any suspect switches. Unplug the VCR for a few minutes to reset the controller - it may be in a weird mode.

2. Dirty contacts on the RCA audio in jack - some automatically assume you want to record from there if anything is plugged in. (Or, you may have left your CD plugged into the jack several months ago when you last used it!) Usually, inserting an RCA plug into the jack a couple of times will clean the contacts at least well enough to confirm that this is the problem.

3. Bad cable or bad connections inside the VCR. There is often a separate cable for audio (and video) between the tuner and the mainboard - reseat and/or test it.

4. Electronic fault resulting in not selecting the audio. This will require a schematic.

Previous (non-HiFi) audio is not erased on new recordings

If the old audio track is unchanged - you get the new video but old audio, check that any dubbing switches are set correctly - to enable audio.

If you are getting a mixture of old and new audio, then there could be a problem with the audio erase head (part of the A/C head stack) or its circuitry.

Clean the audio/control head (the stationary head to the right of the video drum near where the tape re-enters the cassette. Check for dirt or tape oxide on or around the audio/control head.

Beyond this, testing will probably require a schematic. However, if you can locate the connections to the audio erase head, use an ohmmeter to test for continuity of the coil. Check with an oscilloscope for the high frequency erase signal during record.

Poor quality sound on HiFi VCR

The VCR may be switching between HiFi and linear audio at random (with the HiFi light also flickering on and off or simply not selecting HiFi audio at all. This may be happening with only one audio channel (usually the right channel in this case).

The sound out of a HiFi (not just stereo) VCR should be virtually indistinguishable from the original and for good quality source material, nearly as good as a CD.

What to look for if it is really playing HiFi (try at slowest tape speed as this will have little effect on HiFi quality but will turn the linear track quality to crud). Use a tape with a musical recording for this:

- Almost no tape hiss (background should be virtually silent).
- Excellent frequency response (treble notes should sound natural).
- Excellent dynamic range (loud louds and soft softs).
- No detectable wow or flutter (no short or long term wavering in pitch).

However, problems are possible:

- Since the HiFi heads are on the rotating video head cylinder, they are subject to the same problems as video heads - and the same difficulties in diagnosing head problems. Dirt, damage, or electronic defects can cause the HiFi sound to be absent or distorted. A broken or badly worn HiFi head will simply cause the VCR to switch to the linear audio tracks. HiFi head alignment is more critical than video head alignment so this may need to be checked.

  Try adjusting the manual video tracking control as this will also affect HiFi audio tracking and see if this clear up the sound.

- As with video heads, poor quality playback of self recorded tapes but fewer or no problems when playing pre-recorded tapes is one sign of worn heads.

  Like video, recording HiFi audio needs to use the heads twice. Thus, a slight loss in sensitivity or frequency response may still enable pre-recorded tapes to work reasonably well but will result in problems of playing back self-recorded tapes. Note that slight tape path misalignment would not affect self-recorded tapes anyhow but would result in poor playback of others - the opposite effect.

- Old, worn, dirty, or bargain basement tapes will have many more dropouts than new name brand tapes. These will show up as noise, streaks, or dots in the picture *and* as pops or increased noise in the HiFi audio output.

- It is possible that only one audio channel is affected. The audio may be missing, scratchy, distorted, or fading in and out. Where problems mainly affect one audio channel, it is usually the right one. One reason for this is that it is recorded at a higher carrier frequency (1.7 versus 1.3 Mhz for the left channel). Thus, problems are more likely to show up in the right channel due to either worn heads or a misaligned tape path. Since some of the audio processing is separate, electronics problems can easily affect one channel as well.

- A whine, buzz, or hum in HiFi audio playback may indicate that the A/C head is too high - recording the control track on top of the ends of the video and HiFi tracks. However, other problems - particularly with tape interchangeability would almost certainly result.

  Note that A/C height doesn't change on its own - someone has likely been mucking with your adjustment screws (and who knows what else)!

  To confirm, record a couple minutes on a brand new or bulk erased tape. If the last 5 to 10 seconds of the recording is clear, the A/C head alignment is at fault since it is writing over the ends of the HiFi tracks 5 to 10 seconds *after* they are laid down and the end of the recorder will be unaffected.

- A hum or buzz may be the result of problems in concealing the head switching point for the HiFi track. This could require an adjustment or be a failure or design flaw. See the section: Hum or buzz in HiFi audio.

- Electronic adjustments or faults in the HiFi audio circuitry could of course also result in record or playback problems.

Help for marginal HiFi heads

Also see the chapters: "Video Heads and Upper Cylinders" and "Tape Path Alignment and Backtension Adjustment".

(From: Jerry ().)

The HiFi heads are more critical than the video heads. If they are warn down a bit, they can be very instable. Sometimes I can get a bit of a better response by increasing the tension arm tension a little. If you do this, you may have to touch up the guides.

(From: Anthony Falvo (afalvo@borg.com).)

I have had good luck making the HiFi tracking point meet the video head tracking point with slight adjustment of the 30 Hz switch point.

hum or buzz in HiFi audio

(From: Liam Keane (106350.3410@CompuServe.COM).)

The noise you are hearing is FM audio track switching noise - from the changeover between the hi-fi audio heads on the head cylinder. The difference between video and audio switching noise is that the video noise can be shoved out of sight in the vertical blanking interval. The trouble with the audio is that our ears listen all the time! Some VCR's exhibit this worse than others. You can try adjusting the switching point to minimize it, but by the same token, some precorded tapes are particularly bad, with Disney tapes being about the worst I have ever heard.

Fluttering or noisy HiFi audio

Where a VCR has seen a lot of use, the video and HiFi audio heads are likely to be worn. However, evidence of video problems may or may not proceed HiFi audio degradation:

(From: (Parker C. (parkerc@halcyon.com).)

Your hifi audio is, technically speaking, not fluttering. The distortion you hear is the head switching noise becoming audible as the hifi heads are wearing out.

On the outside chance you are not dealing with a worn out upper drum, you should first check the video envelope and confirm that your machine is mechanically adjusted correctly - i.e. check that the drum guides have not slipped. Hifi audio would typically become distorted if the tape path is not adjusted correctly. Audio playback level will not help the situation. Hifi Record levels almost never need to be adjusted, unless someone has been tweaking them in the field. (hint, hint).

A note on record levels: occasionally we find that decreasing the video record levels on machines with poor hifi audio recordings will quiet things down for a little while. Did everyone get that? (decreases the video penetration into the hifi region of the tape).

Squealing noise from VCR in certain modes

Unusual noises from inside the VCR may be an indication of a problem or just a badly made cassette - try a different one.

The most common cause for a squealing noise are tired weak belts that are slipping. Less likely is the need for lubrication.

- A squeal when entering play or record mode - with the VCR perhaps aborting the operation - is usually caused by a slipping loading belt.
- A squeal during fast FF or REW may indicate a slipping drive belt.
- A squeal or whine during play or record (perhaps intermittently when the video head drum is spinning)

could be a worn video head drum bearing or dirty or improperly positioned static brush (see also: "High pitched whine from inside VCR").

See the appropriate sections on cleaning, rubber parts replacement, and lubrication.

- A whine or buzz from the audio during playback of tapes not recorded on this VCR may indicate a grossly misadjusted A/C head - the linear audio heads are picking up the ends of the video tracks due to the A/C head being too low.

  Note that A/C height doesn't change on its own - someone has likely been mucking with your adjustment screws (and who knows what else)!

- A whine from the audio (of the TV) while using the VCR may indicate bad grounding of the internal shields, other bad connections, or electronic problems.

High pitched whine from inside VCR

Your first thought is probably of an expensive repair to a motor bearing or replacement lower cylinder. If there is a high pitched whine coming from inside the VCR when in PLAY, REC, or other mode which spins the video heads, you may simply have a dirty or improperly positioned antistatic brush.

There is usually a metal strip with a carbon contact pressing against the center of the video drum spindle either above or below the deck. In rare instances, the brush may be BETWEEN the upper and lower cylinders requiring more disassembly. It is very common for it to vibrate is just the right way to sound like a cat being strangled. Gently press on this strip or lift it off of the spindle while you hear the sound. If the whine disappears, cleaning and slight repositioning of the strip should be all you need to do. Do not remove this strip - it is needed to ground the rotating drum to prevent static buildup and video noise problems (see the section: Firing (static) lines in picture during playback.

Note: You may find that if you measure the resistance between the brush to the chassis that it is far from 0 ohms - perhaps in the 10s or 100s of K or higher. This is perfectly normal (as long as it isn't infinity!) as static doesn't take much current flow to be eliminated.

Tapes play back in a foreign language

> "Have recorded tapes with a Mitsubishi U52 that play back in English on same, but play back in Spanish with some other VCR's. What's up?"

(Portions from: David R Mulligan (skipper@interlog.com).)

It sounds like you are recording the SAP audio channel on the mono audio track, but normal on the HI-FI track. This would indicate that your television station broadcasts a Spanish dub over the SAP channel for those who prefer that language.

Check the position of the audio playback source select. Also, any problem with the HiFi record or playback would also result in the VCR defaulting back to linear track playback.

14. Back to VCR Repair FAQ Table of Contents.

Signal and Interference Problems

VCR color problems

There are two typical situations:

- Playback is always in B/W.
- Record is B/W but playback has normal color.

If you can play pre-recorded tapes in color but tapes recorded on this VCR do not play back in color, there may be several possible causes. The simplest is that your input signal is too weak - a misadjusted antenna or cable with a large number of splitters - and the VCR's color killer thinks there is no color. Sometimes the threshold for detecting the color signal is set higher on the VCR than the TV which you are using to monitor the recording.

Some questions:

- Is the color TV's fine tuning set correctly?
- Does it play pre-recorded tapes in color?
- Does the tuner output produce color?
- Does the video output work in color?
- Is the problem the same for all recording speeds?
- Do the tapes you record on this VCR play in color on another one?

If the answer to all but the last question is 'yes', then the problem is most likely in the video/chroma circuitry associated with recording function. It could be as simple as the color killer setting being too low.

Possible sources of problems with color recording:

1. Weak signal - check and/or adjust antenna.
2. Color Killer set to low.
3. Problems in tuner - does the video output work in color from the tuner?
4. Problems in chroma circuits.
5. Sometimes, marginal heads - less likely if it plays in color.

If recording works fine as indicated by tapes made on this VCR playing fine on another one but pre-recorded tapes do not play back in color and the VCR works fine in all other respects there could be several possible causes:

1. Weak chroma signal level from VCR.
2. Color Killer set to low on TV.
3. Problems in chroma circuits.
4. Marginal or dirty video heads.

Note that in all cases of missing color, checking with another TV and/or adjusting the TV's controls should be tried first as slight differences in signal levels between tuner and playback may cause a TV with marginal settings (fine tuning, color killer, chroma circuits) to switch unexpectedly between color and B/W.

RF signal problems

First determine whether there is a problem with broadcast or cable, playing tapes, or both. If it is only broadcast or cable, then your source may be at fault. If it is fine with the VCR off but noisy when using its tuner, the problem could be in the tuner itself.

Verify that the direct video output (RCA jacks) works properly with a pre-recorded tape. If this is noisy as well, then there are problems with the video circuitry or video heads.

If there are problems with the Channel 3/4 output but the direct video outputs are fine, then suspect a weak or dead RF modulator. This is a little metal metal box with the Antenna In and TV Out connectors. It has circuitry which switches between the VCR's internal video signal and the antenna input. It also converts the video baseband signal to the channel 3/4 output required by the TV.

Before you conclude that the RF modulator is to blame, check that the channel and fine tuning of the TV are properly set and that there are no other problems with the TV. Test the VCR with another TV. It could be that the signal from the VCR is just a little weaker than it is used to be. Try moving the channel 3/4 switch back an forth - it may have developed a bad contact. Try the other channel (3 or 4) - it may work better. Try moving the VCR away from the TV - sometimes interference from the TV will degrade the video quality.

If you do conclude that the RF modulator is at fault, generic replacements are available from the parts sources listed near the end of this document or other electronics distributors for less than $25. Replacement is straightforward since there are only a couple of soldered connections but getting to the unit physically is sometimes a challenge.

VCR will not tune broadcast or cable

Are you sure that the input signal is making to the VCR? Does the pass- through connection work? Double check the connections. Connect the cable you have on the ANTENNA IN of the VCR directly to the TV. Make sure it's center pin is not bent over or broken off. Try a new cable. Is the tuning mode switch (broadcast, CATV, etc.) set correctly on the VCR?

If the signal is preset into the VCR, there still may be a bad connection inside preventing it from making it to the VCR's tuner. Sometimes, there are RCA style plugs inside that work loose.

Otherwise, the tuner of the VCR is not working. This could be because it is broken or power to it is bad or missing. If all other functions of the VCR are working, it is likely (though not guaranteed) that the power supply is fine. There could be bad connections or dirty connectors as well.

Beyond probing for bad connections and verifying your antenna hookup, there is not much that can be done without a service manual and test equipment.

If the problem is that it won't tune upper cable channels, that may be by design. Older VCRs - despite being called 'zillion channel cable ready', may not be able to deal the upper channels of modern cables systems:

For example, a typical older 110 channel cable ready VCR is able to receive only these: Cable: 14-36, A to W, 95 to 99, A-5 to A-1, VHF 2 to 13, and UHF 14 to 83. Total: 110 Channels. The only way around this is to get a cable box capable of receiving all of the channels that your cable company provides and set your VCR on channel 3 or 4, or buy another VCR that will tune in all of the cable channels.

Interference patterns such as parallel or diagonal lines

This may be due to the proximity of the VCR to a TV or other component, outside interference, or a fault in the VCR.

Determine if it in the video signal or is it only present when the VCR is close to or sitting on/under the TV? If so:

- Have you rearranged your setup recently? It is common for TVs and VCRs to interfere with each other's operation. Your only easy fix may be to shuffle the components in your entertainment center.

  One simple test to see if it is the TV doing the interfering is to record a program partially with the TV off and then with it on - without changing anything else. If the quality of the recording is noticeably worse with the TV on, you know what is at least partly to blame.

  It is probably interference from the TV's switching power supply, deflection, or other circuits getting into the low level video circuits of the VCR. Either the TV or VCR or both are inadequately shielded. Hey, but the makers saved a few cents!

  Is probably isn't the cables but see if moving them around changes anything. If it does, then better (shielded) cables might help.

  It might be worth trying a position a grounded copper sheet between the TV and the VCR. I don't know how much if at all it will help.

Does it happen when watching from the antenna/cable or only when a tape is playing or recording?

- Interference patterns on cable may indicate a problem with the cable company or the hookup. It may even be system wide and under investigation - such temporary service problems are not uncommon.

- If you are using one or more splitters to distribute the signal to multiple locations, be aware that each one introduces some signal loss and eventually this results in noticeable degradation making the system more susceptible to even low level interference which might otherwise be undetected.

- Interference patterns while using the antenna may indicate just generally poor reception. Try repositioning the rabbit ears or outside antenna (if you have that option. Also check the connections and wiring - all the twisting and maneuvering can break or damage antenna cabling.

  If you live in an apartment complex - especially newer building of steel or steel reinforced concrete construction - reception may be inherently dreadful. Many of these offer a rooftop antenna feed or cable and for good reason. Try relocating the equipment - sometimes a different part of the room will have fewer problems.

- Interference patterns only on recorded tapes that was not there in the original program may indicate a problem in the record circuitry of the VCR or interference from the TV (only if on).

- Interference patterns only on playback of tapes regardless of where they were recorded may indicate a problem in the playback circuitry of the VCR or interference from the TV.

Did this just start suddenly without you changing *anything*?? Does it now happen at all times of day?

- If it does not happen all the time, try to determine what is common about when it does occur. Consider other sources of interference - local ham radio operators or other transmitters, light dimmers, compact or other fluorescent lamps, vacuum cleaner - even your microwave oven. Although less likely, it may be a neighbor's appliance doing the interfering.

- To eliminate the VCR as the source of the problem, you may need to take it on a field trip to a friend or relative in a different neighborhood. If the patterns are still the same, it is probably a fault in the VCR and not outside interference.

Proximity to other equipment

Depending on the combination of VCR and the TV (or other A/V equipment), there may be situations where either the VCR will not operate normally. For example, placing the VCR directly underneath the TV may result in erratic behavior or noise or other patterns in the video (playback or record as well). All this means is that there is some RF emission from the TV that is getting into the logic or video circuitry of the VCR. While shielding is possible in theory, the only easy solution is to rearranged your setup to they aren't so close together. There is really no way to know which models are subject to these problems or which configuration(s) of equipment will be best without trying them.

Firing (static) lines in picture during playback

These may be described as static or short bright or dark lines in the picture. They usually have a sharp start and may trail off or stop abruptly. They may be occasional (once every few seconds) or frequent (multiple instances per video frame). Also see the section: Are your video heads really bad? for video head problems as large quantities of firing lines may be due to dirty, worn, or defective video heads.

First, try a different tape - preferably a new recording made on a different VCR or a new commercial video. It is possible that these streaks are simply due to dropouts on the tape - missing bits of oxide or dirt causing momentary loss of video signal. Old, worn, or cheap off-brand tapes are particularly prone to dropouts.

One characteristic of dropouts is that they may span video lines as well as video frames. If your lines are very short and random, they may be caused by a dirty, missing, or improperly positioned video drum static brush. In most VCRs, you will see a metal strip with a carbon contact pressing against the center of the video drum spindle either above or below the deck (or in rare instances, BETWEEN the upper and lower cylinders). The brush is there to provide electrical contact between the rotating video drum and the stationary lower cylinder and chassis. This is necessary since the bearings on which the upper cylinder rotate may not provide adequate contact and any static buildup caused by the spinning head cylinder rubbing against the tape may discharge through the bearings resulting in these firing lines. Carefully remove the static brush and clean the end of the spindle and carbon contact. This may be all you need to do to remove the static lines from your picture.

(From: Michael James (michaeljjames@biglake.com).)

The following is for a JVC based deck which is often used by Philips. You need to use GREAT care as this requires removal of the drum motor and it's mounting. This will affect the switching point which will cause the picture to roll uncontrollably or to have noise at the bottom of the picture.

Symptom - White dashes across the screen.

Remedy - Very carefully note the position of the drum motor with relation to the shaft running through the drum assembly. Remove the screws holding the drum motor. Note the position of the brass bush and loosen the Allan nut holding it. Remove the video heads and clean the excess grease off of the static discharge brushes. If the fault persists replace the brush assembly with a new brush

If you do not feel confident that you can do this take it to a repair shop, this job should take no longer than 1 hour to complete.

15. Back to VCR Repair FAQ Table of Contents.

General System Problems

Multiple system problems

Most VCR problems will be limited to a specific subsystem - video, audio, tuner, servo, control. When multiple seemingly unrelated problems occur at the same time, suspect a power supply problem since multiple systems may be fed from common power supply outputs.

There are always several different voltages used within a VCR - if one of these dies, some subsystems will work but will not receive the proper signals from the dead parts. So, nearly any kind of behavior is possible.

Therefore, the first test is to determine, if possible, that the power supply outputs voltages are correct - both with power off and power on.

Power supply problems - unit totally dead/major system problems in all modes

Power supply problems can range from intermittent behavior due to slightly out of tolerance voltages, hum, or noise to a totally dead VCR. Multiple system failures can result if one or more of the half dozen or so voltages used within the VCR are incorrect or missing.

Some power supply problems are caused by power surges. These may result in a totally dead VCR or in overstress and subsequent failure of various components. A power strip with a circuit breaker, even with surge protector is not a reliable protection against power surges especially during lightning storms. The only sure protection is unplugging electronic equipment during storms - but then, what would your insurance agent have to do?

Fuses and IC protectors in VCRs

A variety of protective devices are used in VCRs.

Of course, where the VCR is stone dead, check for a blown line or secondary fuse in the power supply. Occasionally, a fuse will blow due to a power surge or for no good reason and a new fuse is all that is needed. However, this is usually not the case and a new fuse will blow immediately. There is a chance that additional damage may result - proceed cautiously. If the fuse element is vaporized - black or silver coating on the glass, a short in the power supply is likely. However, a violent surge on the power line can also result in such a symptom.

Various subsystems of the VCR may be protected by individual fuses as well. Sometimes, one of these will blow resulting in a variety of multiple systems problems but not a totally dead VCR. Look for fuses on the mainboard as well as the power supply.

IC Protectors (ICPs) may be present on a single chip or small subsection of a circuit. Most common types are miniature fast acting fuses. Typically, they come in a black TO92 or rectangular .1"x.3" plastic case with two leads. Test these like a fuse - an IC protector should be a short if good.

In some cases you may find a PTC (Positive Temperature Coefficient resistor - resistance increase dramatically due to excessive current heating the element) type of fuse or IC protector - these are self resetting once the overload has been removed. However, this also means that testing with power off will show low resistance even if a fault still exists (unless you test immediately). Measuring voltage across such a device with power on is one way of identifying a problem. One common form of this device appears as a little metal metal sandwich - the two plates are separated by the active material.

VCR power supplies

Reread Safety info before tackling any power supply problem in a VCR!

VCRs typically use one of four types of power supplies (There are no doubt others):

1. Power transformer with linear regulator using 78/79XX parts or discrete components. The power transformer will be large and very near the AC line cord.

2. Power transformer with hybrid regulator like STK5481 or any of its cousins - multioutput with some outputs switched by power on. If it has one of these, check ECG, SK, or NTE, or post to sci.electronics.repair and someone can probably provide the pinout. Again, the power transformer will be large and very near the AC line cord.

3. Small switching power supply. Most common problems: shorted semiconductors, bad capacitors, open fusable resistors. In this case there is usually no large power transformer near the line input but a smaller transformer in a more central location.

4. Combo of the previous - these are less common. An input power transformer may supply low voltage to a switcher.

5. Camcorders and portable video camera-VCR combos include a battery charger and run all normal VCR (and camera) functions off of the battery. The required voltages are derived using DC-DC inverters.

First try to identify which type you have. Here are some general comments for each type:

1. Troubleshooting is quite straightforward as the components are readily identified and it is easy to trace through from the power transformer, bridge or centertapped full wave rectifiers, regulators, caps, etc. The circuitry is not usually complex and the most common failures tend to be quite obvious. It should be possible to determine the correct output voltages from basic circuit principles.

Start at the line cord - if there is infinite resistance between the two prongs, there is a problem in the primary side of the transformer. A fuse may be blown, the transformer primary may be open (or a thermal fuse under the outer layers of insulation may be blown), or there may be bad connections between the line cord and the transformer. If this checks out, there may be a problem on the secondary side - bad rectifiers, transistors or IC regulators, or bad connections. It is unlikely that the secondary winding of the transformer itself is bad.

See the document: Notes on the Troubleshooting and Repair of Audio Equipment and Other Miscellaneous Stuff for more info.

2. Failures of one or more of the outputs of these hybrid regulator blocks are very common. Use ECG/STK/NTE cross reference to identify the correct output voltages. Test with power switch in both positions. Any significant discrepancy indicates a likely problem. While an excessive load dragging down a voltage is possible, the regulator is the first suspect. See: "VCR Power Supply Regulators" for pinouts of some of the common ones. The correct output voltages will be specified by on the regulator pinout. Replacement cost is usually under $10. If you find *no* voltages on the regulator at all, go back and check starting at the line cord as above.

3. Switching supply problems are tougher to diagnose but it is usually possible without service literature by tracing the circuit and checking for bad semiconductors with an ohmmeter. Common problems - dried up capacitors, shorted semiconductors, open startup resistors, and bad solder joints. For a sample circuit, see the document: Various Schematics and Diagrams which includes an example of a switching power supply found (with minor differences) in many models of Panasonic (and clone) VCRs.

   In a supply that is dead - has blown the main fuse - check **all** semiconductors, capacitors, and resistors as a failure in one may damage others and just replacing the first one you find that is bad may result in it just blowing immediately. Fusable (flameproof) resistors (blue or brown body or boxy ceramic power type) may open up if there was a shorted switching transistor. Power resistors supplying current for the startup circuit may open from age. See the document: Notes on the Troubleshooting and Repair of Small Switchmode Power Supplies for more detailed information. Correct output voltages can be determined with some work - tracing the circuit. However, it is usually safe to assume that there should be at least one around 5 to 6 V output for the logic and one or more others at 12 V or higher for the motors and other electronics.

   Note: The initial test in (1) for power transformer based supplies of checking between the prongs of the line cord cannot be used with a switcher - it will likely always read open even if the supply is perfectly good.

4. Problems in either the power transformer/rectifier/filter capacitor section (usually no regulator) or switching supply are possible. However, they can pretty much be dealt with independently. Note: the switching supplies used in these usually run off of a lower voltage input than the more common off-line non-isolated type making them somewhat less hazardous to your health to work on. See (1) to (3), above.

5. Problems can occur in either the battery charger or power supply section. Short running time on battery alone is usually caused by a bad battery. If possible, try a known good battery or battery eliminator first to determine which it is. The older style portable units were quite reliable and easy to service. However, modern camcorders are so jam packed with microminiature surface mount unmarked circuitry that troubleshooting and repair is definitely not fun. Not to mention the joys of just getting inside with only a finite use of expletives.

Always check for the possibility of bad solder connections as well.

Internal fuse blew during lightning storm (or elephant hit power pole)

Power surges or nearby lightning strikes can destroy electronic equipment. However, most of the time, damage is minimal or at least easily repaired. With a direct hit, you may not recognize what is left of it!

Ideally, electronic equipment should be unplugged (both AC line and phone line!) during electrical storms if possible. Modern TVs, VCRs, microwave ovens, and even stereo equipment is particularly susceptible to lightning and surge damage because some parts of the circuitry are always alive and therefore have a connection to the AC line. Telephones, modems, and faxes are directly connected to the phone lines. Better designs include filtering and surge suppression components built in. With a near-miss, the only thing that may happen is for the internal fuse to blow or for the microcontroller to go bonkers and just require power cycling. There is no possible protection against a direct strike.

Most VCRs have their own internal surge protection devices like MOVs (Metal Oxide Varistors) after the fuse. So it is possible that all that is wrong is that the line fuse has blown. Remove the case (Unplug it first!) and start at the line cord. If you find a blown fuse, remove it and measure across the in-board side of fuse holder and the other (should be the neutral) side of the line. With the power switch off, this reading should be very high. With the switch on, it may be quite low if the VCR uses a large power transformer - a typical primary resistance is 15 to 30 ohms.

Some VCRs may be outside this range but if the reading is extremely low, the power transformer could have a partially or totally shorted primary. If it is very high (greater than 1 K ohms), then the primary of the power transformer may be open or there may be blown thermal fuse under the insulation wrappings of the transformer windings.

If the VCR has a switching power supply, see the document: Notes on the Troubleshooting and Repair of Small Switchmode Power Supplies.

If the resistance checks out, replace the fuse and try powering the unit. There will be 3 possibilities:

1. It will work fine, problem solved.

2. It will immediately blow the fuse. This means there is at least one component shorted - possibilities include an MOV, line filter capacitor, transformer primary.

3. It will not work properly or still appear dead. This could mean there are blown fuses or fusable resistors or other defective parts in the power supply or other circuitry. In this case further testing will be needed and at some point you may require the schematic.

Use of surge suppressors and line filters

Should you always use a surge suppressor outlet strip or line circuit? Sure, it shouldn't hurt. Just don't depend on these to provide protection under all circumstances. Some are better than others and the marketing blurb is at best of little help in making an informed selection. Product literature - unless it is backed up by testing from a reputable lab - is usually pretty useless and often confusing.

Line filters can also be useful if power in you area is noisy or prone to spikes or dips.

However, keep in mind that most well designed electronic equipment already includes both surge suppressors like MOVs as well as L-C line filters. More is not necessarily better but may move the point of failure to a readily accessible outlet strip rather than the innards of your equipment if damage occurs.

It is still best to unplug everything if the air raid sirens go off or you see an elephant wearing thick glasses running through the neighborhood (or an impending lightning storm). Generally, the backup battery or supercap will retain the clock and programming information long enough to ride out a typical storm.

Miscellaneous Problems

VCR poops out after a couple of hours

What could be the cause of the video dying on a VCR after it is playing for a couple of hour? Here are some questions:

Do all modes 'go out' or just PLAY?

Does it happen suddenly or just gradually worsens until it is total snow? Or, do you get the 'blue screen' if it has this function rather than snow?

Does the tuner still work?

Conversely, does PLAY work but not the tuner?

Do other functions like FF and REW always work?

How is the time it sits turned off related to how much on time you get?

Have you verified that the TV is fine?

Is it possible that the VCR is covered up/closed in/installed with inadequate ventilation?

It could be a loose connection or bad component. The usual way to narrow down the possibilities is to use what is called 'cold spray' or 'circuit chiller' on the appropriate sections of the circuit board until you locate the component that is failing with when it gets hot. I once had a VCR that needed a little fan blowing on it to keep it happy - much easier solution than actually hunting down the fault.

If play or record just stopped and the tape unloaded, it could also be a mechanical problem like a marginal idler tire, idler clutch, or worn belt.

VCR blows fuse once in a blue moon

These are the kinds of problems that put gray hairs on parts of your body you didn't think could grow hair (hey, maybe that is good).

First confirm that the correct fuse type and value was used for this particular model and revision number.

Of course, measurements of the supply current on the bench show a wide safety margin (i.e., 2:1).

I don't suppose there was any mention of what was being done when it stopped working?

While monitoring the current, try really exercising the FF and REW, switching between editing/tape movement modes, performing FF and REW to the end of tape stops, etc. These are where I would expect to see current spikes. It may be some peculiar combination of actions that results in a momentary jam or conflict.

Unless of course it is just some cosmic connection that takes place every 3 months!

VCR was dropped

So your cat decided it was time to practice the long-jump and didn't quite pick a stable destination. Your VCR is on the floor, Tabby is in the basement, and what to do?

Overall, VCRs are quite tough. However, falling in just the wrong way can do substantial and possibly not immediately visible damage.

If you take it in for service, the estimate you get may make the national debt look like pocket change in comparison. Attempting to repair a VCR that has been dropped is a very uncertain challenge - and since time is money for a professional, spending an unknown amount of time on a single repair is very risky. There is no harm is getting an estimate (though many shops charge for just agreeing that what you are holding is a VCR!)

This doesn't mean you should not tackle it yourself. There may be nothing wrong or very minor problems that can easily be remedied.

First, unplug the VCR even if it looks fine. Until you do a thorough internal inspection, there is no telling what may have been knocked out of whack or broken. Electrical parts may be shorting due to a broken circuit board or one that has just popped free. Don't be tempted to power the VCR even if there are no obvious signs of damage - turning it on may blow something due to a shorting circuit board.

Then, inspect the exterior for cracking, chipping, or dents. In addition to identifying cosmetic problems, this will help to locate possible areas to check for internal damage once the covers are removed.

Next, remove the top and bottom covers and front panel. Check for mechanical problems like a bent or deformed cassette basket, broken or cracked plastic parts, and anything that may have shifted position or jumped from its mountings.

Carefully straighten any bent metal parts. Replace parts that were knocked loose, glue and possibly reinforce cracked or broken plastic. Plastics, in particular, are troublesome because most glues - even plastic cement - do not work very well. Using a splint (medical term) or sistering (construction term) to reinforce a broken plastic part is often a good idea. Use multiple layers of Duco Cement or clear windshield sealer and screws (sheetmetal or machine screws may be best depending on the thickness and type of plastic). Wood glue and Epoxy do not work well on plastic. Some brands of superglue, PVC pipe cement, or plastic hobby cement may work depending on the type of plastic.

Cycle the cassette loading and tape loading mechanism manually by turning the appropriate motor shaft, if possible. Check for free movement of the various parts of the tape transport.

Inspect for any broken electronic components - these will need to be replaced. If the fluorescent panel is broken, you can run the VCR without it but of course will not be able to see any front panel displays. Check for blown fuses - the initial impact may have shorted something which then blew a fuse.

There is always a slight risk that the initial impact has already fried electronic parts as a result of a momentary short or from broken circuit traces and there will still be problems even after repairing the visible damage and/or replacing the broken components.

Examine the circuit boards for any visible breaks or cracks. These will be especially likely at the corners where the stress may have been greatest. If you find **any** cracks, no matter how small in the circuit board, you will need to carefully inspect to determine if any circuit traces run across these cracks. If they do, then there are certainly breaks in the circuitry which will need to be repaired. Circuit boards in VCRs are never more than two layers so repair is possible but if any substantial number of traces are broken, it will take a great deal of painstaking work to jumper across these traces with fine wire - you cannot just run over them with solder as this will not last. Use a fine tipped low wattage soldering iron under a magnifying lens and run #28-30 gauge insulated wires between convenient endpoints - these don't need to be directly on either side of the break. Double check each connection after soldering for correct wiring and that there are no shorts before proceeding to the next.

If the circuit board is beyond hope or you do not feel you would be able to repair it in finite time, replacements may be available but their cost is likely to be more than the VCR is worth. Locating a junk VCR of the same model to cannibalize for parts may be a more realistic option.

Once all visible damage has been repaired and broken parts have been replaced, power the VCR up and see what happens. Be prepared to pull the plug if there are serious problems (billowing smoke would qualify). Determine if it appears to initialize correctly - without shutting down. Play a garbage tape to determine if there are any problems that might damage the tape. Watch and listen carefully for any evidence of poor tracking, video noise, tape speed instability, or weak or muddy audio that might indicate that tape path alignment requires further attention. Listen as well for any unexpected mechanical sounds that were not there before.

Very likely, the VCR will be fine, you can replace the covers, and now find a more secure spot for it to prevent this sort of event in the future. Use your own judgment with respect to the cat.

VCR or camcorder went to the beach (sand and/or surf)

Someone took your camcorder to the beach this summer and now it has sand or perhaps salt inside. Or, that cup of tea on top of the VCR wasn't as stable as you thought. Now, it behaves, well, strangely. Can this possibly be fixed? Will it be worth the effort or expense?

Unless this is a really sophisticated (i.e., costly) unit, I doubt whether it will pay you to take it anywhere for repair. Even if it is successfully repaired, its reliability may be questionable. Furthermore, as with equipment that has been dropped or physically abused, few repair shops will be inclined to touch the job. They really don't like challenges of this sort.

That leaves you!

If anything got wet with saltwater and it has been just sitting, you can probably forget it. Without immediate attention (and I mean immediate, not later, not tomorrow, NOW!), saltwater corrosion can set in very quickly and attacks electronic components, circuit board traces, cable wiring, and mechanical parts. The only thing worse might be a peanut-butter-and-jelly sandwich 'played' in your VCR. On second thought, that probably would not be all that bad.

Although it is probably too late, the first thing to do when electronic equipment gets wet is to remove the power source - pull the plug or remove the batteries. Don't be tempted to apply power until you have determined that everything is completely dried out inside and out.

DO NOT use strong solvents anywhere! These may attack various plastic parts or cause internal damage to electronic components.

The following was written assuming sand, salt, and liquid contamination everywhere! Modify based on your specific situation.

Mechanical intensive care:

1. Disassemble as much as possible - sand and surf (or other liquids) find their way into the tiniest nooks and crannies. You need to get it all.

2. Make a drawing of the belt routing, remove the belt(s), wash and dry them, label and set them aside.

3. Use a soft brush (like a paintbrush) to dust out as much sand as possible. Hopefully, you can get it all this way. A vacuum cleaner with a wand attachment may prove handy to suck out sand. Sand will tend to collect on lubrication, especially grease, which will need to be completely cleaned out and replaced. Don't use high pressure compressed air, you will just spread it around. Any grease or oil on which sand has collected will need to be totally removed and replace with fresh lubrication.

4. If there is evidence of salt (remember, I said forget it...but), you will need to wash it off. Yes, wash it. Keep water out of the motors. Use low pressure compressed air (a blow dryer on low heat should be fine) to dry so that it does not rust. Ditto if it is still wet with contaminated liquid (we won't say where this came from), wash with fresh water to remove all traces of it as quickly as possible. Then dry completely. Depending on the situation, a final rinse with 91% or pure isopropyl alcohol may be desirable to decrease drying time. This should be safe for most mechanical assemblies. Degreaser may be used if it is safe for plastic and rubber parts.

   Lubricate all bearing points with a drop of light machine oil - electric motor oil, sewing machine oil, etc. (Never never never WD40). Lubricate gears, cams, and sliding parts with a light plastic safe grease such as Molylube.

   Parts like the idler clutch may need to be disassembled to get at the friction felt. Other mechanical parts like cam gears may need to be removed to be properly cleaned. Don't mess up the timing relationships when you do this!

5. Reinstall the belts and reassemble in reverse order.

Electronic intensive care:

1. Remove the circuit boards and label the connectors if there is any possibility of getting them mixed up. If the circuit board(s) are soldered to the rest of the equipment, then you will have to improvise and work

in-place.

2. Wash with water and dry thoroughly. This does work. I use it routinely for degunking remote controls and rubber membrane keypads, for example. I have heard of people cleaning contaminated computer keyboards in their dishwasher! The important objective should be to get corrosive liquids off the components and circuit traces as quickly and completely as possible. A final rinse with 91% or pure isopropyl alcohol will decrease drying time. However, there is a slight risk of damage to sensitive electronic components should some be trapped inside. Pat dry, then use warm air from a hair dryer (or heat gun on low) to completely dry everything. Moisture will be trapped in controls, coils, selector switches, relays, transformer cores, connectors, and under large components like ICs. DO NOT operate until everything inside and out is thoroughly dry.

3. Use spray contact cleaner on the switches and control cleaner on the control and adjustment pots. DON'T turn the internal adjustments without precisely marking the original position - else realignment will then be needed. However, exercise the user controls to help the cleaning process.

Note: drying time may be quite long. For parts with inaccessible areas like membrane keypads, you may need to wait a week before normal operation is restored. Be patient!

Once everything is completely dry as a bone and reassembled, power it up but be prepared to pull the plug or pop the batteries if there are serious problems See if the display comes alive and the transport appears to initialize. Attempt to play a garbage tape to determine if there are any mechanical problems that might damage the tape. Look and listen for any abnormalities which may require additional attention. Then address specific problem areas. Also see the section: VCR was dropped for additional info.

Obviously, this description is very simplistic. The important thing is to get every last grain of sand, salt, and other contaminants off of the mechanisms and circuit boards quickly.

As noted above, moisture may collect inside certain electronic parts and it is essential that these be dried completely before attempting to apply power to the unit. If you do not, at best it will not work properly and you may do additional serious damage due to short circuits.

For the mechanics, the same applies though this is trickier since certain parts need to be lubricated and these may not be readily accessible or obvious. Don't be tempted to overdo the lubrication - too much is worse than too little.

For camcorders, some parts of the optics or enclosed DC-DC converters may be impossible to access and clean of scum.

Dead or missing remote controls or lost codes for universal remotes

See the document: Notes on the Troubleshooting and Repair of IR Remote Controls for extensive information as well as links to the web sites of manufacturers of universal remote controls - these include setup info.

Recovering damaged or broken tapes

So you just pulled your favorite tape from the VCR and there are two tape ends dangling from it. Or, perhaps, your VCR has just munched on that tape and a section is now seriously crinkled. Maybe you haven't been following the recommendations on preventive maintenance; maybe your VCR was just hungry. In any case, what to do? The recording is, of course, irreplaceable.

If it is only slightly crinkled, the tape may be salvageable (though it will never likely play without some dropouts). How serious is 'serious'? Hard to say but ironing may help. See the section: Uncrinkling a crinkled tape.

However, if it is broken - even partially, or stretched and scrunched, I recommend you throw it away (and make sure no one else can pull it out of the trash and ruin *their* VCR!).. An imperfect splice or seriously crinkled section of tape can shatter your video heads - the most expensive single part in a VCR. If it is something you really treasure, than what I would do is to follow the procedure below.

Note: If you have never seen the inside of a video cassette, try the following on a couple you really don't care about first so that if you screw up, there is no great loss. Too bad AOL doesn't send out Internet software on video cassettes, huh?

CAUTION: The video tape itself is really really thin and easily crinkled. Be very gentle when handling it and avoid touching the oxide (dull side) if at all possible.

1. Locate a garbage cassette and disassemble it. Throw away the tape but save everything else including the reels. See the section: Disassembling a VHS cassette.

2. Construct two cassettes from the combined collection of parts you now have. Cut out any sections of tape that got mangled.

   Cassette 1 has the first section of tape (before the break) and uses one empty reel from the garbage cassette for the supply reel. Rewind this to the beginning.

   Cassette 2 has the second section of tape (after the break) and uses the other empty reel from the garbage cassette for the takeup reel.

   Use the little plastic plugs that came from the garbage tape reels or some adhesive tape to connect the tape to the reels.

3. If the break is at one end, you can just reconnect the bulk of the tape to the reel and dispose of the original leader. Just don't rewind or fast forward all the way to the end as the automatic end sensor will not work (for the particular end that has been repaired). What will happen is that instead of the sensor stopping REW or FF (as appropriate), the tape will run to the end and the VCR will then shut down when it discovers that the tape isn't moving. This can put additional stress on mechanical parts and/or rip the tape from the reel. Serious damage to the VCR isn't really that likely.

4. Copy to a good cassette.

5. Dispose of the original(s) or clearly mark 'DO NOT USE' with a detailed explanation.'

   Filip (I'll buy a vowel) Gieszczykiewicz (filipg@repairfaq.org) is a little more definitive about this: "I find the destruction of it more fulfilling :-) ... put it in a paper bag and smash the life out of it with a big, heavy hammer - or a small ball hammer for an even higher satistfaction ratio :-) "

The idea is to never have a splice in a VHS cassette. (Even a seriously crinkled tape such as might result from a tape eating incident can damage the heads.) It is possible to splice safely but as noted, it can be quite costly if you don't get it quite right.

Uncrinkling a crinkled tape

WARNING: Discarding a seriously crinkled tape is really the safest option from the point of view of the health of your VCR. However, if you really must view it, there are some relatively low risk options. The following only applies if there is absolutely NO evidence of even partial breakage or puncture of the tape's backing (it's OK if some of the oxide has flaked off):

Just winding the damaged section back into the cassette and then FFing or REWing as appropriate to put several layers of tape on top of it may help. Leave it like that for a few days and then carefully return to the crinkled section to see how it is doing. WARNING: Do all this on a VCR that DOESN'T have an instant response transport so that there is no chance of the video heads contacting the damaged part of the tape. You may have to do this a few times.

Passing the damaged section (backing side) around a blunt edge (like a table top) back and forth a few times may help as well.

(From: Paul K. Sagi (paul_sagi@astro.com.my).)

I had a go at a seriously crinkled VHS tape that my mom was wanting to show her class at temple. I put the crinkled section between pieces of the kind of paper that is sold for some kind of cooking use, can't remember what it is called. I then ironed it (heat only, no steam) and it worked OK except a couple of seconds dropout."

(From: Steven Van Assche (steven.vanassche@yucom.be).)

CAUTION: Use with care!!

I use the following: Get your iron, the one used for T-shirts, not your soldering iron! ;-)

What I do:

1. Let the iron warm up.

2. Release the reel latch by pushing something in the hole on the bottom, disengage and lift the lid, and then pull the tape gently out of the cassette. Make sure the *backside of the tape is lying upwards*.

3. Now go in one pass from left to right over the crinkled part with the iron. You can repeat this, if needed. Due to the heat, most crinkles will go away.

Now, to play it safe, copy it to another tape. and mark the old one as damaged.

The most important factor here is heat: Too hot and you will burn the tape instantly while too cold and nothing will happen. It is best to start from cold to warm, and slowly increase the heat until you see an improvement...

Disassembling a VHS cassette

These instructions should enable you to get inside a cassette for the purpose of reattaching a leader that pulled off of one of the reels or to enable you to transfer its contents or a portion thereof to another shell or vice-versa.

1. Peel off the label on the side or carefully slice down its center line with a knife or razor blade. This is necessary to allow the cassette halves to be separated.
2. Place the cassette upside-down and remove the five (5) phillips head screws and set aside.
3. While holding the cassette together, place it label side up on a clean surface.
4. Gently remove the top (along with the hinged door) to reveal the interior.

At this point, you should see something that looks like VHS Cassette - Inside Top View.

When you reassemble the cassette, take care to avoid crunching the tape under the hinged door - depress the unlock button on the side and lift it clear if needed.

Cassette rewinder problems

Cassette rewinders typically consist of a low voltage motor powered from a built in transformer or wall adapter, a belt, a couple of reels, and some means of stopping the motor and popping the lid when the tape is fully rewound.

Note that some designs are very hard on cassettes - yanking at the tape since only increased tension is used to detect when the tape is at the end. These may eventually stretch the tape or rip it from the reel. As noted, I don't really care much for the use of tape rewinders as normal use of rewind and fast forward is not a major cause of VCR problems. Sluggish or aborted REW and FF may simply indicate an impending failure of the idler tire or idler clutch which should be addressed before the VCR gets really hungry and eats your most valuable and irreplaceable tape.

Problems with tape rewinders are usually related to a broken or stretched belt or other broken parts. These units are built about as cheaply as possible so failures should not be at all surprising. The drive motor can suffer from any of the afflictions of similar inexpensive permanent magnet motors found in consumer electronic equipment. See the section: Types of Motors in VCRs. A broken belt is very common since increased belt (and tape) tension is used to switch the unit off (hopefully). Parts can pop offof their mountings. Flimsy plastic parts can break.

Opening the case is usually the biggest challenge - screws or snaps may be used. Test the motor and its power supply, inspect for broken or dislocated parts, test the power switch, check and replace the belt if needed. That is about it.

Why VCRs will not copy (Macrovision) copy protected tapes

> "I've got one of the Damark ones and it does work for Macrovision protection, depending on the input deck. My 10 year old Panasonic VHS Hi-Fi (No MTS tuner, Dolby(tm) B linear stereo non-Hi-Fi audio too) works fine as an input deck, while my new JVC Hi-Fi doesn't. Why some input decks work and others don't is my question. Anyone know? Is there added circuitry that the newer decks have to defeat the stabilizer boxes?"

(From: Jeroen H. Stessen (Jeroen.Stessen@philips.com).)

JVC owns the patent for VHS. JVC has made a deal with Macrovision that from a certain date in the past *no* VHS recorder licensed by JVC shall be able to record any video signal that contains Macrovision's copy protection pulses. Any video recorder from before that date (VHS or other) might well work OK on the altered video signal! The copy protection pulses upset the video AGC and H-sync. TV's usually don't have a video-AGC.

Thus the whole idea of the Macrovision method is to disturb the video AGC that is inside every VCR - the manufacturers even *must* make the video AGC sensitive to those pulses!

In the TV, the horizontal sync processing may be disturbed by the Macrovision pulses. Indirectly that also disturbs the DC clamping circuit. So you may see horizontal phase as well as brightness disturbances at the top of the picture.

The stabilizer box removes the extra pulses and makes it into a normal video signal again. No VCR should ever know the difference, so they should all record properly again.

At the same time, all TV's are required to ignore the copy protection pulses. As a TV-designer I can tell you that this is sometimes far from trivial. Not in the least because in the beginning we were not included in "the deal". There may be TV's around whose brightness and/or sync will be disturbed by the Macrovision pulses. Officially, this is the reason for existence of the stabilizer boxes: to view better, not to copy better. Unofficially, they are sold for copying, of course.

Keep in mind that the Macrovision 'standard' (pardon me) has been improved several times. Old decoders may not be able to cope with newer tapes. In order for the decoder to key out the pulses in the vertical blanking interval, it must first synchronize properly itself. That process too may be disturbed (by extra pulses on newer tapes to older decoders).

Those Macrovision a**holes are smarter than you think. Unfortunately, their signal may also disturb some TVs which are used legitimately. And then it becomes *our* problem too.

The next step will be that digital-TV decoders will output an analog TV signal with Macrovision copy-protection pulses so that you may watch but not record your pay-per-view program. Same problem, same solution ...

And I thought that PAL/SECAM/NTSC were *standards*, sigh ...

VCR AGC and Macrovision copy protection

(From: Mark T. O'Bryan (obryan@gumby.cc.wmich.edu).)

Look at it this way. The reason that you see changes in brightness is that the "protection" signal that is added makes the unit's AGC (auto- matic gain control) think that the level has shifted, when it hasn't. So it adjusts to compensate.

So if you have an older VCR without AGC (or a mild application), it may not be affected as much (or at all, after passing through a "stabilizer" box). If the sensitivity of the AGC is high (like it is on most JVC's) and the response-time is short, any small amount that leaks through will still cause problems.

For those familiar with the electronic circuitry in VCRs, both the time constant in the RC circuit for response-speed, as well as the AGC sensitivity can be adjusted by manipulating simple resistor values. I don't have any specifics on this (and it varies on different machines), so don't bother asking for it :-).

But at least you now know why some decks react differently.

Problems with closed caption decoding

> "I've just started to use the closed caption feature of my TV and have a problem with pre-recorded video tapes, and am wondering if it could be the VCR. The problem is simple: about half the tapes I've watched displays the CC information incorrectly (many missing characters and/or lines), or will not display it at all. Sometimes I can improve the CC display by adjusting the VCR tracking to the point where the picture starts to become fuzzy, but for the most part it remains garbled and uncorrectable."

Of course, as with so many other problems, poor quality or well worn tapes can result in erratic closed caption decoding. Therefore, I would not recommend diving into the bowels of your VCR before trying out some other tapes.

(From: Thomas D. Kite (tom@olive.ece.utexas.edu).)

Sounds to me like the head switching point is too far down the screen, i.e. the point at which the VCR switches between the video signals from the two heads is too late. You can check this if you have a TV with vertical hold.

Set the hold to give a stationary or slowly rolling picture so that you can see the head switch, which will appear as a tearing of the picture. This should occur during the blanking period, but I suspect that your VCR is switching sometime later. If so, open it up and look for a preset on the main board labeled 'Head SW PT' or something like that. Twiddle it so that the tearing backs up the screen into the blanking part (again, do this while the picture is rolling slowly). Hopefully, this will mean your VCR has done its switching by the time it gets to Line 21, and the CC information will be intact.

(From: Richard Beeler (vcrmonthly@earthlink.net).)

This could be Copy Guard on tapes interfering with the closed caption decoding. We had one that was doing the same thing on some pre-recorded tapes and not others. We finally had to add a 'video stabilizer' between VCR and TV - that corrected the problem.

F-connector broken off rear of TV or VCR

Sometimes this just happens due to poor manufacturing and a slight tug. However, usually, there has been some severe trauma - like the TV or VCR falling off a shelf while still attached. When else would it fall off a shelf? :-)

I recently repaired a Panasonic VCR with a dangling F-connector. It required removing the cover, main board, unsoldering the A/V block and part of the power supply, just to get at the RF modulator. Then it was a simple matter of resoldering the center conductor to the printed circuit board (fortunately, nothing else was damaged) and the shell of the F-connector to the metal box.

From: Glenn Watkins

We get a lot of sets with broken "F" connectors broken off - both VCR's and TV's. The job can be quite involved depending on the exact set. It may take an hour just to open it, remove the tuner or RF modulator and open the case. Then if you're lucky, there is no additional damage inside the unit due to people probing with pencils, screwdrivers, etc.

On some TV's including Sharp, there is a antenna(cable) isolation device that connects between the tuner and antenna. This device comes in a few flavors and is very easy to install if broken. I've seen them as cheap as $4.95 each mail order.

Whirring sounds from VCR when tape inserted

The most likely cause is that your VCR uses an "instant start" transport and the sound is from the video head drum spinning. The drum starts spinning as soon as a tape is inserted and until several minutes after the last tape motion ceases (PLAY, REW, CUE, REV). It's possible that due to wear, this sound may become louder over time but should never get to the point of being annoying. If there's a high pitched whine, the problem could be the "static brush" associated with the head drum. See the section: High pitched whine from inside VCR. Control/power supply faults can result in the head drum spinning when it's not supposed to on non-instant start VCRs but there would almost certainly be other more serious problems.

---

17. Back to VCR Repair FAQ Table of Contents.

A Few Model Specific Problems

Dead clock in Hitachi manufactured VCR

The clock display is dark but other functions are normal.

Your VCR probably was made by Hitachi (Sears is one of several brands that may be manufactured by Hitachi). If so, probably your DC to DC converter went bad.

Please note that the the converter is close to the front of the VCR and not on or near the main power supply board.

Also check the IC protector (possibly ICPN5) as it may have blown. You should also replace the two 47 uF 50 V and the 100 uF 35 V capacitors near the DC to DC converter. These are known to go bad resulting in failure of the DC to DC converter.

Complete repair kits are available from suppliers like MCM Electronics. These will include all components likely to have gone bad.

For some models:

(From: Sire Johnathan (sirejohn@bbs-la.com).)

Behind the Channel selector is an upright PCB. on the upper inside corner find a 1/2" sq. transformer can with top hole and slotted core adjust.

The schematic nomenclature is T101 or T102. Next to it, find a TO-220 power transistor. Replace the Pwr Xstr, filter caps in secondary side rectifier with DOUBLE the voltage ratings, and a small choke (L1?) that feeds primary power to the power transistor (fuses open). When working properly, current draw through primary circuit should be less than 200 mA.

JVC tracking problems and dropped parts

You have a JVC VCR, 1990 or so vintage and it upped and died on you.

JVC, huh? How did it die? What are the symptoms? Major tracking problems? Eats tapes? JVC VCRs of that era tend to shed parts in the tape loading mechanism - easily fixed. Unless it is a serious electronic problem (there is a minor one which results in similar symptoms - see below), a service manual may not help. And even then, it may not have the information you need.

Check the roller guide assemblies (see the sections: "Parts of the tape transport in a VCR" and "General tape path alignment problems").

There are two types of failures that occur frequently on various JVC models:

1. If one of them flops around (they normally will be loose except in the fully loaded position but should not come off the track), then it has lost the brass guidepost underneath. Remove the bottom cover and you should see it drop out. Without the guidepost, the roller guide will not seat properly and tracking will be way off. Use a dab of Epoxy or superglue to replace the brass post fully against the shoulder in the cast roller guide base. Just popping it back in, even if the post appears snug, will result in a callback. If this is done carefully, tape path realignment should not be needed.

   Alternatively, replacement roller guide assemblies are available.

   WARNING: do not attempt to load a tape if a roller guide assembly can be lifted off of the track - it may smash the rotating video heads - very expensive lesson. Of course, it may already be too late :-(.

2. If a roller guide does not seat fully against the V-Stopper (the end piece) but the brass pin has not fallen off or loosened, then a linkage pin may have loosened. This is plastic pin which is the hinge for the linkage which moves the roller guide assembly. I have used a tiny screw from the top to firmly reattach this pin. Clearances are really tight so if the screw head sticks up more than a mm or so, it will restrict movement of the roller guide assembly resulting in loading and/or unloading problems. Alternatively, a dab of plastic cement may work. In either case, tape path realignment should not be needed.

To get at the bottom of the roller guides or hinges, you will probably have to convince the VCR to start loading a tape and then pull the plug just as the mechanism is in a position where you can get to it.

- Another common cause for a band of video noise at the top or bottom of screen on some JVC models: Defective capacitor (may be C6, 3.3 uF, 50 V) on drum motor resulting in bad PG pulse. It looks like a tantalum cap but a regular electrolytic should be satisfactory. Even Radio Shack will likely have a replacement.

  In some severe (or shall we say, strange) cases, good and bad/no video may occur randomly each time the VCR enters PLAY mode but will remain that way until the tape is unloaded.

(From: Mark Shoberg (mewzaq@webtv.net).)

When replacing the 3.3uf cap on the motor board (this is for the older bottom mounted types) just cut away the plastic piece covering it a little bit. This way you don't risk damaging the video heads and it is easier as well.

(From: John Poulton (John@TellyCare.freeserve.co.uk).)

This is a very common problem on these machines. To check it out carry out the following check:- Set the machine to play a pre-recorded tape. While observing the picture on screen, stop the head drum rotation by pressing your fingers on the top surface of the drum for a fraction of a second. The instant the drum stops, release it and let it start up again.

This must be done very quickly, otherwise the machine will shut off. If you find that each time this is done the picture re-appears in a different state, it means that the 3.3uF capacitor on the board of the head motor is faulty. It can be replaced without removing the deck from the cabinet if a small section of the plastic base is cut out.

Magnovox tracking problems and dropped parts

(From: Frank Fendley (frank.fendley@datacom.iglou.com).)

There were more Magnavox models made by JVC in the early 90's than many people realize. The following models were all made by JVC:

VR1835, VR3440, VR9020, VR9040, VR9140, VR9142, VR9160, VR9162, VR9240, VR9241, VR9260, and VR9362.

All used the same chassis which JVC used in their HR-Dxxx series of VCRs.

See the section: JVC tracking problems and dropped parts.

Panasonic error codes

I'm not sure for which models these are valid.

(From: John (johnbrewer@webtribe.net).)

01 - Drum motor stopped
02 - Tape reel stopped
03 - Mech stopped during loading to drum
04 - Mech stopped during unloading from drum
05 - Capstan rotation fault
06 - Mech stopped during tape-in/eject

Most of these faults are caused by either the mode switch or that horrible plastic thing on the end of the loading motor shaft.

A number of Panasonic and other Matsushita brand clones use a switching power supply which has a couple of common failure modes.

- Blown fuse and shorted switchmode transistor and possible other failed parts. Replacement of the obvious shorted or open parts usually cures these. Test all semiconductors and fusable resistors - do not assume that a single part is bad. If you just replace the first bad part you find, it may just be blown again by other bad parts.

- Low output voltages. If the 5 V (approximately) outputs measure low, 3.5 V, for example, then there is a leaky capacitor in the power supply startup limiter. A common part number is C14 or C21 (depending on model) which is 1 uF, 50 V. Almost any reduction below 5 V will cause problems.

- The primary and secondary side filter and other electrolytics may lose capacity resulting in hum or ripple and regulation problems. Replacing all electrolytic capacitors in the power supply is probably the best solution.

The same power supply is used with minor variations in a wide variety of Panasonic (and clone) VCRs from the 1980s and 1990s (and may continue to this day). Depending on the specific model, there may slightly different output voltages and number of outputs but the general organization is identical. These use discrete components throughout with feedback from the primary output (5 to 5.2 V depending on model) using an optoisolator to essentially short out the drive to the main chopper transistor (Q1) when the output equals the desired voltage. The most common problems found with any of these supplies is dried up electrolytic capacitors. Generally, the first to go will be C16 and C17 on the +5.1 VDC line and/or C21 in the feedback path (actual part type and number may vary slightly with model). Symptoms will be either that the primary output is somewhat low (4 to 4.5 VDC) or that the supply has gone overvoltage and blown the protection zener (D15) resulting in a high pitched whine as the chopper struggles to drive current into a short circuit (this usually doesn't damage any other parts if caught in a reasonably timely manner). If any capacitor related problems are found, it is a good idea to replace all the electrolytics in the supply. Model specific capacitor kits as well as total rebuild kits are available from places like Studio Sound Service and MCM Electronics.

- Get the schematic for the typical Panasonic VCR switchmode power supply in PDF format: VCRPS-SCH.

Some of the sources listed in the section: Suggested Parts Suppliers sell power supply rebuild and capacitor kits. Unless your power supply is missing, one of these kits will probably fix it - and all you need to know is how to solder!

Also see the section: Quick tips for troubleshooting Matsushita/Panasonic SMPSs.

Quick tips for troubleshooting Matsushita/Panasonic SMPSs

This general approach applies to most switchmode power supplies found in Matsushita manufactured VCRs (includes Panasonic, some Quasar, RCA). Symptoms may be a totally dead VCR, unresponsive front panel/remote but working display, poor or erratic play/record, and/or random shutdowns.

1. Measure all the output voltages. You should see a bunch of high ones (e.g., +15, +45, +31, etc.) and 2 or 3 that are in the range: +5 to 5.2 V.

2. If there are no +5 to 5.2 V outputs but some in the +2 to 4.4 V range, you most likely have bad electrolytic capacitors - usually either the 1 uF, 50 V (excess electrical leakage) in the feedback and/or the 330 or 1000 uF, 6.3 V filter capacitors on the +5 to 5.2 V line (greatly decreased uF value).) A capacitor replacement kit (about $7, see the sections starting with: "Suggested Parts Suppliers") is the easiest solution since other electrolytic capacitors are likely on their way out as well. If you opt to order the capacitors from a general electronics distributor, make sure to obtain 105 DegreeC rated parts.

3. If supply is whining, you have a blown 18 V zener (the original is a fat glass diode coded with brown and gray bands) probably in addition to bad capacitors. This zener protects the VCR from overvoltage due to regulation failure (also caused by bad capacitors).

4. If it is totally dead with a blown fuse, then a complete rebuild kit (not just the caps, about $14) will probably fix it and/or see the document: Notes on the Troubleshooting and Repair of Small Switchmode Power Supplies - check all semiconductors for shorts, resistors for opens, etc. Q1, the main switchmode transistor on the heatsink, will be shorted, its emitter resistor may be open, and other parts may have failed as well.

5. To test the power supply outside of the VCR (recommended but not essential since the 18 V zener does a pretty good job of catching overvoltage!), you need a load on the +5 line such as a 20 ohm 2 W resistor. I use a Variac and series 40 W light bulb just to be doubly safe.

Multiple system problems with various RCA, GE, and Samsung VCRs

Symptoms include anything from erratic behavior to acting totally dead. There are many models for which the info below applies.

(From: Ken Koskie (aw345@lafn.org).)

This may be one of the RCA VCRs plagued with intermittent diodes. RCA recommends replacing the following diodes; D108, D109, D110, D112, D114, D1103 and D1104. Their part number for the diode kit is 201066.

> "I am currently working on a GE VCR Model VG-4016 with the following problem. When the tape is inserted it loads fine the head starts spinning but it doesn't play because the capstan is not turning. If you push play a second time it start to play but is in the X2 mode so its going to fast."

(From: Frank Fendley (frank.fendley@datacom.iglou.com).)

Common solution for this - replace D108, D109, and D110 - even if they test good with a meter. ECG125 works well for this (2.5A/1000PIV). While you are at it, also replace D105, D106, D111, D112, D113, D114, using the same replacement. Samsung must have purchased 40 billion bad diodes when they built these units. Funny thing is, they almost always test OK with a meter but replacing them fixes the problem. Apparently they go open under operating voltage, but not under the lower voltage provided by a meter.

Alternate solution (fairly uncommon) - replace IC201.

(From: Mark Z. (zmachar780@aol.com).)

If this model is the type I think it is, there is an open diode along the inside edge (toward the mechanism rear) of the top circuit board. There is actually about 7 diodes which tend to go bad in these due to underrating. Five are in the area I mentioned, that is two along the edge at the middle of the board, and three further back, and two are located under the power transformer. Other problems, such as no display or no power, will occur if any of the others go bad. Suggest you replace them all; Any decent 1N4007 or such will do fine. Radio Shack has "2.5A 1kV" diodes which would be fine.

For some RCA VCRs with somewhat similar symptoms:

(From: TVman (tvman@newwave.net).)

For the RCA VR321 which appears dead, clock display may come on after a few minutes, Q1 runs hot: Replace: C09 (22 uF, 16 V) non polarized capacitor in power supply.

(From: Chuck Yung (cbelect@pce.net).)

For the Samsung VR3711, there are a total of seven diodes that should be changed, they are: On the main board: D108, D109, D110, D112, D114; In the power supply: D1103, D1104.

Samsung (and clone) power supply problems

(From: Gilbert (osmyn@together.net).)

Many Samsung VCRs, (and possibly other makes) use a DC to DC switching power supply built onto it's own separate, shielded PCB which plugs into the main circuit panel, and is secured in place by two or three screws. On this power supply, located right next to the switching regulator transistor (Q1) there is a 16 V, 22 uF, non-polarized electrolitic capacitor which frequently fails, probably due to constant exposure to the heat generated by Q1. (Refer to Sansung VCR Power Supply Parts Location.) When this capacitor is faulty, the VCR's flourescent display will usually flash about once per second when the set is first plugged in, and possibly after some time, the display will become steady and the unit will function normally. In extreme cases where the capacitor is completely open the display may never light up at all. If the power supply is removed from the VCR, and tested under a no-load condition, all voltages will likely appear normal, giving the false impression that the VCR is overloading it. When working on this panel, please bear in mind that it is directly connected to the 120 VAC power line, and therefore presents a significent danger of electrical shock - BE CAREFUL.

Erratic behavior of Sharp VCRs

Two words: Mode Switch (at least with older models, see below). Whenever you have problems that seem to come and go or go away temporarily with repeated attempts to play or enter some other mode, the problem is very likely a dirty (or worn) mode switch (may be called the 'mechanical state switch' by some.

The chassis of Sharp VCRs come in several flavors. Here is a description of two of them with respect to getting at the mode switch:

- Newer models (e.g., VC-A607) have the mode switch as part of a modular loading motor assembly. This is found on the top in the far right corner of the transport. It is mounted by 3 screws, easily removed. There are no timing relationships to get messed up as long as you don't try to cycle the mechanism while disassembled. Therefore, it can be removed and replaced without concern for gear timing. The link between the mode switch and drive gear is keyed so it will go back together properly.

  To access the mode switch, unplug the connectors, remove the single belt that drives the eject mechanism, and remove the 3 screws. It should now be possible to detach the entire assembly. Underneath, you will see a disk with a keyed center hole - this is what must be replaced with the same orientation as it was before removal. The disk snaps off easily revealing the tracks and contacts of the mode switch. Thoroughly clean and slightly increase the spring pressure of the contacts. Replace in reverse order. Make sure the post slips into the keyed hole as you replace the assembly and double check that it is seated before tightening the screws.

- Older models (e.g., VC7864U) are a bit trickier. The mode switch on these models is sandwiched between the loading gears and a mounting plate - all parts of what I will call the 'loading gear assembly' underneath the tape transport. To access the mode switch, this entire unit needs to be removed and partially disassembled. The gears operate the roller guide loading mechanism, and a couple of cam operated levers which are conveniently hidden when it is removed or reinstalled. It is driven by the loading motor via a couple of idler gears.

Timing marks: There is at least one critical timing relationship that needs to be preserved when the loading gear assembly is removed. I recommend that you put your own timing marks on all gears before loosening the 3 screws that anchor this unit. You will need to unsolder 4 connections as well before it will come free. Once the bottom of this unit is accessible, the mode switch can be snapped apart and cleaned.

I believe this is best done with the VCR in the unloaded and ejected state. However, there are still a couple of levers that will need to engage properly when the loading gear assembly is replaced. These press on internal cams that are hidden when everything is together. Much fun.

(From: Lill Tommy (tommy@caves.net).)

For newer models like the Sharp VC-H956, it may act like a mode switch problem but it isn't and you need to change the takeup and supply reel LEDs and cam switches and D706 to D709. (Sharp part # for D706 and 707 - RH-PX0252GEZZ; for D708 and D709 - RH-PX0253GEZZ).

Late model Sony VCR munches tape on eject

Symptoms are that upon eject, a loop of tape may be hanging out and possibly held by an arm inside the deck. The cause is gummed up lubrication on the pivot of that 'half loading arm' on the right side of the transport. It is supposed to help pull the tape out of the cassette during loading and then spring back when unloading. If the lubrication gets sticky, it does not spring back and grabs onto the tape during eject. Remove the half loading arm by unscrewing the locking nut. Count the revolutions of the nut as you do this since it sets the height which is somewhat critical. Clean the bearing and shaft and then lubricate it with a drop of light oil or a dab of light grease.

If you forgot to count the turns or the nut had originally loosened up, just center its height within the range over which the tape moved stably past the first fixed guidepost and/or A/C head. Then confirm reliable loading and unloading with several different tapes. Try using forward and reverse search to assure that the tape isn't moving up or down on the guides. Make sure there is absolutely NO tape edge damage.

Someone gave me a fancy Sony HiFi VCR with the request "I will pay up to $150 to fix it. Circuit City said that it could not be repaired for less than $250 because my kids had gotten into it and recommended replacement" (I wonder why). It was the stupid loading arm. Obviously, the grade-A techs at Circuit City were either under orders not to suggest repairs if they could get away with it and/or had never even taken the top off of the thing because the owner had mumbled something about his kids.

I could have made a bundle off of that. I could have had a nice VCR for nothing. I just gave it back and told him about the bit of cleaning and drop of oil.

(From: Sire Johnathan (sirejohn@bbs-la.com).)

I recall well from counting turns until that elastic nut lifts off the stud is very repeatably 6.5 - 6.75 turns. Checking it with the Sony height specs is always within limits. Don't forget to check the smooth running of tape over this 1/2 load pre-threading guide pin in the reverse scan direction. The tape should maintain same height when changing rapidly between FWD SCAN and REV SCAN. A worn conical pinch roller can cause tape height shifting and tape edge-rippling or top-slacking because the pinch roller becomes the primary tape guide in REV SCAN. Changing quickly between REV SCAN & PLAY modes while monitoring normal linear audio treble and tracking can reveal any mis-skewing of the tape path as it 'returns into the groove' in PLAY mode. Sony pinch rollers are notoriously short-lived causing most tape edge-rippling and mistracking. BEWARE of 3rd party substitute parts as they are frequently out of tolerance and poor bearings necessary for Sony mechanisms.

Sony VCR error codes

(From: VCRMonthly (vcrmonthly@aol.com).)

Later Sony VCR's have "emergency" codes that show up in the Fluorescent Display on certain failures. The code shows up in the "seconds" position and they are as follows:

```
 Code              Problem
-----------------------------------------------
  00         Normal.
  01         Abnormal Take-up reel rotation.
  02         Abnormal Supply reel rotation.
  03         Abnormal drum (head) rotation.
  04         Abnormal forward cam motor rotation.
  05         Abnormal reverse cam motor rotation.
  06         Abnormal cassette loading.
  07         Abnormal cassette unloading.
```

Play a tape until the VCR shuts off and then check the failure code to help diagnose the problem. These codes are cleared when AC is removed or when another function button is pushed.

Some Sony VCRs may use the error coding summarized below:

```
  Error Code       Block              Problem
--------------------------------------------------------------
   00                           No error
   01 - 09        Control motor
                  (encoder)       Unable to detect the position

   10             Mechanism       Loading not completed
   11              (deck)         Unloading not completed
   12                "            No eject
   13                "            End sensor fault (take-up side)
   14                "            End sensor fault (source side)
   15                "            Dew detected

   20              Drum           Drum motor won't rotate
   21                "            Drum servo not locked

   30             Capstan         Capstan motor won't rotate
   31                "            Speed not locked

   40              Reel           Take-up reel FG not locked
   41                "            Source reel FG not locked
   42                "            Measure abnormally ended (whatever this means)
```

Others may use an "hours-minutes" format:

(From: John Poulton (John@TellyCare.freeserve.co.uk).)

The centre part tells which mode the machine was in when the fault occured (the "minutes" part). It is the last part of the code that is important (the "seconds" part).

The code is as follows

Code	Problem
00	No fault
01	Take up reel not rotating
02	Supply reel not rotating
03	No drum rotation
04	Clockwise rotation of capstan motor incorrect
05	Anticlockwise rotation of capstan motor incorrect
06	Cassette loading incorrect
07	Cassette loading incorrect

Sony capstan motor (bearing) problems

A typical set of symptoms and questions:

> "The capstan motor on my Sony VCR has lost the war and is in need of replacement. Based on my Dejanews search on this topic, this is evidently not an uncommon occurrence :(.
>
> My local repair shop diagnosed the problem for $30 and gave me a $200 estimate to fix it. 3 questions:
>
> 1. Is this reasonable?
>
> 2. Does a capstan motor for this VCR really cost $95?
>
> 3. Given that I'm fairly handy with electronic repair, but inexperienced with VCR repair, is this something that I should attempt without a service manual? In other words, is this a particularly difficult or tricky repair?
>
> To satisfy the curious: the symptoms were a jittery picture on playback of tapes. The problem began with playback in EP mode only (the picture would freeze and hi-fi audio would "ratchet" as though the tape had come to a halt). It progressed until this started happening in SP mode as well. The problem got much worse the longer the unit was running (or the farther into a given tape I watched...)."

(From: Bob Groger (BobG1@msn.com).)

This is a common problem, but you don't need to replace the motor! Sony sell a new bearing assembly for about $25. There is a service bulletin out on this. The bearing housing bends after a period of time from pinch roller pressure. The new one is much stronger. Quick but temporary cure is to grasp the top of the bearing housing with big pliers and bend slightly towards pinch roller. This is NOT a guarantee!

(From: ZMachar780 (zmachar780@aol.com).)

They have a lot of bad capstan motors on these. The bearing collapses a little, then the flywheel scrapes on the drive coil. Sony sells a replacement bearing assembly which would save a few bucks over a cap motor, but frequently the capstan shaft is worn anyway and should be replaced. Sony will ID the part number(s) and sell you the part directly (on a credit card). Call them at 800-282-2848.

(From: Willis Chung (nikonkidf3@aol.com).)

This is the classic Sony capstan motor bearing problem. The capstan motor is a direct drive unit with a large flywheel/magnet assembly mounted just below a set of flat coils. The bearing that the capstan turns through is also part of the bracket that supports the motor. With time, the bearing wears out, allowing the capstan to tilt ever so slightly. This tilt causes the capstan flywheel to come into contact with the coils, causing a scraping sound, intermittent pauses, and eventually causing the motor electronics to die.

Stop using the VCR now to prevent damage to the motor's electronics. The capstan motor bearing can be replaced without having to replace the entire motor. The bearing is available direct from Sony for about $12, but the entire motor costs about $45 to $55.

For the SLV-575, the part number for the bearing assembly is X-2625-269-1. However, replacements for other VCRs have different part numbers - best to check before ordering.

Replacing the bearing is straightforward, and anyone can do it (well just about anyone!).

1. Remove top and bottom covers with machine unplugged

2. Unplug connector cable to capstan motor circuit board

3. Unscrew motor from chassis (3 screws accessed from top of chassis.

4. Remove capstan flywheel and shaft from motor (just pull to separate it from the rest of the motor)

5. Unscrew capstan bearing from motor assembly (3 screws)

6. Assembly is reverse of disassembly.

7. Play junk tape to see if there is any folding of the upper or lower edges of the tape, especially just past the capstan. You may need to make some adjustments to the metal guides to the right of the capstan.

8. Make comments to people around about cheap motors, using harsh language.

The repair is easier to do than to explain!

(From: David A. Sanders, II (capeone@aol.com).)

The bearing part number for the Sony SLV-R5UC VCR is X-2625-356-2. The motor part number is 8-835-350--02. Check the winding on your motor. Many times when the bearing fails, it allows the magnet assembly to rise, which in turns starts to cut into the windings.

Symphonic/Funai brand vcr won't rewind or fast forward

(Portions of the following from: blatter@amiga.icu.net.ch ((Martin A. Blatter))

Belts and idler tires are always the first thing to check for this sort of problem but older Symphonic/Funai VCRs (Those without the 'quickstart' type mechanism) also have a small rubber bumper/stop for the brake levers, etc. on top of the deck by the tape reels. It wears out and then the lever catches don't engage properly. The old mechanism was replaced by a compact direct drive type which is mounted directly on the PCB in 1993 (at least on the European PAL models).

Part #8059-02-23 is available at electronics distributors such as Fox International in Ohio or MAT Electronics in PA. Symphonic/Funai Corp, 100 North St, Teterboro, NJ 07608 phone 201 288-2606. Alternatively, just wedge a bit of plastic inside the rubber bumper to fatten it a bit or just turn it around to expose the unworn side. This works just as well as a replacement part.

Additional Symphonic/Funai comments

(From: Tony Buffone (uproc@Aol.com).)

On the subject of the funai type rubber bumper problem I would like to give an additional symptom of that problem. After repairing hundreds of these units one goofy symptom I've found is the fact that customers may complain that the machine will eject a tape that is fully rewound and will play a tape if it is anywhere else on the tape. The FF/REW problem may or may not show up at this time. Also note that the best cure is the original part from symphonic. I have found that generic bumpers from MAT or MCM for example have cost me callbacks because there just not cut perfectly.

(From: Matthew L. Kruckeberg (MKRUCKEBERG@pol.org).)

I have run into a few of these Funai mechanisms where the replacement rubber bumper is too thick causing the mechanism to lock up in various positions. If you still have the original one try reinstalling it backward and see if your problem goes away. I would not recommend turning the bumper around permanently since the repair is short lived due to deterioration of the rubber but it will generally work at least for test purposes.

Zenith model VCRs with erratic tracking of rental tapes

> "Has anybody had any experiences with a Zenith VR2422HF VCR having auto-track problems with certain rental tapes? This is the second one I've had in the shop where it will switch back and forth between sp and SLP speeds. has anybody seen any mods or heard anything?"

This is a common problem with certain Zenith VCRs. It is caused by the copy guard present on certain rental tapes. Zenith will modify these VCRs at no cost. The modification inverts the sync pulse by adding a transistor, a resistor and modifying the circuit board. If the model number starts with VRJ or VRL (possibly others as well), this is likely to apply.

If you don't want to do the modification yourself but really want to sound like you know something, suggest that the problem is covered by Zenith Field Service Bulletin #94-16 :-).

Two very similar modifications follow:

(From: Guitarzan (guitarzan@aol.com).)

Locate IC201 on left of top circuit board and IC 202 on right. Cut the trace between IC201 pin 56 and IC202 pin 17. I've found it easier to remove the wire jumper directly beside pin 56 as this leaves a place to mount the transistor.

Install a general purpose NPN transistor (ECG123A, Zenith 921-2161 or 921-2134, or 2N2222) with base to IC201 pin 56, emitter to ground, collector to 10K 1/4 W resistor, other end of resistor to W2H5, or another +5 V source. The current drain is very minimal so pick the most convenient source of +5 V.

All this does is invert the servo pulse and keeps the circuit from becoming 'confused'. If only it would do the same for me.

Fire it up and all should be well. Try an EP tape, if its installed incorrectly, EP won't track at all.

(From: Brian Hughes (bkhughes@usa.net).)

Required parts: Small signal NPN transistor (ECG85, ECG2357, KRC103M), 10K 1/4 W resistor.

Locate IC 201 on the main circuit board, cut the trace between W2C4 and IC201 Pin 56. Solder resistor between W2C4 and W2H5. Solder transistor as follows: Base - IC201 Pin 56, Collector - W2C4, Emitter - IC201 Pin 5.

Insulate all exposed leads (I like hot-melt glue, it secures things in place as well.) Finis.

Why it works: Many pre-recorded tapes have timing marks inserted in the control-track signal. These extra pulses confuse the servo circuit in these machines. This modification inverts the signal before it reaches the servo so that it is not detected.

Video Heads and Upper Cylinders

What is a Video head?

The flying video heads in a VCR or camcorder are the actual transducers which scan the tape during REC and PLAY. The head drum or upper cylinder, as it is often called, spins at 1800 RPM (for NTSC, actually 29.97 Hz) with one complete rotation representing a video frame (525 lines in the US consisting of 2 fields which are interlaced). The result of the spinning head is to provide an effective head-tape speed of over 24 feet/second needed to achieve the required video bandwidth.

The actual video heads are the nearly microscopic transducers that contact the tape and magnetically record or playback the video information. The upper cylinder is the entire rotating assembly including the video heads. The heads are aligned and locked in place on the upper cylinder at the time of manufacture and this alignment should never be touched.

(Note that the terms 'video heads' and 'upper cylinder' are often used interchangeably but strictly speaking this is not correct.)

The heads themselves are made from ferrite which is an extremely hard ceramic magnetic material which is also very fragile. The head chips can be seen at the very bottom of the rotating upper cylinder. The actual construction is of a 'C' shape with a very small gap between the arms of the 'C' - about 1 um or so. This is filled with with a non-magnetic material to force the magnetic field out of the head into the tape and to prevent material from collecting in the gap. A few turns of fine wire form the coil of an electromagnet for recording and as a pickup coil for playback. If you look at a head chip from below (on a cylinder that has been removed) you can see the coil and the shape of the core, though you will not be able to tell if a head is bad or worn by this inspection unless there is obvious damage). A powerful microscope is needed to even see the gap.

VCRs are described as having '2 heads' or '4 heads' or whatever. This actually refers to the number of head gaps and not actual head chips though usually this is the same number. However, two head chips may be placed very close together and thus appear to be a single head when in fact there are a pair of head gaps. Therefore, without a close examination, there may only appear to be 2 heads when in fact there are 4 - in 2 pairs. You are not being short changed.

Two heads are required for any play, record, or search function. Usually, these are exactly 180 degrees apart - directly opposing one another on the upper cylinder. With 4 head (or 3 head or 5 head) VCRs, various combinations of heads are used for each mode to optimize record or playback video quality by selecting a pair of heads with optimal widths and other characteristics. These may end up not being exactly 180 degrees opposed requiring video delay line to line up the two video fields in a video frame properly. This complicates head testing as it is not always obvious even which set of heads is used in any given mode.

An additional pair of opposing heads is required for HiFi VHS audio and another one is present if the VCR has flying erase head. Usually, there is only a single flying erase head - it is double width and clears a pair of tracks (fields) on each pass. So, there may be up to 7 (or even more) heads competing for space on the upper cylinder!

Also, see the section: Video head construction.

(From: Andy Cuffe (baltimora@psu.edu).)

It's impossible to use more than 2 heads for normal playback. If you look at the theory of VCR operation you will see why this is so. VHS camcorders do use 4 heads for normal play, but thy do that to reduce the size of the head drum. On an NTSC 4 head VCR 2 heads are used for SP (2hr) and the other 2 are used for LP (4hr) and EP (6hr). All 4 heads are used for still, slow and search (it picks the head with the highest RF output). On my Sony SL-HF1000 you can actually see a difference in the pattern of switching points in search depending on the tape.

On a PAL machine 2 heads are used for SP (3hr) and 2 heads are used for LP (6hr). All 4 heads are used for still, slow and search just like in NTSC. The only difference is the that the head gaps are designed for PAL tape speeds. A good 2 head should look almost identical to a good 4 head.

Video head construction

The actual video head chips themselves are mounted just about flush with the lower edge of the spinning assembly called the head drum or upper cylinder. They are made of ferrite - an extremely hard but fragile material. In terms of physical strength, its properties are similar to glass. The head actually consists of the core, pole pieces, and gap filler molded as a single unit and fired at high temperature along with the coil wound on the core after firing. This 'chip' is then glued to a metal support which is screwed to the bottom of the drum. A screw presses against this support from above and is used at the factory for final head height adjustment on the drum.

CAUTION: Do not touch these mounting screws or the height adjustment screw accessible from above the drum. It is virtually impossible for these to become loose or misadjusted on their own and alignment in the field is not possible except by trial and error.

These structures may be viewed under a strong (e.g., 10X) magnifier though the actual record/play gap between the pole pieces will not be visible except under a powerful microscope. It is filled with a hard non-magnetic material in any case.

The thickness of the ferrite chip is about .1 to .15 mm but the width of the active part of the pole tips narrows down to around .03 mm. This is one of the dimensions that is optimized for various special effects in VCRs with more than 2 video heads.

The gap azimuth angle of + or - 6 degrees (for VHS) is implemented by actually twisting the pole pieces during the molding process. This is actually visible if you look carefully with the magnifier even though you cannot actually see the gap. (The azimuth angle has obviously been exaggerated in the diagrams below due to the limitations of ASCII art.)

The coil used to generate the magnetic field during recording and to sense the magnetic field for playback consists of a dozen or so turns of fine insulated wire with a typical resistance of 1 to 1.5 ohms.

HiFi audio head construction is generally similar except that the gap azimuth angles are +/- 15 degrees instead of +/- 6 degrees.

Damage to the core, pole pieces, or coil, and oxide on the surface or clogging inside of the core can be seen with the magnifier in many cases.

Diagram of single video head

The diagram below shows a typical single video head as would be found on a 2 head VCR. Two of these (with opposite gap azimuth angles) would be mounted exactly 180 degrees apart on the upper cylinder. This is a view as would be seen from the bottom of the upper cylinder:

```
           ____________________________
          |                            |
          |           _______          |
Coil+ o---------------+      |         |---o Coil-
         +------------+     +-----------+
      .  +------------+     +-----------+  .
      .  +------------------/          |   .
      .   |           \  /             |   . Side of upper cylinder v
-----------\____________||____________/-----------------------------------
                     -->||<-- Record/Play gap, width about 1 um
```

The same head viewed from the edge:

```
           ______________ _____________      Bottom of upper cylinder v
------    |_____________//_____________|    ----------------------------
      |                                    |
       -----------------------------------
          |<---------- 1/8" ---------->|
```

Diagram of double video head

The diagram below shows a typical double video head as would be found on a VCR with more than 2 video heads if video heads are grouped together. The quite visible space in between the two head chips should not be confused with the actual microscopic record/play gaps in the pole pieces even though the total width of the two head chips (1/8") is about the same. For a 4 head VCR, there would be two such assemblies (with opposite gap azimuth angles for each head) mounted 180 degrees apart on the upper cylinder.

This is a view as would be seen from the bottom of the upper cylinder:

```
                           Coil1+ o o Coil2+
              ____________________ | | ____________________
             |                    || ||                    |
             |          _______   || ||   _______          |
  Coil1- o---|         |     +-----+ +-----+     |         |---o Coil2-
            +------------+    +-----+ +-----+    +------------+
         .  +------------+    +-----+ +-----+    +------------+  .
         .   |          \----------+ +----------/          |   . Side of upper
         .   |            \  /    |   |   \  /             |   . cylinder v
      --------\_____________||___/-----\___||_____________/---------------------

                        -->||<--       -->||<-- R/P gaps, widths about 1 um
```

The same head viewed from the edge: Bottom of upper

```
              _______________ _____     _____ _______________      cylinder v
      ---    |______________//_____|   |_____\\______________|    ----------------
         |                                                     |
          ----------------------------------------------------
             |<----------------- 1/8" ----------------->|
```

Photo of a typical upper cylinder

Here is a photo of a typical 6 head upper cylinder from a JVC HiFi VCR. This unit was damaged by the infamous "floating roller guides syndrome" and one of the head chips is smashed.

- Typical 6 Head Upper Cylinder

Note that the two video heads in each pair are close together and have opposite azimuth angles. This permits them to both be active during special effects modes - whichever one has the stronger video signal is used. Being close together, you might mistake them for a single video head and think you were short-changed and only got a 4 head machine!

The actual head gaps are way too small to be seen in even the closeups but the pairs of coils on each ferrite core are clearly visible.

Upper cylinder (video drum) diameter

For most regular VHS VCRs, someone in their infinite wisdom picked 2.45". Yes, there are probably good reasons for this - a compromise between tape track length, writing speed, and so forth. Or, maybe it was the size of the engineer's nearest handy juice can lid. :-)

For camcorders where compactness is important, the drum diameter is reduced to 2/3rds of this or 1.65". However, in order to record and playback properly, 4 heads equally spaced around the circumferance of the drum with alternating azimuth angles are required in all modes. The drum speed is also increased to 3/2 of the normal 1800 rpm or 2700 rpm. If you work this out, you will find that this results in exactly the same writing speed and track length when successive heads for each video field are located 3/4ths of the way around the drum (instead of half way as with normal VHS). These will have the required alternating azimuth angles. This uses a 270 degree wrap (the tape must wrap 3/4ths of the way around the drum as opposed to the normal 180 degree wrap for VHS).

(From: Andy Cuffe (baltimora@psu.edu).)

Beta camcorders used a half sized drum with what looks like one head (actually 2 heads very close together). It required a non-standard video signal from the camera and used almost 360 degree wrap.

How do the signals go to/from the upper cylinder

The rotating upper cylinder and stationary cylinder form a transformer - the space between them is very small and coupled the signals between the primary and secondary ferrite cores. Each of the heads for R/P video, HiFi audio, and flying erase, are electrically independent. The cores are arranged coaxially which should get to be pretty tight for a 6 or more head VCR!

Are your video heads really bad?

No picture (total snow or a blue/black screen depending on model) or a snowy picture in play modes and/or failure to produce a good recording may indicate dirty or bad video heads. First, make sure that the VCR's tuner and RF modulator are working by viewing a broadcast or cable channel. Next, refer to the section: Video head cleaning technique and follow the instructions carefully. If there is no change even after a couple of cleanings, then your video heads may have problems. Of course, if your inspection reveals any physical damage, you will need a new set of heads (new upper cylinder).

Indications of a bad video head include:

- Any visible damage to the ferrite chips. Heads nearly always appear in opposing pairs on the upper cylinder (head drum). Any visible discrepancy between the chips in a pair is probably damage. Sometimes 1/2 of the core breaks off leaving the windings dangling. Common causes for this damage are improper cleaning techniques or the use of damaged or spliced tapes. Use a magnifying glass and bright light to examine the heads but do not touch!

  By the way - improper splicing of broken video tapes is a good way to break video heads. Any kind of splicing should be avoided if at all possible. (See the section: Recovering damaged or broken tapes.)

- Excessive video snow which cannot be eliminated by the tracking controls. The appearance may also be of trailing lines or bullet shaped streaks particularly following highlights.

  Note: in rare instances, similar symptoms are the result of a static brush not making proper contact with the shaft of the spinning drum. See the section: Firing (static) lines in picture during playback.

An image where more or less good video alternates with snow at a 30 Hz rate means that one of the 2 heads in a pair is probably either dirty or bad. If your TV has a wide range vertical hold control (yeh, right, give me a time machine), then you may be able to display both fields on the screen at the same time.

- Excessive video snow or no picture (total snow or blue/black screen depending on model) for some playback speeds (SP, LP, EP, X2, still, slow, etc.) since different sets of heads (in 4 head or more) machines are often used for different speeds. If this is due to wear, then it would probably gradually deteriorate and not happen suddenly.

- Inability of certain internal adjustments such as backtension to eliminate erratic tracking problems may indicate a worn video head. Horizontal bands of video noise may come and go at various places in the picture depending on what speed is being used or the playback location on the tape (beginning, middle, end). These may come and go in a periodic cycle.

- Need to frequently clean the video heads even if you are only using new good quality (name brand) tapes. Video heads are normally self cleaning but very worn heads can tend to collect tape oxide resulting in a noisy, snowy, or totally missing picture.

- You have just been playing a rental, damaged, or spliced tape and you notice any of the above symptoms.

  The video heads may have picked up some oxide and are no longer making proper contact with the tape. Letting the VCR play a newer tape for a few minutes may clear this if it is minor. Otherwise, video head cleaning (using the proper technique!) will be needed. However, seriously damaged or improperly spliced tapes can result in serious damage requiring video head (upper cylinder) replacement.

If your VCR has HiFi audio, similar symptoms may apply to the HiFi audio heads on the rotating drum. Noisy or loss of HiFi audio or erratic switching between linear and HiFi audio may be due to bad HiFi audio heads (but could also be a tracking problem since HiFi audio tracking can be even more critical than video tracking).

However, many other problems can result in similar symptoms - video head diagnosis is one of the most difficult to make (except for physical damage).

Some pros claim to be able to determine if a video head is worn by feeling it with a finger. I can guarantee that you will not be able to do this, so the set of guidelines given above is the best to go on.

More on evaluating video degradation

(From: Frank Fendley (frank.fendley@datacom.iglou.com).)

It depends on what's wrong with the picture. If you are getting "highlight streaking in high luminance areas" (meaning that white objects in the picture seem to have "tails" trailing off to the right of the object), then a new head would help immensely. If there are random lines in the picture (especially on tapes you have recently recorded on that machine), then a new head will most likely help.

If the picture just isn't as sharp as the VCR next door, then a new head probably won't help much. Technology has improved picture quality considerably since your VCR was manufactured.

One recommendation - if you want the best picture quality from *any* VCR, forget about recording programs in SLP or LP. The SLP (or EP) speed should be banned and made illegal - the picture and audio quality are terrible. LP should only be used on programs which exceed 2 hours. You should use SP speed on everything you record if at all possible.

Effects of video head wear on HiFi audio

(Portions from: Peter (peter@puttonen.com).)

The HiFi audio is placed on the tape first to a depth of 4 microns. The video head follows with video RF, which overwrites the audio to a depth of 1 micron. Some of the original audio is erased, but 3 microns worth should still remain. (This is why there can be interaction between audio and video on some HiFi VCRs.)

A problem starts with head wear. As the head wears, the magnetic field it generates actually increases. The video goes deeper than 1 micron, erasing more of the HiFi audio. As the video goes deeper, tracking also becomes more critical for the audio. However, self recordings should still have optimal tracking assuming there isn't something wrong with the servo systems.

A temporary solution is to reduce the video record current, but this does not replace the worn head material. The real solution is to replace the head drum or buy a new VCR.

Need for video head cleaning

When should you clean a video head? Only when symptoms point to a problem with the head. See the section: Are your video heads really bad?. Periodic cleaning is not necessary and may cause excessive wear if done with a head cleaning tape, especially the dry kind which may be excessively abrasive. Frequent cleaning by hand, while not damaging, still represents a slight risk since you never can tell when you might do something you will regret!

VCRs should be cleaned periodically, but video heads usually do not need periodic cleaning as the spinning heads performs a self cleaning function. If it ain't broke, don't fix it.

Automatic head cleaners

I do not see any advantage in buying a VCR which claims to have automatic video head cleaning. Healthy video heads are basically self cleaning in any case. The automatic head cleaner is a foam roller that contacts the rotating heads for a couple of seconds when the tape is loaded. In my opinion, this is worse than useless as any crud collected by this foam may just be redeposited on the heads during the next cleaning cycle. So, if your VCR has this 'feature' and you experience symptoms of dirty video heads after each tape, remove the 'feature' and performance will improve :-).

As noted below, there is a slight risk that at some point they may actually destroy the video heads - no doubt timed to be 1 day after your warranty runs out. In addition, they do nothing to clean those portions of the VCR that really may need periodic maintenance like the rubber parts, A/C head, and tape guides.

The only benefit of an automatic head cleaner is to the manufacturer of the VCR as it increases their profit margins!

(Portions from: Joseph E. Fealkovich (jef812@ix.netcom.com).)

I would pull those 'automatic head cleaners' out and let the customer know about it. I hate those things, they do more trouble than good. The least they can do is redistribute the garbage back onto the heads, the worst, actually catch on a head and tear it right out of the drum, (I've seen this happen on a Goldstar VCR). When new, they do a fairly good job 'dusting' off the video heads, but they wear out quickly, (they work every tape loading and unloading cycle), and can seriously ruin the heads.

Furthermore, they clean only the video heads when they work; they do absolutely nothing for the grooves cut into the drum, I'll say that's the most important part, as the grooves form an 'air bearing', where the tape floats on the drum, without that that effect, the heads can wear out prematurely due to the tape sticking to the drum. My opinion on 'self cleaning' VCR's is, they've done just about everything dumb and automatic on these VCR's.

Video head wear and instant start VCR tape transports

While it may seem that this design - where the tape remains in contact with the video heads even during FF and REW is a bad idea, additional wear, if any should be minimal and not worth worrying about.

Even if the tension is maintained (which is probably not the case), the worst will be the same wear as an equivalent time in normal playing. Most of the wear is from the spinning head-tape contact. Whether the tape is moving at 0.3 ips or 100 ips is mostly irrelevant.

However, there will be additional wear of the roller guides and anything else the tape contacts but even this shouldn't be a concern. I've never heard of a VCR failing due to worn roller guide rollers. :)

Note that this approach is driven by the desire for rapid response, not laziness on the part of the engineers. It is more difficult to design a transport that performs FF and REW effectively while the tape is in the loaded configuration.

How NOT to clean your video heads or a very expensive lesson

The following is a true story. Don't let it happen to your VCR!

Read the section: Video head cleaning technique before breaking out the pliers and sandpaper (well almost).

(The following is from someone who not surprisingly would rather remain anonymous).

> "Thanks a lot for the FAQ on VCR repair (unfortunately too late --- sam). I now realize that I have made a boo-boo of quite unprecedented magnitude!! You're not going to believe this... (I'm almost too ashamed to admit to this!).

My friend asked me to clean the heads on his VCR. I got out my isopropyl alcohol spray (good) and my cotton buds (not good!).

I proceeded to scrub the upper drum furiously, getting lots of lovely black deposits on the cotton buds. I, ahem... also scrubbed vigorously around the four little 'recesses' positioned around the bottom of the drum. When I spotted a little bit of metal sticking out of one of the recesses, I got out my tweezers.....

(You can stop reading here if it's too painful!)

...and poked around, thinking 'this will cut the tape to ribbons if I don't get it out'. After succeeding in removing the offending piece, I noticed a very fine copper wire emerging from the hole too.... OUT IT CAME (with the tweezers of course). I checked the other three holes and succeeded in removing some more shrapnel from one other.

Guess what? It wouldn't play properly after this.... but the sound was OK.

To be fair, I was fairly sure I'd screwed up big time when I saw the copper wire... but of course it was far too late by then.

I admitted to my friend that I thought I'd broken his video head and that I would replace it for him. Thinking that heads cost around the $30 mark, according to most of my catalogs, I was horrified when I got a price for his particular model.... $162.00 + 17.5% tax and postage..... However, this was much less than what the original manufacturer wanted: #350!! Well, I finally found a replacement for $85. Still, an expensive lesson."

Video head cleaning technique

CAUTION: Read the following in its entirely to avoid an expensive lesson.

As noted, improper cleaning can destroy your video heads. The head chips are very fragile and just rubbing them in the wrong direction (NEVER use an up-and-down motion) can break the chips off requiring replacement of the entire upper cylinder assembly - one of the most expensive parts in your VCR!

Manual cleaning using the proper head cleaning sticks is best but requires that you gain access to the interior of your VCR - i.e., take off the cover.

If you do not want to do this, you can try a commercial wet cleaning tape. These is some slight risk, however. The material used in some of these may have an excessively coarse fiber structure which can catch a video head and break it off. I have not seen this happen nor could I recommend a specific brand as there is no way of knowing what their current product uses. I do not recommend the dry type at all as these are almost always much more abrasive and may cause premature wear of your video heads especially if used regularly. When using the wet type cleaning tapes, follow the directions and - very important - wait sufficient time for everything to dry out or else you will have a tangled mess inside your VCR.

Regular video head cleaning should not be needed! Therefore, the regular use of a cleaning tape is not recommended. As noted, some cleaning tapes will cause excessive wear to the video heads and no cleaning type can adequately deal with other parts of the tape path anyhow. If you find yourself needing to clean your video heads frequently, the video heads may be worn, the backtension may be set too high, or you may be playing old or dirty (literally) rental tapes.

To clean by hand, you will need what are called 'head cleaning sticks'. These are covered by chamois and are safest. DO NOT USE Q-TIPS (COTTON SWABS). These can catch on the ferrite cores and damage them or leave fibers stuck in the heads. Q-tips can be used for cleaning the other parts like the rollers and audio/control head as described above but not video heads.

To use the cleaning stick, moisten it with head cleaner or alcohol. Pure isopropyl is best, however, the 91% medicinal stuff is OK as long as you dry everything pretty quickly. Don't flood it as it will take a long time to dry and you run the risk of any water in the alcohol sitting on surfaces and resulting in rust (very unlikely, but don't take the chance).

Gently hold the flat portion of the chamois against the upper cylinder where it is joined to the lower (non-rotating) cylinder. Rotate the upper cylinder be hand so that the heads brush up against the moist chamois. DO NOT MOVE THE HEAD CLEANING STICK UP-AND-DOWN - you will break the fragile ferrite of the heads - $$$$. Side-to-side is OK as long as you are gentle.

(The following tip from: Steve (sreed@amsupply.com).)

> "A good quality automobile chamois (the real thing, not the fake stuff), cut up into 1 to 2" squares, is far

> cheaper and easier to manipulate than the sticks. After cleaning the heads, the chamois square can be re-moistened with cleaning fluid and used to clean the A/C head, rollers, guides, etc.
>
> There is another advantage to this approach. The chamois sticks can on some occasions "catch" on a video head, because the chamois area is small and the edges are rigid. Using a larger cut-up square of chamois eliminates this problem because the edges of the chamois are away from the rotating head and you're simply holding it against the drum with your index finger."

I know people who use a piece of moistened typing paper, a business card, Mr. Coffee filter paper - or even their Mark-1 thumb for video head cleaning but I would not recommend these for a general service procedure at least until you gain some experience with the use of chamois first!

(I suppose the only real requirement to prevent damage is that the material have a fine enough structure and not have fibers that can get stuck in the heads. So, the short list of acceptable materials is quite long - some more effective than others. My concern for a general recommendation is that people's interpretation of these requirements can vary quite a lot. If a novice comes to me and asks what to use, I will say 'cleaning sticks'. Once they understand the characteristics of the heads and their mounting, they are free to use whatever works.)

Depending on how dirty your heads are, a couple of passes may be enough. Let everything dry out for at least 1/2 hour. This may need to be repeated for stubborn clogs. However, one pass will often do it. As noted, under NO circumstances should you be going up and down even though you might think this would work better given that the head gaps are vertical (or nearly so). Aside from the possibility of breaking the head chips completely, there is no need. The head gaps are solidly filled with a material of similar hardness to the ferrite. Stuff can't get trapped in the gap - only on the surface, above or below, and inside the winding area. Look at a head chip closeup under a microscope sometime. :)

In addition, inspect and clean the drum itself staying safely away from the video head chips. The five fine grooves in the drum help control the air bearing that the tape rides on and helps to stabilize tape motion. These should be clear of dirt and tape oxide (DO NOT use anything sharp - the moistened head cleaning sticks will work).

Rob's alternative video head cleaning techniques - use with care

(From: Rob-L (rob-l@superlink.net).)

As an alternative, I'd use a *dry* bit of paper. Moderate finger pressure against the whole side of the drum, overlapping to the motor assembly. Then twirl the drum in each direction a few times. Look at the paper and you'll see exactly where the dirt is coming off. Once you can do this and get no marks, you're heads are relatively clean. A tiny, soft, short brush and a puff of air will dislodge any paper fibers. The paper and its fillers are generally not going to harm the drum/ferrite-chips with this brief contact. And you can pop a tape right in without waiting for solvents to evaporate. Besides, solvents may soften any encapsulants on the chips, and cause residue to get on the polished surface.

Once in a while, I run into a set of heads that seem to be bad, even after cleaning with different methods. This is characterized by poor signal strength in all or part of the picture, sometimes one field only, and sometimes tracking range is extremely narrow as a result. On S-VHS units, S-VHS recordings get noisy and may get blanked, while the same unit will work in VHS with minor tracking problems.

Upon 30x pocket microscope inspection of the heads, I find a speck of what appears to be a cloudy polymer, firmly bonded to the edge of one or more of the chips. How did it get there? My guess: too much solvent - may have dissolved encapsulant and/or dust that was at the edge of the chip.

Solution: *carefully* drag a jeweler's flat-blade screwdriver along the chip (under magnification). Sounds a bit risky, but this has never damaged a head in my hands. Follow this with a final paper-buffing, and usually the VCR is tracking fine, with a much improved picture. Saves mucho bucks. 'Course, sometimes the heads are just plain worn out.

My advice: Invest in a pocket microscope before you start pricing heads.

Expected life of video heads

(From: Jerry Greenberg (jerryg50@hotmail.com).)

The normal MTBF (Mean Time Between Failure) rating for a standard VHS video head is about 5,000 to 6,000 hours on the new machines. This figure will vary from one manufacture to another, depending on the outcome of their own research. This really means that after this amount of time the head normally will be warn past its specs. This means that if you look at the RF envelope on a scope, it will no longer meet the exact specs for its output. it also will not be guaranteed to work anymore.

The actual life is really where it reaches the point where your playback quality is considered unacceptable. This means it can probably last about 10,000 hours in most cases.

What saves a head is that all the tapes used are of top quality, they are not played in dirty or misaligned machines causing creasing of the tape edges, or dirt transfer. The dirt or oxide stain from the tapes can be a bit abrasive on the heads, thus accelerating some wear.

If the heads and tape path are kept clean, and high quality tapes are used in the machine, you should reach a very high amount of hours with the head.

I found that rental tapes are the worst for tape heads. This is because many people play the tapes in dirty or misaligned machines, and or handle the tapes with dirty hands from food.

I had one customer that played a rental tape in a machine, and it started to become unstable during the playback. When I checked the machine, I found peanut butter inside. It turned out that someone had peanut butter on their hands when they handled the tape!

Advanced video head testing techniques

Assuming cleaning does not help and you have the time and inclination, some additional test can be performed to confirm or rule out a bad set of video heads (upper cylinder).

To check the signal from the video heads you need a circuit diagram so that you can locate the relevant test points and expected voltage levels in the head preamp. This will be housed in a metal enclosure, usually right next to the head assembly (at the rear). This should be done with an alignment tape, but any known good recording should provide a reasonable approximation.

Other basic checks such as visual check with a magnifying glass, continuity tests on the heads as well as power supply voltages in the preamp can also help.

If your VCR has 4 video heads (not including HiFi audio heads) and only certain modes or speeds do not work, then the following procedure may permit you to isolate the problem to a head or its preamp. Basically, the idea is to interchange the wiring of the two pairs of heads. While the heads will no longer be optimized properly for each mode, there is a good chance that they will work well enough to determine gross changes. For example, if SP play originally had alternating fields of good and bad video and works moderately well after this rewiring (but maybe with tracking noise), then you know that the bad head is no longer being used for SP play. Since the same head preamps are being used, a bad head must be at fault. Video drums where the heads are wired with flying leads are somewhat easier to cross-wire than those with a PC board. This is not fun and may not work in all cases, but if you are hesitant to risk the cost of a new head, it may be worth a try.

And, once you have looked at your 1000th bad head or so:

(From: Jerry Jansen (rjansen@bcpl.net).)

Try using a jewelers loop, along with a small pencil point flash light. The diagonal formed into the chip is easy to see with the loop. As the chip wears, you will see the angles length gets shorter.

Measuring video head wear

You mean your thumb isn't calibrated to the micrometer (um)?

> "I'm trying my hand at VCR repair. Sony specifies a hand-held device that connects to a non-rotating video head and that measures how worn the head is (Beta machine). I'm trying to imagine how it works. Is it the head gap itself that gets bigger as the head wears?

(From: Raymond Carlsen (rrcc@u.washington.edu).)

There is (was?) a device to check for head wear by measuring the inductance of the head itself. The head must be disconnected from the rotary transformer, of course. Older machines had wires on top of the head that could be easily disconnected (like the Beta decks) without removing it. Heads on some newer machines must be removed from the VCR because the leads are underneath.

Apparently, the inductance of the head changes slightly as the ferrite material wears away. The head gap itself doesn't change as the head wears. If the gap were to open, the head wouldn't work at all, and I assume that the inductance would be significantly different than a used good head. In most cases, the head chip(s) wears to the point that the tip penetration is not sufficient to keep it in intimate contact with the tape. The heads tend to clog more easily as they approach end-of-life.

The inductance type of head tester does have a few drawbacks. It's rather expensive, and to accurately tell how much usable life a head has left using only the tester, you must have a "sample" of exactly the head under test for comparison... each one is different. The measurement is relative, not a "good-bad" reading.

However, I have been using several other methods to test video heads for the last 10 years. Here are some options:

- If the image is good in SP, try search reverse in that mode and see if the upper third of the screen gets noisy. A noise band there can mean the heads are close to worn out.
- Another method (in SP) is to pull the back tension band to the right slightly to reduce the tension. If the image breaks up or goes to snow, that's another indication the heads are close.
- The most critical measurement is tip penetration. I learned to gauge the tip penetration by feeling the rotating head chips as the tape is moving through the machine. A well-calibrated finger placed lightly on the tape on the

exit side of the drum is very revealing. I use a well calibrated finger. Of course you need to know what both good and bad *feels* like, so this may not help. I apply a finger *very* lightly to the tape on the right side of the scanner so I can feel the heads through the tape. The amount of "buzz" gives a pretty good indication of wear. If you can hardly feel it, the heads are close. There is some difference in brands.

- Streaking or comet-tailing on recordings of small bright objects usually means the heads are close to being worn out (gap starting to open up).

- A microscope is good to check for the more obvious broken or chipped head, and to see if a stubborn clog is actually gone.

Different VCR brands will show different results to my finger test: Old Hitachi decks will show bad heads before they actually "feel" worn out. One usually goes first, producing alternating fields of snow and picture. I've seen a few older Panasonics that still worked even when the heads were worn down where they couldn't be felt any more.

How do you tell the difference between worn out heads and a head clog? Clean the heads and try it again. Then feel it. Tentel Corporation makes a test fixture that actually measures tip penetration, but with a bit of experience as a guide, the best test instrument is still the mass of grey mud between the ears.

When a repair job hits my bench, I use a combination of these methods to evaluate whether a machine is worth fixing. If heads are close, I factor the replacement cost into the estimate. I've only seen a few open heads (and rotary transformers) over the years... quite rare. Loss of EP only can be that both EP heads are clogged, but that's not likely if SP works well. Very worn heads tend to clog more easily, but wear will be about equal for both sets of heads. The only exception to that is HiFi machines where the high fi sound gets bad before the picture shows up worn heads. If you suspect an electronic fault, you might try making a recording in EP mode and playing it back on another deck. If only the playback EP mode is bad, it's possibly in the head amp switching circuit and not the heads themselves.

(From: Frank Fendley (frank.fendley@datacom.iglou.com).)

There are two methods (that I know of) which measure wear on video heads.

One is a protrusion gauge, which measures how far out the heads extend past the edge of the drum. Once the heads fall below a minimum extrusion, they are considered worn. It's similar to measuring the tread left on a automobile tire.

The other is a "Video Head Tester", sold for either Beta or VHS models. Essentially it is an inductance bridge. You connect each head to the test leads, calibrate the unit, and then measure the inductance of the head. The theory here is that as the head wears, its inductance goes down due to loss of the core material. Past a certain minimum, the head is declared worn out.

Bear in mind that a head could fail both of the above tests and still give a good quality picture (although it is true that its days are probably numbered).

It is also quite possible that a head could pass either or both of the above tests and be defective.

Are the the testers worth it? In my opinion - probably not, unless you are a real purist and like to have a lot of test equipment.

More than you even wanted to know about video head tip penetration

Remember how I told you never to even think about adjusting the video head chips themselves? Well, it seems some people never listen :-).

(From Jerry Greenberg (jerryg@total.net).)

I researched out tip penetration specs on video heads for VHS and Beta (home) machines. I got a number of people interested in this one to the point that a few machines came off the shelf, and the research began. We had the tools at our disposal to get this done.

The following measurements are in mm (millimeters).

Brand new heads off the shelf in both Beta and VHS were about 0.12 to 0.16 mm penetration.

At about 0.05 mm the video signal starts to degrade. But the head will still record well.

At about 0.02 mm the video is very noisy. If you loosen the head and push it out a bit, you improve it slightly. But, the gap is now wider. Therefore, the signal is a bit stronger (due to the additional penetration) but has more noise. Overall, a slight improvement.

Also the horiz angle of the head effects the switch point a bit. If out, a slight horizontal jitter (flag waving) is noticed, and the PG is slightly out. You can correct with the PG adjust to a point, but the head effective angle from the opposite one must be better than 2 deg.

As the head wears, we found that the head surface leaves the tape too soon, and starts reading the tape too late. If the heads are down to about .05 mm the effective error (both heads summed) is about 2 to 3 degrees. The puts it slightly out of spec for the switch-over point and causes some instability. This problem is also summed because the carrier output is at about 60% of the normal amount. As the head wears from this point, the carrier drops more rapidly. It is not linear. It follows the inverse square law factor.

Highlight tearing and bad video heads

Highlight tearing - trailing lines adjacent to bright areas of the picture - often indicates a worn video head. Sometimes, this only shows up severely for tapes recorded AND played back on the same machine. Why?

(From: Jaclyn (lambert@sos.net).)

The reason why it **appears** to be a record only problem is fairly straightforward if you understand what's up.

When you make a recording with bad or marginal heads the resultant recording is poor. Perhaps a vcr with good heads will be capable of producing an "acceptable" picture, perhaps not. Depends on the alignment and how good those heads are. When you try to play the "poor" recording back on the vcr in question the resulting performance is unacceptable because the heads on that vcr are marginal at best and are simply not going to have the gain required to pull the crappy recording off. Get it? It's a double whammy two fold effect.

Video heads don't just go "bad". They wear down after time and early symptoms sometimes also include poor vertical stability (as is so common in Hitachi VCRs) and snow "lines" which hover about 2 inches from the top of the screen. Occasional loss of horizontal sync is also typical.

Where to obtain replacement video heads

Once you have concluded that a replacement head is required, you need to decide whether you will undertake this yourself or take the VCR to a shop. Video head replacement is relatively straightforward and low risk as long as you are comfortable working on mechanical devices and take your time. A little unsoldering and soldering is usually required.

Electronics suppliers such as MCM Eectronics, Premium Parts, and Dalbani stock a wide range of video heads for VCRs that are more than a couple of years old. (They may not have heads for the latest models.) In some cases, they will offer two kinds of heads for the same model - a generic version and a 'name brand'. Unless you are extremely critical, there is probably no need to spend the extra on the 'name brand' head. There is also no need to pay the premium charged by the original manufacturer of your VCR - it is often priced 2:1 or more over what a generic head will cost with no substantial difference in performance, if any. You may even end up with exactly the same head manufactured on the same assembly line!

Note that currently, the price of many upper cylinders (video heads) for 2 head VCRs is well under $25 so ordering a replacement may be a better investment of time and effort than a long diagnostic procedure especially if the old head has high mileage and video quality has been steadily decreasing.

Upper cylinder not replaceable as a separate assembly?

On some newer VCRs, it seems that in the manufacturer's infinite wisdom (or cost crunching), the normal video head drum or upper cylinder cannot be replaced by itself. Only the entire expensive cylinder unit is available.

Unless you can find a junk VCR (try Allbrand, see the section: Used VCR parts), repair may be too expensive. Just buy a different brand next time, which, of course, may not matter. :-(

Video head replacement technique

1. Do not touch the actual video head chips themselves. Handle the head as little possible. You can touch the upper part of the head cylinder if necessary. One thumb through the center hole with fingers resting on the upper edges works pretty well.

2. Before you unmount the old one, mark or make a note as to its position - sometimes it is possible to mount the new head 180 degrees off from way it is supposed to be oriented causing tracking problems at the least as the opposing heads are not identical. (The azimuth angles are +/- 6 degrees for VHS, +/- 30 degrees for VHS HiFi audio). Also make a note of the wiring if there is any possibility of confusion (i.e., there are individual wires, not connections from below to a printed circuit board).

3. Unsolder the connections between the head and the upper cylinder. There will be 2n solder connections for an n head VCR. (Sometimes there is some kind of connector rather than solder connections, but this is rare.) Examining the new head should reveal exactly where to unsolder. For pins through the printed wiring board type, you should use some kind of desoldering tool - solder pump, SolderWick, or a vacuum rework station.

   CAUTION: Make sure ALL connections are actually freed from the PCB before attempting to remove the old head. Use a pair of needle-nose pliers or other suitable tool to separate the wire from any residual solder. Otherwise, it may rip off parts of the rotating transformer assembly, possibly ruining the entire cylinder unit.

   In rare cases where there are individual wires, a generic replacement head may not be color coded the same or have the wires originating from different places than the original. In this case, you will have to try to determine which physical head chip the wires originally connect to. You must get each of the connections from the lower cylinder to the head in the same physical head as before (though the polarity or phase of the pair of connections to each head should not matter).

4. Unscrew the 2 or 4 philips head screws holding the old head in place. It should be obvious from the new head which screws need to be removed. You may need to remove the static brush if your VCR has one or some other usually obvious stuff to get at it. DO NOT touch any other screws on the head drum as these are critical adjustments one should not mess with.

5. Lift the old head straight up and off. You should not need to use any drastic measures though a little jiggling may help. I have never actually needed a head puller.

   Do not yank or pull hard. The head should come off easily. If it does not, make sure the solder connections have been completely removed. See CAUTION above.

6. Replace in reverse order, solder the connections, replace any other hardware that was removed. Refer to your notes on the position of the old head and/or the color codes (wire colors, dabs of paint, etc.) as to orientation on the drum.

7. Carefully clean any fingerprints from parts of the head drum you touched. Again, do not touch the video head chips themselves. You may use 91% medicinal alcohol, though pure isopropyl is preferred. Avoid rubbing alcohol especially if it contains any additives. Let the machine dry completely.

8. Unless you tweaked any mechanical adjustments, the VCR will very likely work fine assuming the video head was the problem. Try recording and playing back at all speeds as well as playing pre-recorded tapes as well. Carefully examine the video for excessive snow, jittering, or tracking problems. For HiFi VCRs, also confirm that the HiFi audio is solid and stable - that the HiFi light is not flickering in addition to audible dropouts or muting.

   If the tracking is now way off or you experience serious video noise, lack of or erratic color, or bad or missing HiFi sound, refer to your diagram and double check that you didn't replace the head rotated 180 degrees from the proper position by accident. Make sure the drum is seated properly - not on a bit of dirt on one side. DO NOT be tempted to adjust tape path alignment - if the heads were the problem, it should be fine. Also see the section: HiFi/video tracking problems after upper cylinder replacement.

   It is a good idea, however, to perform what is known as the 'Tape Interchangeability Adjustment' (this terminology is used in Panasonic VCR service manuals, meaning is self evident) in any case. This procedure consists of adjustments to the roller guides, other guide posts, and the A/C head. See the chapter "Tape Path Alignment and Backtension Adjustment" or follow the set of steps in your service manual. On rare occasions, some electronic adjustments will also be required to obtain optimum video quality but this is the exception rather than the rule. Tapes recorded at EP speed will almost always be more finicky and may require these adjustments more so than those recorded at SP speed.

How about when the head drum refuses to budge?

(From: Raymond Carlsen (rrcc@u.washington.edu).)

If it's a Samsung based machine, you might need a head puller. I got one at a service seminar many years ago and need it once in a great while to pull a stubborn one, usually a Samsung. Avoid the temptation to pry up with screwdrivers. I've seen the results of such abuse... not pretty. Look for threaded holes in the head drum. That's a clue it needs a puller, which attaches to the head drum and presses downward on the center spindle with a few twists of the handle. The new head (also a tight fit) is seated by alternately tightening the two mounting screws.

You could make a puller with a bar of metal and some long screws. Drill two holes in the bar to fit the spacing of the threaded holes in the head wheel and one in the center between the other two. Tap the center hole (8-32 is big enough). Use screws (small metric) long enough to thread into the drum to attach the bar. Run a screw down the center hole until it contacts the center shaft of the drum. Keep rotating until the drum pulls off.

What if the replacement upper cylinder doesn't work?

There are a number of possibilities and one of the more common particularly with generic replacements is, guess what? A defective replacement!

When replacing the upper cylinder, the orientation and wiring must be exactly the same as the original. For many VCRs, this is automatic since the mounting is keyed and the wiring is via direct printed circuit board connections. However, there are also many where it is possible to screw up either the orientation or wiring or both:

- For lack of color, erratic color, excessive video noise, and tracking problems double check its orientation. Accidentally replacing the head drum 180 degrees from its correct orientation will result in a variety of video quality problems.

- Where individual wires are used rather than soldered connection to a printed circuit board from below, make sure you have attached the lower cylinder terminals to the proper heads. Some generic heads apparently do not have the identical layout. It may be necessary to visually trace the wiring on the old and new upper cylinders to determine which actual video/HiFi audio head chips are attached to which wires. Also don't assume that the wiring color codes are same! However, you are lucky in one respect: The polarity or phase of the pair of connections to each head should not matter!

HiFi/video tracking problems after upper cylinder replacement

Unless you had such symptoms originally where best settings of the tracking control for the HiFi audio and video are at grossly different positions, the problem is with the video head drum itself or its installation.

(From: John R. Hepburn (jhepburn@recorder.ca).)

If you have an oscilloscope and service manual, check the envelopes for maximum output. Audio and video should max at roughly the same tracking position. If they do, forget about heads or any mechanical problems, it is electronic (but probably existed before the replacement - possibly masked by an originally defective set of heads!).

If they do not, then it is probably a drum problem. DO NOT adjust your roller guide height or any other posts! They were in the right position before (unless you have already moved them) so they are in the right position now. Minor post adjustments are OK after heads are replaced, but that is just to peak it out. No serious problem has ever been solved on a VCR by adjusting posts that are in their original position. Remove the heads and check for proper seating. You would hate to make a big deal out of this, only to find one side of the drum was seated on a small piece of residue.

Comments on HiFi tape path alignment

(From: Jerry Greenberg (jerryg50@hotmail.com).)

You should be using the test tape that has both the standard video on it and the HiFi envelope as well. The lateral alignment of the control track head is extremely critical, and should be done along with the guide alignment.

Also the head switching pulse should be checked closely. In some machines the switching pulse is not adjustable. If this is the case, you should be using the original factory replacement head for sure (not a cheaper sub). The universal replacement ones have given me a lot of trouble...

As for the slow speed, there is no real test standard. The slow heads should be accurately aligned from the factory on the drum to match. You cannot adjust the slow speed separately for the tracking. On some very high end machines, especially the older ones, they had a separate head switching adjustment for the slow speed...

Tape interchangeability

Since video heads are not all manufactured exactly the same, there is a slight chance that you will experience problems of playing tapes recorded on other VCRs in yours. However, before adjusting the roller guides or other settings, make sure that the *other* VCR is aligned properly.

(From: John F. Reeves (jreeves@uwf.edu).)

Take an alignment video-cassette tape and verify that the P2 and P3 posts are adjusted properly. you should use a scope and monitor the RF envelope while adjusting the above mentioned posts. Once this procedure is done, make a recording and play it back in another VCR. If it still does not track properly, it may necessary to perform the tape interchange ability adjustment. This adjustment in more critical and more in depth, should be performed be a qualified technician.

What are the symptoms of a video head that is on backwards?

Suppose I screwed up and installed a video head 180 degrees rotated from what is correct. What will happen?

First confirm that it is even possible to do this - some are keyed in such a way that a hammer would be needed.

The effects will depend very strongly on the particular VCR but the following are among the possible symptoms:

- Tracking that is way off for tapes recorded on another (properly adjusted) VCR. It may be so bad as to be beyond the correctable range with the user tracking control. The azimuth angles of the head pairs are opposite of what is expected and this directly affects tracking.

- Noisy picture or no/erratic color in some or all play and search modes. On 4 or higher head VCRs, even opposing pairs of heads have different characteristics so these will not be matched to the electronics with the head on incorrectly.

- Flying erase will not work where only a single flying erase head is used. To test for this (assuming your VCR has a flying erase head), record over an old recording. If flying erase is not working, you will get a rainbow pattern (assuming you get any color at all) which will wipe down the screen over a 10 second or so period (just like a VCR that lacks flying erase). The 7th head in a 7 head VCR is likely a flying erase head.

Can I substitute a video head from another VCR?

The quick (and long) answer is: NO. The heads themselves are in no way standardized. You can substitute a video head drum (upper cylinder) if it is identical - VCRs sold under different labels are often manufactured by the same few companies. Check a cross reference if you have a dead VCR with a good set of heads but not the same model as the one you are trying to repair. As far as the heads themselves, don't even think about attempting to interchange the actual head chips - even if your replacement were physically and electrically compatible, you would never be able to get the alignment within tolerance since you do not have the factory jigs. Not to mention that the head chips themselves are really really tiny and really really fragile and their specifications all vary - head width, azimuth angle, etc. Forget it.

Disassembling the lower cylinder

It is rarely necessary to do this but if you should - from curiosity or anything else - beware that the reference for the #1 head may be a magnet attached to the motor shaft. This may not be keyed and unless you carefully mark everything beforehand, will have no way other than trial and error to get if back at the proper angle.

- Back to VCR Repair FAQ Table of Contents.

Tape Path Alignment and Backtension Adjustment

General tape path alignment procedures

There are separate descriptions of the procedures for adjusting the various components of the tape path - in particular, A/C head azimuth, tilt, and height; and roller guide height. Before you attempt these, you need to determine whether either of these are likely to be your problems.

For really major tracking problems with all tapes, check for broken or missing parts or for problems which prevent proper positioning of the roller guide assemblies during tape loading. Types of symptoms include: broken up picture, snow across part of picture, multiple breaks (sort of like the VCR is in a search mode such as CUE or REV but is not) in picture, totally unstable picture, or multiple of the above. Of course, someone before you may have messed with various mechanical (or heaven forbid, electrical) adjustments without having a clue of what they were doing.

Symptoms of bad A/C head alignment

The following are some symptoms you may experience indicating the need for A/C head adjustments:

- Weak, muddy, or wavering sound. (Azimuth, height, or tilt adjustment).
- Tracking incompatibility between this VCR and tapes recorded on other VCRs - you always need to adjust tracking or keep the tracking control way off center when playing tapes from other VCRs. However, if it is only one other VCR, that VCR may be misadjusted. (Mechanical tracking adjustment).
- Erratic loss of synchronization or frame lock, or speed changes. (Height or tilt adjustment).

Before you try to adjust the A/C head, make sure that there is not some obvious mechanical problem that has shifted its position. There may be a bit of something stuck in the mechanism. If this appeared after you did some work on the VCR, you may have accidentally caught a cable or something else preventing the A/C head assembly from returning to its proper position. This is particularly likely if the problem happened suddenly.

Once you change its settings, any tapes recorded on your VCR prior to these adjustments may not play back properly.

For example, if you touch the A/C azimuth screw to correct a muddy weak sound problem when playing tapes from other VCRs, any tapes previously recorded on your VCR will now sound muddy and weak. You need to decide which is more important - your recorded tape library or compatibility with other VCRs.

Symptoms of bad roller guide height adjustment

The following are some of the symptoms you may experience indicating the need for roller guide height adjustments:

- Video noise at top (supply/left side roller guide) or bottom (takeup/right side roller guide) of picture that cannot be removed with the user tracking control.

- Video noise in various areas of picture that comes and goes in a few second cycle. For example, a few lines of video noise may travel up or down the screen or start at the edges and meet in the middle. (Misadjustment of either roller can cause these symptoms.)

- A jumpy picture - as though the vertical hold control (which most TVs no longer have) is misadjusted. (The supply/left side roller guide is probably misadjusted.)

Before you try to adjust the roller guide height, make sure that there is not some obvious mechanical problem which is preventing the roller guides from seating properly. This is particularly likely if the problems happened suddenly. See the section below on: "Likely causes for sudden change in tracking behavior".

Gently check each roller guide to see if one is loose in its threaded mount. If one turns with finger force, that one is likely the problem AND YOU SHOULD NOT TOUCH THE OTHER ONE! Where both are loose or have been adjusted, it may take quite a bit of trial and error to get them both set correctly again. Try not to make this an issue!

Tape path alignment shifting over time

No, it isn't your imagination. Those wedding videos no longer play on your VCR without adjusting the user tracking control even though you swear they used to.

Considering the precision required to maintain alignment, especially for the slow (SLP/EP) speed, it's a wonder these things work at all! With a track pitch of 19 um (.019 mm) at this speed, a shift by more than the diameter of a human red blood cell (about 7 um) will result in alignment problems. Tolerances of SP and LP speeds aren't quite as bad but are still measured in almost imperceptible fractions of a mm.

Changes in roller guide height is probably the one most likely to occur. Note that many modern VCRs no longer use locking screws so these do eventually loosen and shift position. Wear to other parts like the V-stoppers and tracks on which the roller guides ride, as well as the ridge on the lower cylinder, are also possible.

However, before attempting realignment or replacing expensive components, make sure that the roller guides are seating properly and that a proper cleaning and inspection has already been done.

A/C alignment adjustment locations

While there are many variations on the exact locations of each of the A/C head alignment adjustments, the following description is for one of the most common layouts. See the appropriate sections elsewhere in this chapter for the adjustment procedures for the A/C head.

- A/C mechanical tracking. This is a conical nut on a small shaft fastened to the transport base. It is wide on top and tapers down below. A slot across the top allows the nut to be turned and thus raised or lowered. It's angled side presses against a projection on the A/C assembly base plate. Thus raising or lowering the nut moves the A/C head assembly from side-to-side.

  - When raised (counterclockwise), the A/C head assembly moves away from the video heads increasing the delay between the video and sound.

  - When lowered (clockwise), the A/C head assembly moves toward the video heads decreasing the delay between the video and sound.

  You may need a special screwdriver with a cutout in the middle of its blade (or modify one of your own) to easily adjust this nut.

- A/C head height - A hexagonal nut on a large shaft behind the A/C head. This moves the entire A/C head assembly up and down. A spring underneath provides both the upwards pressure to keep the A/C head assembly against this nut and torque to keep it against the conical A/C mechanical tracking nut.

- A/C head tilt - A Philips screw is directly behind the A/C head on the plate that the head sits on. This adjusts the A/C head forward and backward (with respect to the tape).

- A/C head azimuth - Another Philips screw is to the right or left of the head on the same plate just mentioned. It probably has (had) some red (or other color) paint on it to lock its position. This adjusts the A/C head azimuth angle (side-to-side) with respect to the tape.

- A/C head plate pressure. A third Phillips screw (on the opposite side of the A/C head from the azimuth screw) with a spring under it. This should just be left alone as its only function is to provide downward pressure to keep the A/C head assembly in place as determined by the tilt and azimuth screws and a pivot point underneath near the front. However, if it seems loose, tighten it a few turns clockwise. This should not affect any of the other settings.

Adjustment of A/C head - problems with tracking or sound (linear audio)

If the problems happened suddenly, it is probably not a misadjusted audio/control head but some other mechanical fault - eliminate this possibility before considering A/C head adjustments.

Note: For the procedure below, the linear audio tracks must be monitored. So, if this is a HiFi VCR, select an audio mode that forces the linear audio tracks to be used as output. There will usually be a switch or menu setting for this.

The following will attempt to get your mechanical settings back to something approaching normal even if the audio/control head was tweaked:

I assume that you have cleaned it and replaced any dead rubber parts.

I also assume that someone (we won't name anyone) has tweaked just about every mechanical adjustment.

I would adjust the audio/control (A/C) head as best you can (don't touch this unless you know it was messed up by someone):

- Play a tape that you know was recorded on a good machine. It may be easier to start with a tape recorded in SP mode since this is less critical. Once the basic alignment is complete, go back and fine tune with a tape recorded in EP.

- Adjust the A/C tilt as vertical as you can by eye. If necessary, fine tune it for most stable tape movement - the tape should be at the same angle moving over takeup roller guide, A/C head, and adjacent fixed I guide.

- Adjust the A/C height for loudest sound. At each end of the range of this adjustment, you will lose tracking/sync and tape speed may fluctuate (in addition to the sound becoming weak).

- Adjust the A/C azimuth for best treble (high frequency) sound. This is a precise adjustment - a 1/16 of a turn is significant. There will be a very small range over which the sounds will be clear and natural. A tape with music is best for making this adjustment.

- With electronic tracking control centered, adjust A/C mechanical tracking (usually, a conical nut that moves the entire A/C assembly) until you get the least snow (if you have a picture at this point). Satisfactory tracking may be obtained at several positions of this control. However, only one will produce current video-audio sync. For the others, the words and the picture will be off by some multiple of 1/30th of second.

- You may need to go back and touch up some of these again.

If you are aligning a HiFi VCR, (re)enable HiFi mode and tweak the mechanical tracking to center both video and audio within the electronic tracking range. In some cases (if the rotating video/audio heads were not manufactured perfectly), the peaks may be at slightly different positions and you will have to split the difference in the adjustment.

There can still be other problems in the tape path including the height and angle of the roller guides and the height of the impedance roller assembly (on the left before or after the full erase head.)

Roller guide height adjustment

You can do this by eye. Sophisticated test equipment and expensive test tapes are not needed. One trick is of course not to mess with both guide posts at the same time - but even if you do it isn't the end of the world. This doesn't even require a scope - the video picture is an excellent alignment tool! It does take patience and a steady hand.

Also, have you touched any other mechanical adjustments - other guideposts, etc? Hope not. Also, I assume that any repairs to the guideposts have left them perfectly vertical - if they are tilted, then other tape path instabilities can result.

The following checks and adjustments are made in PLAY mode.

There is a ridge on the lower (stationary cylinder) on which the tape should ride - not above and not below. Play a tape that is in good condition and look closely at its bottom edge to see if it is sitting precisely on this ridge. If it is not, first verify that both roller guides are snug against the 'V-Stoppers' - the brackets at the end of the tracks where the roller guides stop in PLAY and REC. If they are not, then you need to determine what is binding or what has fallen off of the tape loading mechanism. See the section: General tape path alignment problems. Assuming that the roller guides are correctly positioned on the tracks, the first step is to visually adjust the roller guides so that the tape just rides on that ridge on the lower cylinder. That ridge is a very critical part of the guide mechanism.

There will be a set screw to lock each of the roller guideposts from turning. The appropriate one(s) will need to be loosened slightly - just enough to that the post is snug but can be turned by hand. The set screws may require a miniature metric hex wrench. Some just have a square head screw which can be loosened with a pair of needlenose pliers. Adjust each guidepost so that the tape just rides on top of the ridge.

Now, for the fine adjustments. Which part of the picture is bad?

- Left guide -> mostly problems with top of picture.
- Right guide -> mostly problems with bottom of picture.

Misadjustment can also cause a periodic loss of sync on a several second cycle.

Make careful **small** adjustments of each one - then wait for a few seconds for any results to become apparent. Since the tape moves so slowly, it takes several seconds for the tape motion to stabilize to the new guide position. The left guide will affect the top part of the picture (mostly) and the right guide will affect the bottom.

Once you are happy with SP, get a tape recorded on a known good deck in EP (SLP) mode since the tracks are narrower and fine tune it.

Tape path alignment comments:

- An EP recording requires the best tracking, and will thus make the best test source. (But it must have been recorded on a unit that was aligned properly).
- Using forward and reverse search modes helps to narrow the adjustment. The guide height on the "feed" side for whichever direction you're going will have more affect. In other words, tweak one while searching forward, and the other while searching in reverse.
- You could have the tape centered at the middle of the contact path, but too low at one end and too high at the other.
- You could have the entire contact path too high or too low, and be in- advertently "correcting" by misadjusting the tracking control. You could be off by an entire track getting a good but very unstable picture since the ridge is not providing any guidance.

Roller guide tilt: The roller guides (but not the fixed guide posts next to them) should be perfectly vertical. Sometimes there is an adjustment for this but usually not. Roller guide assemblies that have tilt due to wear will need to be replaced.

Likely causes for sudden change in tracking behavior

If it is impossible to find a position of the user tracking control that results in a stable picture, this section is for you. Some amount of the picture may be noisy - top or bottom - or the tracking may be fluctuating with a few second cycle.

Mostly, these symptoms are related to problems with the roller guide assemblies. (though electronic causes are also possible). The roller guides are on the assemblies that move on curved tracks to wrap the tape around the video head drum in play and record modes (and on newer instant start VCRs, other times as well). Each roller guide assembly includes a white cylindrical roller which should turn freely on a metal guidepost, and a fixed guidepost at approximately a 20 degree angle.

1. Roller guides not fully engaged against 'V-Stoppers' (the metal brackets at the end of the track on which the roller guide assemblies move when entering PLAY or RECORD modes. Common causes:

- Obstruction or ridge on track preventing guides from completing their movement. Visually inspect and observe behavior while entering and leaving PLAY mode. Sometimes with use, an edge develops and the guide gets hung up. A fine file can sometimes remove this.

- Parts have fallen off (don't laugh - JVCs tend to do this). Various parts of the mechanical linkage that move the roller guides may loosen with use and either fall off entirely or change position enough to prevent full engagement. Compare left and right roller guide assemblies, they are usually nearly identical in their operation and you should be able to identify parts missing or out of position. These are usually on the underside of the deck and will necessitate removing the bottom cover (unplug the unit!). To gain access to critical parts of the linkage which may be obscured by circuit boards or other components, you may need to power the VCR, turn it on, press PLAY, and then pull the plug just as the roller guides are in the middle of the track and accessible.

  For the JVC problems, the parts are usually either a brass post or a plastic link. The brass post can be glued back in place using a drop of Epoxy. Make sure its shoulder is fully flush with the body of the roller guide casting. For the plastic link, I have used a very small screw to secure it in place from above. Some plastic cement may work as well.

- Tracks on which roller guide assemblies slide are dirty and/or need lubrication. Clean and grease.

- Obstructions such as toys or Cheerios blocking tracks.

Check the roller guides while the machine is playing a tape. They should be firming pressed against the V-Stoppers. Any looseness indicates a problem preventing full engagement. If pushing the offending guide into position fixes the tracking problem, this confirms the diagnosis.

Note that in modes where the roller guides are retracted, the roller guide assemblies are relatively loose and free to move. However, the amount of movement possible should be similar for the left and right roller guides and you should not be able to lift either entirely off of the track - the ability to do so means missing parts underneath the deck. If the missing parts can be located, they can usually be glued back into position.

Warning: if you find a roller guide assembly that can be lifted off the track DO NOT attempt to load a tape - the floppy roller guide assembly can smash into the spinning video heads ruining them - and your entire day.

- One of the fixed guide posts next to roller guides (the ones that are tilted about 20 degrees) have worked loose and fallen off. There should be a tilted guide post next to each roller guide. If one is missing, it has probably fallen into the machine. Immediately unplug (to avoid the possibility of it jamming something and/or shorting components in the electronics). Locate the escaped post - turn the unit upside down, sideways, shake it, whatever until the loose post falls to the table or floor. Glue it back into position with a drop of Epoxy or other household cement.

- The backtension band has come loose or broken. The backtension band provides the force needed to keep the tape pressed against the video and audio head. A backtension lever on the left side just as the tape leaves the cassette is connected to a felt lined metal band that presses against the edge of supply reel. The position of the level determines the tension and is set up with mechanical feedback so that the tape tends to move it against spring force just enough to provide the correct amount. Test by moving the backtension lever a bit in each direction - you should be able to observe the tension change. Backtension bands are easily replaced. See section: Backtension adjustment.

- Mechanical damage due to trauma such as VCR falling off of TV. Cure, if possible, will depend in extent and type of damage.

Backtension adjustment

Most VCRs use a backtension band - a thin metal band with a felt liner - to apply a carefully controlled torque to the supply reel during forward tape motion in play, record, and CUE. A backtension lever or arm contacts the tape as it leaves the supply side of the cassette and provides feedback to control the tension on the backtension band and thus how much it resists the rotation of the supply reel.

If the backtension is too low, poor tape-head drum contact results and you get a noisy intermittent picture.

If the backtension is too high, there will be excessive head wear and in extreme cases, the drum will slow or stop entirely.

Backtension is normally set using a special backtension gauge which you most likely do not have. If you own a TV with a vertical hold control, you can adjust backtension by setting the vertical hold so that you can view the head switching point - just above the vertical blanking bar. Above this point, you see the video from one head and below you see it from the other. When properly adjusted, these two segments should more-or-less line up.

There are two adjustments for backtension: a spring position and the effective length of the band.

To set the length, there is a setscrew which allows the end of the band to be moved back and forth. It is unlikely that you would need to set this unless you have just replaced a band or unmucked someone else's repair attempt. I usually consider the length to be correct when the angle that the tape makes going around the lever post is about 90-120 degrees. In other words, the tape should not be so tight as to not be deflected by the arm but should not be so loose as to be near or at the end of its possible travel.

Then, set the spring force to align the picture above and below the head switching point. If you do not have access to vertical hold, you may be able to set backtension in the middle of the range where flag waving (see the section: Flag waving - top portion of picture wiggling back and forth) is absent or minimized.

No, you don't need a fancy back tension meter

(From: Alan McKinnon (alan.mck@pixie.co.za).)

Well, I'm about to open myself up to all sorts of scathing comments, but here goes: You can get by without a back tension meter. You will notice that just about every VCR ever made puts the back tension pole between a post and the impedance roller. Adjust the pole landing position so that it lines up with the middle of the impedance roller. Check your picture. If you have flagging at the top, or wavy lines, adjust the position. Fiddle it both ways to get the feel of it. Once you have experience, you can gauge the back tension by holding a screwdriver against the tape after it has passed over the full erase head. Your fingers are probably more accurate than most gauges anyway - I've never seen two give the same readings. My meter lies unused most of the time. I've lost count of the number of times I have chased around the VCR only to find my backtension meter was leading me astray.

More on adjusting backtension

(From: Paul Weber (webpa@aol.com).)

The objective of the back tension adjustment is to prevent "flagging" which is horizontal displacement of scan lines at the top of the picture. You can use either B&W or color TV (or video monitor), provided that the unit has an accessible vertical hold (vertical sync) adjustment. You mis-adjust it until the picture rolls half-way and you can see the horizontal sync bar. This lets you see the very top of the picture (just below the bar).

To make the adjustment, you need a known-good reference tape. You might trust a commercially-produced movie, but I'd recommend a real vcr alignment tape if you can find one. If you use a movie, then try four or five different ones to help insure you don't have one made on a defective machine. Adjust your machine so that vertical lines in the very top of the picture are as straight as possible.

As to the specifics of what to adjust on your machine: You didn't mention the make or format of your machine, but I'll wager that the moving arm nearest the feed reel is attached to a felt-covered metal band (the brake) that wraps partially around the feed reel table. With tape loaded and moving, the arm balances tape tension applied by the drive system against tension supplied by a spring. If the tape tension becomes excessive, the brake is applied more; if the tape loosens, the brake is relaxed. Look at the attachment points for the spring attached to the arm. Usually, the back tension adjustment is at the chassis end of the spring. It may be an eccentric post than can be turned with a screw driver or a special tool, or it may be that you have to gently bend the tab. Either way, adjust the spring tension in very small increments, then observe the effect on the picture.

VCR Sensors and Tape Counters

Tape start/end sensors

VHS cassettes use a clear leader and trailer for the purposes of detecting beginning or end of tape. A light source that pokes up in the center of the cassette illuminates photodetectors on either side of the cassette through passages in the plastic passing through the tape as it leaves and enters the cassette. This is shown in VHS Cassette Showing Start and End Sensor Locations.

The light source can fail - this is common on older VCRs where this was an incandescent lamp but rare on modern VCRs which use a special IR LED. The failure of this light source can produce a number of symptoms:

- The VCR may simply shut down and refuse to do anything. VCRs with incandescent lamps often were able to figure out that the light bulb was burnt out since it was drawing no current and then shut down or flash an error code.

- The VCR may go through the motions of playing a pre-recorded tape thinking that a tape is present because the sensors return signals indistinguishable from what it would see if a tape were present. Eventually, it may give up and probably shut off power.

- The VCR may do strange things when you attempt to load a cassette since the microcontroller is receiving conflicting signals - the cassette is out but the sensors think otherwise.

If your VCR uses an incandescent lamp and it is not lit when power is on, then the bulb is most likely burnt out.

If either sensor fails open, then similar symptoms may result.

If the sensor on the supply side fails shorted, then it will appear as though the tape is at the end. The VCR may refuse to play or FF or will attempt to rewind as soon as a cassette is inserted.

If the sensor on the takeup side fails shorted, then it will appear as though the tape is at the beginning. The VCR may refuse to REW.

In both cases, sometimes you can trick the VCR into cooperating and confirming that there is a sensor problem by pulling the connector for the appropriate sensor once the cassette is loaded.

If you can get at the connectors, you can test the sensors by monitoring the voltage on the outputs.

One test you might try if the VCR attempts to play an imaginary pre-recorded tape as soon as power is turned on is to locate the microswitch for record lockout protection - it will be located near the front (where the record protect tab would be once the cassette is loaded). Press this in while you turn power on. If the VCR now just initializes and displays cassette-in without trying to play, then it really thinks there is a cassette in place most likely due to a faulty sensor.

In some cases, there could be other problems like a faulty mode switch or microcontroller producing symptoms that might be mistaken for faulty start/end sensors.

Start/end sensor testing

The start and end sensors are usually a combination of a light source (IR LED) and IR photodiode. With a little effort, these can be tested for functionality.

- For an incandescent lamp (older VCRs), if it is not lit with VCR power on, it is most likely burnt out. Test with an ohmmeter.

- For an IR emitter, an IR detector like the circuit provided elsewhere in this document or an IR detector card can be used to determine if the LED is operating.

You can also try powering the LED with a low voltage supply and 500 ohm or so resistor using the IR detector to see if it works. Disconnect it from the circuitry first! Try both polarities to be sure you got it right.

The sensors themselves can be tested by disconnecting them from the circuitry and shining an IR source on them (a remote control or incandescent bulb) while monitoring the resistance with a VOM or DMM. Use the polarity which give the higher reading (reverse bias). This resistance should drop dramatically if they are functional.

If the start and end sensor assemblies are interchangeable, swapping them may be instructive. For example, this may shift the symptoms from play to rewind or vice versa.

Tape counters

There are two kinds of tape position counters: reference and real-time.

What I call a reference counter is what all VCRs used up until a few years ago. A sensor counts revolutions of the takeup reel (usually) either directly or via a belt drive. A mechanical or electronic counter displays an arbitrary number which provides some idea of location. Since the rotation rate of the reel is not constant with respect to the actual time of the tape, it is not possible to use this for anything other than a reference. In addition, the tape may slip a bit and be wound tighter or looser depending on whether it was wound in play, FF, or REW. Thus, even the reference is not accurately repeatable.

Failures can be caused by a broken or weak belt for the mechanically operated counter or defective circuitry for the electronic display. A failed sensor would most likely also cause the VCR to shut down and unload the tape as this is what is used to confirm that the takeup reel is rotating and that tape is not spilling into the bowels of the VCR.

Real-time counters - which really are a vast improvement - operate off of the control track pulses from the control head. Tape location is measured in hours, minutes, and seconds though it is still relative and must be reset at the beginning of the tape if an absolute location is to be determined.

The only disadvantages of real-time counters are that:

- They do not operate with a new or bulk erased tape since there is no control track. Thus, it is not possible to leave a specific length section of such a tape unrecorded by using the counter to space over it. You must lay down a control track first by recording something - anything - for the time you want. However, it is advisable that this be a valid video source so that the sync pulses occur with the proper timing.

- The tape must be in contact with the control head for all operations. In principle, this results in more head (and tape) wear though I know of no cases of the A/C head stack requiring replacement because of this design.

Failure of the real-time counter on a VCR that otherwise works normally is quite unlikely and is probably an electronic problem since the control head must be functional for all record/play modes to work properly. However, it is possible that a failure of a half loading arm to fully extract the tape would result in problems in (non-search) FF or REW.

Reel rotation sensors

Reel rotation is detected most often using optical sensors under the reels though some older VCRs may use mechanical or optical interrupters driven off of belts from the reel spindles. The optical approach is depicted in VCR Reel Rotation Sensor.

- There will always be a takeup reel sensor - even on a VCR with a real-time counter. It has two functions: to (1) confirm that the reel is rotating and that tape is not spilling into the bowels of the machine and (2) to operate the (non-real-time) tape counter.

  Failure of this sensor will cause the machine to shutdown almost immediately and will result in a stuck tape counter.

- Some VCRs will have a similar sensor on the supply reel. The output from this sensor can be used to confirm proper rotation of both reels both during modes involving tape motion as well as during the tape load and unload operations. Exactly when each is used will vary by design.

  If your VCR has identical sensors monitoring both reels, swapping the sensor assemblies may be instructive: the behavior will change if one is bad. For example, a VCR that would shut down in a couple of seconds in play mode may continue to operate correctly but now have problems with rewind.

- Some fancier VCRs will display an estimate of tape remaining using the difference in rotation rates of the supply and takeup reels based on assumptions about tape thickness, hub size, and total length (which you may have to tell it).

- Sometimes, reel rotation sensor problems are simply due to accumulated dirt on the reflective surfaces - clean them. In other cases, replacement sensors will be needed. While you are at it, replace both sides where appropriate - most of the cost to you is in your time, the cost of the sensors themselves is modest.

Note that on VCRs with real-time counters, the real-time display as well as possibly the tape movement sensing operates off of the A/C head control pulses. Failure here could be due to dirt, a bad A/C head, tape path alignment problems, or failure of a half loading arm to properly extract the tape so that it contacts the A/C head.

Reel rotation sensor testing

The counters on some VCRs are active at all times - rotate the appropriate reel and the counter will change (count up or down depending on its default mode - the direction of rotation probably will not matter). If your VCR is of this type, testing is particularly easy. Slowly rotate the takeup (usually) reel by hand. The numbers should change several times - probably 4 - per revolution. There should be no missed counts and there should be no positions where the counter free runs - the display increments or decrements on its own very quickly. Any of these could indicate a problem with the sensor or LED, a buffer amplifier, bad connection, or the microcontroller or other IC that actually drives the counter and display.

For electrical tests, first, locate the LED and photodiode. You can tell the difference by testing with a DMM on its diode test scale - the LED will have the higher forward voltage drop. Sometimes, the connections are even marked. What a concept!

Momentarily touch and remove a resistor (1K ohms or so should work) across the sensor leads (while the VCR is in PLAY mode before it quits if needed). This should make the counter change if the the LED is bad or the photodiode is open. Alternately, a remote control may be able to activate it providing pulses that will look to the counter exactly like reel rotation.

If this has no effect, unsolder the sensor (or unplug the sensor assembly from the main board if there is a connector) and try the resistor across the terminals where it was connected. If you now get a response, the sensor was shorted (or the connection was bad).

If you do not get the counter to change in either case, there is a problem with an intermediate buffer amplifier, the electronics on the main board, or a bad connection leading to the main board. You will need to obtain the service manual or trace the circuit leading to where the sensor signal is detected.

It is possible that the counter will only change when the microcomputer expects the reel to be moving, so a test while in STOP mode may not be valid.

An alternative test is to use an ohmmeter across the photodiode on a high ohms scale. Use the polarity which gives the higher resistance and shine a light on the sensor. The resistance should drop dramatically with a bright incandescent light (these put out a good amount of IR). If it is infinite in both directions, the photodiode is open. If it is low in both directions, it is shorted. You may be able to make a measurement while the sensor is still in circuit, though other components may mask the resistance change. As noted, the IR sensor/LED combination is often a pluggable assembly. Using my VOM on a photosensor, I read infinite ohms with no light and 200 ohms with a bright light. However, your mileage may vary.

If you have an oscilloscope, monitor the sensor output. If it is a voltage signal at this point (likely), then you should see it go high and low as you rotate the reel or shine light on it. With the reel rotation, the low and high periods should be roughly equal. There may be a buffer amplifier driven by the sensor - check its output as well. The signal there should be a cleaned up version (low pass filtered and possibly inverted) of the sensor output. In all cases, the signal should be a DC value without noticeable ripple or noise (block external light as fluorescent lamps in particular may add a 120 Hz ripple to your detected signal). Even at transitions between low and high or high and low, the level should change smoothly. You may be able to trace the signal to its final destination, the microcontroller or other large multilegged part, and monitor it there as well.

Play a T120 tape recorded at EP speed near the end of the tape. This will result in the slowest takeup reel rotation. Or, if your VCR has the counter active in stop mode with the cassette out, rotate the takeup reel by hand very slowly.

If the counter skips or 'free runs' at certain positions of the reel, there may be a problem with the hysteresis circuit. If this is external to the microcontroller, a resistor may have opened or there may be some other easily identified bad component. If it is internal to the microcontroller - either an actual circuit or firmware - then replacing the microcontroller may be the best solution unless you want to add your own circuit - I have done this to repair a Sears VCR with an erratic counter problem. It is a simple 1 or 2 transistor circuit (depending on what external circuits are already present).

Monitor the sensor output when rewinding a T120 tape to the very end - this will be the worst case test as the pulses will be at the highest rate. There should be no missing pulses and the high and low times should still be similar. A bad sensor might result in unequal high and low times and dropped pulses at high speed.

Stan's tips on reel sensors

(From: Stan Cramer (stvcrm@Gramercy.ios.com).)

Try removing the take-up reel disk. Look on the bottom surface to see if there are a series of pie-shaped vanes - shiny, dark, shiny, dark, etc. If the shiny vanes get misted with smoke or general grak, the symptom is the same as if the sensor itself is faulty. Use some Windex or some such mild cleaner on the vanes and test the machine again.

On some earlier machines, the take-reel disk might have a series of evenly spaced slots - blank,solid,blank,solid etc.- that interrupt the flow of IR light creating an electronic pulse stream. If your machine has this type of motion sensor, you can try brushing or blowing out the dust that may have accumulated in the small recesses surrounding the IR emitter and receiver devices on the sensor assembly.

If these attempts don't do the trick, you probably have a faulty sensor.

Motors and Rotors

Types of motors in VCRs

There may be anywhere from 2 to 6 or more motors in your VCR. Some designs use a single motor to power all functions except the video head drum. Others have separate motors for each function. Most typical are 3 or 4 motors. Motors perform the following functions:

1. Cassette loading (front loaders only).
2. Tape loading (position tape around video head drum, etc.).
3. Video head drum rotation (servo controlled).

4. Capstan rotation (servo controlled).
5. Takeup reel rotation (PLAY, REC, FF, CUE).
6. Supply reel rotation (REW, REV).

The video head drum (3) always has its own motor. It is internal to the lower cylinder or above the upper cylinder (except in the very oldest VCRs) and directly drives the spinning upper cylinder.

Most consumer VCRs use a single motor for the capstan and the takeup and supply reels. Some also use this same motor for cassette and/or tape loading. Several possible types of small motors are typically used in VCRs:

Small brush-type permanent magnet (PM) DC motors similar to those found in small battery operated appliances, CD and tape players, and toys may be used for cassette loading and/or tape loading.

1. A similar but larger PM motor may provide power for the capstan and reel rotation and possibly multiple other functions (older VCRs).

2. A single low profile or 'pancake' brushless DC motor may provide power for a direct drive capstan, reel rotation, and possibly multiple other functions.

3. Brushless DC or 3 phase direct drive motors are usually used for the video head drum. Some of the very earliest VCRs used a belt drive for the video head drum.

Testing and repairing small motors

Aside from obvious mechanical problems and lubrication if needed, you usually cannot do much to repair defective motors. If you enjoy a challenge, it is sometimes possible to disassemble, clean, and lubricate a motor to restore it to good health. However, without the circuit diagram, even knowing what the proper voltages and signals should be on (2) or (3) type motors would prove challenging.

The following are some of the possible problems that can occur with the basic permanent magnet motors:

- Open or shorted windings or windings shorted to case.

- Partial short caused by dirt/muck or carbon buildup on commutator.

- Burnt out armature due to defective driver, power supply, controller, or mechanical overload.

- Dry/worn bearings.

An open or shorted winding may result in a 'bad spot' - a position at which the motor may get stuck. Rotate the motor by hand a quarter turn and try it again. If it runs now either for a fraction of a turn or behaves normally, then replacement will probably be needed since it will get stuck at the same point at some point in the future. Check it with an ohmmeter. There should be a periodic variation in resistance as the rotor is turned having several cycles per revolution determined by the number of commutator segments used. Any extremely low reading may indicate a shorted winding. An unusually high reading may indicate an open winding or dirty commutator. Cleaning may help a motor with an open or short or dead spot but most likely it will need to be replaced. Note that unlike a CD player which uses some motors constantly, the small PM motors in VCRs are only used for loading operations and are generally quite reliable unless damaged by other problems.

For more information on small PM motors, see the chapter: "Motors 101" in the document: Notes on the Troubleshooting and Repair of Small Household Appliances and Power Tools.

Capstan problems

Capstans are expensive especially if they are integral with the capstan motor, but unless it is bent (very unlikely), or the bearings are totally shot, or it is direct drive and the motor is bad, the capstan should not be a problem as long as you **carefully** clean off all of the black tape oxide buildup with alcohol and a lint free cloth or Q-tips. Don't get impatient and use anything sharp! The black stuff will come off. A fingernail may help. A dry bearing may need a drop or two of light oil (electric motor or sewing machine oil). Sometimes, there is a bearing cover washer that works its way up and interferes with the tape movement. Push it back down.

Some Sony VCRs have had problems with defective capstan motors resulting in intermittent pausing or stopping of video playback when hot. The entire motor or just the bearing assembly needs to be replaced in this case.

Some capstan motor information

(From: Mike Whitmore (whitmore@jila.colorado.edu).)

VCR capstan motors are servo-controlled to allow precise speed and phase control. Typical signals are:

> VCC - power to chip/motor- probably 9-12 V
> FG - frequency generator output from motor to servo loop
> CTL - control track pulse from Audio/Control head
> F/R - forward/reverse (one high, one low)

There will probably be other connections for a variety of servo voltages, braking, grounds, etc. - You may need to find service literature for this VCR or the datasheet for the particular driver chip to get more info. Data will also tell if motor is 3-phase. This is common for many capstan motors and would require this IC to run it.

Items of Interest

Why is a tracking control needed

In order for the video to be read off of the tape properly, the spinning video heads must be centered on the very narrow diagonal tracks. The width of these tracks is as small as .019 mm. The actual reference point is not on the video heads but the A/C head - several inches away. The control pulses put down during record are used to phase lock the capstan to the spinning video heads. The distance between the control head and the video heads determines whether the required centering will be achieved. In the ideal world, the distance would be identical for all VHS VCRs - that is the goal. It is part of the VHS specification.

However, whether from wear and tear, or even if the technician doing the setup in the VCR factory had an off day, this distance may not be quite identical on the VCR that the tape was recorded on and the machine being used for playback. Therefore, a way is needed to adjust the effective distance. A mechanical control would be possible but not very elegant. Therefore, an electronic tracking control is provided. This basically allows adjustment of the time delay or phase of the control pulses from the control head during playback. Record tracking is fixed. Actually, there may be as many as three tracking controls: (1) the user tracking knob or buttons, (2) an internal master tracking adjustment, and in fancier models, (3) an autotracking servo system. (Note: tracking is always automatically reset to the default when a cassette is inserted.)

VCRs with 2, 4, 6 or more heads - what is the difference?

A single pair (2) of heads is needed for basic record and playback. With more heads, various aspects of these functions can be optimized to improve picture quality - usually for the special effects like CUE and REV. For example, a 4 heads are usually needed to produce decent quality playback in CUE and REV modes for SP recorded tapes.

Another set of heads is required for HiFi audio.

The only possible difference for record or at normal playback speeds is in picture quality since with 4 or more heads, head widths/gaps can be better optimized for each speed. For example, a wide track width can be used at SP speed and a narrower one for EP speed. Which VCRs do this, I have no idea. In fact, such differences might only be visible to the average viewer in an A/B comparison under controlled conditions.

The stability of the video playback has nothing to do with the number of heads. A jumping picture during playback is due to a servo system problem. With problems of this type particularly on a new VCR commercially recorded or rental tapes, it is more likely that the VCR is having problems with some kind of copy protection scheme.

Which combination of heads are used for what modes?

The quick answer is: "almost any combination which includes at least one head of each azimuth angle on each side of the video drum" :-).

For a 4 head VCR, this may even include all 4 at once. In this case, signals from both heads of the pair on each side of the drum are monitored and the one with the greatest amplitude is sent to the video circuitry. This provides clearer special effects for SP recorded tapes in particular - CUE, REV, SLOW, and PAUSE - where the video heads may be crossing tracks of both azimuth angles. Such an approach may be called a 'double azimuth' design by the manufacturer.

For record and play modes, an opposing pair will be used but which pair will depend on speed - EP, LP, SP.

Thus, almost anything is possible and it gets to be confusing very quickly! Don't count on finding this information in the service manual either.

More on 6 head VCRs

(From: Paul Weber (webpa@aol.com).)

A six head (VHS) vcr has 4 video heads and 2 audio heads on its rotating upper cylinder. The 2 audio heads record VHS Hi-Fi. They are about 1/3 the width of the most narrow video heads (about 6 microns). A four head machine lacks the audio heads and is therefore incapable of playing or recording Hi-Fi. There are also 2 head machines on the market. They use the same pair of video heads for all tape speeds. 4 and 6 head machines use the 28 micron wide heads for SP (highest speed), and the 19 micron heads for LP (middle) and EP or SLP (slowest) speed. Some machines have a 7th head: the flying erase head. It is about 40 microns wide, and when activated, can erase the recorded tracks of both video fields that make up a frame. Most vcrs use all 4 video heads to smooth out the picture when scanning in fast forward and rewind. This is why 2 head machines have much more noise in the picture when scanning.

Machines that have a switch to turn off the 19 micron heads do so in an attempt to improve the playback of tapes made on old 2-speed (SP and LP) machines. These machine had video heads that were something like 22 microns wide, and scanning them the narrower heads of a modern machine sometimes produces unacceptable results.

Compatibility problems between machines are a fact of life because of mechanical differences. Recording at the highest possible speed minimizes problems, but hi-fi audio tracking problems can happen even then because the tracks are so narrow. If you have video tracking problems between 4 and 6 head machines on tapes recorded at the highest speed, it is because of mechanical differences, not because of the number of heads on the machine; the number of video heads is identical. The differences are in the alignment of the audio/control head that controls synchronization of the video upper cylinder, and in alignment of the video heads themselves.

Choice of SVHS or high quality 4 (or greater) head VHS VCR

SVHS won't be better than a good 4 head (+2 HiFi) unless:

1. You use high quality (read: expensive) SVHS type tapes (usually, there may be exceptions and some people claim that premium VHS tapes will work for SVHS recordings if the proper hole is drilled in the case but don't count on it).

2. The recordings are actually made in SVHS mode.

3. They are played back on another SVHS deck.

Since few people have SVHS decks, there is probably little benefit if the objective to to make high quality recordings to share.

I would probably go with a good 6 head (including 2 HiFi) since it will be compatible with everyone.

However, just saying it has 4 or 6 or 25 heads doesn't mean it will produce a high quality result - there is a lot of variation in video and to some extent HiFi audio quality.

About VISS and VASS

I assume VISS stands for "VHS Index Search System" or something similar. In any case, VISS and VASS provide the means to mark the start (usually of a video segment so that it can be accessed quickly later on.

> "How standard is this system? My Goldstar VCR has VISS and now I see reference to an LXI brand with the same system. I've heard of other VCRs with functionally similar features, but never had the opportunity to try exchanging tapes. Do they use the same marks? When my Goldstar finally bites the bullet (beyond my powers to resuscitate it), will the collection of indexed tapes I've built up be useless, or will another VCR with indexing features find the marks that Goldstar put on them?"

(From: Ed Ellers (kd4awq@iname.com).)

VISS is a real standard, issued by JVC in 1986. There is also a VASS -- VHS Address Search System -- using the same techniques, but it was taken off the market in 1988 after a patent infringement suit by a German company; JVC settled that case, but VASS never came back (at least not in North America); JVC later developed a more sophisticated system called CTL Coding, but it's not used on consumer VCRs over here either. VASS records four-digit codes instead of a single index mark; CTL coding records an actual time code on the control track, and also provides for VISS and VASS use.

Incidentally, VISS and VASS work by altering the duty cycle of the 29.97 Hz square wave recorded on the control track; the servos still work on the average phase of the signal, but the changes in duty cycle are decoded into a slow bit stream. Before VISS was developed a number of VHS VCRs had a different indexing system that recorded a low-frequency signal across the entire tape, using a special head on an arm that contacted the tape while it was rewound into the cassette; these index codes could only be placed at the beginning of a recording and couldn't (then) be read except during rewind and fast forward modes. Theoretically a modern VCR could be made to read this signal using the control head, but this would require a special circuit to be added; I don't know of any VISS-capable decks that can do this, and given the small number of recordings likely to still exist with the old index signal it wouldn't seem to be worth the trouble.

How does the "commercial skip" feature work?

(From: Matt Kruckeberg (sackmans@ndak.net).)

My understanding of commercial advance is that the program is monitored during recording for fade to black and silent audio between programming and commercials and between commercials. The microprocessor stores these events in memory until the recording session is over. It then analyzes these events to determine whether an event was part of a group of commercials or just a dark silent passage of programming. The tape is then rewound and the beginning and end of the commercial groups are marked with special start and end signals recorded on the control track, similar to index search marks. During playback with the feature activated the unit will automatically forward search when a start signal is detected and resume normal play when an end signal is detected.

Old clunkers and the march of technology

It always amuses me to listen to comments about how anything older than 6 months (or 30 minutes) should be tossed in favor of some newer, more cheaply made piece of crap. Yes, convenience features and HiFi audio have made newer VCRs a lot nicer in many ways. But for time shifting and the kids, that old clunker will do just fine, thank you. Some of the older VCRs will just keep going and going and going and going with a cleaning and a few rubber parts from time-to-time.

On the other hand, I had to repair my high-end (for 1990) moderately used Mitsubishi VCR because a 10 cent plastic part broke (their cost, my cost - $10) - clearly an exercise in design-to-fail engineering. For about 0.5 cents more, it could have been built never to fail. The replacement part was identical to the original, so I give it about 4 years.

Comments on quality of consumer electronic equipment construction

(From: Stan Cramer (stvcrm@Gramercy.ios.com).)

In recent years, the rapid decline in the quality of construction of VCR's has been widely chronicled here and in other forums. Through all of this criticism, I have staunchly defended JVC as the last bastion of construction integrity! Alas - no more!

Tonight, I had the occasion to open up a JVC HR-J620U and was shocked at what I saw! I am sad to announce that even the once venerable JVC has sold out to the concept of making machines really light and really, really crummy! This new JVC transport is the epitome of designing "throw away" machines - even worse than the transports offered by

Matsushita or Funai! Glaringly absent is the modular power supply. You may no longer fall back on the last resort - replace the power supply! Folks, this is just an unmitigated piece of unadultered crap!

As both a consumer and a VCR technician, I am truly offended by the shoddy construction of all new VCR transports and, in particular, by the caving in of JVC to make machines geared to the lowest common denominator. All of us should be outraged!

(From: Greg Monbourquette (gregm@globalserve.net).)

I too am concerned about the lack of care that the engineers who put these things together take when considering the amount disassembly required in order to only clean a lousy belt. (I'm talking mostly about the RCA/GE models with a plastic plate covering the bottom of the VCR) And yes there was once a time when you could buy/sell a vcr and KNOW that the customer won't have any problems for at least 5 years . I tell my customers all the time when they finally decide that the 15 year old TV that finally died (for the first time) will be replaced by a new one, " don't expect 15 years out of any TV you buy today. Oh well we've (I've) ranted long enough. I now know my feelings aren't only mine.

(From: CLSNOWYOWL (clsnowyowl@aol.com).)

I have been doing repair for 15 years and I can actually tell you that during my career as a technician, I have actually seen the actual quality get worse over time on all electronics devices, including VCR's for three basic reasons:

1. When I first started repair, the VCR's and other devices with a mechanism actually had hard, rugged metal that used to cut my hands when I opened the chassis in getting at the critical components of a mechanism. The gears were also made of a fairly heavy metal. The main gears often did not break or strip. Many of the key problems of those older type devices (namely VCR's) were rubber belts and idlers.

   In today's devices, I see brittle plastic gears that actually break just from use and I can actually bend the metal in the devices with my bare fingers, if I apply any real force at all.

2. I liked the older style tuner that could actually pull in a station, even if you received a partial signal. These tuners had really good quality electronics in them and were fairly resistant to even higher powered signals going into them.

   The newer type tuners actually will only display a channel if a picture actually comes in clearly. If the channel barely comes in or comes in even fairly decently, you get a blue screen.

3. The tolerances of electronics components of 10 + years ago were fairly liberal and allowed for a plus or minus 10% error, which meant that the failure rate of those components in the electrical sections would be much less likely.

Today's devices use components with very strict electrical tolerances of say plus or minus one to three percent (1-3%), which means that in the newer devices, the likelihood of a failure is anywhere between 67%-90% more likely.

It is clear that I have more margin of error on an electronic components from plus or minus 10% or even plus or minus five percent than I do with a component that has a plus or minus 1 to 3%.

So, for these three reasons, the overall quality of the actual manufacture of new electronics devices has gotten significantly worse than a device made back in 1990 or before.

Can I add an S-Video input to my VCR?

Possibly, but why bother? You will most likely be limited by the VCR's circuitry anyhow.

All S-Video means is (1) a special connector and (2) separate luminance (Y) and chrominance (C) rather than composite video.

In a VCR, you will need to bypass the input circuitry and get to the place where Y and C are separate. This may or may not be possible depending on its design.

It is probably not worth it as you will likely not gain much in picture quality but if you really are determined, a schematic will be essential.

If all you want to do is allow for an S-video input, there are single chips which will combine the Y and C into a normal composite video signal.

Can a VHS VCR record single video frames at a time?

It would be nice if it were possible to output still frames from a PC, for example, to record computer animation on video tape. This would permit images to be generated slowly and then played back in real-time.

However, there are a couple of problems with attempting to cleaning record single frames on a consumer grade VCR:

- Without moving the tape, only a single field (of the two interlaced fields in a video frame) can be recorded since the tracks for the A and B heads will be superimposed. I doubt that any VCR not specifically designed for single frame recording has any support for moving the tape in this manner.

- The control and synchronization circuitry to cleanly switch the record for a single frame may not exist. This will depend on the model - the more sophisticated the editing functions that are supported, the more likely that this precision will be supported.

- The VCR must have a flying erase head or you must use new or pre-erased tapes to avoid the rainbow interference on the first few hundred frames of any recording made over old video.

Other than that, there is no reason that the video writing circuitry cannot be turned on during pause - some VCRs will do this if you go into record mode while in pause.

Obviously, anything you can do from the front panel or remote you can do under computer control. There could be hidden functions accessible via a special connector or key sequence but you would need documentation for your unit which may not be readily available, if at all.

Controlling one or more VCRs from a PC

Here is one approach to using a PC to program multiple VCRs. Obviously, the techniques described below can be extended to more complex functions. Feedback could be added to inform the PC of end-of-tape or other fault conditions.

(From: Bill Mohler (bill@cs.oberlin.edu).)

We did a project to control multiple VHS VCRs where time and cost were major factors. Our VCR's were the same brand (assorted models with same IR codes), so we hacked a remote to interface to a PC's parallel port. The basic idea was to have the PC select a VCR then "push" a button for function.

The remote hack was simply an analog switch (TTL input) across the switch contacts and a 754XX peripheral driver to select an IR LED mounted right in front of each VCR's IR window.

The software was simple. We only needed 4 VCR's and 4 functions, so we split the 8-bit printer output into two 4-bit commands ("VCR select" and "function") and "poked" away. Not bad for a days work.

You could use decoders or the printer control port to get the extra "bits" you need.

Using a VCR overseas or vice-versa

Some VCRs and TVs may have a selector switch or be universal but you would have to check the manual.

Power wise using a transformer will probably be fine. The power line frequency is not used for anything in the TV or VCR except possibly the clock on the VCR which will run slow or fast.

Standards differ and you won't be able to watch or record broadcasts/cable unless your equipment supports multiple standards.

Differences in blank VHS tapes between US and Europe

The only difference between using a blank tape purchased in the US then used in the UK is the playing time will be different ie, a T120 (2 hours) from the US will have a longer playing/record time in the UK. This is due to the different head drum speed i.e., 60 Hz (1800 RPM) and 50 Hz (1500 RPM).

Why is a special VCR needed for multiple video standards?

A VCR is not simply 'analog playback' in the same way that an audio recorder doesn't care whether you record classical or rock. The VCR must synchronize to the video timing and demodulate the luminance and chrominance information in order to lay down the tracks on the videotape. There are enough differences among world video formats that while technically possible (and such multiformat VCRs exist) it is not automatic - or free. The video timing and modulation techniques for video formats like NTSC, PAL, SECAM, etc. are sufficiently different that additional circuitry is necessary to handle multiple formats. In the U.S. at least, there is not enough demand

to justify the added expense.

The technology of video recording makes interesting reading and the sophistication of the circuitry and mechanism of a $200 VCR is quite amazing.

TVs are more likely to accommodate difference standards than VCRs. Even a regular TV may be able to be used to play from a different standards VCR. For example, NTSC 30/525 and PAL 25/625 use very similar horizontal frequencies but different vertical rates and color encoding. Playback will be possible (in B/W at least) if the vertical lock circuitry (or the vertical hold control if there is one) on the TV has enough range. A simple color code converter can then be easily constructed using a couple of chips and some discrete parts.

Recording HiFi audio only on a HiFi VCR

The use of a $2 T120 tape with a HiFi VCR permits the recording of up to 2 hours of audio with near-CD quality.

However, some designs require a video input to stabilize the drum speed and possible degradation (e.g., wow and flutter, noise, etc.) of the recorded audio. Some VCRs will work fine without any video. Others need it to stabilize the drum speed from the vertical sync. For best results of audio-only recording, find a source of video-black such as a camcorder with the lens cap on to minimize possible video interference (though this is usually not a problem).

Stereo output from VCR RF connector?

(From: Mike Appenzeller (Michael.W.Appenzeller@lmco.com).)

I don't think any stereo modulators exist, other than very expensive professional models. The processing for TV stereo sound is much more complex than FM stereo, involving dbx companding/NR on the L-R difference signal. Hi-Fi VCRs mix the two audio channels together before feeding a mono-audio modulator.

I laugh at all the people who buy a Stereo TV, HiFi Stereo VCR, then insist on using the Channel 3/4 VCR RF outputs instead of the direct A/V connections.

They are getting MONO Sound!

Dubbing only video and linear tracks on HiFi VCR

"Is it possible to rerecord the video (and linear audio) tracks but preserve the HiFi audio?"

You cannot do this without disabling the erase head(s). If this is done, you will get interference from the previously recorded video - the rainbow patterns present at the beginning of recordings over old material on VCRs without flying erase heads.

Even if it were possible, I don't know how robust writing over the HiFi audio tracks would be - you might get degradation after 1 or 2 dubs.

Can I use an Uninterruptable Power Supply (UPS) to retain the programming?

Some VCRs do not have much of a long term memory should there be a power failure. Can a UPS designed for a computer system be used with these VCRs so that all the programming (and possibly channel settings as well) are not lost every time the power line burps?

A UPS might be a solution but there are some issues to keep in mind:

- If your VCR uses a switching power supply (with no input power transformer), it may be fine as the waveform does not matter that much. If it uses a power transformer, then there could be problems if the waveform put out by the UPS is far from sinusoidal - which it likely is.
- The VCR is a very light load. I don't know if this could be a problem with some UPSs.
- The inverter in a typical UPS may generate Radio Frequency Interference (RFI) but this probably doesn't matter

if it only runs when the power fails and you aren't viewing or recording at the time.

If your VCR recently developed this amnesia, then you might consider attempting to locate the cause (a shorted NiCd backup battery or bad supercap) and correcting it rather than tying up a UPS for this purpose.

Can a VCR be used for computer backup?

The answer is yes but I would not recommend it. In order to provide reliable backup, totally error free storage and retrieval must be guaranteed. This is a non-trivial problem given that the video tape is an analog storage media prone to noise and dropouts. Redundant information would need to be stored and sophisticated error detection and correction circuitry must be included. By the time you are done, the theoretical capacity of a T120 video cassette of, perhaps, 5-10 GB is greatly reduced. Furthermore, you probably want somewhat rapid random access and this **will** be very hard on a consumer grade tape transport designed for movie viewing and time shifting of soaps.

With the cost of reliable tape and disk storage units having enough capacity to backup a 1 GB hard drive available or on the way for less than $200, it doesn't make sense to use a VCR with a totally incompatible format and questionable reliability when you will need it most - in a data emergency.

I have no idea if the following is any good - I kind of doubt it - but various products of this type were developed before devices like cartridge tape (and now the Zip(tm) drive) backup became popular.

(From: Robin Gilham (gilham@stb.dfs.co.za).)

I saw an ad for a plug in card and software only yesterday, claiming 2G of storage on a 240 minute VHS tape. Wait.... yes, here it is.

The product is called "BACKER", and in .nl available from Timtronics (+31-50-314 0937). Comes with interface card and Windoze software, will backup harddisks at speeds of up to 9MB per minute for DFL159 (which is less than US$100).

(From: then@superpallo.cs.hut.fi (Tomi Holger Engdahl).)

The manufacturer of BACKER is Danmere Technologies Ltd and they have WWW-pages at http://www.danmere.com/. What they claim by 9 MB per minute, that is the data rate at the maximum speed, maximum compression and minimum error correction. The uncompressed data rate is 5 MB per minute at highest speed.

(From: Karl-Henrik Ryden (kalle@pobox.com).)

I have one of their cards. It works, but is rather tedious to use. It is kind of like in the old ZXSpectrum/VIC64 days. :-)

How can I use an old deceased VCR as a sophisticated appliance timer?

First, you might be able to repair the VCR and prolong its life. Why are you reading this section and considering such a transgression? Grrrr.

OK, so you really want to just use its timer. There are two things you would have to do:

1. Trick the transport into thinking there is a recordable tape in place even though there is none. Then you don't have to worry about your non-recorded tape from running out or wearing out. This shouldn't be that hard. A

cassette shell may come in handy for this. Depending on the VCR, it may be sufficient to block the start/end sensors. Some may require that the takeup and supply reels (inside the cassette shell or the reel tables of the VCR) be linked with a rubber band or old belt so that one turns the other during initialization.

2. Find a signal that can be used to control a relay, solid state relay, or optoisolated triac. If you are electronically inclined, this should not be too hard. If nothing else, the record LED or any switched power bus would suffice. A solid state relay or optoisolated triac takes a logic signal and will control a resistive AC load. Check the specifications if you want to control some other type of load like a motor or external tape deck. A suitably rated normal relay could also be used but a driver circuit may be needed to power the coil.

   Some (rare) VCRs have a switched outlet in which case this is trivial.

Can I control the tuner from a VCR using my PC?

Perhaps, you have this fantasy:

> "I'm wondering if it's possible to take the tuning circuit (tuner and associated circuitry) out of a VCR and somehow controlling it with a PC (say through the parallel port), and then feeding the composite signal to the input of a video capture card?"

If removed from the VCR, you will need the complete specs on the digital interface between the VCR's system controller and the tuner (assuming it isn't on of those old types selected by mechanical switches!), as well a substitute power supply. This information may not be available even if you purchase the complete service manual. However, you may be able to infer it by monitoring the relevant signals with an oscilloscope or logic analyzer :-).

An easier approach may be to use the entire VCR intact and interface via the front panel (by simulating the Chan +/-, TV/VCR, etc. buttons) or via IR by simulating its remote control.

What is a delay line and where is it used?

The question you originally asked might have been: What is this alien looking thing in my VCR?

The object in question may look like a pentagonal shaped frosted glass slab with two pairs of wires sticking out of adjacent edges. What it is, is an acoustic delay line implementing a one TV line (1H) delay - around 63 microseconds (NTSC). The crystal is a shaped cavity and the polished edges are acoustic reflectors. There are a pair of piezoelectric transducers - one to launch a wave and the other to pick it up. The acoustic waves bounce around in a zig-zag pattern which increases the effective path length, thus the unusual shape.

Uses in a VCR include a comb filter and tape dropout masking.

The comb filter is part of the chroma circuitry and computes the sum of the current and previous video lines during recording and playback. The acoustic delay line therefore implements a delay of exactly one horizontal line. Due to the various games that are played with chroma signal phase in the NTSC-VHS system (as well as Beta and PAL), the end result is that chroma signal amplitude is doubled and crosstalk between adjacent tracks is canceled out. This is because the chroma signal is always exactly in phase between successive video lines but the crosstalk between adjacent tracks is always exactly out of phase. The name 'comb filter' is derived from the shape of the frequency response of the comb filter - its evenly spaced spikes look somewhat like a hair comb and it is used to 'come out' the crosstalk components of the chroma signal.

Another use for am acoustic delay line is dropout masking. The surface of the tape is not always perfect - bits of oxide fall off or slight dips or bumps result in momentary loss of head-tape contact. One way to minimize visible streaks in the video is to replace the lost signal with video from the previous scan line.

Nothing alien about it, just not your everyday electronic part.

Comb filters in camcorders?

(From: Jeroen H. Stessen (Jeroen.Stessen@philips.com).)

There is no need for a comb filter in a camcorder!

Signals from the CCD are not first combined into CVBS to then be separated by a comb filter again. That would make no sense.

(However, since modern camcorders are full function VCRs without a tuner, this function may still be needed for dealing with external video input. --- sam)

Other applications for delay lines are drop-out compensation and delay equalization between luminance and chrominance.

Did you ever wonder what happened to the ultrasonic glass delay lines that were once used by the millions in every PAL television, for U/V separation? They were replaced in nearly *all* applications by the Philips switched capacitor delay lines TDA4660(-61,-62).

(From: David Lawson (dlawson@ime.net).)

the color signal(chroma) takes longer to process than does the b/w or luminance channel so to get the color to line up with the b/w picture, the B/W signal has to be delayed slightly.

What are photocouplers and how are they different than optoisolators?

You have probably been unable to sleep at times thinking about this subject!

They are similar - perhaps identical in some cases as the terms both mean the same thing. If there is no optical output/input, then they are likely the same type of device.

Optoisolators are used the switching power supplies to couple the feedback from the low voltage to the line-connected (non-isolated) input.

With 4 leads, these are a combination of a an LED and photodiode or phototransistor.

With 6 leads, there may be additional circuitry providing a logic level output, or base connection to the phototransistor, or just extra unused pins.

Photo interrupters or reflective sensors are used for detecting reel rotation cassette presence, and mechanism position. In this case the optical path - either direct or reflective - is external to the device.

A datasheet will clarify any functional or circuit details.

Photo interrupters or reflective sensors are used for detecting reel rotation Testing is accomplished (1) with a multimeter for shorts or opens on the LED and (2) by providing drive to the LED and checking the resistance of the photodiode or phototransistor with a multimeter - it should go down dramatically if the LED is on.

Also see the sections on sensors and sensor testing.

Why are there so many different designs for VHS transports?

Don't expect an amazing answer - this is a set of questions.

Why are there so many totally different designs to do basically the same thing? I fully understand the pressures of cost and manufacturability. However, it would seem that with VCRs, for example, every manufacturer (of which there are only a limited number who actually manufacture the tape decks themselves) and every couple model years has a totally unique design. You would think that after almost 20 years of manufacturing VHS decks, the technology would be mature. True, there have been advances with respect to quick start, HiFi, and so forth. Nonetheless, the required functions have not changed. And, for that matter, the performance of the typical mechanical deck has not improved that much in the last 10 years or so. If anything, the old designs seem to be remarkably robust. I can keep a 10 year old machine going virtually forever by replacing the rubber every few years. I am not sure that I can say the same of a modern VCR.

Is it only a matter of maximizing performance at a given cost or is there something more? NIH syndrome? Maintaining control over repair parts and service? Or, use of entry level engineers who might provide a new outlook on the design?

Service center honesty?

After taking your totally dead VCR into an authorized service center, it is a month and still no diagnosis. When pressed, they finally 'discover' that a diagnosis has been made and the estimate is $80.

The repair place is jerking you around. It should not take them as long as you have experienced to make a diagnosis - especially if they are authorized and have the service manual. They like the really easy problems like "My VCR started eating tapes last week. Is it hopeless?" 50 cents worth of rubber (idler tire), charge $50 - easy money. And they appear to be heros. To fix the electronic problems you need at least the intelligence of a carrot and time - and time is money. OK, so maybe they give a quick cleaning also.

If it were my VCR, I would bitch, moan, claim poverty, threaten to report them, etc. But, get it back and fix it myself. I assume you checked the fuses. $80 dollars to fix doesn't sound like it could have been much more than a fuse. With the typical markup on parts (4:1 for small parts), those alone could easily push the bill to more than $80. The longer they hold it, the tougher the problem seems so that when presented with the (larger) bill the customer figures it is justified.

VCR repair saga - a shop that hasn't seen this FAQ

The following is a true story. It appears to be an example of incompetence compounded by a lack of basic decency in dealing with the customer. The indented quoted text is from someone who wishes to remain anonymous.

> "Recently my 4-5 year old JVC HR-D910U (Hi-Fi Stereo) VCR stopped loading tapes properly. More specifically, a rubber roller which is lifted up and out of the way when the tape is ejected would come down right on top of the tape after the tape was loaded. This occurred because some metal guide, which moves as part of the loading sequence, wasn't properly pulling the tape out of the way of the (downward

moving) roller. Other than this problem, the VCR performed normally: i.e., if one manually moved the metal guide to pull the tape out of the way and then hit "PLAY", the machine would behave completely normally in all modes until the tape was ejected and another tape was loaded in."

If this were a Sony, I would say that it needed a single drop of oil on the half-loading arm shaft - which causes quite similar symptoms. Possibly the JVC transport is similar.

At this point, there is not much wrong with the VCR - maybe a mechanical problem like a stripped gear or the aforementioned gummed up lubrication. It could conceivably be electrical like a dirty or worn mode switch. However, I would go with something mechanical - and simple to identify and repair.

"I took the machine to a local repair shop that seemed reputable (has been in business for a long time, does the actual repairs for local stores of a large consumer electronic chain, etc...)."

Of course the latter is not a testimonial. Electronics chains make their money from selling new VCRs not from repairing old ones. Therefore, they may have incentives to discourage people from repairing their equipment (though mucking it up is not the usual approach - simply declare it not worth fixing - which is I guess what they did in the end).

"After charging me a $30 estimation fee (to be used towards the repair if I so chose), they concluded that there was something wrong with some gear in the loading mechanism as well as the mode switch. The price for the estimated repair seemed reasonable, and so I authorized them to go ahead. To make a long story short, after about 2 months (!) of waiting (they claimed to have had trouble getting the parts) they reported that they had replaced the parts, but the VCR still did not work. In fact, it now loaded properly, but didn't play well, and in general was confused about what mode it was in. For example, after ejecting a tape, the spindles that insert into the VHS tape cartridge would continue to spin around (as if there were a tape in there in PLAY mode)."

They should have been able to clean the mode switch as a temporary fix and confirmation of the problem. A broken gear would be obvious - they should still be able to produce it for you - not that this would mean very much as there is no way of demonstrating that it originated in your VCR.

Two months is way too long to wait for common service parts.

At this point, the timing is probably messed up - the novice bozo who was assigned to your VCR had not read this document and violated Rule #1: always mark all positions of mechanical components or adjustments before replacing, removing, moving, or changing anything.

"Their claim was that now there was something wrong with the micro- controller on the VCR and that it was putting out some sort of incorrect voltages. Moreover, this problem was allegedly masked by the earlier problems, and only became apparent after they had performed the repairs they had done."

If the microcontroller is messed up, it very likely a result of what they did. Their 'repairs' should not have made the situation worse. It used to be possible to play a tape by helping the loading mechanism to complete its cycle.

"In their estimation, the price of replacing the controller wasn't worth it, and so they wanted to just give me the VCR back, with the repairs that had already done (but keeping the $30 estimation fee)."

A reputable place would give you a total refund, no questions asked. Even if it was your VCR that was hopelessly screwed up from the beginning, it was their responsibility to recognize this.

> "The repair place speculates that some voltage spike must have injured the controller which may have coincidentally resulted in the loading problem. Or, another theory they proposed was that the loading problem caused some motor to over-strain itself in some way which caused an electrical problem which injured the microcontroller."

Balderdash. The original symptoms simply do not support this in any way, shape, or form.

> "My theory is that, since the VCR was normal other than the loading problem described, they must have screwed the machine up during the repair, but do not want to take responsibility for that fact, and after putting in a couple dollars worth of parts are happy to keep the $30 "estimation fee" themselves."

This is much more likely. However, there still may be nothing seriously wrong - the gears may just need to be retimed. This may require s service manual, some consultation with a genuine JVC technician, or even another similar model VCR tape transport to compare it with.

> "So, is their version of the story even remotely possible? If not, I feel that they destroyed a perfectly good machine with a minor problem and I'm wondering what, if any, recourse I might have in this sort of situation."

While anything is possible, I think, to put it bluntly, they do not have a clue. Motors do not damage microcontrollers. There was nothing seriously wrong when you took it to them - it should at least be possible to put it back in that condition. Since they did not do this, whatever they did is now the cause of more significant problems. However, it is quite possible that even these can easily be remedied by proper timing of the gears and mode switch - in addition, possibly, to that single drop of oil.

My recommendation would be to take it to an authorized JVC repair center with this story printed out (not to blame the other people but to give them something to start with). A competent technician should be able to quickly determine what is going on. If they concur with your assessment of the situation, then you can try to get your $30 back from the VCR repair shop from Hell you have not already been credited.

Testing of IR LEDs

The only differences in testing between a visible and IR LED (or IR Emitting diode - IRED) are that:

- The voltage drop across an IR LED will be slightly lower - perhaps 1 to 1.5 V instead of around 1.7 to 2 V for visible types.
- The light is not usually visible to most humans. Thus you need something sensitive to IR. See the section: IR detector circuit or try a CCD camcorder or those IR detector cards. Some people are supposed to be able to detect light well into the IR. I am not one of them.

For in-circuit tests with power applied:

- If you measure 0 V across it, the LED is shorted or the power supply is bad or disabled.
- If you measure greater than 1.5 V across it, the LED is open.

IR detector circuit

This IR Detector may be used for testing of IR remote controls, CD player laserdiodes, and other low level near IR emitters.

Component values are not critical. Purchase photodiode sensitive to near IR - 750-900 um or salvage from optocoupler or photosensor. Dead computer mice, not the furry kind, usually contain IR sensitive photodiodes. For convenience, use a 9V battery for power. Even a weak one will work fine. Construct so that LED does not illuminate the photodiode!

The detected signal may be monitored across the transistor with an oscilloscope.

    |    ===========================================  ========
    v              Control track                       .75 mm
-------  -------------------------------------------  --------
                   Bottom edge of tape
```

Note: ==== denotes the .15 mm guard bands between video, and the audio and control tracks. Thus, once the audio, control, and guard bands are taken into consideration, only about 10.65 mm or .42 inches is available for the diagonal video tracks.

For a VCR with HiFi audio, the HiFi audio heads travel the same path as the video heads but record their information just before the video heads pass over the same spot on the tape. Although some of this is then partially erased by the video, enough remains deep in the tape oxide to to permit reconstruction of CD quality sound. The difference in azimuth angles of the video (+/- 6 degrees) and HiFi audio heads (+/- 30 degrees) minimizes interaction. (The audio is also recorded on the linear audio tracks for compatibility with non-HiFi VCRs.)

For a VCR with monophonic audio, the left and right audio tracks and their guard band are combined into a single audio track of about 1 mm width.

Dimensions are most definitely *not* drawn to scale. The Audio and control tracks are very narrow in comparison to the tape width. To get an idea of the actual slant angle of the video tracks, imagine the tape stretched horizontally by about a factor of about 10. (The length of a video track representing one field or 262.5 scan lines is about 3.8 inches.) There are also actually more than a hundred tracks at any given location side-by-side across the less than 0.42" available for the video information. This number of tracks is equal to 175 at SP, 350 at LP, and 525 at EP speed (for NTSC 525/60 - note that this is not a coincidence but that is another story). Think of the alignment precision needed for proper tracking! You can estimate this number by just timing how long it takes for the rainbow pattern to wipe down the screen when re-recording over an old tape at either speed on a VCR without flying erase heads and multiplying this time by 60.

VHS specifications

```
Tape width:     1/2 inch         12.7 mm

Tape length:    240 meters, T120 - 120 minutes at SP speed, most common.
                Other lengths up to T160 and perhaps more.

Tape speed:     SP      1-5/16 ips      1.3125 ips      33.3375 mm/sec
                LP       21/32 ips       .6563 ips      16.6688 mm/sec
                EP        7/16 ips       .4375 ips      11.1125 mm/sec

                (Newer NTSC VCRs tend to only support SP and EP/SLP for
                 record but will play at all three speeds.  All PAL and SECAM
                 VCRs may only support SP and LP for play as well.)

Track pitch:    .058 mm         (SP)
                .039 mm         (LP)
```

```
                .019 mm         (EP)

Track length:   3.8 inches      96.5 mm

Writing speed:  229 ips         5.84 m/sec

Min wavelength: 1 micrometer (.000001 meter or .00004 inches)

Recording density:      (SP) 34K transitions/sq. mm

Recording time: SP      120 minutes     2 hours
(T120 cassette) LP      240 minutes     4 hours
                EP      360 minutes     6 hours

Drum diameter:  2.44 inches (VHS VCRs).
                1.63 inches (VHS Camcorders).

Drum speed:     30 RPS          1800 RPM    (NTSC at 30 frames/s)

Rotation:       Counter-clockwise viewed from above.

Tape movement:  Left-right viewed from front.

Heads (typ):    2 for normal recording/playback.
                1 to 3 optional for SP freeze frame/slow motion, etc.
                2 optional for HiFi audio.
                1 or 2 optional for flying erase.

End sensing:    Clear leader and trailer.

Brake torque:   Supply forward = 450 - 650 g-cm
                Supply reverse = 70 - 130 g-cm
                Takeup reverse = 450 - 650 g-cm
                Takeup forward = 70 - 130 g-cm

Back tension: 20 - 25 g.

Takeup torque:  Play - 80 - 160 g-cm
                FF - greater than 350 g-cm
                Rew - greater than 400 g-cm

Lum. Carrier:   3.4 Mhz

Color sbcrrier: 629 kHz

Azimuth angles: +/- 6 degrees

Frame length:   7.7 inches      196 mm

Field length:   3.85 inches     98 mm

Line length:    .0147 inches    .3723 mm

Skew:           SP - 1.5 H      (sync tips align)
                LP -  .75 H
```

```
                EP -  .5 H      (sync tips align)

Color Vector    A head is + 90 degree/H
     rotation:  B head is - 90 degree/H

Luminance Specifications for various VCR technologies:

 Type      Video Resolution     FM Deviation      Freq. Range
-----------------------------------------------------------------
 VHS         (240 lines)          1.0 Mhz         3.4-4.4 Mhz
 SVHS (*)    (400 lines)          1.6 Mhz         5.4-7.0 Mhz
 Beta1       (250 lines)          1.3 Mhz         3.5-4.8 Mhz
 Beta2/3     (240 lines)          1.2 Mhz         3.6-4.8 Mhz
 SuperBeta   (285 lines)          1.2 Mhz         4,4-5.6 Mhz
 ED Beta     (500 lines)          2.5 Mhz         6.8-9.3 Mhz

(*) The tape for SVHS must have a higher coercivity since the frequency is
    higher (information more dense) and the demagnetizing forces are greater.

Linear audio    .0384 inches     1 mm     (mono, along top of tape)
 track width:   .0138 inches     .35 mm   (L or R stereo, R at top of tape,
                                           .3 mm guard band between L and R)
Audio bias:     67 kHz

Control track:  .0288 inches     .75 mm   (along bottom of tape)

Guard bands:    .0059 inches     .15 mm   (linear audio track to video)
                .0059 inches     .15 mm   (video to control track)
```

Video recording theory

The majority of maintenance and repair procedures on VCRs and camcorders can be carried out without really understanding **how** the video magic is performed. However, if you want to really get into the nitty-gritty or are simply curious, then the following book is for you. However, you probably want to find it at a library - the suggested retail price is $55!

- Video Recorders: Principles and Operation
  Z. Q. You and T. H. Edgar
  Prentice Hall International (UK), 1992
  ISBN 0-13-945890-5, TK6655.V5Y68.

This book includes basic aspects of helical scan video recording; various formats including VHS, Beta, U-matic, and 8mm; as well as advanced principles of video encoding (with equations) relating to the chrominance and luminance recording and playback channels.

VCRs are both NTSC and PAL compatible?

(From: drblake (drblake@bellsouth.net).)

I have found out that VCRs are produced by many manufacturers but if one reads the "Sams' Photo facts" and checks the pin configuration on the LSI, they will notice that there is a leg marked NTSC/PAL with either a low voltage sign over the PAL or the NTSC symbol. In other words they manufacture 1 VCR for both Europe and the US but either put a +5 V. or a Ground (Hi or Low) voltage on the appropriate leg to make it either an NTSC or PAL VCR.

This is obviously to save money and manufacture 1 design for both the US and Europe, but to change the voltage input based on weather that VCR is going to the US or Europe.

I know this because, I shall relate the following story.

Aside from this inconspicuous notation in the Sam's Photofacts library which I have access to, a person came to our shop from Colombia S.A. a few months ago and said he would like his VCR converted back to NTSC !!!.

We told him, "What did you mean"? "It is impossible, these are made either, or but not convertible". He told us that for $27.00 US he had his VCR converted to PAL from NTSC. We opened the VCR to examine it and sure enough there was a small 1" circuit board with a few wires coming from it and going to the main board or mother board of the VCR.

We checked the Sams Photofacts and found hat the board was wired to a leg of the CPU that had the notation NTSC/PAL !!! It was then that it dawned on us that many manufacturers make 1 VCR with Chips that have a leg that can be *TRIGGERED* to either generate an NTSC or PAL signal.

I would like to get some of those little 1 inch boards that they use in South America to convert or Trigger the CPU chips to generate a PAL signal in an NTSC VCR. SONY US, HITACHI US and PANASONIC US deny any knowledge of this but their technical manuals on their VCRs tell a *Different Story*.

Why is it that TV techs in a Banana Republic like Colombia know about the conversion, but the Technical advisors at the corporate service centers in the USA don't know about these "Special Modifications"?

If anyone has any information or experience in how to trigger the chips or if they know where to get the little boards, that modify the vcrs. or how to wire the VCRS so that they can be switched from NTSC to PAL, Please contact me.

Smoke damaged cassettes

(From: xcuseus9@mail.idt.net)

It is characteristic of a house fire to generate 'fire debris', often referred to as 'soot'. Fire debris, thanks to the plastic content of a house and it's furnishings, is an airborne particulate, as small as 1 micron (um, 1/100th the diameter of an 'average' human hair) that has a high petroleum content.

Internal air currents created by a house fire are often high enough that the minutely sized particulate fire debris will find its way into the interior of most consumer electronic equipment. Cabinets, covers, jackets, and the like (unless they are totally airtight), are ineffective in preventing such infiltration.

Fire debris is abrasive. While little or no damage is done to the video tape that is wound tight on the reel(s), the exposed tape could be contaminated, effectively making it as rough as a piece of fine sandpaper. Cleaning videotapes after a fire prevents damage to the video heads when the tape is later played.

Sour grapes?

The following appeared as a reply to a sincere request for help on the USENET newsgroup sci.electronics.repair. The company is unknown and I have deleted the email address - this sort of comment is usually not constructive. However, I include it to provide all points of view. :-) :-(It isn't that the comments are without validity - just the way they are presented.

(From: National Service Manager.)

> "Why do people insist that they have the knowledge to repair something as complicated as an electronic circuit when they can't even program a VCR??. If you are not familiar with switch mode power supplies, don't attempt to repair it. If you are attempting to repair it and know of the consequences and are prepared to pay more for the extra damage you cause, or if your prepared to purchase a new VCR then go for it. But just don't do it to try to save a few bucks. Good luck in whatever you decide to do."

Setting channels on older VCR

Auto tune on a VCR 15 years old? You have to be kidding! These are typically varactor tuners, not modern quartz synthesizers.

Yes, with a model of that era, you have to twiddle each one individually.

Think of it this way: There are 16 or so memory locations each of which can store the tuning info for one channel. You select the memory location, tune your favorite channel in, set its real channel number, and the store that in the memory location. So, when you are selecting channels with the up/down buttons, you are actually indexing into a memory containing both the varactor voltage and your channel number.

The easiest way I have found is to have a TV with its own tuner sitting next to the VCR so you know which channels are which. If you do that, it really doesn't take long.

The details will vary by model but it usually isn't difficult to figure out the procedure with a bit of trial and error.

Another use for dead VCRs

(From: Mark Kinsler (kinsler@bobcat.ent.ohiou.edu).)

We have an huge, old, utterly-inoperative Fisher-Sanyo top-loader VCR that we have kept for many years for the cat to sleep upon. I think the power supply and the eternally-flashing display probably put out about ten watts.

Sebastian the Cat (black-and-white male, long-haired, with the demeanor of a Supreme Court Justice) started the practice when the VCR was a working affair and I'd watch my Mississippi State U. electric power course tapes on it. We brought it with us when we moved to Athens. When the VCR developed sufficiently severe mechanical problems to warrant its replacement we kept it for the cats. On Sebastian's passing, it was inherited by Samantha, the small calico with impeccable white paws and a large attitude. The VCR is now inhabited exclusively by Marmalade, the long-haired orange tabby Mississippi beauty queen who was adopted from a Starkville parking lot.

She's over there right now, asleep upon its silver plastic expanse, curled up with her nose buried in her fluffy tail. It's always 0:00 pm for a cat.

Notes on the Gemini/Rabbit video multiplier

This consists of an RF transmitter and one or more receiver modules to allow a single video source (typically a VCR) to be sent to TVs in other rooms of the house.

(From: Jim Stanisich (jstanisi@isd.net).)

I can tell you about the Gemini. The voltage required is 18 VDC at 300 mA. The three frequency. settings are set at the factory in the 900 Mhz band. You can change these if you wish by removing the cover, and you will see three corresponding trimpots near the front of the transmitter. They can be set anywhere from 900 to 940 Mhz with a frequency. counter. Also by the antenna there is a tin enclosure which is the RF amp. Inside there is a B+ pot and a trimcap. These can be adjusted to produce a output of approx. 7 mW instead of 1 mW. If you turn it up too high the video will distort so watch the received video if you do this to keep it linear.

Note that the access holes in the RF section are covered with solder from the factory. Sometimes they did such a good job you don't even know they are there.

- Back to VCR Repair FAQ Table of Contents.

Service Information

Advanced VCR troubleshooting

If the solutions to your problems have not been covered in this document, you still have some options other than surrendering your VCR to the local service center or the dumpster. Fortunately, VCRs are among the most popular of consumer appliances to be addressed by literature that is readily available - at all levels of sophistication.

If you are tackling an electronic fault, a service manual with schematics will prove essential. Some manufacturers will happily supply this for a modest cost - $20-50 typical. However, some manufacturers are not providing schematics - only mechanical and alignment info. Confirm that a schematic (not just a block diagram) is included before purchasing if possible.

Sams Technical Publishing (formerly Howard Sams) publishes Sams Photofacts service data for almost every model TV that has ever been sold but their selection of VCRfacts is limited and the newer ones tend to have strictly mechanical information. However, they are worth a shot, especially if your local large public library subscribes to the Sams series as many do. Some of the older VCRfacts are quite detailed and complete.

Web resources

Radio Shack has a nice web resource and fax-back service. This is mostly for their equipment but some of it applies to other brands and there are diagrams which may be useful for other manufacturers' VCRs, TVs, CD players, camcorders, remote controls, and other devices.

- Radio Shack Product Support

In addition to Tandy products, there is at least one Sony model. Furthermore, since Tandy does not manufacture its own VCRs or camcorders - they are other brands with Realistic, Optimus, or other Radio Shack logos - your model may actually be covered. It may just take a little searching to find it.

For camcorders specifically:

* Vidcam Video Repair Page

Not much there now but they do have some photos showing the disassembly of a Sony camcorder which might be of use to someone.

Popular books on VCR maintenance and repair

There are a variety of books dealing with all aspects of VCR maintenance and repair. All will cover the basic cleaning and rubber replacement. Some of these only address mechanical problems (but, hey, this covers most failures) while other are heavy into the basic recording theory and electronic troubleshooting. Your local public library probably has some of these in the electronics section - around 621.38 if your library is numbered that way. Technical bookstores, electronics distributors, and the mail order parts sources listed in this document carry a variety of these texts.

If you want to get an idea of what is out there, search for the keywords 'VCR' and 'repair' at http://www.amazon.com/. Several dozen titles are listed. (I have no affiliation with amazon.com nor am I suggesting that you purchase from them, but the search engine is convenient.)

Here are a couple of typical titles which I have used (there are many others and I am not necessarily recommending these above the others):

1. VCR Troubleshooting and Repair
   Robert C Brenner and Gregory R. Capelco
   SAMS, a division of MacMillan Computer Publishing
   11711 North College,Carmel, Indiana 46032

2. Home VCR Repair Illustrated
   Richard C. Wilkins and Cheryl A. Hubbard
   TAB Books, a division of McGraw-Hill, Inc.
   Blue Ridge Summit, Pennsylvania 17294

The following is a recent publication:

3. In-Home VCR Mechanical Repair and Cleaning Guide
   PROMPT Publications (Howard W. Sams), 1-800-428-7267
   ISBN #0-7906-1076-0. $19.95

   From the advertising blurb for this book:

   "PROMPT Publications, an imprint of Howard W. Sams & Company, has released the In-Home VCR Mechanical Repair and Cleaning Guide, a comprehensive guide that anyone can use to fix their own VCRs at home (even start a VCR repair business). Full of illustrations, diagrams, and helpful, step-by-step instructions. ISBN #0-7906-1076-0. $19.95. 222 pages. Call 800-428-7267 to order or for more info."

   (From: Neil Preston (npreston@cctr.umkc.edu, npreston@CCTR.UMKC.EDU))

   If you teach consumer electronics repair, I've run across a text that you should check out:

4. Practical VCR Repair
   David T. Ronan

Delmar/ITP publishers
ISBN # 0-8273-6583-7

I've looked at several VCR repair books in the past, and almost all of them are very weak on the explanation of the mechanical problems in VCRs, which account for 90% of the problems. This text does an excellent job of explaining exactly how the tape transport system works in VCRs and what each part does. It has lots of photos with parts clearly identified. It assumes NO prior experience. I believe I could take a beginner student and let him walk his way through it.

The table of contents pretty well describes it:

1. VCR Operations & Controls
2. Removing covers & getting started
3. Understanding the videotape path (Also with a detailed appendix describing operation of tape load shuttles, video heads & drum, capstan & pinch roller)
4. Video Cassette examination & repair
5. Troubleshooting loader and Transport Malfunctions (Includes timing!)
6. How to perform VCR Maintenance and common repairs
7. How to align tape path and make adjustments
8. Understanding basic electronics
9. How to use a multimeter
10. Electronic components
11. How to solder
12. VCR Power supplies
13. Checking motors, optical sensors & remotes
14. VCR Microprocessors & servos
15. How a TV picture is made
16. Recording on videotape
17. Beyond standard VHS
18. Using manufacturer's Service manuals
19. Common audio and video problems
20. Service considerations: The business side of VCR repairs

This is by far the best book I've seen on the subject.

(Please note: I have no connection with the publisher nor anything to gain by bringing this to your attention.)

For basic mechanical problems, I could not have said the following any better.

(From: scott.holderman@mogur.com (Scott Holderman).)

One of the best I have seen is called:

5. How To Keep Your VCR Alive (VCR Repairs Anyone Can Do)
   Steve Thomas
   Retail Book Sales, Worthington Publishing Co.
   P.O. Box 16691-B, 6907-202B Halifax River Drive, Tampa FL 33687-6691
   (Tel: 813/988-5751)

This book describes in a step-by-step fashion how to repair a VCR without expensive test equipment or special tools. Fixes are described for different machines by brand & model #, and there is also a list of parts suppliers.

I'm not affiliated with these people in any way - just impressed with the book.

Here are a few mnore:

6. All Thumbs Guide to VCRs
   Gene B. Williams
   TAB Books, Inc., 1992
   Blue Ridge Summit, PA 17294-0214
   ISBN 0-8306-4181-5 (paperback)

   This one is even more basic but does cover the most common problems and has illustrated instructions for video hookup, cleaning, rubber parts, cassette repair, etc.

(From: cx163@FreeNet.Carleton.CA (Morton Lee Cohen))

Some of the books that you can find in your local library about the repair of VCRS are listed below. One of the good books is HOME VCR Repair Illustrated. These are all in the EE section: 621.38.

	Author	Date	Title
1	Ronan, David T.	1995	Practical VCR repair
2	Wayne, Victor A.	1992	Operating your VCR.
3	Capelo, Gregory R.	1991	VCR troubleshooting & repair.
4	Wilkins, Richard C.	1991	Home VCR repair illustrated.
5	Thomas, Steve.	1990	How to keep your VCR alive.
6	Brenner, Robert C.	1987	VCR troubleshooting & repair guide.
7	Goodman, Robert L.	1996	Maintaining & repairing VCRs
8	Williams, Gene B.	1993	All thumbs guide to VCR's.
9	Goodman, Robert L.	1993	Maintaining and repairing VCRs.
10	McComb, Gordon	1991	Troubleshooting and repairing VCRs.
11	Williams, Gene B.	1990	Guide to VCRs, camcorders, & home video.

FCC ID Numbers of VCRs

Only a few manufacturers actually produce the vast majority of VCRs. For example, Radio Shack, Magnavox, and Emerson do not make their own VCRs (I can tell you are not really surprised!). Or, how about a brand of 'Pulsar' sold through a store chain with the name of Canadian Tire? Rubber companies really do not design VCRs (even if there is something inside a VCR called an idler tire. :-)

How do you determine the actual manufacturer? For most types of consumer electronic equipment, there is something called an 'FCC ID' or 'FCC number'. Any type of equipment that may produce RF interference or be affected by this is required to be registered with the FCC. This number can be used to identify the actual manufacturer of the equipment.

A cross reference and other links can be found at:

- S.E.R FAQ FCC ID Page

The chart below probably has your VCR so you probably do not need to use the Web resource.

(From: William Miller, ASEET, eagle@trader.com)

This is a chart used to find the original manufacturer of a VCR. Find the FCC-Listed or UL-Listed code (first few digits), then you'll see who REALLY made it!

ORIGINAL MANUFACTURER	UL LISTED CODE(s)	FCC LISTED CODE(s)
Akai	186Z	ASH
Daewoo	41K4	C5F
Fisher/Sanyo	403Y	AFA
Funai	333Z, 51K8	ADT, EOZ, BFY
Goldstar	86BO	BEJ
Hitachi	238Z	ABL, AHA
JVC	439F	ASI
Matsushita (1)	679F	ACJ, AIX, AJU
Mitsubishi	536Y	BGB
NEC	781Y	A3D, E74
Orion-Emerson	44L6, 722	A7R
Philips (2)	645Y	BOU
Samsung	16M4, 414K	A3L
Sharp	504F	ATA, APY
Sony	570F	AK8
Toshiba	174Y, 84X7	AGI, G95

(1) Matsushita is the parent company of Panasonic, Quasar, and Technics (2) (North American) Philips is the parent company of Magnavox and Philco

Sears model series to original manufacturer:

```
564.  -  Sanyo/Fisher
565.  -  Sanyo/Fisher
934.  -  Hitachi
580.  -  Goldstar
274.  -  RCA
626.  -  Phillips (Mag)
```

Determining belt, tire, and pinch roller specifications

Belts are normally specified by their cross section - square, flat, round, and their inside circumference (IC). The IC is used since it is virtually impossible to accurately measure the diameter of a belt.

Assuming you cannot locate an actual part number, determine the type of belt; square, flat, or round. If you do not have the old belt, this is usually obvious from the pulleys. Most small belts (as opposed to V-belts on 1 HP shop motors!) used in consumer electronic equipment are of square cross section though flat types are sometimes found in the main drives of VCRs, cassette/tape decks, and turntables (remember those?). Measure or estimate the thickness.

The IC is always specified with the belt fully relaxed. This can be measured by hooking the old belt on one end of a ruler and pulling it just tight enough so that it more or less flattens out. Read off the length, then double it for the IC. Get a new belt that is 5% or so smaller to account for the old one be somewhat stretched out. Of course, if the belt broke, measurement is real easy. Or, if you do not care about the old belt, just cut it and measure the total length.

If the old belt decomposed into a slimy glob of jellatinous black goop or is missing, you will need to use a string or fine wire around the appropriate pulleys to determine the IC. Reduce this by 10-25% for the replacement. Very often the match does not need to be exact in either thickness or length - particularly for long thin belts. A common rubber band may in fact work just as well for something like a tape counter!

However, there are cases where an exact match is critical - some VCRs and belt driven turntables or tape decks do require an exact replacement for certain drive belts but this is rare.

Some parts suppliers make determining replacement belts very easy with the PRB system in which the part number fully codes the shape, size, and thickness.

Idler tires are specified by their inside diameter, outside diameter, and thickness. Some parts catalogs provide actual size drawings so that all you need to do is match up your old tire to the picture. Since tires do not generally decompose or stretch significantly and hold their shape, measurement is usually quite easy,

Pinch rollers are specified by diameter and height along with bearing inside diameter. The match must be exact so using the original manufacturer's part number is best but generic replacements are available.

Parts suppliers generally provide quite complete cross references to their replacement rubber parts and complete belt kits are available for most model VCRs.

About decayed tan or brown glue on circuit boards and leaking capacitors

Larger components like electrolytic capacitors are often secured to the circuit board with some sort of adhesive. Originally, it is white and inert. However, with heat and age, some types decay to a brown, conductive and/or corrosive material which can cause all sorts of problems including the creation of high leakage paths or dead shorts and eating away at nearby wiring traces.

The bottom line: Most of the time, this stuff serves no essential purpose anyhow and should be removed. A non-corrosive RTV or hot-melt glue can be used in its place if structural support is needed.

One comment: make sure you scrape and clean off all the old glue. I have heard and seen cases where this stuff turns conductive with obvious bad consequences.

Note: do not mistake the hot melt glue or silicone sealer often used to anchor capacitors or other large components to the circuit board for leakage. One tip-off is that leaking chemicals will not tend to climb up the side of a component! However, if it is on the circuit board and decomposed, various erratic symptoms or other failures are possible.

(From: Gillraker (eternity@mail.cybertron.com).)

Extremely common in older Mitsubishi's!!!! Take it off of all your circuit boards, some of that old glue is caustic, it eats into the traces and becomes conductive as previously mentioned...sure way to tell is look at it and see if it is rust colored around the edges....and there doesn't have to be much rust either...that glue still puzzles me at times....even had to replace leads that have been eaten totally away....

(From: Alan Hurst (alan@sastro.demon.co.uk).)

I had a dead display on my Sony SLV-777 (similar to 715 and 747 models) which turned out to be caused by a leaking capacitor in the power supply. The leakage had eaten through two tracks which supply power to the display.

The problem with leaking capacitors on the PS secondary is apparently very common to the extent there is a service kit available from Sony to replace all the capacitors on the secondary side of the power supply and has caused a wide range of strange faults in this range of models.

Where did all the adjustment go?

Like TVs and monitors, newer VCRs have much more of their adjustments done digitally inside complex integrated circuits. What this means is that there may be no easy way to tweak some of the common parameters without either a special remote control or a computer interface and software. Good for the manufacturer; bad for the DIYer and even professional repair person.

For example:

> "Does anyone know which variable resistor adjusts the head switching point in a Sony CCD-F401 camcorder, where it is?"

(From: Paul Weber (webpa@aol.com).)

There is a very good chance that there is no "variable resistor" for adjusting the head switching point or anything else in your machine. Most recent Sonys use are setup entirely with an EEPROM which is programmed with a special wired remote control (RM-95). Even if there is, you are going to need the shop manual, or you run a high chance of breaking something important just taking the thing apart.

(From: Varlod (varlod@aol.com).)

I recently got a job where I will be doing repairs on VCR's. I have been out of the business for a short while. I just got a service manual to repair a Panasonic AG-131 and noticed a few changes. I remember servicing JVC VCR's in the mid 80's and they had dozens of pots on each board. This VCR has none!! The electronic adjustment section of the service manual tells you to put the VCR in the service mode, put in an alignment tape and let the VCR do all the adjustments. This is incredible, are most other newer VCR's the same? Of course I still have to do the mechanical alignment if needed, maybe in a few years that will adjust itself also.

Interchangeability of components

The question often arises: If I cannot obtain an exact replacement or if I have a VCR, tape deck, or other equipment carcass gathering dust, can I substitute a part that is not a precise match? Sometimes, this is simply desired to confirm a diagnosis and avoid the risk of ordering an expensive replacement and/or having to wait until it arrives.

For safety related items, the answer is generally NO - an exact replacement part is needed to maintain the specifications within acceptable limits with respect to line isolation, X-ray protection and to minimize fire hazards. However, these components are not very common in a VCR except for the power supply.

For other components, whether a not quite identical substitute will work reliably or at all depends on many factors. Some deflection circuits are so carefully matched to a specific horizontal output transistor that no substitute will be reliable.

Here are some guidelines:

1. Fuses - exact same current rating and at least equal voltage rating. I have often soldered a normal 3AG size fuse onto a smaller blown 20 mm long fuse as a substitute.

2. Resistors, capacitors, inductors, diodes, switches, potentiometers, LEDs, and other common parts - except for those specifically marked as safety-critical - substitution as long as the replacement part fits and specifications should be fine. It is best to use the same type - metal film resistor, for example. But for testing, even this is not a hard and fast rule and a carbon resistor should work just fine.

3. Rectifiers - many are of these are high efficiency and/or fast recovery types. Replacements should have at equal or better PRV, Imax, and Tr specifications. For line rectifiers, 1N400x types can usually be used.

4. Transistors (except power supply choppers) - substitutes will generally work as long as their specifications meet or exceed those of the original. For testing, it is usually OK to use types that do not quite meet all of these as long as the BVceo and Ic specifications are not exceeded. However, performance may not be quite as good. For power types, make sure to use a heatsink.

5. Switching power supply transistors - exact replacement is generally best but switchmode transistors that have specifications that are at least as good will work in many cases. See the documents: "Notes on the Troubleshooting and Repair of Television Sets", "Notes on the Troubleshooting and Repair of Computer and Video Monitors", and "Notes on the Troubleshooting and Repair of Small Switchmode Power Supplies" for more info.

6. Video heads (and lower cylinders) - generally not possible unless it is a very similar model as even the mounting is usually unique to a particular manufacturer and it may change from model to model. However, since, multiple brands may be manufactured by the same company, substitution may sometimes be possible - check a cross reference (e.g., your parts supplier's catalog) for compatibility.

7. A/C and full erase heads - may be possible if the mountings are reasonably compatible. However, there could be other unknowns like coil impedance drive requirements. The connectors are not likely to be similar.

8. RF modulators - there is a certain amount of standardization. Therefore, if you have one that fits (or you can make it fit), this is worth an attempt.

9. Motors - small PM motors may be substituted if they fit physically. Capstan motors - especially the direct drive type - are probably not interchangeable.

10. Sensors - many are sufficiently similar to permit substitution.

11. Power transformers - in some cases, these may be sufficiently similar that a substitute will work. However, make sure you test for compatible output voltages to avoid damage to the regulator(s) and rest of the circuitry.

12. Belts, tires, and pinch rollers - a close match may be good enough at least to confirm a problem or to use until the replacements arrives.

13. Mechanical parts like screws, flat and split washers, C- and E-clips, and springs - these can often be salvaged from another unit.

The following are usually custom parts and substitution of something from your junk box is unlikely to be successful even for testing: SMPS (power supply) transformers, interstage coils or transformers, microcontrollers, other custom programmed chips, display modules, and entire power supplies unless identical.

Suggested Parts Suppliers

For general electronic components like resistors and capacitors, most electronics distributors will have a sufficient variety at reasonable cost. Even Radio Shack can be considered in a pinch.

However, for consumer electronic equipment repairs, places like Digikey, Allied, and Newark do not have the a variety of Japanese semiconductors like ICs and transistors, or VCR specific components like RF modulators, idler assemblies, belts, tires, pinch rollers, video heads, etc.

See the document: Major Service Parts Suppliers for some companies that I have used in the past and others that have been recommended.

For VCR parts in particular:

```
 Studio Sound Service            (Rebuild kits for many popular VCR switchmode
                                   power supplies, VCR parts, some components.
  U.S. Fax: 1-812-949-7743         They will be happy to identify specific VCR
  Email:                           part numbers as well based on model and
   studio.sound@datacom.iglou.com  description as well - see below.)
  Web: http://www.iglou.com/studiosound/
```

See the additional comments below about Studio Sound Service. (I have no affiliation with this company but have purchased parts from them.)

Also see the documents: "Troubleshooting of Consumer Electronic Equipment" and "Electronics Mail Order List" for additional parts sources.

VCR service parts and assistance for the do-it-yourselfer

(From: Frank Fendley (studio.sound@datacom.iglou.com).)

If you work on VCRs occasionally, for yourself or friends, you know that most VCR problems are mechanical in nature, and usually require a replacement idler, belt kit, or other small mechanical part. Most of these parts are inexpensive, but you run into a problem when you try to order from electronics distributors -- most require a $20 or $25 minimum order.

Studio Sound (see the previous section for contact info) stocks a large selection of VCR parts, including belts, idlers, gears, mode switches, semiconductors, etc, and will ship direct to you with no minimum order! Our prices are competitive with electronics distributors such as MCM and others, but you can order as little as one belt, and we'll ship it. Just the cost of the part, plus $5.00 shipping is all you pay. Many distributors charge $6.00 or $6.50 shipping, in addition to the $20 or $25 minimum order!

We'll even help you determine which part you need, if you don't have the part number - at no extra charge.

Need a part for a VCR? Fax or Email the information to us, and we'll respond with a price quote before you order. We accept check, money order, Visa or MasterCard - sorry, no CODs. Send all of the information you have (make, model, part description, part number if you have it), plus a return e-mail address or fax number, and we will be glad to give you a quote on your part. Don't wind up paying $25.00 plus shipping to get a $3.00 part! Let us help.

We also stock a large selection of Panasonic switch mode power supply rebuild kits, and have just added Samsung power supply rebuild kits to our line.

Used VCR parts

Perhaps they would get more respect if they were called 'previously owned' or 'broken-in' VCR parts. :-)

The following companies are sources for inexpensive used VCR parts:

- Allbrand Audio and Video Parts
  368 Ball Hollow Road
  Pulaski, Tennessee 38479
  Phone: 1-615-427-6262
  Email: allbrand@juno.com
  Web: http://www.usedvcrparts.com/

  Huge quantities of used and rebuilt VCR parts. A lower drum for a two-head machine usually goes for around $15. Major parts come with a 30 day warranty. Well, it beats no warranty, I guess!.)

- VCR Parts and Help for the Do-It-Yourself Technician. They will provide quotes (and assistance in identification) on new and used VCR parts via email. Site includes some information on VCR cleaning and troubleshooting.

These are even better than junk yards as they do the searching and pulling for you. For major subassemblies in older VCRs, this may be the only realistic economical option even if the original part is available from the manufacturer.

Other Sources

(This section from: ac557@detroit.freenet.org (Ted C. Gondert).)

Look in the Thomson (a.k.a. RCA and GE) "VCR/Camcorder Sourcebook" TCE publication # 1J9780 available from your local Thomson distributor. Publish date October 1994 (maybe newer version is out now) This book lists the most common parts for many brands and models of VCR and tells which Thomson or SK parts fit. Also has some solid state parts listed crossed to Thomson part #. RCA VR470 uses belt #192179 or SKBK0516 and pinch roller #202113. Similar to VR450 through VR475, made by Hitachi.

Service manuals for RCA/GE/Thomson are available from Thomson Consumer Electronics publications, P.O. Box 1976 Indianapolis IN (317)-267-5799. Or maybe their at 10003 Bunsen Way, Loisville, KY 40299.

Microfiche for VCR is about $10. Older model series are available by the year for good prices. I bought 1985 to 1990 for $50 or so. I have the microfiche for RCA VR470. Also looked through my file cabinet and found a printed service manual for VR470 in excellent condition, only used once. Have extra microfiche set for 1985 vcr including models VLT250 to VLT470, VLT600HF to VLT700HF, VLP800 to VLP970HF. I'll sell those service manuals for a good price maybe $15 or so? (will pay for shipping). Or I'll check with local high school electronics class if they want them. Don't know if they are still fixing vcr or not, last time I talked to instructor he said it was too many problems and they were getting away from repair.

Tandy (Radio Shack) can order PRB belts and have a CDROM to look up model # belt guide. For just one set of belts, Radio Shack is much more accessible to people then mail order with $20 minimum orders and shipping/handling.

SAFETY:

If all you are doing will be working on a video cassette, then common sense use of small screwdrivers and sticky tape will be all that is needed. :)

However, if the cover of the VCR needs to be removed, there will be a few additional precautions though most of these disappear if the VCR is unplugged from the electric outlet (or in the case of a camcorder, the battery pack is removed.

Once you remove the cover(s) of a VCR (ignoring the warnings about no user serviceable parts, etc.), there are some risks to you and your VCR. You also, of course, void the warranty (at least in principle). Therefore, if the unit is still under warranty, having it serviced professionally may be your wisest option.

Since nearly everything described below can and should be done with the plug pulled from the outlet, there is little danger to you electrically as long as you stay away from the power supply (usually where the cord connects) where some large capacitors may retain a charge for as much as few minutes.

There are, however, various sharp sheet metal brackets which will be out to attach you if you reach into the bowels of the VCR. Just be aware of this hazard as you poke and prod (but only where directed!).

To avoid damage to the VCR, don't turn anything you don't understand fully and stay away from the video drum (the roughly 2.5 inch diameter cylinder mounted on an angle (this is normal, don't use Vise Grips in an attempt to straighten it out!!!). The reason is that the parts of the VCR that scans the tape - the video heads - are very fragile being little chips of ferrite - a brittle ceramic material.

DISCLAIMER

Once a VCR becomes hungry or a long neglected tape turns to a pile of what looks more like adhesive tape, there is no guarantee that the situation can be resolved with damaged to either the VCR or partial or total loss of irreplacible family memories. For tapes you consider to be really valuable (or just those Tom and Jerry cartoons you treasure!), consider a professional video recovery service. They won't be cheap but will probably have a better chance of success than you will if you've never seen the inside of a VCR or cassette before.

We will not be responsible for damage to equipment, your ego, county wide power outages, spontaneously generated mini (or larger) black holes, planetary disruptions, or personal injury or worse that may result from the use of this material.

- Back to VCR First Aid Table of Contents.

Introduction

This document is intended to address those problems with your VCR that just cannot wait. For detailed troubleshooting and repair procedures, refer to "Notes on the Troubleshooting and Repair of Video Cassette Recorders" which is also available at this site. Most of the information in this article is a subset of what in in that document.

VCR behaving strangely

Try unplugging it for a couple of minutes. Sometimes, a power surge will put the internal microcomputer into a confused state and just resetting it is all that is needed.

Ejecting a cassette from an uncooperative VCR

It is a common experience - the rental movie is due back at the video store **now** but no matter how you press the EJECT button, yell, scream, hold your breath, or jump up and down, the cassette refuses to be appear.

This section only deals with getting the cassette out without damaging either your (or the video store's) valuable recording or VCR.

Under no circumstances should you force anything - both your tape and your VCR will be history! If the rental tape really needs to be go back and you are unable or unwilling to risk going into your VCR, explain the situation to the video store - they would rather you get it out in such a way that it is not damaged just as much as you do.

First, see if the VCR just got into a confused state - pull the plug and patiently wait a minute or two. This will seem like an eternity but may reset the microcontroller and all will be well. These things happen.

If this is not successful, you will need to open up the VCR (unplug it first!) and attempt to cycle the mechanisms by hand. Probably, both the top and bottom covers will need to be removed. This will require a medium size philips screwdriver. There are usually 2 to 4 screws on top and 2 to 10 screws on the bottom. Don't be tempted to turn anything you see in there just yet!

CAUTION: Do not plug the VCR into the AC outlet while in the middle of this treament as there is no telling what it will do. The end result might be more of a mess than what you had originally! The VCR might in its infinite wisdom decide to complete the eject cycle but catch the tape on some guidepost or crinkle it in some other creative manner.

The following procedures assume that there are no broken parts, foreign objects, or other damage which might prevent manual cycling of the tape loading and cassette loading mechanism. (Inspect for toys and rocks.) Also note that some VCR designs use solenoids to engage various operations. This will complicate your task (to put it mildly) as locating and activating the proper ones at the appropriate time is, well, a treat.

Please refer to the photo: Typical VHS VCR Tape Transport Components for parts identification. (Photo courtesy of: Brian Siler (bsiler@PROMUS.com).) This VCR is shown in the fully unloaded position. The roller guides are in their retracted position. The cassette itself and cassette mechanism (called the basket or carriage) have been removed. Assuming that your cassette is in and down in the loaded position, its front-end would be just covering the roller guides, backtension arm, and capstan.

Depending on what the VCR was doing or attempting to do when it got confused, you may need to do both (1) and (2) or just (2). (For Panasonic and clone VCRs, see the section: Removing the cassette from Panasonic and clone VCRs.

1. Tape unloading: The first step is to determine if the tape has been unloaded from the video head drum back into the cassette. If the tape is fully retracted into the cassette - there is no tape showing, then go on to step (2). If not, you will need to figure out which shaft or pulley to turn to

unload the tape. Trace the linkage or gears that move the roller guide assemblies back to their motor - it may be the main capstan motor or a separate small motor used only for this purpose. (The roller guide assemblies include a white (usually) ceramic roller on a vertical post along side a funny looking tilted guidepost. They slide on tracks on either side of the video head drum and position the tape wrapped around the video drum.). Rotate this in the direction which moves the roller guides back towards the cassette.

It will take many revolutions - be persistent. If you feel any significant resistance or the roller guides move out toward the drum, turn the other way. The tape is fully unloaded when the roller guides are all the way into the cassette and the tape is straight across the cassette's stationary guideposts.

If turning the shaft is impossible, you can disconnect the wire leads going to the motor from the circuit board and apply 6 to 12 VDC from a battery, power supply, or wall adapter directly to the motor. It is essential to disconnect the motor completely to prevent damage to the circuitry in other parts of the VCR. Take care - reverse the connections if it seems to spin in the wrong direction and don't let it force anything. Motion should be smooth.

If a single motor performs both the tape loading and cassette loading functions, stop turning as soon as you see the cassette start to rise and read the next section before proceeding.

If you are not fully successful or if there is still a tape loop outside the cassette even once you have been turning for what seems to be an eternity, you can still try to eject the cassette but will need to be extra careful not to crinkle the tape as the cassette door closes with the tape sticking out. Before proceeding on in this case, try to find a way to turn one of the reels to pull that tape back in as this will make your task a lot easier. There may be an idler that swings between the two reels and this may be accessible from the bottom (the cassette will block it on top).

Sometimes, if for some reason the tape in the cassette is a bit loose when you go to insert it into the VCR, the tape may jump over a guide post or the pinch roller as the cassette is lowered into position. This tape will then get caught when the VCR goes to eject the cassette - it may come half way out and get hang up on the tape loop. The VCR then tries in vain to complete the eject sequence but gives up after a few seconds. It then either just shuts down or pulls the cassette back into position on the transport. If this happens, the tape is almost certainly damaged enough to be unusable and cutting the tape may be the easiest option. If you want to save what is on the tape, see the section: Recovering damaged or broken tapes.

2. Cassette unloading. Once the tape is fully retracted into the cassette, the cassette can be ejected safely. If a tape loop is still sticking out of the cassette - and you care about the recording - you will need to be especially careful not to crinkle the tape as the cassette door closes. It is usually not possible to get the cassette fully out without its door closing, so the best you can do is to make sure when this happens, the tape is flat across the gap. With care, it should survive.

   On a top loader, there is usually a solenoid specifically for EJECT or a simple mechanical pushbutton. Once the appropriate lever is pressed, the cassette should pop up - hold the basket with one hand as you do this to prevent any exposed tape loop from being crinkled.

On a front loader, locate the cassette loading motor and begin turning it in the appropriate direction - this will be fairly obvious assuming there are no broken gear teeth or other broken parts and that something isn't totally jammed. If this is the main capstan motor, then just continue turning as in (1). Eventually the cassette should raise up and out.

As above, applying external low voltage power (6 to 12 VDC) to the motor *after* disconnecting it is an alternative if you cannot gain access to its shaft to turn it by hand.

If you have a tape loop, be extra careful not to catch it on any guideposts or obstructions as you remove the cassette. Then, wind it back into the cassette by turning one of the reels (you may have to depress the release button on the bottom of the cassette with a pencil - this is the small hole in the center near the label side.)

And in some cases, just turning the VCR upside-down and gently easing the cassette out will work. But as noted, don't force anything.

Assuming the tape is not torn and not badly crinkled, it should be fine. If it is severely damaged, refer to the section: Recovering damaged or broken tapes.

Removing the cassette from Panasonic and clone VCRs

About now (1998), a variety of VCRs manufactured by Matsushita (these include Panasonic and several other brands) in the late 1980s and early 1990s are dying (or at least going into a coma) due to capacitors drying up in their power supplies. Thus, it is very common to attempt to turn on one of these VCRs and find it totally unresponsive. (These ARE easily repairable - see the companion VCR repair guide, "Notes on the Troubleshooting and Repair of Video Cassette Recorders" for more info. Among the panasonic models are those beginning with PV28 and PV48.

To determine if your VCR was made by Matsushita, search for its FCC number at: List of FCC ID numbers. One way to identify this mechanism is to remove the top cover (power off!): A large circuit board covers nearly everything but the area of the cassette and a white plastic circular knob like thing (great description, huh?) is visible poking though near the right hand side just beyond the cassette (DON'T touch or turn it!).

You will need to remove the bottom cover.

On this design where a single motor operates everything, there is a little tab next to the main gear (underneath near the capstan motor). Gently pressing this tab sideways (away from the gear) allows the mechanism to cycle through the various tape and cassette loading and unloading operations.

With the tab in the engaged position, turning the main motor or the big flywheel counterclockwise unloads the tape from the video heads, retracts the roller guides, and winds the tape back into the cassette, and then ejects the cassette itself. The tab will have to be engaged several times to accomplish all these tasks. DON'T force anything as it will move easily unless there is something binding or you reach the end of its travel. Take care that a loop of tape doesn't get caught behind a guide post or pinch roller. With care, the cassette will pop out as though nothing were wrong :-).

Manually winding a loop of tape back into the cassette

When you extract a tape from an uncooperative VCR, there is likely to be a loop of tape dangling in mid-air. Where the tape tape hasn't been seriously crinkled, mashed, torn, or otherwise damaged, it may be possible to get it back into the cassette with low risk of further problems.

WARNING: If the loop of tape is badly crinkled, mashed, at all torn, or damaged in any other way such that it could catch the spinning video heads, throw it away. If you must save the material, see the section: Recovering damaged or broken tapes.

There is a hole in the bottom of the cassette about 1/4" in diameter in the middle approximately 1 inch from the label side (front). Depress this with a suitable tool (a pencil will usually suffice), and the reels will be free to turn. Carefully wind the tape back into the cassette. That's it!

Video turns to snow while watching a movie

The most likely cause especially with old or rental tapes is that some oxide came off of the tape and clogged the spinning video heads. The oxide on old tapes tends to flake off and rental tapes are subject to abuse in VCRs of questionable pedigree. They may be creased or crinkled. Sometimes more serious damage results but in most cases, a good cleaning of the video heads (and other parts of the transport while you are at it - see the VCR FAQ additional info), possibly by hand, will restore your VCR to perfect health.

CAUTION: Read the following in its entirely to avoid an expensive lesson. Improper cleaning can ruin your expensive video heads. The head chips are very fragile and just rubbing them in the wrong direction (NEVER use an up-and-down motion) can break them completely off.

Manual cleaning using the proper head cleaning sticks is best but requires that you gain access to the interior of your VCR - i.e., take off the cover.

If you do not want to do this, you can try a wet type head cleaning tape. I do not recommend the dry type as they are much more abrasive and may cause premature wear of your video heads especially if used regularly. When using the wet type cleaning tapes, follow the directions and - very important - wait sufficient time for everything to dry out

CAUTION: If you do not wait long enough, the conseqauences can be unfortunate (and impressive) - wads of tape wrapped around the drum and caught in places where no tape should tread. Damage to the heads can also result. Needle to say, that tape will be ruined.

To clean by hand, you will need what are called 'head cleaning sticks'. These are covered by chamois and are safest. DO NOT USE QTIPS (COTTON SWABS). These can catch on the ferrite cores and damage them or leave fibers stuck in the heads. QTips can be used for cleaning the other parts like the rollers and audio/control head but not the video heads.

To use the cleaning stick, moisten it with head cleaner or alcohol. Pure isopropyl is best, however, the 91% medicinal stuff is ok as long as you dry everything pretty quickly. Don't flood it as it will take a long time to dry and you run the risk of any water in the alcohol sitting on surfaces and resulting in rust (very unlikely, but don't take the chance).

WARNING: Do not use any strong solvents like acetone (nail polish remover), paint thinner, fuming sulphuric acid, etc. Some of these may eat at the adhesives or plastic components of your VCR.

Gently hold the flat portion of the chamois against the upper cylinder where it is joined to the lower (non-rotating) cylinder. Rotate the upper cylinder be hand so that the heads brush up against the moist chamois.

WARNING: DO NOT MOVE THE HEAD CLEANING STICK UP-AND-DOWN - you will break the fragile ferrite of the heads - $$$$. Side-to-side is ok as long as you are gentle.

Depending on how dirty your heads are, a couple of passes may be enough. Let everything dry out for at least 1/2 hour. This process can be repeated. However, one pass will usually do it.

In addition, inspect and clean the drum itself staying safely away from the video head chips. The five fine grooves in the drum help control the air bearing that the tape rides on and helps to stabilize tape motion. These should be clear of dirt and tape oxide (DO NOT use anything sharp or hard - the moistened head cleaning sticks will work).

WARNING: Don't be tempted to try to clean the heads when they are spinning while playing a tape. Professionals may have their favorite technique but just stick to the recommendations above until you have cleaned your 1000th VCR!

Recovering damaged or broken tapes

So you just pulled your favorite tape from the VCR and there are two tape ends dangling from it. Or, perhaps, your VCR has just munched on that tape and a section is now seriously crinkled. (If it's only slightly crinkled, see the section: Uncrinkling a crinkled tape.) Maybe you haven't been following the recommendations on preventive maintenance; maybe your VCR was just hungry. In any case, what to do? The recording is, of course, irreplaceable.

If it is only slightly crinkled, the tape may be salvageable (though it will never likely play without some dropouts). How serious is 'serious'? Hard to say but ironing may help. See the section: Uncrinkling a crinkled tape.

However, if it is broken - even partially, or stretched and scrunched, I recommend you throw it away (and make sure no one else can pull it out of the trash and ruin *their* VCR!).. An imperfect splice or seriously crinkled section of tape can shatter your video heads - the most expensive single part in a VCR. If it is something you really treasure, than what I would do is to follow the procedure below.

Note: If you have never seen the inside of a video cassette, try the following on a couple you really don't care about first so that if you screw up, there is no great loss. Too bad AOL doesn't send out Internet software on video cassettes, huh?

CAUTION: The video tape itself is really really thin and easily crinkled. Be very gentle when handling it and avoid touching the oxide (dull side) if at all possible.

1. Locate a garbage cassette and disassemble it. Throw away the tape but save everything else including the reels. See the section: Disassembling a VHS cassette.

2. Construct two cassettes from the combined collection of parts you now have. Cut out any sections of tape that got mangled.

    - Cassette 1 has the first section of tape (before the break) and uses one empty reel from the garbage cassette for the supply reel. Rewind this to the beginning.

    - Cassette 2 has the second section of tape (after the break) and uses the other empty reel from the garbage cassette for the takeup reel.

    Use the little plastic plugs that came from the garbage tape reels or some adhesive tape to connect the tape to the reels.

3. If the break is at one end, you can just reconnect the bulk of the tape to the reel and dispose of the original leader. Just don't rewind or fast forward all the way to the end as the automatic end sensor will not work (for the particular end that has been repaired). What will happen is that instead of the sensor stopping REW or FF (as appropriate), the tape will run to the end and the VCR will then shut down when it discovers that the tape isn't moving. This can put additional stress on mechanical parts and/or rip the tape from the reel. Serious damage to the VCR isn't really that likely.

4. Copy to a good cassette.

5. Dispose of the original(s) or clearly mark 'DO NOT USE' with a detailed explanation.'

    Filip (I'll buy a vowel) Gieszczykiewicz (filipg@repairfaq.org) is a little more definitive about this: "I find the destruction of it more fulfilling :-) ... put it in a paper bag and smash the life out of it with a big, heavy hammer - or a small ball hammer for an even higher satistfaction ratio :-) "

The idea is to never have a splice in a VHS cassette. (Even a seriously crinkled tape such as might result from a tape eating incident can damage the heads.) It is possible to splice safely but as noted, it can be quite costly if you don't get it quite right.

Uncrinkling a crinkled tape

WARNING: Discarding a seriously crinkled tape is really the safest option from the point of view of the health of your VCR. However, if you really must view it, there are some relatively low risk options. The following only applies if there is absolutely NO evidence of even partial breakage or puncture of the tape's backing (it's OK if some of the oxide has flaked off):

Just winding the damaged section back into the cassette and then FFing or REWing as appropriate to put several layers of tape on top of it may help. Leave it like that for a few days and then carefully return to the crinkled section to see how it is doing. WARNING: Do all this on a VCR that DOESN'T have an instant response transport so that there is no chance of the video heads contacting the damaged part of the tape. You may have to do this a few times.

Passing the damaged section (backing side) around a blunt edge (like a table top) back and forth a few times may help as well.

(From: Paul K. Sagi (paul_sagi@astro.com.my).)

I had a go at a seriously crinkled VHS tape that my mom was wanting to show her class at temple. I put the crinkled section between pieces of the kind of paper that is sold for some kind of cooking use, can't remember what it is called. I then ironed it (heat only, no steam) and it worked OK except a couple of seconds dropout."

(From: Steven Van Assche (steven.vanassche@bluebottle.com).)

CAUTION: Use with care!!

I use the following: Get your iron, the one used for T-shirts, not your soldering iron! ;-)

What I do:

1. Let the iron warm up.

2. Release the reel latch by pushing something in the hole on the bottom, disengage and lift the lid, and then pull the tape gently out of the cassette. Make sure the *backside of the tape is lying upwards*.

3. Now go in one pass from left to right over the crinkled part with the iron. You can repeat this, if needed. Due to the heat, most crinkles will go away.

Now, to play it safe, copy it to another tape. and mark the old one as damaged.

The most important factor here is heat: Too hot and you will burn the tape instantly while too cold and nothing will happen. It is best to start from cold to warm, and slowly increase the heat until you see an improvement...

Disassembling a VHS cassette

These instructions should enable you to get inside a cassette for the purpose of reattaching a leader that pulled off of one of the reels or to enable you to transfer its contents or a portion thereof to another shell or vice-versa.

1. Peel off the label on the side or carefully slice down its center line with a knife or razor blade. This is necessary to allow the cassette halves to be separated.

2. Place the cassette upside-down and remove the five (5) phillips head screws and set aside.

3. While holding the cassette together, place it label side up on a clean surface.

4. Gently remove the top (along with the hinged door) to reveal the interior.

At this point, you should see something that looks like VHS Cassette - Inside Top View.

When you reassemble the cassette, take care to avoid crunching the tape under the hinged door - depress the unlock button on the side and lift it clear if needed.

Restoring old gummed up tapes

Where you have some really old tape that won't play or leaves excessive residue on the heads and elsewhere, it may be worth considering the info in the Curing Sticky Tape Problems by Baking Page. I have not tried this so can't guarantee that it will work and could make the problem worse. For really precious tapes, consider a professional video tape recovery service.

What about accidentally erased tapes?

Unfortunately, there isn't much hope if your prized wedding cassette got recorded over with the Simpsons. In fact, in a normal VCR, recording over a tape erases the original material twice: once using the stationary erase head and a second time by the rotating video heads. Even the combined might and technology of the FBI, CIA, NSA along with MI5 and the KGB would probably not succeed. Sorry.

Introduction

Scope of This Document

This is a collection of various useful and interesting schematics. Some of these are also referenced by or included in other documents at this site. Some are my own designs while many have been reverse engineered from commercial equipment. Many are the sorts of circuits you won't find in any textbook or in any other readily available on-line or print media. Some are just cute. :)

Safety Considerations

Some of these circuits operate at extremely lethal voltage and current levels. The energy storage capacitors in even the smallest disposable camera flash operating from a 1.5 V AA battery can be deadly under the wrong conditions. Line powered devices - including little ones - may have an added danger of high power at high voltage AND are often non-isolated (no power transformer). Do not attempt to troubleshoot, repair, or modify such equipment without understanding and following ALL of the relevant safety guidelines for high voltage and/or line connected electrical and electronic systems.

Related Information

Before thinking about experimenting with anything using or producing high voltages or connected to the AC line - even opening up a disposable camera that may have been laying around gathering dust (the capacitor can still be charged - outch!), see the document: Safety Guidelines for High Voltage and/or Line Powered Equipment. Something that looks innocent can really ruin your entire day!

Perhaps the larges collection of all sorts of on-line schematics and links in the explored universe can be found Tomi Engdahl's Lights and Electronics Page.

There are many other documents at the Sci.Electronics.Repair (S.E.R) FAQWeb site or one of its mirror sites which may be of use in the design, testing, and repair of electronic equipment. The Main Table of Contents (ToC) provides links to a variety of information on troubleshooting and repair of many types of equipment, general electronics, an assortment of schematics, over 1,000 technology links, and much more. Most of these documents are nicely formatted, indexed, and cross-referenced. (Silicon Sam's Technology Resource, which may be present at this site and others, usually contains slightly more recent versions of many of these same documents but most of those under the S.E.R FAQ Main ToC are easier to use and the actual content differences are likely to be minor.)

- Laser power supplies and other laser related schematics will be found in the document: Sam's Laser FAQ: Safety, Diode Lasers, Helium Neon Lasers, Drive, Info, Links, Parts.

- Additional electronic flash and other strobe related schematics will be found in the document: Notes on the Troubleshooting and Repair of Electronic Flash Units and Strobe Lights and Design Guidelines, Useful Circuits, and Schematics.

- Information on isolation transformers (essential for safety) and variable transformers (Variacs), series light bulb adapter, and other Incredibly Handy Widgets(tm) for your test bench will be found in the document: Troubleshooting and Repair of Consumer Electronic Equipment and possibly in the specific document for each type of equipment.

- General nifty gadget and other pack rat stuff can be found in the document: Salvaging Interesting Gadgets, Components, and Subsystems which identifies useful components which may be removed from common consumer electronics and appliances as well as unconventional uses for their subsystems, modules, or replacement parts.

See the Home and Mirror Site Locations for other possibilities which may be faster from where you live.

High Voltage Power Supplies

Simple High Voltage Generator

This basic circuit is capable of supplying up to 30 kilovolts or more from a low voltage DC source using a flyback (LOPT) transformer salvaged from a TV or computer monitor. Typical output with a 12 VDC 2 A power supply or battery will be around 12,000 V. Current at full voltage is typically around 1 to 2 mA. Higher currents are available but the output voltage will drop. At 2 kV, more than 10 mA may be possible depending on your particular flyback transformer.

- Go to: Simple High Voltage Generator - Low Voltage DC In, up to 30 kV Out

---

- Back to Sam's Schematic Collection Table of Contents.

Adjustable High Voltage Power Supply

This circuit uses a pair of 555 timers to provide variable frequency variable pulse width drive to an inverter using a flyback transformer salvaged from a black and white or color TV or computer monitor. At very low repetition rates, it will produce individual sparks. At high rates with a low uF value high voltage capacitor, the output will essentially be HV DC with a specific value dependent on input voltage, pulse rate and width, and load. None of the component values is critical. The particular transistor used for Q2 seemed to be zappier better than a common horizontal output type but they work as well.

The input voltage can range from about 5 to 24 V. Using a flyback from a MAC Plus computer which had its bad primary winding excised, an output of more than 20 kV was possible (though risky since the flyback is probably not rated for more than about 12 kV) from a 24 VDC, 2 A power supply. By adjusting the drive frequency and duty cycle, a wide range of output voltages and currents may be obtained depending on your load.

With the addition of a high voltage filter capacitor (0.08 uF, 12 kV), this becomes a nice little helium neon laser power supply which operates on 8 to 15 VDC depending on required tube current and ballast resistor. See the document: Sam's Laser FAQ.

The transistor types are not critical. Those were selected basically because I had them in my junk box. A TV or monitor horizontal output transistor (HOT) should be satisfactory for the chopper but will require good strong drive. The lower voltage, high current transistor I used (2SD797) has both a higher current and higher Hfe rating than typical HOTs. Even a 2N3055 will probably survive and not be too bad in the performance department.

The drive transformer is from a B/W computer monitor (actually a video display terminal) and has a turns ratio of 4:1 wound on a 5/16" square by 3/8" long nylon bobbin on a gapped ferrite double E core. The primary has 80 turns and the secondary has 20 turns, both of #30 wire. Make sure you get the polarity correct: The base of the switching transistor should be driven when the driver turns on. You should be able to wind a transformer similar to this in about 10 minutes if a similar size (doesn't need to be exact) core is available.

Where the flyback includes an internal rectifier and/or you are attempting to obtain the maximum output voltage of a specific polarity, the direction of drive matters as the largest pulse amplitude is generated when the switching transistor turns off. Since flyback transformers are not marked, you will have to try both possible connections to the drive coil. Use the one that produces the higher output voltage for a given set of input conditions (drive and pulse rate/width).

Many variations on this basic circuit are certainly possible. The dual 555 circuit can be reduced to a single 555 with some loss in flexibility (unless you use the cute non-standard modification that allow independent adjustment of the high and low times - left as an exercise for the student).

One nice thing about running it at 24 VDC or less (as opposed to line voltage) is that it is much more difficult to let the smoke out of th circuit! The 5 A power supply I was using shut down on several occasions due to overcurrent but the only time I blew the chopper transistor was by accidentally shorting the base to collector.

- Get the schematic for HVGEN32 in PDF format: HVGEN32-SCH.

Evertron Model 3210 Gas Tube Power Supply

(Thanks to Jeff Zurkow (jeff@atrox.com) for reverse engineering this device and drawing the schematic.)

Evertron Model 3210 Gas Tube Power Supply is the schematic of an inverter type unit for driving a neon sign. It has a pair of power MOSFETs driving a flyback style high voltage transformer, with a whole bunch of open-wound primaries and a potted secondary.

- Back to Sam's Schematic Collection Table of Contents.

Ricoh 3E06-1 High Voltage Power Supply

This is the high voltage power supply for a Ricoh laser printer or copier as shown in Photo of Ricoh Model 3E06-1 High Voltage Power Supply. It has two *negative* outputs of -5.3 kVDC at 0.3 mA max (output C) and -5.7 kVDC at 0.4 mA max (output T). I assume these stand for something like "Corona" and "Transfer" based on their functions. The two sections are independent with the only components in common being the power connector and a filter capacitor. Each section is based on a TL494 PWM controller IC. This is the same one used in many/most PC power supplies. A Web search will quickly locate a datasheet. Separate enable inputs permit each voltage to be turned on individually. All the low voltage circuitry is exposed with the high voltage circuitry being inside a module filled with red goop. I have not yet ungooped it so the circuitry inside the potting is essentially guessed at this point. The two sections are on separate schematic pages which are virtually identical except for part numbers and a few part values:

- Get the schematic for RI-3E1 in PDF format: ri3e1sch.pdf and ri3e2sch.pdf.

The adjustments on each section are for the current limit, not output voltage as might be expected. The output voltage for each section is set by fixed resistors (one of which is inside the potted HV module).

- Output C (5.3 kV) is approximately Vref*R101/(R8||(R12+R13)).
- Output T (5.7 kV) is approximately Vref*R121/(R28||(R32+R33)).

It would be a simple matter to replace R12 or R32 to vary the C or T output voltages within a modest range (like 4 to 6 kV). But going too high is asking for smoke. :) If pots are used, make sure their maximum value will limit the output voltage to something reasonable.

Jacobs Ladders

The climbing arcs of old bad sci-fi movies are always a popular item. Just make sure you understand the safety implications before constructing one of these. See the document: Safety Guidelines for High Voltage and/or Line Powered Equipment.

- Go to: Jacob's Ladder (Climbing Arc) Construction

- Back to Sam's Schematic Collection Table of Contents.

Assorted High Voltage Circuits

Assorted High Voltage Circuits Introduction

These are assorted circuits which produce pulses or continuous high voltage for various purposes around the house. There is also an ultrasonic cleaner (sort of high voltage) here because it didn't seem to belong anywhere else. :-)

- Back to Sam's Schematic Collection Table of Contents.

Range, Oven, and Furnace Electronic Ignition

Many modern gas stoves, ovens, furnaces, and other similar appliances use an electronic ignition rather than a continuously burning pilot flame to ignite the fuel. These are actually simple high voltage pulse generators.

- Where starting is manual (there is a 'start' position on the control(s), a set of switch contacts on the control(s) provides power to the ignition module.
  - A problem of no spark with only one control indicates that the fault is with it or its wiring.
  - A problem with continuous sparking even with all the controls off or in their normal positions indicates a short - either due to a defective switch in one of the controls or contamination bypassing the switch contacts.
- Where starting is automatic, an electronic sensor, thermocouple, or bimetal switch provides power to the ignition module as needed.

The Harper-Wyman Model 6520 Kool Lite(tm) module is typical of those found in Jenne-Aire and similar cook-tops. Input is 115 VAC, 4 mA, 50/60 Hz AC. C1 and D1 form a half wave doubler resulting in 60 Hz pulses with a peak of about 300 V and at point A and charges C2 to about 300 V through D2. R2, C3, and DL1 form a relaxation oscillator triggering SCR1 to dump the charge built up on C2 into T1 with a repetition rate of about 2 Hz.

```

Bug Zapper 1

You know the type - a purplish light with an occasional (or constant) Zap! Zap! Zap! If you listen real closely, you may be able to hear the screams of the unfortunate insects as well :-).

The high-tech versions consist of a high voltage low current power supply and fluorescent (usually) lamp selected to attract undesirable flying creatures. (Boring low-tech devices may just use a fan to direct the insects to a tray of water from which they are too stupid to be able to excape!)

However, these devices are not selective and will obliterate friendly and useful bugs as well as unwanted pests.

Here is a typical circuit:

```
         S1        R1         C1            C2            C1-C4: .5 uF, 400 V
  H o----o/ o--+--/\/\--------||---+--------||---------+  D1-D5: 1N4007
               |  25K       D1    |   D2        D3    |   D4
               |         +---|>|---+---|>|---+---|>|---+---|>|---+
              +-+       |        C3        |        C4          |
 AC Line      |o| FL1    +---+----||----+----+---+----)|----+----+--o +
              +-+ Lamp    |   |    R3    |        |    R4    |       500 to
               |         |   +---/\/\---+        +---/\/\---+        600 V
```

```
               |    R2     |        10M                   10M              to grid
  N o----------+--/\/\---+------------------------------------------o -
                   25K
```

This is just a line powered voltage quadrupler. R1 and R2 provide current limiting when the strike occurs (and should someone come in contact with the grid). The lamp, FL1, includes the fluorescent bulb, ballast, and starter (if required). Devices designed for jumbo size bugs (or small rodents) may use slightly larger capacitors!

- Back to Sam's Schematic Collection Table of Contents.

Bug Zapper 2

This is your basic brute force approach!

(From: Andrew Bowers (falcon_@geocities.com).)

This is from my friend's bug zapper:

```
                        +----------------------+--o A
        H o-------+ ||(                        |
                   )||(                        |
         115VAC    )||(    Approx. 300V to     |
                   )||(    Fluorescent Tube    |
        N o-------+ ||(                        |
                    || +-----o F1    F2 o-----+
                    ||(
                    ||(
                    ||(
                    ||(
                    ||(
                    ||(
                    ||(
                    |  +-------------------------o B
        G o---------+
```

F1 and F2 connect to the ends of the purple fluorescent tube. A and B supply 5600VAC to the grid. We know this because it was one of the features of the zapper - said it right on the box in a big yellow sunburst: "5,600 Volts!!!". :)

This is your ultimate simple bug zapper -- no power switch, although the metal plate that the transformer and other parts are mounted on is grounded.

- Back to Sam's Schematic Collection Table of Contents.

Electronic Air Cleaner HV Generator

At least I assume this cute little circuit board is for an electronic air cleaner or something similar (dust precipitator, positive/negative ion generator, etc.)! I received the unit (no markings) by mistake in the mail. However, I did check to make sure it wasn't a bomb before applying power. :-)

This module produces both positive and negative outputs when connected to 115 VAC, 60 Hz line voltage. Each is about 5 kV at up to around 5 uA. It is probably similar to the high voltage power supply in the AirEase(tm) Personal Space Ionization Air Cleaner from Ion Systems, Inc., a small table top unit. (Unfortunately, the HV module in the AirEase was totally potted so I could not determine anything about its internal circuitry.)

```
                   D1                                           T1  o
  H o--------------|>|----+---+-------------------+               +-----o A

          IL1 LED   250V ---               _|_     |  +-------+ ::(
        +--|<|---+        |              C2 ---    |  |        )::(
        |   R1   |   R2   |        .0047 uF  |     |  | .1 ohm )::(
  N o---+--/\/\--+--/\/\--+                  +-----+--+        )::(
           470      3.9K  |                                 +--+    +--+--o B
           1 W      2 W   |                                 |    R4    |
                          +---------------------------------+---/\/\---+
                                                               2.2M
```

The AC input is rectified by D1 and as it builds up past the threshold of the sidac (D2, 100 V), SCR1 is triggered dumping a small energy storage capacitor (C1) through the primary of the HV transformer, T1. This generates a HV pulse in the secondary. In about .5 ms, the current drops low enough such that the SCR turns off. As long as the instantaneous input voltage remains above about 100 V, this sequence of events repeats producing a burst of 5 or 6 discharges per cycle of the 60 Hz AC input separated by approximately 13 ms of dead time.

The LED (IL1) is a power-on indicator. :-)

The transformer was totally potted so I could not easily determine anything about its construction other than its winding resistances and turns ratio (about 1:100).

```

                                 B o--+----------------------+
```

The secondary side consists of a voltage tripler for the negative output (HV-) and a simple rectifier for the positive output (HV+). This asymmetry is due to the nature of the unidirectional drive to the transformer primary.

From my measurements, this circuit produces a total of around 10 kV between HV+ and HV-, at up to 5 uA. The output voltages are roughly equal plus and minus when referenced to point B.

I assume the module would also operate on DC (say, 110 to 150 V) with the discharges repeating continuously at about 2 kHz. Output current capability would be about 5 times greater but at the same maximum (no load) voltage. (However, with DC, if the SCR ever got stuck in an 'on' state, it would be stuck there since there would be no AC zero crossings to force it off. This wouldn't be good!)

The secondary side circuitry can be easily modified or redesigned to provide a single positive or negative output or for higher or lower total voltage. Simply removing R4 will isolate it from the input and earth ground (assuming T1's insulation is adequate).

Where there is no high voltage from such a device, check the following:

- Make sure power is actually getting to the high voltage portion of the unit. Test the wall socket and/or AC adapter or other power supply for proper voltage with a multimeter.

- Excessive dirt/dust/muck/moisture or physical damage or a misplaced paper clip may be shorting it out or resulting in arcing or corona (a strong aroma of ozone would be an indication of this). With such a small available current (only uA) it doesn't take much for contamination to be a problem. Thoroughly clean and dry the unit and check for shorts (with a multimeter between the HV electrodes and case) and then test it again. Your problems may be gone!

- If this doesn't help and the unit is not fully potted (in which case, replacement is the only option), check for shorted or open components, especially the power semiconductors.

- Back to Sam's Schematic Collection Table of Contents.

Auto Air Purifier HV Generator

Well, maybe :-). This thing is about the size of a hot-dog and plugs into the cigarette lighter socket. It produces a bit of ozone and who knows what else. Whether there is any effect on air quality (beneficial or otherwise) or any other effects is questionable but it does contain a nice little high voltage circuit.

```
                                                                 DL1 +-+ |

```

T1 is constructed on a 1/4" diameter ferrite core. The D (Drive) and F (Feedback) windings are wound bifilar style (interleaved) directly on the core. The O (Output) winding is wound on a nylon sleeve which slips over the core and is split into 10 sections with an equal number of turns (100 each) with insulation in between them.

DL1 to DL4 look like neon light bulbs with a single electrode. They glow like neon light bulbs when the circuit is powered and seem to capacitively couple the HV pulses to the grounded grid in such a way to generate ozone. I don't know if they are filled with special gas or are just weird neon light bulbs.

- Back to Sam's Schematic Collection Table of Contents.

Ultrasonic Cleaner

Ultrasonic cleaning is a means of removing dirt and surface contamination from intricate and/or delicate parts using powerful high frequency sound waves in a liquid (water/detergent/solvent) bath.

An ultrasonic cleaner contains a power oscillator driving a large piezoelectric transducer under the cleaning tank. Depending on capacity, these can be quite massive.

A typical circuit is shown below. This is from a Branson Model 41-4000 which is typical of a small consumer grade unit. The H and N are Hot and Neutral of the 115 VAC line. WARNING: Line connected input. Use isolation transformer for safety when troubleshooting.

```

           |                   |   |        Output: 460 VAC, pulsed 80 kHz
  N o------+-------------------+---+
```

The power transistor (Q1) and its associated components form an self excited driver for the piezo-transducer (PT1). I do not have specs on Q1 but based on the circuit, it probably has a Vceo rating of at least 500 V and power rating of at least 50 W.

Two windings on the transformer (T1, which is wound on a toroidal ferrite core) provide drive (D) and feedback (F) respectively. L1 along with the inherent capacitance of PT1 tunes the output circuit for maximum amplitude.

The output of this (and similar units) are bursts of high frequency (10s to 100s of kHz) acoustic waves at a 60 Hz repetition rate. The characteristic sound these ultrasonic cleaners make during operation is due to the effects of the bursts occuring at 60 Hz since you cannot actually hear the ultrasonic frequencies they use.

The frequency of the ultrasound is approximately 80 kHz for this unit with a maximum amplitude of about 460 VAC RMS (1,300 V p-p) for a 115 VAC input.

WARNING: Do not run the device with an empty tank since it expects to have a proper load. Do not touch the bottom of the tank and avoid putting your paws into the cleaning solution while the power is on. I don't know what, if any, long term effects there may be but it isn't worth taking chances. The effects definitely feel strange. At high enough power levels, it could indeed pulverize bones as described below. Whether that could happen with the typical small ultrasonic cleaner, I don't know and am not about to find out!

> (From: BIll Perry (perry.williamr@tacamo.navy.mil).)
>
> "While stationed on board the now-decommissioned submarine USS Hawkbill (SSN-666), I pondered this as well. One of my senior shipmates related a story of a sailor who had done that very act on his previous submarine. The guy put his feet it the cleaner while it was powered on. He remarked that it felt very good and relaxing. After a few minutes, he pulled his feet out, and as soon as he stood up and applied his full bodily weight on his feet, all the bones in his feet had shattered. He got permanent disability from it. Apparently, it had rattled his bones apart. Wow!"

Where the device doesn't oscillate (it appears as dead as a door-nail), first check for obvious failures such as bad connections and cracked, scorched, or obliterated parts.

To get inside probably requires removing the bottom cover (after pulling the plug and disposing of the cleaning solution!).

CAUTION: Confirm that all large capacitors are discharged before touching anything inside!

The semiconductors (Q1, D1, D2, D3) can be tested for shorts with a multimeter (see the document: Basic Testing of Semiconductor Devices.

The transformer (T1) or inductor (L1) could have internal short circuits preventing proper operation and/or blowing other parts due to excessive load but this isn't kind of failure likely as you might think. However, where all the other parts test good but the cleaning action appears weak without any overheating, a L1 could be defective (open or other bad connections) detuning the output circuit.

Where the transistor and/or fuse has blown, look for a visible burn mark on the transducer and/or test it (after disconnecting) with a multimeter. If there is a mark or your test shows anything less than infinite resistance, there may have been punch-through of the dielectric between the two plates. I don't know whether this could be caused by running the unit with nothing in the tank but it might be possible. If the damage is localized, you may be able to isolate the area of the hole by removing the metal electrode layer surrounding it to provide an insulating region 1/4 inch in diameter. This will change the resonant frequency of the output circuit a small amount but hopefully not enough to matter. You have nothing to lose since replacing the transducer is likely not worth it (and perhaps not even possible since it is probably solidly bonded to the bottom of the tank).

When testing, use a series light bulb to prevent the power transistor from blowing should there be a short circuit somewhere (see the document: Troubleshooting and Repair of Consumer Electronic Equipment) AND do not run the unit with and empty tank.

Also see the info on ultraonic humidifiers in the document: Troubleshooting and Repair of Small Household Appliances.

Simple Linear Power Supplies

Simple Linear Power Supplies Introduction

This is a (currently somewhat meager) collection of basic power supply circuits that will hopefully grow as time passes.

- Back to Sam's Schematic Collection Table of Contents.

Converting an AC Output Wall Adapter to DC

Where a modest source of DC is required for an appliance or other device, it may be possible to add a rectifier and filter capacitor (and possibly a regulator as well) to a wall adapter with an AC output. While many wall adapter output DC, some - modems and some phone answering machines, for example - are just transformers and output low voltage AC.

This is also the simplest and safest way to construct a small DC power supply as you do not need to deal with the 110 VAC at all.

To convert such an adapter to DC requires the use of:

- Bridge rectifier - turns AC into pulsating DC.
- Filter capacitor - smooths the output reducing its ripple.
- Regulator - produces a nearly constant output voltage.

Depending on your needs, you may find a suitable wall adapter in your junk box (maybe from that 2400 baud modem that was all the rage a couple of years ago!).

The basic circuit is shown below:

```
            Bridge Rectifier   Filter Capacitor

    AC o-----+----|>|-------+---------+-----o DC (+)
            ~|              |+        |
   In from   +----|<|----+  |       +_|_   Out to powered device
   AC wall               |  |      C ___   or voltage regulator
```

```
Adapter   +----|>|----|--+       -  |
          |           |             |
 AC o-----+----|<|----+------------+-----o DC (-)
         ~                -
```

Considerations:

- An AC input of Vin VRMS will result in a peak output of approximately 1.4 Vin - 1.4 V. The first factor of 1.4 results from the fact that the peak value of a sinusoid (the power line waveform) is 1.414 (sqrt(2)) times the RMS value. The second factor of 1.4 is due to the two diodes that are in series as part of the bridge rectifier. The fact that they are both about 1.4 is a total coincidence.

  Therefore, you will need to find an AC wall adapter that produces an output voltage which will result in something close to what you need. However, this may be a bit more difficult than it sounds since the nameplate rating of many wall adapters is not an accurate indication of what they actually produce especially when lightly loaded. Measuring the output is best.

- Select the filter capacitor to be at least 10,000 uF per 1000 mA of output current with a voltage rating of at least 2 x Vin. This rule of thumb will result in a ripple of less than 1 V p-p which will be acceptable for many devices or where a voltage regulator is used (but may be inadequate for some audio devices resulting in some 120 Hz hum. Use a larger or additional capacitor or a regulator in such a case.

- Suitable components can be purchased at any electronics distributor as well as Radio Shack. The bridge rectifier comes as a single unit or you can put one together from 1N400x diodes (the x can be anything from 1 to 7 for these low voltage applications). Observe the polarity for the filter capacitor!

The following examples illustrate some of the possibilities.

- Example 1: A typical modem power pack is rated at 12 VAC but actually produces around 14 VAC at modest load (say half the nameplate current rating). This will result in about 17 to 18 VDC at the output of the rectifier and filter capacitor.

- Example 2: A cordless VAC battery charger adapter might produce 6 VAC. This would result in 6 to 7 VDC at the output of the rectifier and filter capacitor.

Adding an IC regulator to either of these would permit an output of up to a fraction to 2.5 V (depending on type) less than the filtered DC voltage.

- Back to Sam's Schematic Collection Table of Contents.

Adding an IC Regulator to a Wall Adapter or Battery

For many applications, it is desirable to have a well regulated source of DC power. This may be the case when running equipment from batteries as well as from a wall adapter that outputs a DC voltage or the enhanced adapter described in the section: Converting an AC output wall adapter to DC.

The following is a very basic introduction to the construction of a circuit with appropriate modifications will work for outputs in the range of about 1.25 to 35 V and currents up 1 A. This can also be used as the basis for a small general purpose power supply for use with electronics experiments.

What you want is an IC called an 'adjustable voltage regulator'. The LM317 is one example - Radio Shack should have it along with a schematic. The LM317 looks like a power transistor but is a complete regulator on a chip.

Here is a sample circuit:

```
                    I +-------+ O
    Vin (+) o-----+---| LM317 |---+--------------+-----o Vout (+)
                  |   +-------+   |              |
                  |       | A     /              |
                  |       |       \ R1 = 240     |
                  |       |       /              |           ___
                 _|_ C1   |       |            +_|_ C2      |_0_|  LM317
                 --- .01  +-------+             --- 1 uF    |   |  1 - Adjust
                  |  uF   |                    - |          |___|  2 - Output
                  |       \                      |           |||   3 - Input
                  |       / R2                   |           123
                  |       \                      |
                  |       |                      |
    Vin(-) o------+-------+----------------------+-----o Vout (-)
```

Note: Not all voltage regulator ICs use this pinout. If you are not using an LM317, double check its pinout - as well as all the other specifications. For a single output not referenced to a common, it doesn't matter whether a positive voltage regulator (as shown) or negative voltage regulator is used. However, were multiple power supplies like this are needed WITH a common point, negative voltage regulator ICs must be used for the negative ones.

Here are pinouts for the most common types:

```
  78xx (Fixed Pos)   79xx (Fixed Neg)    LM317 (Adj Pos)     LM337 (Adj Neg)

   ___                 ___                 ___                 ___
  |_O_|               |_O_|               |_O_|               |_O_|
  |   | 1 = Input     |   | 1 = Common    |   | 1 = Adjust    |   | 1 = Adjust
  |___| 2 = Common    |___| 2 = Input     |___| 2 = Output    |___| 2 = Input
   |||  3 = Output     |||  3 = Output     |||  3 = Input      |||  3 = Output
   123                 123                 123                 123
```

Note: Various manufacturers may label the pins differently than shown just to be confusing. For example, 1,3,2 instead of 1,2,3. However, the location of each pin will be the same so double check with the diagram.

For the LM317:

1. R2 = (192 x Vout) - 240, where R2 in ohms, Vout is in volts and must be at between 1.2 V and 35 V.

2. Vin should be at least 2.5V greater than Vout. Select a wall adapter with a voltage at least 2.5 V greater than your regulated output at full load.

   However, note that a typical adapter's voltage may vary quite a bit depending on manufacturer and load. You will have to select one that isn't too much greater than what you really want since this will add unnecessary wasted power in the device and additional heat dissipation.

3. Maximum output current is 1 A. Your adapter must be capable of supplying the maximum current safely and without its voltage drooping below the requirement in (2) above.

4. Additional filter capacitance (across C1) on the adapter's output may help (or be required) to reduce its ripple and thus the swing of its input. This may allow you to use an adapter with a lower output voltage and reduce the power dissipation in the regulator as well.

   Using 10,000 uF per *amp* of output current will result in less than 1 V p-p ripple on the input to the regulator. As long as the input is always greater than your desired output voltage plus 2.5 V, the regulator will totally remove this ripple resulting in a constant DC output independent of line voltage and load current fluctuations. (For you purists, the regulator isn't quite perfect but is good enough for most applications.)

   Make sure you select a capacitor with a voltage rating at least 25% greater than the adapter's *unloaded* peak output voltage and observe the polarity!

   Note: wall adapters designed as battery chargers may not have any filter capacitors so this will definitely be needed with this type. Quick check: If the voltage on the adapter's output drops to zero as soon as it is pulled from the wall - even with no load - it does not have a filter capacitor.

5. The tab of the LM317 is connected to the center pin - keep this in mind because the chip will have to be on a heat sink if it will be dissipating more than a watt or so. P = (Vout - Vin) * Iout.

6. There are other considerations - check the datasheet for the LM317 particularly if you are running near the limits of 35 V and/or 1 A.

7. For a negative output power supply, use the corresponding negative voltage regulator and note that their pinout is NOT the same as for the positive variety. See above!

- Back to Sam's Schematic Collection Table of Contents.

Dual Output Power Supply Using Centertapped Transformer

Where a centertapped secondary is available, a power supply outputting both positive and negative regulated or unregulated voltages can be constructed basically like a pair of the circuits above. The following would work for a +/- 15 VDC regulated unit to power analog circuitry like op-amps:

```
       28VCT,1A
   H o--+ T1
         )||       D1                   V+  In +------+ Out
         )|| +--+--|>|-----+--------------+----| 7815 |---------+----o +15 VDC
         )||(  ~|  D2      |         C1 +_|_   +------+    C3 +_|_
         )||(   +--|<|--+  |    5,000uF  ---   Com |     10uF  ---
         )||(  L1       |  |        25V - |        |       25V - |
 110 VAC )|| +----------------------------+--------+------------+--+-o Analog
         )||(  L2  D3   |  |         C2 +_|_       |       C4 +_|_ V   Common
```

```
        )||(   +--|>|--|--+    5,000uF  ---   Com |     10uF  ---
        )||(  ~|  D4   |          25V - |    +------+   25V - |
        )|| +--+--|<|--+-----------------+----| 7915 |---------+---o -15 VDC
        )||                            V-  In +------+ Out
  N o--+    D1-D4: 1N4007 or 2 A bridge
```

Note: Pinouts for 78 and 79 series parts are NOT the same!

For an unregulated supply, take the outputs from V+ and V-.

- Back to Sam's Schematic Collection Table of Contents.

Dual Output Power Supply Using Non-Centertapped Transformer

Without a centertap, it is still possible to provide both polarities of output voltage but a half wave configuration must be used. This is similar to the wiring of a voltage doubler but we are using the common point as ground:

Here is a circuit for a +/- 12 VDC supply:

```
       12V,1A
  H o--+ T1
        )||      D1           V+  In +------+ Out
        )|| +--+--|>|------------+----| 7812 |---------+----o +12 VDC
        )||(   |           C1 +_|_   +------+    C3 +_|_
 110 VAC )||(   |      10,000uF  ---   Com |     10uF  ---
        )||(   |           25V - |        |      25V - |
        )|| +--|----------------+--------+------------+--+-o Analog
        )||    |           C2 +_|_        |       C4 +_|_ V   Common
  N o--+       |      10,000uF  ---   Com |     10uF  ---
               |  D2       25V - |    +------+   25V - |
               +--|<|------------+----| 7912 |---------+---o -12 VDC
                               V-  In +------+ Out
```

For an unregulated supply, take the outputs from V+ and V-.

Since only half-wave rectification is used, the main filter caps, C1 and C2, should be at least twice the uF value compared to full wave or bridge circuits to obtain the same ripple.

Another disadvantage of this configuration is that if the currents drawn from the outputs aren't equal, net DC flows through the transformer secondary (with a voltage doubler having no output connection to the common point, this isn't possible). Core saturation may result if operating near the transformer's maximum current ratings.

- Back to Sam's Schematic Collection Table of Contents.

Higher Current Operation

By adding a PNP power transistor like a 2N2955 to either a fixed or adjustable regulator, maximum current can be easily increased. The circuit below will permit a very simple 3 to 5 A, 5 V power supply to be constructed assuming the power transformer/rectifier can supply this current. Q1 MUST be mounted on a large heat sink since it is dissipating power equal almost the entire output current times the difference between input and output voltage! Also, keep in mind that the filter capacitor(s) on the supply providing Vin must also be sized accordingly to keep ripple to a manageable level.

```
                 E     C
           +-----. Q1  .-------------+
           |     _\___/_             |
           |       B|                |
           |   R1   |   I +------+ O |
    Vin (+) o---+--/\/\--+-+---| 7805 |---+-+-----o Vout (+)
               5      |   +------+     |              ___
                      |       | C      |             |_O_|  7805
                     _|_ C1   |       +_|_ C2        |   |  1 - Input
                     --- .01  |        --- 1 uF      |___|  2 - Common
                      |  uF   |       - |             |||   3 - Output
                      |       |         |             123
    Vin(-) o--------------+-------+--------+-----o Vout (-)
```

The way this works is that once the current exceeds about Vbe(Q1)/5 A, Q1 turns on and bypasses current around the 7805.

For a negative supply based on a 79xx regulator, use an NPN transistor like a 2N3055 and reverse the capacitor polarities. Don't forget that the pinout for the 79xx and other negative voltage regulators is NOT the same as for the positive variety. See the section: Adding an IC Regulator to a Wall Adapter or Battery.

- Back to Sam's Schematic Collection Table of Contents.

Adjustable High Current Regulated Power Supply

This adds a gain stage to improve regulation compared to the circuit in the section: Higher Current Operation and is shown using an adjustable regulator though a fixed regulator could also be used. This is similar to the circuit in the Texas Instruments LM317 datasheet. Although not specified, I expect this is good for up to 5 A or more depending on the actual voltage difference between input and output and the size of the heat sink used for the power transistor, Q2.

```
+------------------.C   E.-------+
|               Q2 _\___/_       |
|            2N3055    |         |
|                      |    R5   |
+---------.E   C.------+---/\/\---+
|      Q1 _\___/_          500   |
|  2N2905     |                  |
|             / R4               |
|             \ 5K               |
|             /                  |
```

```
            |      R3    | I +-------+ O      | 1N4002
Vin (+) o---+-+---/\/\---+---| LM317 |---+----+--+------+-------+---o Vout (+)
              |    22      +-------+   |       |      |       |
              |                  | A     /      _|_     |       |
              |                  |       \ R1   /_\ D1  |       |
              |                  |       / 120   |      |       |
             _|_ C1              |       |       |    +_|_ C2   /
             --- 10uF            +-------+---+---+     --- 47uF \ RL*
              |                  |           |        - |       /
              |                  \ R2       +_|_ C3     |       |
              |               +->/ 5K        --- 10uF   |       |
              |               |  \         - |          |       |
              |               |  |           |          |       |
Vin(-) o------+---------------+--+-----------+----------+-------+---o Vout (-)
```

* For proper regulation, RL must be low enough in value to guarantee at least a 30 mA current at the selected output voltage. It can be a separate resistor or part of the actual load.

For even higher current operation, multiple power transistors (Q2) can be wired in parallel as a pass-bank with small (e.g., .1 ohm) emitter resistors to balance the load. In this case, Q1 may need to be a slightly bigger transistor and R4 reduced in value to provide adequate base drive. Details will depend on your particular needs.

As with the other circuits, a negative power supply can be constructed by using the appropriate regulator IC, swapping NPN or PNP transistors, and reversing all the polarities of the capacitors and diode.

- Back to Sam's Schematic Collection Table of Contents.

1.5 V Alkaline Cell Eliminator

I constructed this to provide a means of testing and experimenting with electronic flash circuits and (modifications to these circuits) that run on single Alkaline cells as their appetite for these is quite huge. See the section: Up to 350 VDC Inverter from 1.5 V Alkaline Cell.

```
                                         IC1
               D1                   I +--------+ O
            +--|>|--+-----+--------+--| LT1084 |--+------+-----o +1.5 VDC
       T1   |       |     |        |  +--------+  |      |
H o--+      |  D2   |     |        |      | A     / R1   |          IC1
      )|| +-+--|<|--|-+   |        |      |       \ 220  |        LT1084CP

            +--|<|----+---+--------+------+--------------+-----o Return
```

The power transformer (T1) that I used was actually rewound from one that was rated at 12 V, 1 A. This was a high quality transformer, so removing 2/3rds of the secondary was quite a pain. Actually, the purpose was an experiment to see if it could be done non-destructively. Conclusions: Just barely. :-) Obviously, a transformer actually designed to produce about 4 or 5 V at 3 A could also be used.

D1 to D4 can be individual diodes or a bridge rated for at least 3 A.

The regulator (IC1) is an LT1084CP which is similar to an LM317 but is a low dropout type rated at 5 A max. I had a pile of these left over from a certain multi-million dollar project that had been cancelled due to upper management foot in a** disease..... An external pass transistor may be needed to use an LM317 because of the peak current requirement.

Despite the transformer only being rated for 1 A, with IC1 on a modest heatsink, the supply seems perfectly happy putting out 3 A at 1.5 V for an extended period. I don't know that I would run it all day at this high current but for my purposes, it seems fine.

It turns out that the typical electronic flash circuit from a disposable camera like the Kodak MAX (see Schematic and Photo), actually draws more than 3 A at the start of its recharge cycle. So, the voltage does dip a bit but this doesn't affect much of anything. Recharge time with the power supply is at least as rapid as with a fresh Alkaline cell. The voltage from an Alkaline cell also dips a bit under these conditions.

Obviously, the circuit could be easily modified to put out 2.4 VDC (for a pair of NiCd cells), 3 VDC (for two Alkalines), or whatever else you might need.

Full Wave Voltage Doubler

A problem with most voltage doubler circuits is that the positive and negative outputs operate on alternate half-cycles so ripple is at the power line frequency rather than at twice the power line frequency. The transformer is also not utilized efficiently since only half of the secondary winding is passing current at any given time.

Here is a cute circuit that gets around both these problems. The original article is at: George Hrischenko's Genuine Full Wave Voltage Doubler Page.

```
   +-----------------+
||(                  |      +
||(        +---|>|---+-+---)|-----+---|>|---+
||(        |   D1      |   C1     |    D5    |
||(        |           |   D3     |          |
||(        |           +---|>|--+ |          |
||(   +----+                    | |          +---+
||(  _|_   |           +---|>|--|-+          | +_|_
||( ////   |           |   D4   |            |  --- C3
||(        |   D2      |   C2   |     D6     |  _|_
||(        +---|>|-+---+---)|---+-----|>|---+ ////
||(                |         +
   +---------------+
```

The output voltage is approximately 2.8 times the RMS rating of the transformer secondary (primary not shown). Ripple is at 2X the power line frequency.

Boost Supply for PC

Boost Supply to Produce Clean Regulated +12 VDC shows an approach for getting a higher voltage than +12 VDC from an unmodified PC power supply. In this specific case, a source of +12 VDC for an audio or instrumentation PCI card was needed to be derived from the normally noisy +12 VDC output of a standard PC power supply. Any filtering would reduce the voltage below an acceptable level. The 555 implements an oscillator that runs at somewhere around 50 kHz which drives the MOSFET chopper and stepdown transformer to generate a few VDC which is added to the original 12 VDC from the PC. This is then regulated down using the 7812. By only generating a few V boost (just enough for the dropout requirements of the linear regulator) rather than the full output voltage, the components can be smaller since less power is involved.

Obviously, other voltages than +12 VDC can be produced in this manner - the example was a coincidence.

This could also be done with fewer components using modern SMPS ICs designed DC-DC converter applications but I don't have any suggestions off-hand.

Switching Power Supplies

Panasonic VCR Switching Power Supply (PV48XX and Clones)

This circuit was reverse engineered from the switching power supply from a Panasonic VCR. It is typical of the small switchers used in the Panasonic PV28XX, PV48XX, and many other models, their Magnavox clones, as well as other Matsushita manufactured VCRs. Many VCRs of other brands use similar designs.

Errors in transcription are possible. Some models use additional outputs each fed from a single rectifier diode and filter capacitor (not shown). Some part numbers and the connector pinout may not be the same for your particular VCR.

A totally dead supply with a blown fuse usually means a shorted switchmode power transistor, Q1. Check all other components before applying power after replacement as other parts may be bad as well.

The most common problems resulting in low or incorrect outputs are dried up or leaky electrolytic capacitors - C4, C16, C17, C21.

See the document: Notes on the Troubleshooting and Repair of Small Switchmode Power Supplies for more info.

- Get the schematic for VCRPS in PDF format: VCRPS-SCH.

Power Supply for Small SVGA Color Monitor

This is the complete schematic for the switchmode power supply (SMPS) from a small (probably 14 or 15 inch) "I guarantee you never heard of the brand name" SVGA color monitor.

The AC line input and degauss components are at the upper left, the SMPS chopper, its controller, and feedback opto-isolator are in the lower left/middle, and the secondaries - some with additional regulation components - occupy the entire right side of this diagram. Even for relatively basic application such as this, the circuitry is quite complex. There are more than a half dozen separate outputs regulated in at least 3 different ways!

The variable voltage B+ regulator is in the upper right corner. This provides an voltage to power the horizontal deflection which is determined by the video input. To maintain the same picture width, the required voltage to the horizontal output transistor/flyback needs to be roughly proportional to horizontal scan rate.

Inverter Circuits

Inverter Introduction

Most of these circuits were reversed engineered from commercial products. The good news is that this means they probably all work somewhat reliably. The bad news is that a custom wound transformer (you can build in most cases) will be needed and there may be errors in the number of turns and wire sizes listed since these were all determined without totally dismembering the unit in question.

However, the circuit described in the section: Super Simple Inverter" only requires off-the-shelf components but has a pitiful efficiency. But construction is, well, super simple :-).

And, it should be easy to make modifications to the flash units from pocket or disposable cameras as described in the section: Up to 350 VDC Inverter from 1.5 V Alkaline Cell since these are quite readily available for free if you know where to ask!

For more information on fluorescent and xenon lamps, see the documents: Fluorescent Lamps, Ballasts, and Fixtures and Notes on the Troubleshooting and Repair of Electronic Flash Units and Strobe Lights and Design Guidelines, Useful Circuits, and Schematics, respectively.

---

* Back to Sam's Schematic Collection Table of Contents.

Super Simple Inverter

This circuit can be used to power a small strobe or fluorescent lamp. It will generate over 400 VDC from a 12 VDC, 2.5 A power supply or an auto or marine battery. While size, weight, and efficiency are nothing to write home about - in fact, they are quite pitiful - all components are readily available (even from Radio Shack) and construction is very straightforward. No custom coils or transformers are required. If wired correctly, it will work.

Output depends on input voltage. Adjust for your application. With the component values given, it will generate over 400 V from a 12 V supply and charge a 200 uF capacitor to 300 V in under 5 seconds.

For your less intense applications, a fluorescent lamp can be powered directly from the secondary (without any other components). This works reasonably well with a F13-T5 or F15-T12 bulb (but don't expect super brightness). Q1 does get quite hot so use a good heat sink.

  - o------------+------+
```

Notes on Super Simple Inverter

1. Construction can take any convenient form - perf board, minibox, etc. Make sure the output connections are well insulated.
2. C1 must be nonpolarized type - not an electrolytic.
3. D1 provides a return path for the base drive and prevents significant reverse voltage on the B-E junction. Any 1 A or greater silicon diode should be fine.
4. C2 is shown as typical energy storage capacitor for strobe applications. Remove D2 and C2 for use with a fluorescent lamps.
5. D2 should be a high speed (fast recovery) rectifier. However, for testing, a 1N4007 should work well enough. R2 limits surge current through D2.
6. The polarity of the input with respect to the output leads is important. Select for maximum voltage by interchanging the black output wires.
7. Mount Q1 (2N3055) on a heat sink if continuous operation is desired. It will get warm. Other NPN power transistors with Vceo > 80 V, Ic > 2 A, and Hfe > 15 should work. For a PNP type, reverse the the polarities of the

power supply and D1, and interchange one set of leads (where a diode is used for DC output).

8. Some experimentation with component values may improve performance for your application.

9. When testing, use a variable power supply so you get a feel for how much output voltage is produced for each input voltage. Component values are not critical but behavior under varying input/output voltage and load conditions will be affected by R1 and C1 (and the gain of your particular transistor).

10. WARNING: Output is high voltage and dangerous even without large energy storage capacitor. With one, it can be lethal. Take appropriate precautions.

AmerTac Fluorescent Lamp Inverter

(From: (Dennis Hawkins (n4mwd@amsat.org).)

The AmerTac Fluorescent Lamp Ballast is from a portable 12 V light made in China for American Tack & Hardware Co sold in Home Depot stores. It burned out after about 30 minutes of continuous use. (OK, maybe you shouldn't consider duplicating this exactly! --- Sam) So I decided to take it apart and see what was in there.

What it had was a very small circuit board (about 1/2" x 2"). Both the transformer and the transistor were melted beyond recognition. The transformer was apparently custom made out of two 'E' cores taped together. I have another identical unit, so I could read the transistor part number: 2SD882. It is rated 80 V, 5 A, 40 W, typical Hfe of 30, in a TO127 package.

Unlike many of the others, this circuit powers both both filaments in the tube but is otherwise very similar.

I have another identical unit which hasn't been fried so I put a UV bulb in there and fired it up. It is clear that only one end has a glowing filament. It is the end connected to pins 5 & 6 of the transformer. The filament attached to pins 1 and 2 appears to only work as a resistor. The circuit will not operate without the bulb so I wasn't able to get reliable readings.

Archer Mini Flashlight Fluorescent Lamp Inverter

The circuit below was reverse engineered from the Archer model number 61-3724 mini fluorescent/incandescent flashlight combo (no longer in the Radio Shack catalog). The entire inverter fits in a space of 1-1/8" x 1" x 3/4". It is powered by 3 C size Alkaline cells and drives a F4-T5 tube.

This design can easily be modified for many other uses at lower or higher power.

         |          |      |    --- .022 uF
         |          |      |     |
   o-----+----------+------+-----+
```

Notes on Archer mini flashlight fluorescent lamp inverter:

1. T1 is an E-core ferrite transformer. The core is 5/8" x 3/4" x 3/16" overall. The outer legs of the core are 1/8" thick. The central leg is 3/16" square. The square nylon bobbin has a diameter of 5/16". There is a .020" gap (spacer) in between the two halves of the E-core.

   The 315T O (Output) is wound first followed by the 28T D (Drive) and 28T F (Feedback) windings. There should be a strip of mylar insulating tape between each of the windings.

   The number of turns were estimated without disassembly as follows:

   - The wire sizes were determined by matching the diameters of the visible ends of the wire for each winding to magnet wire of known AWG.

   - The number of turns in the Output winding was determined based on its measured resistance, core diameter, and the wire gauge tables.

   - A 50 kHz .1 V p-p signal was then injected into the Feedback winding. The amplitudes of the resulting outputs from the Drive and Output windings were then measured. From these, the ratios of the number of turns were calculated.

2. The transistor was totally unmarked. A general purpose NPN medium power transistor like a 2N3053 or ECG24 should work. For PNP types, reverse the polarities of the power supply and C1.

   Since it is very low power, no heat sink is used in the Archer flashlight. However, for other applications, one may be needed.

3. Some experimentation with component values may improve performance for your application.

4. When testing, use a variable power supply so you get a feel for how much output voltage is produced for each input voltage. Component values are not critical but behavior under varying input/output voltage and load conditions will be affected by C2 and C3, the number of turns on each of the windings of T1, and the gain of your particular transistor.

5. WARNING: Output is high voltage and dangerous. Take appropriate precautions.

6.
```

```

- Back to [Sam's Schematic Collection Table of Contents](#).

Energizer Mini Flashlight Fluorescent Lamp Inverter

The circuit below was reverse engineered from the Energizer model number unknown (worn off) mini fluorescent/incandescent flashlight combo. The entire inverter fits in a space of 1-1/8" x 1-1/8" x 3/4". It is powered by 4 AA size Alkaline cells and drives a F4-T5 tube.

This design is very similar to the Archer model (see the section: [Archer Mini Flashlight Fluorescent Lamp Inverter](#), but eases starting requirements by actually heating one of the filaments of the T5 lamp. Thus, a lower voltage transformer can be used.

```
                                              o  T1  o

Notes on Energizer Mini Flashlight Fluorescent Lamp Inverter

1. T1 is an E-core ferrite transformer. The core is 1/2" x 5/8" x 3/16" overall. The outer legs of the core are 3/32"

thick. The central leg is 3/16" square. The square nylon bobbin has a diameter of 5/16". There is a .010" (estimate) gap (spacer) in between the two halves of the E-core.

The 160T O (Output) is wound first followed by the 16T H (Heater), 32T D (Drive), and 16 T F (Feedback) windings. There should be a strip of mylar insulating tape between each of the windings.

The number of turns were estimated after unsoldering the transformer from the circuit board as follows:

- The wire sizes were determined by matching the diameters of the visible ends of the wire for each winding to magnet wire of known AWG.
- The number of turns in the Output winding was determined based on its measured resistance, core diameter, and the wire gauge tables.
- A 100 kHz .1 V p-p signal was then injected into the Drive winding. The amplitudes and phases relationship of the resulting outputs from the Feedback, Heater, and Output windings were then measured. From these, the ratios of the number of turns and winding start/end were determined.

2. The transistor was an MPX9610. I was not able to locate specs for this part number but a transistor like a 2N3053 or ECG24 should work. For PNP types, reverse the polarities of the power supply and C1.

   Since it is very low power, no heat sink is used in the Energizer flashlight. However, for other applications, one may be needed.

3. Some experimentation with component values may improve performance for your application.

4. When testing, use a variable power supply so you get a feel for how much output voltage is produced for each input voltage. Component values are not critical but behavior under varying input/output voltage and load conditions will be affected by C2 and C3, the number of turns on each of the windings of T1, and the gain of your particular transistor.

5. WARNING: Output is high voltage and dangerous. Take appropriate precautions.

   - o---+---------+------------+-----+--------------+
```

Notes on Pocket Fluorescent Blacklight Inverter GH-RV-B1

1. The original transistor is marked 8050 C0ZC. A 2N3055 works better than the original, the tube starts faster and the transistor runs much cooler.

2. T1 is a ferrite E-core transformer measuring 17mm x 15mm x 15mm. The core seems to be 5 mm thick. The turns ratio has not been determined. Winding W1 is made of ~0.2 mm wire, the resistance is below 1 ohm. The data for winding W2 is the same as winding W1. Winding W3 is made of ~0.5 mm wire and its resistance is 5 ohms.

3. The original tube is an F4T5BLB blacklight tube, but the inverter has been tested with an ordinary F4T5 tube as well as a Philips 6W tube. The 6W tube causes the original transistor to run quite hot, so using a 2N3055 or similar power NPN is recommended.

4. 4.5V seems to be the absolute minimal voltage required to start an F4T5 tube. 5V will start the 6W tube when a 2N3055 transistor is used. Voltage can probably be cranked up above 12V, but that was the highest I tried (Didn't want to test when the tube blows).

5. CAUTION: The inverter can give a nice(?) shock when run with the original transistor on 5V. With a 2N3055 and higher supply voltage, it can be nasty. Avoid touching the tube terminals. The bottom of the PCB can also give quite suprise, as I discovered :-(.

6.

Automotive Light Stick Inverter

(Circuit and description From: Manuel Kasper (mk@mediaklemm.com).)

Here's another schematic from a little light stick intended for use in a car at 12 V. It uses an F8T5 bulb and is quite similar to the Archer inverter (A HREF="#schamf">Archer Mini Flashlight Fluorescent Lamp Inverter) which, BTW, I've built successfully. :) Here's the ASCII schematic (I'm no ASCII wizard, so I took one out of your schematic collection and made the appropriate modifications). Or see the Automotive Light Stick Inverter in .gif format.

```

Notes on Automotive Light Stick Inverter

1. The transformer was an E-core ferrite, most likely E20. The primary and feedback windings were wound side-by-side first, followed by a strip of insulating tape, then the secondary. I'm absolutely positive that it was #38, however the primaries may also have been #26. There were tiny spacers on both outer legs, consisting of two layers of the same yellow insulating tape that was used to hold both halves of the core together. Total not thicker than .004". I could not remove the core without destroying it, so I don't know if there was a gap or spacer on the central leg. Stupid as I am, I forgot to measure the inductance of the secondary before disassembling, so no calculations about the AL value of the core can be made. :(

2. Q1 was in a TO-220 case (not heatsinked) and marked "D313 F5H4", so I suppose it was a 2SD313. If so, from what I know it would have an Ic of 2 A, a Vceo of 50 V and an hFE of 40..320. It ran very cool in the circuit. Power consumption from 12 V was about 250 mA - the tube was lit fairly bright, but of course not at full power. On the label it states "Power: 12 Volt DC at 5 Amps", but I don't think the latter is correct. ;)

3. It has got a long cable with a nice set of plugs - a pair of alligator clips as well as a cigarette lighter plug. It's made in China, cost the equivalent of $8 and could not be disassembled without cutting thick black rubber apart.

Comments on Automotive Light Stick Inverter

I just experimented with rebuilding it a bit. It works fine with a home-made transformer using an E 25 core (25 mm core width, or 0.79"). I tried both an un-gapped (AL = 1750 nH) and a 0.4"-gapped (on central leg; AL = 151 nH) version. Concerning efficiency, the result was more or less the same, but due to the higher switching frequency with the gap, there was no buzzing sound from the transformer. It worked even with 32 primary and 350 secondary turns, secondary wound first with the output and feedback winding not side-by-side but one over another. It's also great as an inverter for use with a G4-T5 to erase EPROMs, as I discovered.

Transistors with low gain don't seem to work well - BD237 and 2N5191 were reasonably good. It's easy to have it operate at more power - just decreasing the 5.1 k resistor and adding a small heatsink works great.

The filter capacitor gets pretty warm; needs to be low ESR or it will probably overheat, especially at higher power levels.

In the original inverter, there was a connection between the secondary and ground. Strange - it doesn't seem to make any sense because nothing changes if you remove it. But they have got their reasons, I suppose.

Low Power Fluorescent Lamp Inverter 1

The circuit below was reverse engineered from a model number FL-12 'Made in Hong Kong' battery (8 AA cells) or 12 V wall adapter powered portable fluorescent lamp. The bulb is an F8-T5.

This design can easily be modified for many other uses at lower or higher power. Note that its topology is similar to that of the circuit described in the section: Super Simple Inverter.

    - o-------+----------+------+
```

Notes on Low Power Fluorescent Lamp Inverter 1

1. T1 is an E-core ferrite transformer. The core is 5/8" x 3/4" x 3/16" overall. The outer legs of the core are 3/32" thick. The central leg is 3/16" square. The square nylon bobbin has a diameter of 5/16". There is no visible spacer between the cores but I did not disassemble to confirm.

   The 350T O (Output) is wound first followed by the 25T D (Drive) and 18T F (Feedback) windings. There should be a strip of mylar insulating tape between each of the windings.

   The number of turns were estimated without disassembly as follows:

   - The resistances of each of the windings was measured to determine the arrangement of the transformer.

- The inverter was run at just enough input voltage for it to oscillate (so the load of the fluorescent tube would not affect the readings) and the voltages on all 3 windings were measured on an oscilloscope. From this, the ratios for the windings were determined.

- An estimate was made of the number of turns likely to be on the Drive winding based on other similar designs. The number of turns on the other windings were calculated based on the turns ratios. Wire size is probably #36 AWG.

2. The transistor was marked 5609 which I could not cross to anything. I would guess that a general purpose medium NPN power transistor like a 2N3053 or ECG24 should work. For a PNP type, reverse the polarities of the power supply and C1.

   Since it is very low power, no heat sink is used in this lamp. However, for other applications, one may be needed.

3. Some experimentation with component values may improve performance for your application.

4. When testing, use a variable power supply so you get a feel for how much output voltage is produced for each input voltage. Component values are not critical but behavior under varying input/output voltage and load conditions will be affected by C2, C3, R1, R2, the number of turns on each of the windings of T1, and the gain of your particular transistor.

5. WARNING: Output is high voltage and dangerous. Take appropriate precautions.

6.

```

Gary's EPROM Eraser

(From: Gary Perry (perry_gary@ascom.co.uk).) I used this circuit based on this design to build an EPROM eraser, using the 4 watt G4T5 germicidal tube.

The tube seems to like 75 VAC in order to 'fire it up'.

I used a 2N3053 transistor and a commonly available commercial 6 - 0 - 6 primary 240VAC 100mA secondary transformer. After 25 minutes constant usage, both transistor and transformer remained cool.

A variable PSU was connected, and the circuit worked first time. The required 75 VAC output was achieved with only 5 VDC input.

- Back to Sam's Schematic Collection Table of Contents.

Low Power Fluorescent Lamp Inverter 2

The circuit below is the type used in inexpensive fluorescent camping lanterns. In this particular model, an F6-T5 lamp was used. It will drive F4-T5 to F13-T5 tubes depending on input voltage. The power source can be a 4 to 9 V, 2 A power supply (depending on the size of your lamp) or a suitable battery pack. This design was reverse engineered from a random commercial unit of unknown manufacture using a lead-acid battery battery that expired long ago.

```

The approximate measured operating parameters are shown in the chart below. The two values of input current are for starting/running (starting is with the Start button, S1, depressed.

Lamp type ---> V(in)	F4-T5 I(in)	F6-T5 I(in)	F13-T5 I(in)
3 V	.9/.6 A	-	-
4 V	1.1/.7 A	1.1/.8 A	-
5 V	1.3/.8 A	1.2/.9 A	-
6 V	-	1.4/1.0 A	1.6/.95 A
7 V	-	-	1.7/1.0 A
8 V	-	-	1.8/1.2 A
9 V	-	-	2.1/1.3 A
10 V	-	-	2.2/1.4 A

Notes on Low Power Fluorescent Lamp Inverter 2

1. Construction can take any convenient form - perf board, minibox, etc. Make sure the output connections are well insulated.

2. T1 is assembled on a square nylon bobbin, 3/8" cubed. Wind the 250T O (Output) first, insulate with mylar tape, 20T D (Drive) next, and 7T F/S (Feedback/Starting) last. Observe directions of windings as indicated by the dots (o). The number of turns for the O winding was estimated based on measured winding resistance, wire size, and the dimensions of the bobbin.

The core is just a straight piece of ferrite 1/4" x 1/4" x 1-3/8" It is fully open - there is no gap.

3. Any general purpose NPN power transistor with Vceo > 80 V, Ic > 2 A, and Hfe > 15 should work. For a PNP type, reverse the polarities of the power supply, C1, D1, and D2.

   Use a good heat sink for continuous operation at higher power levels (6 V input or above). The type used (2SC1826) was a replacement after I fried the unidentified transistor originally installed (103-SV2P001).

4. Pushbutton switches are used to control operation. S1 (Start) provides initial base drive to the transistor via the Feedback/Starting winding of T1 until the tube arc is established. At that point, feedback is sustained via current flowing through the tube. S2 (Off) shorts the base of the transistor to ground to stop the oscillator.

   Like a regular manual start preheat fluorescent fixture, the start switch, must be depressed until the lamp comes on at full brightness indicating that the filaments are adequately heated.

5. Some experimentation with component values may improve performance for your application.

6. When testing, use a variable power supply so you get a feel for how much output voltage is produced for each input voltage. Component values are not critical but behavior under varying input/output voltage and load conditions will be affected by R1 and R2 (during starting in particular), the number of turns on each of the windings of T1, and the gain of your particular transistor.

7. WARNING: Output is high voltage and dangerous. Take appropriate precautions.

Medium Power Fluorescent Lamp Inverter

This circuit is capable of driving a variety of fluorescent lamps from a 4 to 12 V, 2 to 2.5 A DC power supply, rechargeable battery pack, or auto or marine battery. With appropriate modifications (if needed) it may be used for other applications like powering an electronic flash or HeNe laser tube. The transformer will need to be custom wound (by you) but this is not really difficult - just slightly time consuming for the 600 turn O (Output) winding if you don't have a coil winding machine.

I have used it with fluorescent tubes of many sizes: F6-T5, F13-T5, F15-T12, and F20-T12. The arc will be sustained with the filaments hot on an input as low as about 3.5 to 4 V (with a new tube) but during starting, an input voltage of about 5 or 6 V may be needed until the filaments are hot enough to sustain the arc at the lower voltage.

Two nearly identical circuits are shown.

- This design saves a couple of diodes but requires a centertapped feedback winding on the transformer. The input voltage must exceed about 4 V for oscillation to commence:

```
              +Vcc                           o T1
```

```

The switching frequency is about 21 kHz and varies less than 5 percent over the range of input voltage for which the bulb remains lit (it is significantly higher with no load - about 140 kHz). An input voltage of about 4 V is needed to start oscillation (reducing R1 or increasing R2 would lower this at the expense of efficiency at higher voltages) but it will continue well below 3 V.

The measured input current at various input voltages for two lamp types are shown in the chart below. SV (Starting Voltage) is the minimum input voltage required to preheat the filaments before the lamp will turn on (current is lower until filaments are hot). FB (Full Brightness) is the point at which the lamp appears to be operating at the same intensity as if it were installed in a normal 115 VAC fixture.

Lamp type ---> V(in)	F13-T5 I(in)	F20-T12 I(in)
3 V	-	1.37 A
4 V	1.76 A	1.52 A (SV)
5 V	1.80 A (SV)	1.60 A
6 V	1.90 A	1.65 A
7 V	1.96 A (FB)	1.70 A
8 V	2.02 A	1.80 A
9 V	2.16 A	1.90 A
10 V	2.33 A	2.05 A
11 V	-	2.30 A (FB)
12 V	-	2.60 A

Notes on Medium Power Fluorescent Lamp Inverter

1. T1 is an E-core ferrite transformer. Once complete, the cores are installed on the bobbin with a 2 mm gap. Some experimentation with the core gap may be needed to optimize performance for a given lamp type and input voltage.

   Each E core is 1" x 1/2" x 1/4" overall. The outer legs of the core are 1/8" thick. The central leg is 1/4" square. The square nylon bobbin has a diameter of 5/16" and length of 3/8".

   The 600T O (Output) is wound first followed by the 15T D (Drive) and 10T F (Feedback) windings. For convenience, wind the D and F windings bifiler style (the two wires together). Determine the appropriate connections with an ohmmeter (or label the ends). The centertaps are brought out to terminals. Try to distribute the O winding uniformly across the entire bobbin area by winding it in multiple layers. This will assure that no wires with a significant voltage difference are adjacent. There should be a strip of insulating tape between the O and the other windings.

2. L1 isolates the power supply. It is 24 turns of #22 wire wound on a 1/4" ferrite core. The inverter works fine without L1 but seems to have a tad more strength at low voltage with it.

3. The transistors are MJE3055T (2N3055 in a TO220 package) types but are not critical. However, I expect that some faster switching transistors would run cooler. Any fast switching NPN power transistor with Vceo > 80 V, Ic > 3 A, and Hfe > 15 should work. For PNP types, reverse the polarity of the power supply.

   For operation above about 6 V, a pair of good heat sinks will be required. However, power dissipation in the transistors does not seem to increase as much as expected - the base drive is probably more optimal at higher input voltage.

4. Some experimentation with component values may improve performance for your application.

5. When testing, use a variable power supply so you get a feel for how much output voltage is produced for each input voltage. Component values are not critical but behavior under varying input/output voltage and load conditions will be affected by C1, the number of turns on each of the windings of T1, the gap of the core of T1, and the gain of your particular transistor. If the circuit does not start oscillating, interchange the F winding connections to Q1 and Q2.

6. WARNING: Output is high voltage and dangerous. Take appropriate precautions.

Lazar's Comments on F-Lamp Inverter Design

(From: Lazar Pancic (dextter@eunet.yu).)

I planned one week of camping with my friends this summer, so I wanted to make one fluorescent tube run on 12V and studied a lot of Internet places for the ideas. I made some of the circuits (some of them I found on your site) but the performance was not as I expected. Yes, they do run a 8W tube but the brightness is quite obviously lower than when the tube is run on mains supply. Then I started to study app-notes of many different electronic ballasts for fluoro-tubes and got the idea what was wrong. I send my conclusions to you with the hope that it could help others in selecting the good circuit with less trouble than I got :))

1. For the good performance it is important to drive fluorescent tube by pure AC voltage. It may look strange, but simple flyback transformer drives the tube on DC, not AC! Look at one of the flyback circuits: when the transistor is conducting the primary windings get more and more current which produces storage of magnetic energy in the core of the transformer. At the point when the core saturates the base drive for the transistor is being suddenly cut off (this "suddenly" depends on the core material properties), and the stored energy is being transferred by the secondary winding to the tube as a high voltage pulse. Since the orientation of primary and secondary windings and the battery (e.g. accumulator) is always the same this pulse also has the same polarity every time. That's why only one side of the tube gets darker after it is being run on such inverter for some period of time, and that is why the tube can't perform well for some reasonable period of time with the flyback topology of the driver.

2. Because there is one period within the flyback cycle when the transistor is only supplying the transformer with the magnetic energy and the tube doesn't get any portion of the energy during this period, the tube would probably turn off during this. That is not good at all. One of the biggest advantages of the electronic ballasts over older ballasts with the inductors (or transformers) is that the tube is run on high frequency so that it doesn't turn off at any time.

There is no flicker but one more important consequence is that the tube need not be started at the beginning of every single cycle! That's why the tube has 10% more light power when being run on electronic ballasts. Naturally, the good ballasts have no "dead-time" in their operation cycles.

3. For the long lifetime of the tube, many app-notes suggest sinusoidal form of the tube driving voltage, which is not the case with the flyback inverters. The tube voltage would be probably the very high voltage pulse at the very beginning of the tube supply period of the inverter cycle, and approx. 100V of continuous voltage at the rest of the cycle (all of these is during the period while the transistor is not conducting; while it does, the output voltage is 0 V).

4. Since only one transistor is performing the switching job, it's current is at least two times bigger than if there were two of them, for the same output power of the inverter. For example, if the inverter gets constant current of 1 Amp from the power supply, the transistor's peak current would probably be greater then 2 Amps!

   So, it seams that far better topology for fluorescent tube inverters is symmetrical push-pull inverter, such the one described in "Medium Power Fluorescent Lamp Inverter". There is only slightly higher cost for this (one power transistor more), but also fewer resistors and capacitors!

   The output voltage of this circuit is alternating (+/-) square wave. The tube gets constant power supply (it lights during positive as well as during negative half-cycle, which means AC), and it doesn't turn off at all.

5. It is good to preheat the electrodes of the tube before it is being started. There are some of the flybacks that does so, but during this period of operation the peaks of output voltage are even higher. Unfortunately, Medium Power... doesn't preheat the tube. This could be done by adding one high voltage capacitor in parallel with the tube. It's capacitance should be few times lower than the one in series with the tube... (read on :) Notice that the oscillating frequency of the inverter is around 7 times higher with no load (e.g., when the tube is not started yet). At this very high frequency this small capacitor's impedance is low enough so that considerable preheating current could flow through the filaments. Every simple compact fluorescent tube electronic ballast has one of these, the value of which is 2n2/1000V. I suggest using one of them or any with the similar properties.

   One additional good feature of this capacitor is that it heats the filaments of the electrodes even during normal operation of the tube but in much lower rate (about 5% of the preheating current). It may look as a fault but it doesn't. The lamp life would be longer if the filaments are hotter.

6. High speed switching transistors could be the good choice but only if special "hard" ferrite core materials are used. These materials have very sharp hysteresis curve which means that they saturate fast and provide fast and clean switching pulse for the transistors. If normal core is used, fast switching transistors may not be of any benefit. Nevertheless, standard cores for ferrite transformers tend to be made of the "hard" materials (and these materials get better and cheaper) so it could be interesting for enthusiasts to experiment.

7. If you use emitter resistor as I do, it is quite likely that no cooler would be needed for the transistors! It's resistance depends on the power of the tube that is being run and could be calculated with this rule-of-thumb:

   ```
   Re = 1.2V/I(Amps)
   ```

8. Small capacitors in parallel with the base resistors help in starting the oscillations. Their value is not critical (0.33 to 2.2 nF).

9. Finally, there is another way of providing the base drive pulses to the transistors without separate "base-drive" windings. I experimented for some time with this topology and find it satisfactory. Any transistor type would probably need different values for resistors, bud not much different than one I suggested. However - is obviously

much easier to experiment with resistors than with number of base-drive turns :)

With a 12 VDC power supply, this resistor produces around 10% of power loss but if the compactness of the device is important, it is acceptable. Without it the transistors would dissipate almost the same amount of heat as resistor dissipates when is present, so I suggest using it anyway. The inverter runs much more stablely with it and the transistors are much less stressed, which ensures long and reliable operation of the inverter.

Lazar's Improved Medium Power F-Lamp Inverter

Here is the drawing of the inverter I use to power the 18W tube on 12 VDC:

```
+Vcc                              o T1

```

All resistors are rated to 1/4 W except Re, which is 2 to 4 W.

My lamp has survived abt 20 hours being run on this circuit. I will send you an update if I notice something else useful or interesting.

Compact Fluorescent Lamp Electronic Ballast 1

This unit is from a Techna-Bright EDXR-38-16 compact fluorescent lamp used as a (mediocre) replacement for the ubiquitous 150 W outdoor floodlight. It's a 3 U-section tube inside a light weight glass floodlight reflector. With a rated electrical input of only 16 W, I doubt it's even as bright as a 60 W incandescent lamp. The inverter is remarkably simple and must be dirt cheap to manufacture. It uses a pair of 400 V, 4 A bipolar transistors in a self-oscillating configuration which appears to have its output in resonance with a LC network in series with the lamp. The only magnetic components are an inductor for RFI suppression, an inductor in series with the lamp, and a driver transformer for the transistor bases (3 sets of 2 or 3 turns on a ferrite core). An RC and diac circuit provides a kick start to get it going. Protection of sorts (one time) consists of a fusable 0.47 ohm resistor in the AC line input.

- Get the schematic for CFLAMP1 in PDF format: CFLAMP1-SCH.

The same basic circuit could be used on 220 to 240 VAC, 50 Hz but the voltage ratings of the filter capacitor and possibly the transistors would need to increase, and probably some other changes would be needed.

However, note that these ballasts do not seem to be very tolerant of any sort of fault in the lamp circuit itself and may fail instantly if there is a short, open, intermittent connection, or wrong type or size lamp. Thus care should be taken if attempting to use the ballast to power anything other than the original lamp. Double check that all wiring is correct and secure before applying power.

- Back to Sam's Schematic Collection Table of Contents.

Compact Fluorescent Lamp Electronic Ballast 2

This unit is from a General Electric 26 W helical compact fluorescent lamp which is a fairly decent replacement for a 100 W incandescent lamp, but having just over 1/4 the energy consumption. The model number on the CFL is: FLE26HT3/2/SW. However, even what appear to be identical GE CFLs may have slightly different part numbers. The lamp, ballast (bottom view inset), and base are shown in Major Parts of General Electric Helical Compact Fluorescent Lamp.

This inverter uses a pair of N and P channel 250 V, 2 to 2.5 A, MOSFETs in a self oscillating configuration with a transformer (actually labeled L3 on the schematic) boosting the half-bridge output voltage. (L3 may actually have at least one of its windings wired with Litz multistrand insulated wire based on the appearance of the wire ends at its terminals.) Gate drive feedback is via a series L-C circuit. A Positive Temperature Coefficient thermistor provides current to power the tube filaments and then increases to a high resistance while the lamp is running. This is easier on the filaments during starting but uses a bit extra power than might be possible with some sort of active switching circuit to disable them. Protection is provided by a real 1.5 A mini glass fuse wired directly to the center of the CFL screw base.

- Get the schematic for CFLAMP2 in PDF format: CFLAMP2-SCH.

The same basic circuit could be used on 220 to 240 VAC, 50 Hz but the voltage ratings of the filter capacitor and MOSFETs would need to increase, the L3 turns-ratio would decrease, and probably some other changes would be needed.

However, note that these ballasts do not seem to be very tolerant of any sort of fault in the lamp circuit itself and may fail instantly if there is a short, open, intermittent connection, or wrong type or size lamp. Thus care should be taken if attempting to use the ballast to power anything other than the original lamp. Double check that all wiring is correct and secure before applying power.

Basic 200 W Power Inverter

This circuit was reverse engineered from a Tripp-Lite "Power-Verter" Model PV200 DC to AC Inverter - typical of those used for camping or boating applications where the only source of power is an auto or marine battery. This particular model is rated 200 W continuous. The output is a 60 Hz squarewave and there is no regulation or precise frequency control. (Unlike the other circuits in this collection, it is NOT a high frequency inverter.)

Modifications for higher or lower output voltage are easily achieved. For example, a fast cycle strobe requiring 330 VDC, would only require using three times the number of turns on the Output winding and the addition of a bridge rectifier to charge the energy storage capacitor(s). Alternatively, the inverter could be used as-is with the addition of a voltage tripler. A tripler rather than doubler is needed because of the squarewave output. (The RMS and peak voltages are the same so you don't get the boost of 1.414 as you do with the sinusoidal waveform from the power company.)

Circuits similar to this will also be found inside UPSs (Uninterruptible Power Sources) so if all you want is a cheap low voltage DC to line voltage inverter, find a dead UPS - there's a good chance the battery is bad, not the electronics! (However, it may not be designed for 12 VDC input.)

Notes on Basic 200 W Power Inverter

1. Construction was all done point-to-point - there is no circuit board. Layout appears not to be critical.

2. T1 is a relatively large heavy laminated E-I core transformer. The E and I sheets alternate direction to assure a low reluctance magnetic circuit.

   The core dimensions are 3-3/4" x 3-1/8" x 1-1/8" overall. The outer legs of the core are 5/8" thick. The central leg is 1" wide. The square bobbin has a diameter of 1-3/8".

   The 360T O (Output) secondary is wound first as 4 or 5 insulated layers followed by the 31T D (Drive) and 17T F (Feedback) windings. There are insulating layers between each of the windings.

   The number of turns were estimated without disassembly as follows:

   - The wire sizes were determined by matching the diameters of the visible ends of the wire for each winding to magnet wire of known AWG and/or measuring with a micrometer where possible. (The Drive windings are actually wound using square cross-section magnet wire for maximum packing density. This was estimated to be equivalent to #13 AWG round wire.)

   - The number of turns in the Output winding was determined based on its measured resistance, core diameter, and the wire gauge tables.

   - The inverter was run and the amplitudes of the signals on each winding were measured. From these ratios, the number of turns were calculated.

3. The transistor were marked 69-206. ECG29 is a close match - high power amplifier switch - 80 V, 50 A, 300 W, Hfe 20 min. 2SD797 is another readily available power transistor that should work. For PNP types, reverse the polarities of the power supply, C1, C2, and C3.

   The transistors are mounted on heat sinks which form the sides of the case.

4. C3 and R3 are required for starting. Since there is no source of current for the bases of the transistors other than the Feedback windings, this provides a starting pulse to Q2 when the unit is switched on. Ramping the input voltage slowly rather than using the power switch would likely result in the inverter behaving like an inanimate object.

5. Measured frequency of operation was about 56 Hz. This is likely affected by nearly everything - input voltage, capacitance, core saturation, phase of the moon, etc. Therefore, don't expect to drive a clock mechanism from this thing with any accuracy!

6. Some experimentation with component values may improve performance for your application.

7. When testing, use a variable power supply so you get a feel for how much output voltage is produced for each input voltage. Component values are not critical but behavior under varying input/output voltage and load conditions will be affected by C2 and C3, the number of turns on each of the windings of T1, and the gain of your particular transistors. However, See note (3) about starting.

8. WARNING: Output is high voltage and dangerous - even more so if you increase its output for true HV applications. Over 200 W is available continuously. Take appropriate precautions.

9.

Up to 350 VDC Inverter from 1.5 V Alkaline Cell

Using the basic circuit of the electronic flash unit from a disposable pocket camera, it is possible to generate any voltage from a few V to 350 V or more from a 1.5 V AA Alkaline battery. (Similar modifications could be made to other pocket camera or external flash unit circuits.)

The specific circuit described below is derived from the inverter used in a Kodak "MAX" disposable camera electronic flash. The beauty of this approach is that the remains of these cameras are often available for the asking at 1 hour photo developing outfits since they are usually thrown away after extracting the film (though apparently some are recycled, this is probably the exception rather than the rule).

The original Kodak MAX Flash Unit Schematic and Photo of Kodak MAX Flash Unit show what you get for nothing. All newer Kodak disposable cameras including the "Funsaver Sure Flash" and APS (Advanced Photo System) "ADVANTIX" appear to use a similar if not identical circuit but I haven't disassembled one of those as yet.

This is certainly useful intact for strobe and high voltage projects but for the purposes of this discussion, all we need are T1 (which we may modify), Q1, R1, perhaps S1 or an equivalent, C1, and D1.

By rewinding the inverter transformer, any output voltage up to about 350 VDC can be obtained from a 1.5 V Alkaline cell. More than 350 V is probably possible but just thinking about winding the needed secondary makes me tired!

The Mini Power Supply Based on Modified Kodak MAX Inverter shows the simplified circuit. The original circuit board can be used and is very convenient though a more compact unit can be constructed if you use a bit of perf board or your on PCB. Note that for higher voltages, Q2 in the original MAX schematic may be needed. For low voltage operation, performance is much better without it. I don't know what the break-even point is so you may want to leave a spot for Q2 just in case.

The main difficulty is in disassembling T1 in a nondestructive way. It seems that the ferrite core is held together by an adhesive which is very tough and resistant to any solvent that won't destroy the plastic bobbin and wire insulation as well. Therefore, you may need to sacrifice two of these - one so that just the ferrite core can be salvaged by soaking the transformer in some nasty solvent (maybe lacquer thinner will work) to dissolve the adhesive.

For the 6 turn primary, the number of turns required on the secondary is approximately:

```
N = 6 * (Vout + 1.2) / 1.2
```

assuming a small load on the output.

So for: 4 VDC, N = 26; for 50 VDC, and for N = 256 300 VDC, N = 1506.

The original circuit topped out at about 350 VDC with N = 1750.

It may be possible to use multiple output windings to provide more than one output voltage but as will be shown below, all output power must be drawn on the forward stroke of the converter since the flyback pulse of the reverse stroke is needed to drive the voltage on C1 and the base of Q1 negative.

I have done the modifications for the 4 VDC version by removing the original 1,750 turn secondary (I had to do this anyway so I could confirm the number of turns for the circuit description) and replacing it with a 26 turn winding of #32 wire. Unfortunately, I also had to Epoxy the half dozen pieces of the ferrite core back together after somewhat destructive disassembly but I don't think there are any significant gaps left in the core :-((I confirmed that the transformer still worked by installing another set of undamaged original windings and checking that it still charged and fired the flash properly).

With no load, the output reaches about 5 V in a fraction of a second.

With a 100 ohm load, the output drops to a bit over 4 V.

Following a post to sci.electronics.design suggesting this circuit as a simple way of obtaining a dual op-amp supply from a single Alkaline cell (dual part as yet to be tested), we have the following discussion on the theory of operation of this circuit:

(From: Tony Williams (tonyw@ledelec.demon.co.uk).)

> "That sounds about right, rough sums:
>
> Q1 bottoming-V is going to vary from about 0.1V to about 0.3V on the forward stroke, from no-load to full-load.
>
> D1 + Q1Vbe fwd-drop is going to similarly vary from about (0.7 + 0.35)V to (0.7 + 0.6)V.
>
> V/C2(NLoad) = (1.5 - 0.1)26/6 - 1.05 = 5.02V.
> V/C2(Fload) = (1.5 - 0.3)26/6 - 1.3 = 3.9V.
>
> 4 V across 100 ohms is about 160 mW, not bad really.
>
> Well, I still haven't seen what recharges C1 negatively. Some scope waveforms for C1 and D1 would be nice (hint, hint). :)"

After noting that I was impressed that both our numbers work as well as they do, Tony replied:

> "Don't be, it was a pure fluke. The V-drops were only guesstimated and things like primary IR-drop were not even included."

Well, IR-drop should be negligible - 4 inches of #26 wire is only about .013 ohms :-).

Some additional info (after I took the hint) finally appears to have solved the mystery:

I checked the waveform across B-E of Q1. It is around .6 V for most of the cycle with strong -6 V going spikes! So, where are they coming from????

Possible sources include:

- Transformer (T1) Interwinding capacitance.
- Circuit board capacitance.
- Diode (D1) junction capacitance.
- Diode (D1) reverse conduction.

I thought that maybe the relatively long recovery time of the standard-looking (though unknown markings) diode (D1) is providing enough reverse current to turn off the transistor. I tested this by subbing both a fast recovery and high efficiency rectifier - no difference. OK, well maybe just a bit better performance :-). Perhaps it still is the reverse current spike as the transistor switches off that drives the base hard to -6 V.

Now, here is the kicker (no pun....):

Monitoring the waveform ACROSS D1 - do you want to guess what it looks like?

We have a greater than 110 V, 200 ns spikes occurring when Q1 switches off! Geez! 110 V from a 26 turn winding and a 1.5 V battery! It wouldn't take much capacitance or reverse recovery leakage through D1 to drive the base and C1 negative by 6 V. Looking at the equivalent circuit:

```
                        X pF         470 pF
>110 V pulse o-------||-----+------||------+
  ~200 ns                   |             _|_
                            o              -
                       ~6 V pulse
```

X of about 26 pF would result in an appropriate divider ratio. However, this sounds high for the layout and 26 turns. Then again, stranger things have happened :-). But, a combination of the reverse recovery conduction and higher capacitance at low voltage as the diode reverses could probably do it.

Tony replies to this new information:

> "You will recall that I was puzzled about energy transfer on the fwd stroke only. That transformer is going to get stored energy on every fwd stroke, and yet there appears to be no means of dissipating that energy..... There is even no protection for the collector of the transistor. In fact, I would suspect that that is part of the design, in that they did not want the energy clamped by the primary, they needed it as a high voltage reverse dissipation in the secondary.
>
> Think varactor-action. For D1 being spiked from fwd conduction to 110 V negative I would suspect that a 26pF-equivalent for D1 is quite reasonable. Bearing in mind that we have an inherent reverse-Vbe clamp I would not even be surprised if D1 could also be allowed to avalanche."

I just wonder how this design came about. The vast majority of these simple flash inverter circuits use the traditional blocking oscillator topology with a separate winding or portion of a winding for the base drive/feedback. (At this point I have taken a look at over a dozen different types.) This Kodak circuit appears to be unique in letting the high voltage (originally) winding serve double duty. It probably does save 5 cents in the manufacturing cost of the transformer by not having to have a separate winding. :-).

And, Tony's reply:

> "I worked for a chap once (one Jevon Crossthwaite, about 70 now if still alive) who could take a circuit and absolutely *squeeze* the last ounce of performance out of it. This is typical of what he would get up to. I did learn a lot from him, but only partially, because my inbuilt design nature is still yer brick outhouse.
>
> If there are any BOFs around; I think Jevon Crossthwaite, in his early days, worked for Sylvania and for George Philbrick (before and after Teledyne entered the scene), both in the States."

Strobe Circuits

Strobe Circuits Introduction

Don't forget, there are many more electronic flash and strobe circuits in: Notes on the Troubleshooting and Repair of Electronic Flash Units and Strobe Lights and Design Guidelines, Useful Circuits, and Schematics.

- Back to Sam's Schematic Collection Table of Contents.

Variable Intensity Variable Frequency Stroboscope

This circuit (referenced in the document: Notes on the Troubleshooting and Repair of Electronic Flash Units and Strobe Lights and Design Guidelines, Useful Circuits, and Schematics is designed to provide a variety of options in terms of repetition rate, flash intensity, and various repeat and triggering modes.

The design includes:

- Line operated voltage doubler power supply.
- Power transformer operated low voltage logic supply.
- Variable frequency repeat mode controlled by 555 timer.
- Optoisolated external trigger input.
- Selectable flash intensities of .2, 2, and 20 W-s.
- Autorepeat speeds from .05 to 100 Hz.

Note that the flashlamp will NOT operate at all intensities for these entire ranges due to recharge and power dissipation limitations.

Parts of this circuit have been built and tested but the entire unit is not complete. Maybe someday.... :-)

Kevin's Strobe Schematics

(The following two sections are from: Kevin Horton (khorton@tech.iupui.edu).)

High power inverter and trigger circuits

I'm building a super strobe bar! It has 8 strobe tubes under computer control. (Actually a PIC processor, but hey, computer is a computer.) I have all the stuff done except the control section, and I only have 2 of the 8 strobe units done due to the fact that I haven't found any more cheap cameras at the thrift store! (One Saturday morning's worth of garage sales and flea markets would remedy that! --- sam).

It runs on 12 V, at up to 6 A, and can fire the tubes at a rate of about 8-10 times per second. The storage cap is a 210 uf, 330 V model; it gets to about 250 V to 300 V before firing; depending on how long it has had to charge. Because of this high speed, the tubes get shall we say, a little warm. (Well, maybe a lot warm --- sam). I have it set up at the moment driving two alternating 5 W-s tubes. I'm pumping them quite a bit too hard, as the electrodes start to glow after oh, about 5 seconds or so of continuous use. I know, a high class problem, indeed! My final assembly will have 8 tubes spaced about 8 inches apart on a 2x4, with a Plexiglass U-shaped enclosure with a nice 12 V fan blowing air through one end of the channel to cool the inverter and the tubes. Stay tuned.

Inverter - High power 12 V to 300 V inverter for high repeat rate medium power strobes. Schematic in GIF format: inverter.gif

Trigger - Opto-isolated logic level trigger for general strobe applications. Schematic in GIF format: trigger.gif

Teeny Tiny Inverter Design

I have developed a cool little transformer circuit that seems to be very efficient. I built this inverter as tiny as I could make it. It runs off of 3V, and charges up a little 1 uf 250V cap all the way up in about 30 seconds; drawing about 5 to 8 mA in the process. The numbers by the windings tell the number of turns. The primary and feedback windings are #28, while the secondary is #46. Yes, #46! I could hardly tell what gauge it was, as it was almost too small to measure with my micrometer! It may be #44 or #45, but at these sizes, who knows? I used a trigger transformer for the wire. I used all the wire on it, to be exact; it all **JUST** fit on the little bobbin. The primary went on the core first, then the secondary, and finally the feedback winding. This order is very important. I used a ferrite bobbin and corresponding ferrite 'ring' that fit on it. The whole shebang was less than 1 cm in diameter, and about 3-5 mm high! I gave it a coat of wax to seal things up, and made the inverter circuit with surface-mount parts, which I then waxed onto the top. There are two wires in, and two wires out. It's enough to run a neon fairly brightly at 1.2 V, with a 3 ma current draw.

Schematic in GIF format: teeny.gif

Ultra-Compact 350 V Capacitor Charger

These two circuits are based on the inverters from disposable camera flash units. While not having quite the fewest components, they have an advantage in that a simpler inverter transformer like the one in the Kodak MAX Flash with a single primary and single secondary winding can be used. (Some of the other flash inverters require either a separate feedback winding or an additional tap for the feedback.) Even so, the total space for either of these circuits excluding the battery, power switch, and energy storage capacitor may be less than 0.1 cubic inch! And the cost may be $0.00.

The schematics are shown in Ultra-Compact 350 V Capacitor Charger. The only differences between the circuits are whether the HV output is positive or negative with respect to the input and whether one side of the battery and HV are in common. Otherwise, they should behave in a similar manner. (The Kodak MAX is negative output type 1). The versions using 2SD879 or 2SD965 (NPN) transistors for Q1 have both been tested and appear to work about equally well, charging a 120 uF 350 V photoflash capacitor (C2) to 350 V in about 10 seconds. (The 10 uF C2 shown is just an arbitrary example.). This was at least as fast as the original flash using the same transformer. The actual transformer used for these tests is from a newer flash and is somewhat smaller in size than the one found in the original MAX. It may be a more modern version of the MAX since the design and PCB layout look very similar but I don't know for sure. (See: Photo of Disposable Camera Flash Unit. Please contact me via the Sci.Electronics.Repair FAQ Email Links Page if you know for sure from which model camera this originated.) Using the larger transformer should result in a faster charging speed. The value of C1 isn't critical - almost anything will work though values between about 200 pF and 10 nF seem to be best. The versions using PNP transistors should work just as well as long as a transistor with similar gain to the NPN types are used. (The 2SB1050 or ECG12 might work but I have not confirmed this. The 2SA1585S and 2SB1395S, which were the actual transistors found in two versions of the flash from which the transformer I used were taken, oscillated but would have taken a few *minutes* to charge a 120 uF capacitor to a useful voltage. I assume their gain was too low. It's also possible that low gain samples of the 2SD879 or 2SD965 would not work well in the negative output circuit but all the ones I tried were fine though there was some variation in charging rate probably due to variations in gain. In the original flash circuit, an additional transistor in a quasi-Darlington configuration where the collector of the first transistor goes to the supply instead of the collector of the second transistor boosts the gain. This, of course, could be added to be sure of reliable operation.) If S1 is a momentary switch, the inverter will charge to a voltage based on the uF of the energy storage capacitor (C2) where there is no longer enough of a feedback pulse to maintain oscillation. With a C2 of 120 uF, this is between 250 and 300 VDC. (In the original flash circuit, with the additional transistor, the inverter would run to well above 300 VDC at which point the voltage limiter circuit turned it off.) The circuit then shuts off and will not restart until S1 is pressed again. If S1 remains on continuously, the inverter will run continuously. At an input of 1.5 VDC, the output will then top off at 350 to 400 VDC. The inverter may be shut off by shorting the base of Q1 to COM (either directly or via a transistor). However, note that except for the Kodak MAX configuration, note that I've only tested the circuits with S1 on permanently. I do not know if all configurations will work with a momentary switch.

See Photo of Ultra-Compact 350 V Capacitor Charger for an example of the compact construction (shown sitting on a U.S. dime).

The simplest source of power for these circuits is a single AA Alkaline cell. An alternative is the 1.5 V Alkaline Cell Eliminator. The peak current draw is several AMPs - anything that even slightly limits current will dramatically reduce the charging speed. DO NOT attempt to run on much more than 1.5 V as bad things may happen.

If your circuit doesn't oscillate at all, reverse the connections to the primary or secondary of the transformer, but not both.

There appears to be a slight difference in charging speed depending on which end of the HV winding goes to the HV rectifier. This is likely due to the interwinding capacitance or some other parasitic. Try both (reversing the primary as well) and pick the one that performs best. I'd expect the better one to be where the end of the HV winding goes to the HV rectifier.

Other factors which affect charging rate are input circuit resistance (due to the high current) and stray capacitance. These circuits seemed to charge consistently more slowly (by about 10 to 20 percent) when tested on a solderless breadboard compared to the original flash unit or the construction shown in the photo, above.

WARNING: Almost any uF value cap charged to 350+ VDC will result in a shocking experience if touched and may be lethal under the wrong conditions. Take care as potential danger of this little tiny circuit running from a 1.5 V battery easily be underestimated!

- Back to Sam's Schematic Collection Table of Contents.

IR Detector/Tester Circuits

IR Detector/Tester Circuits Introduction

Two approaches are shown below.

- The first uses a bare photodiode as the sensor. It is simpler, lower power, and shouldn't care what, if any, modulation is used by the IR source.

- An IR detector module salvaged from a TV or VCR, or purchased from Radio Shack or elsewhere may be used instead of a photodiode. This will have a much greater dynamic range (response to both weak and powerful signals) than a simple photodiode. However, some of these assume a particular modulation frequency and will be blind to anything else. Power requirements may also be more restrictive - it may insist on regulated 12 V).

- Back to Sam's Schematic Collection Table of Contents.

IR Detector Circuit Using Bare Photodiode

This IR Detector may be used for testing of IR remote controls, CD player laser diodes, and other low level near IR emitters. It will not have the sensitivity or dynamic range of the approach described in the section: IR Detector Circuit Using IR Receiver Module but will respond to all sources of IR falling within the wavelength range of the photodiode used since there is not demodulation or coupling circuitry to get in the way.

IR radiation falling on the photodiode causes current to flow through R1 to the base of Q1 switching it and LED1 on.

Component values are not critical. Purchase photodiode sensitive to near IR - 750-900 um or salvage from optocoupler or photosensor. Dead computer mice, not the furry kind, usually contain IR sensitive photodiodes. For convenience, use a 9V battery for power. Even a weak one will work fine. Construct the circuit so that the LED does not illuminate the photodiode!

The detected signal may be monitored across the transistor with an oscilloscope.

- Back to Sam's Schematic Collection Table of Contents.

IR Detector Circuit Using IR Receiver Module

This one uses an entire IR receiver module as the IR sensor. Its sensitivity and dynamic range will be much better than the circuit described in the section: IR Detector Circuit Using Bare Photodiode since these modules have automatic gain control circuitry built in. However, some modules are tuned to a particular modulation frequency and/or are AC coupled and will not respond to all remotes or other pulsed or continuous IR sources.

The IR receiver module from a TV, VCR, or purchased from Radio Shack or elsewhere, drives the base of Q1 through R1. It may even be possible to eliminate the transistor circuit entirely and connect the LED directly to the module's output (in series with a current limiting resistor to Vcc or Gnd) but that depends on the drive capabilities of the module. You can use whatever Vcc is required for the IR receiver module for the LED circuit as well but may need to change the value of R2 to limit the current to the LED to less than its maximum rating.

The specific case where Vcc is +5 V is shown.

Radio Frequency Circuits

Sam's 6146A RF Power Oscillator

This is a tunable RF generator based on a 6146A - a once popular "beam power tube", which I built about 30 years ago and recently resurrected in conjunction with my laser activities. It is a basic Hartley oscillator capable of at least 15 watts of RF output when powered from a 400 VDC, 100 mA power supply (of the same vintage and also recently resurrected). My most accurate power estimates are based on the "fluorescent lamp brightness test" and when driving a 15 W light bulb as a dummy load. :) The 15 W bulb runs best when attached to a 25 turn, 1 inch diameter air-core coil inserted into the main tuning coil (L2). Impress kids of all ages: Look, it lights with no wires!

However, depending on the tuning and loading cap settings, the oscillator may not start when the bulb is cold (due to its much lower filament resistance and thus too much load) and fully inserted into L2 - it must be partially withdrawn to start up. Much more than 15 W could likely be generated by powering the system from a higher voltage input (the 6146A's maximum ratings exceed 725 V and 250 mA).

With the components values used, its output frequency range is about 2.5 to 5 MHz which almost actually agrees with calculations (at least within a factor of 2. :)

I make no other claims about this circuit either in terms of efficiency or output purity - I know that it produces all sorts of harmonics which mess up local (at least) radio and TV reception depending on the setting of its tuning cap.

Schematic in GIF format: Sam's 6146A RF Power Oscillator.

A note about the power supply: This was probably one of my first electronics projects, back in the days when tubes were king (but in the process of being dethroned). It uses an old TV power transformer, 5U4 full wave rectifier, and a CRC filter with a dual section twist-lock electrolytic cap. It isn't good to put more than 500 V on a 450 V electrolytic cap: I was running the unit on a Variac capable of 140 VAC with the supply outputting 425 VDC or so. While adjusting the oscillator, the plate current went way down and without regulation, the output of the power supply drifted up to 500 or 550 V. While my back was turned, the cap started smoking profusely and all sorts of disgusting icky juice leaked out. Locating a replacement that would fit became a non-trivial exercise. :(

Basic Light Dimmer Circuits

Light Dimmer Circuits Introduction

These are the type of common triac based light dimmers (e.g., replacements for standard wall switches) widely available at hardware stores and home centers.

CAUTION: However, note that a dimmer should not be wired to control an outlet since it would be possible to plug a device into the outlet which might be incompatible with the dimmer resulting in a safety or fire hazard.

While designed for incandescent or heating loads only, these will generally work to some extent with universal motors as well as fluorescent lamps down to about 30 to 50 percent brightness. Long term reliability is unknown for these non-supported applications.

- Back to Sam's Schematic Collection Table of Contents.

Simplest Dimmer Schematic

The first schematic is of a normal (2-way) inexpensive dimmer - in fact this contains just about the minimal number of components to work at all!

S1 is part of the control assembly which includes R1.

The rheostat, R1, varies the amount of resistance in the RC trigger circuit. The enables the firing angle of the triac to be adjusted throughout nearly the entire length of each half cycle of the power line AC waveform. When fired early in the cycle, the light is bright; when fired late in the cycle, the light is dimmed. Due to some unavoidable (at least for these cheap dimmers) interaction between the load and the line, there is some hysteresis with respect to the dimmest setting: It will be necessary to turn up the control a little beyond the point where it turns fully off to get the light to come back on again.

Types of 3-Way Dimmers

There are at least two varieties of inexpensive 3-way style dimmer switches which differ mainly in the switch configuration, not the dimmer circuitry. You will probably have no reliable way of telling them apart without testing or disassembly.

None of the simple 3-way dimmer controls permit totally independent dimming from multiple locations. With some, a dimmer can be installed at only one switch location. Fully electronic approaches (e.g., 'X10') using master programmers and addressable slave modules can be used to control the intensity of light fixtures or switch appliances on or off from anywhere in the house.

However, for one simple, if inelegant, approach to independent dimming, see the section: [Independent Dimming from Two Locations - Lludge #3251](#).

Simple 3-Way Dimmer Schematic 1

The schematic below is of one that is essentially a normal 3-way switch with the dimmer in series with the common wire. Only one of these should be installed in a 3-way circuit. The other switch should be a normal 3-way type. Otherwise, the setting of the dimmer at one location will always affect the behavior of the other one (only when the remote dimmer is at its highest setting - full on - will the local dimmer have a full range and vice-versa).

Note that the primary difference between this 3-way dimmer schematic and the normal dimmer schematic shown above is the addition of an SPDT switch - which is exactly what is in a regular 3-way wall switch. However, this dimmer also includes a choke (L1) and capacitor (C2) to suppress Radio Frequency Interference (RFI). Operation is otherwise identical to that of the simpler circuit.

This type of 3-way dimmer can be used at only one end of a multiple switch circuit. All the other switches should be conventional 3-way or 4-way types. Thus, control of brightness is possible only from one location.

                           |            |           |
                           |   ::::::   |           |
   Black o-----------------+---^^^^^^---+-----------+
                                 L1
                         40 T #18, 2 layers
                       1/4" x 1" ferrite core
```

Simple 3-Way Dimmer Schematic 2

The schematic below is of a 3-way dimmer with a slightly more complex switching arrangement such that when the local dimmer is set to full on or full off, it is bypassed. (If you ignore the intermediate dimming range of the control, it behaves just like a normal 3-way switch.) With this scheme, it is possible to have dimmers at both locations without the dimmer circuitry ever being in series and resulting in peculiar behavior.

Whether this is really useful or not is another story. The wiring would be as follows:

```
              Location 1             Location 2
             3-way Dimmer      A    3-way Dimmer     +---------+
                  /o----------------------o\         |  Lamp   |
    Hot o------o/    Silver 1     Silver 2   \o------|   or    |-----o Neutral
           Brass   o----------------------o   Brass  | Fixture |
                     Silver 2  B  Silver 1           +---------+
```

(If dimming interacts, interchange the A and B wires to the silver screws at one dimmer).

This one uses a toggle style potentiometer where the up and down positions operate the switches. Therefore, it has 3 states: Brass to Silver 1 (fully up), dim between Brass and Silver 1 (intermediate positions), and Brass to Silver 2 (fully down).

```
                        Br  /o---o            Br   o---o          Br/\/o---o
  3-way dimmer is up o---o/   S1   or down o---o\  S1    or Dim o---o  S1
                             o---o                \o---o               o---o
                              S2                   S2                   S2
```

However, it is still not possible to have totally independent control - local behavior differs based on the setting of the remote dimmer (details left as an exercise for the reader).

Like the previous circuit, this dimmer also includes a choke (L1) and capacitor (C3) to suppress Radio Frequency Interference (RFI). It is just a coincidence (or a matter of cost) that the 3-way dimmers have RFI filters and the 2-way type shown above does not.

```

Independent Dimming from Two Locations - Kludge #3251

Here is a scheme which will permit dimming with independent control from two locations. Each location will have a normal switch and a dimmer knob. The toggle essentially selects local or remote but like normal 3-way switches, the actual position depends on the corresponding setting of the other switch:

```
                 Location 1       Location 2
           +--------+  4-way SW    3-way SW
Hot o--+---| Dimmer |----o\ /o--------o\            +---------+
       |   +--------+      /           \o----------| Fixture |------o Neutral
       |              +--o/ \o--------o      Center +---------+ Shell
       |              |                      (brass)           (silver)
       |              |            +--------+
       |              +------------| Dimmer |--+
       |                           +--------+  |
       +---------------------------------------+
```

As usual, the brass screw on the fixture or outlet should be connected to the Hot side of the wiring and the silver screw to the Neutral side.

The dimmers can be any normal knob or slide type with an off position.

Note that as drawn, you need 4 wires between switch/dimmer locations. 4-way switches are basically interchange devices - the connections are either an X as shown or straight across. While not as common as 3-way switches, they are available in your favorite decorator colors.

If using Romex type cable in between the two locations, make sure to tape or paint the ends of the white wires black to indicate that they may be Hot as required by Code.

And, yes, such a scheme will meet Code if constructed using proper wiring techniques.

No, I will not extend this to more than 2 locations!

CAUTION: However, note that a dimmer should not be wired to control an outlet since it would be possible to plug a device into the outlet which might be incompatible with the dimmer resulting in a safety or fire hazard.

Heating Appliance Schematics

Heating Appliance Introduction

This are only two circuits at present - both for toaster oven/broilers. :)

- Back to Sam's Schematic Collection Table of Contents.

Typical Toaster Oven/Broiler

Here is a schematic of a typical 'dumb'toaster oven/broiler - one without a P5-1000 chip if you can believe such a thing exists. :) Most of the complexity of these simple devices is actually in the sheet metal of the toast release mechanism! Like the more elaborate unit described in the section: Toastmaster Toaster Oven/Broiler with Electronic Controls, there is a knob for control of the oven/broiler functions and another for toast Light/Dark. A separate lever engages the toast function which terminates when the toast is done. You will note that other than that unit having an IC for toast timing, the basic circuits are almost the same.

Apparently, the only real difference between a "toaster oven" and a "toaster oven/broiler" is that the latter has a means of disabling the bottom heating element while in oven (non-timed) mode - and, of course, the price!

- The heating elements are either Calrod(tm) type or Nichrome wire coils, possibly enclosed in quartz tubes.

- A single knob selects OFF (full CCW, S1A open), oven temperature S1B opens at selected temperature), and BROIL (full CW, S1C open). Some models may have a separate both/top only switch.

- The Toast Timer can be a mechanical timer and/or a bimetal or other toast temperature sensor. Individual details will vary but when the toast is ready, they will both release the Toast Lever and open S2 as well as possibly signaling with a bell. The Light/Dark control may vary time or the temperature at which toast is considered 'done'.

This diagram is not based on any particular model.

Toastmaster Toaster Oven/Broiler with Electronic Controls

Well, for toast, at least! :)

Aside from the CMOS IC based toast timer, this is a fairly basic design:

- Toastmaster Toaster Oven/Broiler Schematic

The toast function and oven/broiler are controlled separately. A single Power/Temperature/Broil knob controls the oven/broiler. This is entirely electro-mechanical with a conventional bimetal thermostat. Toast darkness is based only on time using CD4541B timer chip to release a manually activated Toast lever. Older 'dumber' toasters often were more sophisticated in their operation using a combination of time and temperature. Not this one.

Its conventional counterpart would be identical except using a mechanical and/or toast temperature sensor in place of the IC timer. Despite what you might think, the most likely failures are NOT in the 'high-tech' electronics but the usual burnt out heating element(s), bad cord or plug, broken wires, and tired switches.

- Back to Sam's Schematic Collection Table of Contents.

Rechargeable Appliance Schematics

Rechargeable Appliance Schematics Introduction

Here are circuit diagrams from several inexpensive rechargeable flashlights. and an electric toothbrush. These all use very 'low-tech' chargers so battery life may not be as long as possible and energy is used at all times when plugged into an AC outlet. The electric toothbrush schematic is more interesting since it uses a high frequency inductive coupling rather than a direct connection.

- Back to Sam's Schematic Collection Table of Contents.

First Alert Series 50 Rechargeable Flashlight

This one is typical of combined all-in-one units using a lead-acid battery that extends a pair of prongs to directly plug into the wall socket for charging.

It is a really simple, basic charger. However, after first tracing out the circuit, I figured only the engineers at First Alert knew what all the diodes were for - or maybe not :-). But after some reflection and rearrangement of diodes, it all makes much more sense: C1 limits the current from the AC line to the bridge rectifier formed by D1 to D4. The diode string, D5 to D8 (in conjunction with D9) form a poor-man's zener to limit voltage across BT1 to just over 2 V.

The Series 50 uses a sealed lead-acid battery that looks like a multi-cell pack but probably is just a funny shaped single cell since its terminal voltage is only 2 V.

Another model from First Alert, the Series 15 uses a very similar charging circuit with a Gates Cyclon sealed lead-acid single cell battery, 2 V, 2.5 A-h, about the size of a normal Alkaline D-cell.

WARNING: Like many of these inexpensive rechargeable devices with built-in charging circuitry, there is NO line isolation. Therefore, all current carrying parts of the circuit must be insulated from the user - don't go opening up the case while it is plugged in!

        |<------- Charger ---------->|<---------- Flashlight ----------->|
```

I could not open the transformer without dynamite but I made measurements of open circuit voltage and short circuit current to determine the value of R1. I assume that R1 is actually at least in part the effective series resistance of the transformer itself.

Similar circuits are found in all sorts of inexpensive rechargeable devices. These have no brains so they trickle charge continuously. Aside from wasting energy, this may not be good for the longevity of some types of batteries (but that is another can of worms).

* Back to Sam's Schematic Collection Table of Contents.

Brand Unknown (Made in China) Rechargeable Flashlight

This is another flashlight that uses NiCd batteries. The charger is very simple - a series capacitor to limit current followed by a bridge rectifier.

There is an added wrinkle which provides a blinking light option in addition to the usual steady beam. This will also activate automatically should there be a power failure while the unit is charging if the switch is in the 'blink' position.

With Sa in the blink position, a simple transistor oscillator pulses the light with the blink rate of about 1 Hz determined by C2 and R5. Current through R6 keeps the light off if the unit is plugged into a live outlet. (Q1 and Q2 are equivalent to ECG159 and ECG123AP respectively.)

Electric Toothbrush with Inductively Coupled Charger

This was found in an Interplak Model PB-12 electric toothbrush but similar designs are used in other appliances that need to be as tightly sealed as possible.

A coil in the charging base (always plugged in and on) couples to a mating coil in the hand unit to form a step down transformer. The transistor, Q1, is used as an oscillator at about 60 kHz which results in much more efficient energy transfer via the air core coupling than if the system were run at 60 Hz. The amplitude of the oscillations varies with the full wave rectifier 120 Hz unfiltered DC power but the frequency is relatively constant.

The battery charger is nothing more than a diode to rectifier the signal coupled from the charging base. Thus, the battery is on constant trickle charge as long as the hand unit is set in the base. The battery pack is a pair of AA NiCd cells, probably about 500 mA-h.

For the toothbrush, a 4 position switch selects between Off, Low, Medium, and High (S1B) and another set of contacts (S1A) also is activated by the same slide mechanism. The motor is a medium size permanent magnet type with carbon brushes.

Solar Powered Walk Light

This was found in a Malibu(tm) LZ1 Solar light set made by Intermatic. It uses a solar cell, approximately 4 square inches in area, to charge a pair of AA NiCd cells during the day which powers a superbright yellow LED at night. I estimate the actual light output to be 2 or 3 mW at around 595 nanometers wavelength (something like stoplight yellow). Actually, it is kind of cool in more ways than one! :) If only the cheap plastic enclosure was actually waterproof....

```

       +----------------+------------+---+------+
```

When there is enough voltage from the solar cell, Q1 is turned on and Q2 (the LED driver) is turned off. As far as I can tell, there is nothing to actually limit current to the LED except for the combination of battery, transistors, LED, and wiring resistance. Both transistors could probably be replaced with 2N3904s. So, if you were duplicating this thing, I'd recommend adding something to control the current to the LED or at least checking it first!

Actual failure of this complex device would most likely be due to worn out NiCd cells or corrosion to due exposure to the weather.

Operational problems like weak output or inadequate lighting time could be due to insufficient Sunlight (the thing is installed under a bush!) or extended cloudy conditions. Of course, these don't produce a huge amount of light in any case!

Miscellaneous Circuits

Discrete Multivibrator

This is an astable multivibrator using discrete parts. Yes, I know, low tech but you can actually fondle all the internal points of interest that way :-).

The time constant of R1*C1 and R2*C2 determine the blink rate. (Try 50K, 10 uF to start for a visible blink rate).

You can also put an LED in series with one or both of the collector resistors (to blink alternately) and do away with any additional buffers.

Modify the values of these pair of Rs and Cs for operation at higher or lower frequencies. Some considerations:

- For very low Cs, stray capacitance and device frequency response will limit highest frequency.
- For very large Cs and/or very large Rs, leakage will limit lowest frequency.
- For very large Rs, gain of transistors may be inadquate.
- For very small Rs, transistors may melt down :-).

Note: C1 and C2 can be either non-polarized or polarized (electrolytic) types. If polarized (e.g., to obtain higher capacitance values for lower operating frequencies), install the capacitors in the direction shown.

Interesting Sequential Neon Flasher

This is a sort of brain teaser since it certainly isn't intuitively obvious how this circuit works (if it works at all). It may be instructive to start with the degenerate case of 2 resistors, 2 neon lamps, and a single capacitor. What happens with that configuration?

(From: Steve Roberts (osteven@akrobiz.com).)

Connect a .22 uF, 200 V capacitor between each of the following pairs of points: A to C, A to D, B to D, B to E, C to E.

Neons will flash in sequence ABCDE if fed off DC. Momentarily removing the DC will cause them to flash EDCBA.

Hint (sort of): This system may NOT do what would be expected when simulated on a computer unless certain conditions are met. What are they?

From an ancient Radio Shack "Pbox" kit - the first kit I ever built!

(From: Tim Conrad (tim.conrad@usoc.org).)

The sequential flasher circuit is very old, going back to the 1950s at least. Operation follows classic neon light theory. As the voltage rises on the lamps, one will reach threshold first, and fire. That drops the voltage (via caps) on the two connected lamps, and to a lesser degree on the lamps those are connected to. The caps will charge through the resistors and one of the far lamps will finally reach threshold and fire. The process goes on from there.

If you really want a strange one, draw 5 points in a circle. Then draw lines between the points. You will have a star inside of a pentagon. Replace each line with a 0.1 uF cap. Replace each point with a neon lamp and resistor. Resistor goes to +v and lamp. Other side of lamp to ground. (polarity doesn't really matter, just needs DC). Similar to your circuit, except more caps.

Power it up and the bulbs will flash in some 5 step pattern, which will repeat until you interrupt power. Only one lamp on at a time.

There are a whole lot of neon lamp circuits like this one. It is possible to build logic elements and flip-flops from them. I suppose one could build a computer with enough parts, although I don't know of anyone who had the patience.

1.5 V LED Circuits

Here are a pair of circuits that will light an LED when powered from a single 1.5 V alkaline cell. They should also operate on the 1.2 V output of a NiCd or NiMH cell as well as from a supercapacitor or ultracapacitor charged to 1 to 1.5 V.

Both circuits and the descriptions below have been contributed by: Andre De-guerin (mandoline@gtonline.net).

1.5 V LED Flasher

This circuit utilizes the voltage doubling principle to flash an LED from a 1.5 source like a single alkaline cell. In addition, it can be dark activated by gating pin 5 of U1 with an LDR (Light Dependent Resistor) and resistor. The current drain is less than 40 uA between flashes. The LED current is 50 mA peak so it's quite bright.

The original source for this circuit is from the ZSCT1555 Application Notes and a standard voltage doubler which was slightly modified so I could use a resistor instead of a diode. Not exactly new, but just a novel use of existing components as it isn't in any literature since the standard 555 timer works down to 3 V whereas this one works down to 0.9 V.

Using a 1 Farad supercapacitor charged to 1.5 V as the power source, the LED flashed for about eight hours. There was no change in oscillator frequency and the brightness stayed constant down to about 1.0 volts.

```

       _|_    _|_ 10nF
        =      -
```

Dark Activated 1.5 V LED Flasher

This circuit uses an ICL7660S to flash an LED from 1.5 V. A second LED in photodiode mode is used as the light sensor, inhibiting IC1 during daylight hours. Use a 9,600 mcd yellow LED for LED1, and a high efficiency red LED for LED2 to get maximum sensitivity. Replace LED2 with an infra-red (IR) LED to make a remote control sensor. The LED will go out when IR is detected

The original source of the this circuit was at: Circuitos Corporation under "LED Flasher" (along with many other interesting schematics). However, the original design used an ORP12 as the sensor instead of an LED. And it didn't work. Evidently, it was never tested.

```
      - |+ BT1,1.5V
    +--||--+----+----------+
    |   |  |   _|_ C2      |
    |      |   --- 22nF    |
  +----------+  |          |
  | 3      8 |  |   LED2    |
  |         7|--+---|>|----+
  |          |    Red LED  |
  |   IC1   6|--+          |  IC1: ICL7660
  |          |  |   LED1    |
  |         5|--+---|<|----+
  | 2      4 | 9,600 mcd yellow LED
  +----------+
    | +  - |
    +--|(--+
       C1
    47uF,6V
```

With only a minor modification (increase C2 to 0.1 uF) a similar flasher can be built with a MAX660. This provides a slightly higher output current and it will flash reliably with a larger time delay between flashes (like up to a minute with a 3.3 uF capacitor).

Additional Notes on Low Voltage Flashers

- I found that connecting pin 1 to ground made the circuit more stable.

- It will flash a blue or white LED if the circuit is run from a 3 V battery.

- To get maximum output from the LED, replace C1 with a 1,000 uF electrolytic and the circuit makes a good night-time flasher for model rocketry.

- If it's low current you are after, the circuit will work with an LED series resistor. You can also use a N channel JFET with gate wired to source in series with the LED in order to limit the flash current to between 1 and 3 mA. Also, use a tantalum bead capacitor for C1. It works well and allows the 7660 to run from up to 24 VDC down to 5 VDC. I set one up last night and it works well using a 4069 as the flasher and it draws 10 uA.

- I have tested this circuit and it runs from a 4 F supercapacitor for eight hours without the above modifications. A possible improvement would be to use a constant current source in series with a 1 F, 5.5 V supercapacitor in order to maximize the flash time.

- Back to Sam's Schematic Collection Table of Contents.

Brinkmann LED Light

This uses a single white LED to implement something that looks like a flashlight though it probably wouldn't win any awards for brightness. The challenge in such a circuit was to run a white LED with a 4+ V drop off a pair of AA batteries. This cute little circuit does it. In fact, it will run (at reduced brightness) at 1.5 V or less. See: Brinkmann LED Light.

The oscillator circuit runs at about 200 kHz producing a more or less squarewave voltage waveform across the LED with a peak of 4.5 to 5 V on fresh AA batteries. At reduced input voltage, the frequency is a bit lower and there is a longer low time as well as slightly reduced peak voltage.

- Back to Sam's Schematic Collection Table of Contents.

Variations on 555 Timer Circuits

Here some simple modifications to the basic 555 astable circuit. (Only the charge/discharge circuits are shown.)

Independently variable high and low time

```
 -----------+                             R1
        DIS |------------------------+---/\/\----o Vcc
            |         R2       D1    |
  555    TH |--+-----/\/\------|<|---+
            |  |      R3       D2    |
         TR |--+-+---/\/\------|>|---+
 -----------+   _|_
                --- C1
                _|_
                 -
```

R2 and/or R3 would typically be variable resistors. The time constant (R1+R2)*C1 controls the charge (high) time. The time constant (R1+R3)*C1 controls the discharge (low) time.

Fixed frequency, variable pulse width

```
         -----------+
                DIS |--------------+----------+
                    |        D1    |          |
           555   TH |--+-----|<|---+          |
                    |  |      R2       D2     v R3   R1
                 TR |--+-+---/\/\------|>|---/\/\---/\/\---o Vcc
         -----------+   _|_
                        --- C1
                        _|_
                         -
```

The time constant (R1+R2+R3)*C1 controls the total time. R1*C1 controls the minimum length of the charge (high) time. R2*C1 controls the minimum length of the discharge (low) time.

DISCLAIMER

Many of the circuits have been reverse engineered - traced from various schematics or actual hardware. There may be errors in transcription, interpretation, analysis, or voltage or current values listed. They are provided solely as the basis for your own designs and are not guaranteed to be 'plans' that will work for your needs without some tweaking.

The power supplies for electronic flash and strobe equipment operate at extremely lethal voltage and current levels. The energy storage capacitors in even the smallest disposable camera flash operating from a 1.5 V AA battery can be deadly under the wrong conditions. Line powered strobes have added danger of high power at high voltage AND are often non-isolated (no power transformer. Do not attempt to troubleshoot, repair, or modify such equipment without understanding and following ALL of the relevant safety guidelines for high voltage and/or line connected electrical and electronic systems.

We will not be responsible for damage to equipment, your ego, county wide power outages, spontaneously generated mini (or larger) black holes, planetary disruptions, or personal injury or worse that may result from the use of this material.

Introduction

Sub-Table of Contents

- Back to Introduction Sub-Table of Contents.

Scope and Purpose of This Document

This collection of material started out in life as a simple repair manual for electronic flash units. It has since evolved to include design information for a variety of types of equipment including many shapes, sizes, and styles of electronic flash units and repeating strobes. In addition, there are numerous circuit ideas and over a dozen complete schematics for commercial and home-built systems covering a range of power levels and power sources.

- Back to Introduction Sub-Table of Contents.

Organization of This Document

For the most part, we assume that your are somewhat familiar with basic electronics and your intended application - be it for photography, measurement, or entertainment. Perhaps you are just curious about how all those flashing lights work!

PART I provides a basic description of the characteristics and principles of operation of electronic flash and related devices based on the xenon flashlamp. Especially important if you intent to be working inside this equipment is the SAFETY information. It is all too easy to electrocute yourself on the energy storage capacitors or line powered circuits.

PART II deals with troubleshooting and repair with emphasis on the kinds of electronic flash units found in photographic equipment - from tiny disposable cameras to high power studio 'speed lights'.

PART III provides information on the design of small to medium size electronic flashes and repeating strobes including basic design guidelines, shortening or lengthening flash duration, power supply component selection. There is a detailed discussion on retrofitting an old camera to use a modern electronic flash. And, there are a variety of circuits for repeating flashes, trigger circuits, inverters, and more.

PART IV provides over a dozen complete (well, very nearly complete, anyhow) schematics for electronic flash units from disposable cameras, external (Hot shoe or side mounted) strobes, higher performance line powered units, as well as repeating stroboscopes and even a timing light.

Note: Links to all the diagrams and photographs referenced from this document can be found in Sam's Strobe FAQ Files.

The single largest collection of hobbyist type xenon flash and strobe information can probably be found at the Don Klipstein's Lighting Technology Web Site which is a valuable resource for information relating to lighting technology in general and also includes additional articles dealing with strobe principles and design. Don's Xenon Flash and Strobe Page also includes a guaranteed late model version of Sam's Strobe FAQ.

A large collection of lighting and strobe related schematics and links can be found Tomi Engdahl's Lights and Electronics Page.

There are many other documents at the Sci.Electronics.Repair (S.E.R) FAQ Web site or one of its mirror sites which may be of use in the design, testing, and repair of strobe equipment. The Main Table of Contents (ToC) provides links to a variety of information on troubleshooting and repair of many types of equipment, general electronics, an assortment of schematics, over 1,000 technology links, and much more. Most of these documents are nicely formatted, indexed, and cross-referenced. (Silicon Sam's Technology Resource, which may be present at this site and others, usually contains slightly more recent versions of many of these same documents but most of those under the S.E.R FAQ Main ToC are easier to use and the actual content differences are likely to be minor.)

- Information on isolation transformers (essential for safety) and variable transformers (Variacs), series light bulb adapter, and other Incredibly Handy Widgets(tm) for your test bench will be found in the document: Troubleshooting and Repair of Consumer Electronic Equipment and possibly in the specific document for each type of equipment.

- Schematics associated with the testing of capacitors, transistors and other semiconductor devices (includes simple curve tracer design), flyback and other transformers, etc., will be found in the document dealing with each of these typse of devices.

- Various Schematics and Diagrams includes a variety of circuits that may be useful in generating the high voltage for xenon flashes and strobes.

- Sam's Laser FAQ, a large collection of information on lasers and laser related equipment, includes among other things, an extensive set of power supply and other schematics as well as a large list of electronics suppliers. Some of this may come in handy with respect to xenon strobe circuits and parts.

- Salvaging Interesting Gadgets, Components, and Subsystems for unconventional sources and uses for neat, useful, and otherwise discarded or neglected parts and equipment.

See the Home and Mirror Site Locations for other possibilities which may be faster from where you live.

Electronic Flash and Strobe Principles of Operation

Sub-Table of Contents

- Back to Electronic Flash and Strobe Principles of Operation Sub-Table of Contents.

Electronic Flash Fundamentals

All modern electronic flash units (often called photographic strobes) are based on the same principles of operation whether of the subminiature variety in a disposable pocket camera, high quality 35 mm camera, compact separate hot shoe mounted unit, or the high power high performance unit found in a photo studio 'speed light'. All of these use the triggered discharge of an energy storage capacitor through a special flashlamp filled with xenon gas at low pressure to produce a very short burst of high intensity white light.

The typical electronic flash consists of four parts: (1) power supply, (2) energy storage capacitor, (3) a means of generating a trigger pulse, and (4) flashlamp, as shown below:

```
       HV+ o------/\/\-------------+----------------+
                Current            |         Anode _|_
     DC Power   Limiting       C1  |              | | |
      Supply    Resistor   Energy _|_+       FL1 |   ||
      (300 V              Storage ---       Xenon |   ||---- Trigger Pulse
      typical)          Capacitor  | -  Flashlamp |   ||
                                   |              | | |
                                   |       Cathode'-|-'
    HV Ret o-----------------------+----------------+
```

An electronic flash works as follows:

1. The energy storage capacitor connected across the flashlamp is charged from a 300 VDC (typical) power supply. This is either a battery or AC adapter operated inverter (pocket cameras and compact strobes) or an AC line operated supply using a power transformer or voltage doubler or tripler (high performance studio 'speed' lights). These are large electrolytic capacitors (100 to 1,000+ uF at 300+ V) designed specifically for the rapid discharge needs of photoflash applications.

2. A 'ready light' indicates when the capacitor is fully charged. Most monitor the voltage on the energy storage capacitor. However, some detect that the inverter or power supply load has decreased indicating full charge.

3. Normally, the flashlamp remains non-conductive even when the capacitor is fully charged.

4. A separate small capacitor (e.g., .1 uF) is charged from the same power supply to generate a trigger pulse.

5. Contacts on the camera's shutter close at the instant the shutter is fully open. These cause the charge on the trigger capacitor to be dumped into the primary of a pulse transformer whose secondary is connected to a wire, strip, or the metal reflector in close proximity to the flashlamp. An SCR or triac can substitute for the contacts

if electronic, remote, or slave triggering is required.

6. The pulse generated by this trigger (typically around 4 to 10 kV depending on the size of the unit) is enough to ionize the xenon gas inside the flashlamp.

7. The xenon gas suddenly becomes a low resistance and the energy storage capacitor discharges through the flashlamp resulting in a short duration brilliant white light.

While details differ, everything from the flashing lights at your local disco to the flashlamps in monster pulsed lasers operate on essentially the same principles.

The energy of each flash is roughly equal to $1/2*C*V^2$ in watt-seconds (W-s) where V is the value of the energy storage capacitor's voltage and C is its capacitance. Not quite all of the energy in the capacitor is used but it is very close. The energy storage capacitor for pocket cameras is typically 100 to 400 uF at 330 V (charged to 300 V) with a typical flash energy of 10 W-s. For high power strobes, 1000s of uF at higher voltages are common with maximum flash energies of 100 W-s or more. Another important difference is in the cycle time. For pocket cameras it may be several seconds - or much longer as the batteries run down. For a studio 'speed light', fractional second cycle times are common.

Typical flash duration is much less than a millisecond resulting in crystal clear stop action photographs of most moving subjects. However to capture really high speed motion like a the splash of a water droplet or a speeding rifle bullet flashes down to 1 millionth of a second or less are needed. These can be provided by specially designed strobe equipment but still based on principles very similar to those used in a pocket flash.

On cheap cameras (and probably some expensive ones as well) physical contacts on the shutter close the trigger circuit precisely when the shutter is wide open. Better designs use an SCR or other electronic switch so that no high voltage appears at the shutter contacts (or hot shoe connector of the flash unit) and contact deterioration due to high voltage sparking is avoided.

Note that for cameras with focal plane shutters, the maximum shutter speed setting that can be used (X-Sync) is typically limited to between 1/60 and 1/120 of a second. The reason is that for higher shutter speeds, the entire picture is not exposed simultaneously by the moving curtains of the focal plane mechanism. Rather, a slit with a width determined the by the effective shutter speed moves in front of the film plane. For example, with a shutter speed setting of 1/1000 of a second, a horizontally moving slit would need to be about 1/10 of an inch wide for a total travel time of 1/60 of a second to cover the entire 1.5 inch wide 35 mm frame. Since the flash duration is extremely short and much much less than the focal plane curtain travel time, only the film behind the slit would be exposed by an electronic flash. For shutter speed settings longer than the travel time, the entire frame is uncovered when the flash is triggered.

For complete schematics of both battery and AC line powered equipment, see the sections starting with: Schematics for Pocket Camera and Externally Mounted Compact Flash Units.

Red-eye reduction provides a means of providing a flash twice in rapid succession. The idea is that the pupils of the subjects' eyes close somewhat due to the first flash resulting in less red-eye - imaging of the inside of the eyeball - in the actual photograph.

This may be done by using the main flash but many cameras use a small, bright incandescent bulb to 'blind' the eyes when the shutter is pressed to meter, then it goes off and the flash preserves the 'closed' pupils. This approach works. Using the main flash would require sub-second recycle time which is not a problem if an energy conserving flash is used (see the section: Vivitar Auto/Thyristor 292 Energy Conserving Automatic Flash. However, it would add significant additional expense otherwise (as is the case with most cameras with built in electronic flash). A separate little bulb is effective and much cheaper.

Failure of red-eye reduction or the automatic exposure control circuits will probably require a schematic to troubleshoot unless tests for bad connections or shorted or open components identify specific problems. However, some of these use fairly simple circuits with mostly standard components and can be traced without too much difficulty. For red-eye in particular, It is also possible for that extra incandescent light bulb to be burnt out but good luck replacing it!

Remotely triggered 'fill flashes' use a photocell or photodiode to fire an SCR (or light activated SCR) which emulates the camera shutter switch closure for the flash unit being controlled. There is little to go wrong with these devices.

- Back to Electronic Flash and Strobe Principles of Operation Sub-Table of Contents.

Automatic Exposure Control Electronic Flash Units

Automatic electronic flash units provide an optical feedback mechanism to sense the amount of light actually reaching the subject. The flash is then aborted in mid stride once the proper exposure has been made. This means that the flash duration will differ depending on exposure - typically from 1 ms at full power to 20 us or less at close range.

Inexpensive automatic flash units just short across the flashlamp with an SCR or second internal 'quench' tube (an internal small xenon tube that looks like an oversize neon indicator lamp) triggered by a photosensor. See the sections starting with: "Vivitar Auto 253 electronic flash circuit". With these units, the same amount of energy is used regardless of how much light is actually required and thus low and high intensity flashes drain the battery by the same amount - and require the same cycle time. The excess energy is wasted. Note that it is not the distance to the subject that matters but the amount of total light energy reflected back to the sensor. The travel time of the light has nothing to do with controlling exposure. True energy conserving flash units use only as much energy as needed and the batteries last much longer since most flash photographs do not require maximum power. Furthermore, when using low power flashes, the cycle time is effectively zero since the main energy storage capacitor does not discharge significantly. Therefore, multiple shots can be taken in rapid succession. See the section: Vivitar Auto/Thyristor 292 Energy Conserving Automatic Flash.

Many energy conserving flash units use a clever approach to avoid having to interrupt the 100 AMPS or more that may be flowing through the flashlamp. Like the non-energy conserving type, they bypass current around the flashlamp at the instant that the flash is to be terminated. But rather than dumping the energy to ground and wasting all of it, the current is diverted into a small capacitor. The voltage across the flashlamp drops to a low value just long enough for the flashlamp to revert to a non-conducting state. Only a small amount of energy is lost (that which goes into the bypass capacitor). More sophisticated units use something like a Gate TurnOff Thyristor (GTO) or high power Insulated Gate Bipolar Transistor (IGBT) to actually interrupt the flash discharge at the proper instant. These save virtually 100 percent of the energy and the circuitry is actually simpler, but the cost and availability of GTOs or IGBTs with the required peak surge rating of 100s of AMPS are a consideration in their design.

Although the high voltage inverter and actual flash tiggering circuitry is usually easy to trace, failure of the automatic exposure control circuit itself will probably require a schematic to troubleshoot unless tests for bad connections or shorted or open components identify specific problems. However, some of these use fairly simple circuits with mostly standard components and can be traced without too much difficulty though the compactness of modern flash units makes this somewhat more of a challenge. The most likely failures are still in the power circuits, not the control.

Safely Working with Xenon Flash and Strobe Equipment

Sub-Table of Contents

- Back to Safely Working with Xenon Flash and Strobe Equipment Sub-Table of Contents.

Xenon Strobe Safety

There are two potential hazards in dealing with the innards of electronic flash and other xenon strobe equipment:

1. The energy storage capacitor. Even on small pocket camera electronic flash units, these are rated at 100 to 400 uF at 330 VDC. This is 5 to 20 W-s which is enough to kill you under the right (wrong?) conditions. Hot shoe or side mounted electronic flash units have energy storage capacitors which are usually larger - typically 300-1000 uF or more. High performance studio speed lights may have 10 times this capacity and at much higher voltages resulting in even greater energy storage. Xenon strobes for pumping of solid state laser rods and other industrial and scientific applications may use many kV power supplies with 1000s of W-s energy storage capacitors - touch one of these and you will be but a puff of vapor in the wind...

   High voltage with high energy storage is an instantly deadly combination. Treat all of these capacitors - even those in tiny pocket cameras with respect. Always confirm that they are discharged before even thinking about touching anything. On larger systems especially, install a shorting jumper after discharging just to be sure - capacitors have been known to recover a portion of their original charge without additional power input. Better to kill the power supply than yourself if you forget to remove it when powering up.

2. Line connected (no power transformer) have all the dangers associated with AC line power in addition to the large power supply and energy storage capacitors. Always use an isolation transformer when probing line connected systems. However, keep in mind that the power supply filter capacitors and energy storage capacitors remain just as deadly.

Additional important safety information regarding shock, excessively bright light, ultraviolet radiation, heat and fire hazards, and other hazards is available from Don's Xenon Strobe and Flash Safety Hints page.

Reading and following these recommendations and heeding the warnings is especially important when working with high power strobes.

General Safety Guidelines

Due to the dangers inherent in even the smallest electronic flash unit, it is imperative that you understand and follow ALL safety recommendations while working inside this equipment.

See the document: Safety Guidelines for High Voltage and/or Line Powered Equipment.

- Back to Safely Working with Xenon Flash and Strobe Equipment Sub-Table of Contents.

Safe Discharging of Capacitors in Electronic Flash Units

A working electronic flash or strobe may discharge its capacitors fairly quickly when it is shut off but most DO NOT do this. Furthermore, do not assume that triggering the flash fully discharges either the power supply filter or main energy storage capacitors fully - especially if it is a sophisticated automatic unit.

The main filter capacitors in the low voltage power supply may have bleeder resistors to drain their charge relatively quickly - but resistors can fail. Don't depend on them. For battery powered equipment in particular, efforts may have been made NOT to bleed the energy storage capacitor to conserve on battery power should another shot be desired at a future time. Some units even keep the flash fully charged when supposedly turned off!

The technique I recommend is to use a high wattage resistor of about 5 to 50 ohms/V of the working voltage of the capacitor. This will prevent the arc-welding associated with screwdriver discharge but will have a short enough time constant so that the capacitor will drop to a low voltage in at most a few seconds (dependent of course on the RC time constant and its original voltage).

Then check with a voltmeter to be double sure. Better yet, monitor while discharging.

Obviously, make sure that you are well insulated!

For the power supply filter capacitors or main energy storage capacitors, which might be 400 uF at 350 V, a 2 K ohm 25 W resistor would be suitable. RC=.8 second. 5RC=4 seconds. A lower wattage resistor (compared to that calculated from V^^2 / R) can be used since the total energy stored in the capacitor is not that great (but still potentially lethal).

The discharge tool and circuit described in the next two sections can be used to provide a visual indication of polarity and charge for TV, monitor, SMPS, power supply filter capacitors and small electronic flash energy storage capacitors, and microwave oven high voltage capacitors.

Reasons to use a resistor and not a screwdriver to discharge capacitors:

1. It will not destroy screwdrivers and capacitor terminals.

2. It will not damage the capacitor (due to the current pulse).

3. It will reduce your spouse's stress level in not having to hear those scary snaps and crackles.

Capacitor Discharge Tool

A suitable discharge tool for each of these applications can be made as quite easily. The capacitor discharge indicator circuit described below can be built into this tool to provide a visual display of polarity and charge (not really needed for CRTs as the discharge time constant is virtually instantaneous even with a multi-M ohm resistor.

- Solder one end of the appropriate size resistor (for your application) along with the indicator circuit (if desired) to a well insulated clip lead about 2-3 feet long. For safety reasons, these connections must be properly soldered - not just wrapped.

- Solder the other end of the resistor (and discharge circuit) to a well insulated contact point such as a 2 inch length of bare #14 copper wire mounted on the end of a 2 foot piece of PVC or Plexiglas rod which will act as an extension handle.

- Secure everything to the insulating rod with some plastic electrical tape.

This discharge tool will keep you safely clear of the danger area.

Again, always double check with a reliable voltmeter or by shorting with an insulated screwdriver!

Capacitor Discharge Indicator Circuit

Here is a suggested circuit which will discharge the high voltage power supply filter capacitors and main energy storage capacitors of most types of electronic flash units and strobe lights. This circuit can be built into the discharge tool described above.

A visual indication of charge and polarity is provided from maximum input down to a few volts.

The total discharge time is approximately 1 second per 100 uF of capacitance (5RC with R = 2 K ohms).

Safe capability of this circuit with values shown is about 500 V and 1000 uF maximum. Adjust the component values for your particular application.

      _\_/_   _/_\_      |
 In 2   |       |        |
o-------+-------+--------+
(GND Clip)
```

The two sets of 4 diodes will maintain a nearly constant voltage drop of about 2.8-3 V across the LED+resistor as long as the input is greater than around 20 V. Note: this means that the brightness of the LED is NOT an indication of the value of the voltage on the capacitor until it drops below about 20 volts. The brightness will then decrease until it cuts off totally at around 3 volts.

Safety note: always confirm discharge with a voltmeter before touching any high voltage capacitors!

Why do Roulette Wheels Sometimes Appear to Spin Backward?

Roulette wheels and wagon wheels spinning backwards represents a form of aliasing due to sampling. OK, the technical jargon aside this effect will only take place in a situation where images are captured at discrete intervals as they are in a motion picture or video - or when illuminated with a repeating strobe. For motion pictures, something like 24 frames per second are recorded; for video there are 30 frames per second (in the US, 25 in many other countries). However, the use of interlacing where a complete frame is scanned in two parts - the even and the odd lines - complicates the explanation so I will restrict the remainder of this discussion to motion picture film).

If the rotation rate of the wheel is such that one spoke or slot goes by a given position in exactly 1/24th of a second, the wheel will appear stationary since successive images will be identical. If it is moving a bit faster than this it will appear to be moving forward slowly. However, if it is going a bit slower, then it will be appear to be turning backwards slowly. The shorter the exposure with respect to the total frame time, the sharper will be the apparent effect. The number of slots per second of perceived motion will be equal to the difference in frame rate and number of slots per second passing a given point. So, a roulette wheel rotating such that 23 slots are passing by per second captured on a 24 frame per second camera will appear to be moving backwards at 1 slot per second.

The same applies to the use of a strobe light to freeze repetitive motion like the rotation of a shaft. It is all a matter of the relative speed of the sampling (the movie, video or strobe) with respect to an object which is periodic like a roulette or wagon wheel.

You can perform a simple experiment: run an electric fan under a fluorescent lamp (one with an ordinary magnetic ballest). The light from such a lamp is not continuous but pulses 120 times per second. Watch for stationary or slowly rotating blade patterns as the fan speeds up and slows down. See if you can compute the speed of the fan from this behavior.

Kevin Attempts to Abuse a Strobe

(This from: Kevin 'Destroyer of Worlds' Horton (khorton@tech.iupui.edu))

Just for funsies, I decided to see how much torture I could inflict on the flashlamp and energy storage capacitor from one of those little Kodak cameras. The tube was 1.2" long, in a metalized plastic reflector, with a thin metal backing to hold it in. The capacitor was 120 uf, 330 V. I hooked it up to my inverter (12 V->300 V at high current) and fired 'er up! Pop, pop, pop, pop, pop, pop, pop, (turn up trigger oscillator frequency) popopopopopopopopopopopopop! It was firing about 30 or 40 times a second; it appeared as it was constantly on! I turned it down to about 15 flashes a second, and let it run. First thing I noticed was that wonderful scent of melting acrylic. Then, I noticed that the tube was kind of skewed in the reflector. The plastic was in full smoke-mode by this point. Still, the tube kept firing! (Let's see: 5 W-s times 15 flashes per second is 75 W average power, not bad for an itty bitty tube --- sam).

I left it on a bit more, and the plastic really started the smoke-signals! I noticed that one electrode was glowing cherry red. Even after all this torture, it kept going! The smoke was getting too much, so I hit the 'off' on my inverter. A few more gouts of smoke, and the little fire I created was extinguished. I let it cool down and then I examined the damage. The reflector was totaled; the tube had all but melted clean through. When I touched it, the little metal plate popped off.

On closer examination, the tube appeared to be in good shape. I couldn't see any visible damage to either the electrodes, or the glass seals. A quick test reveals that the tube still functions. As a side note, the storage capacitor got quite hot; probably around 35 degrees C. All in all, an interesting test, I must say. The next will involve connecting up a normal NE2 neon bulb and observing the results of high voltage and high current on it. I suspect it will be quite spectacular, so I'm taking precautions - It will be performed in a proper enclosure, so if the neon decides to really go 'pop', it won't do any damage.

Really BIG Strobes for Stadium Sized Special Effects (or ET Comm link?)

(From: Ruben (ruben@worldaccess.nl).)

I used to design stage-effects, and played some time with strobes. Built a number, from 750 W-s at high rates to 22,500 W-s single flash. Philips makes xenon lamps, designed for photographic use - they are not flashtubes but burn continually - so using them as flashtube shortens their life span (assuming you increase power). They are expensive, from $250 for the smallest to $1,100 for the biggest.

For caps for the smaller (20 to 100 W-s) strobes, I used a huge array of MKT motor-caps. 10 uF at 630V is cheap, a few dollars, and building an array of these is not too hard. These caps are screw-mount, and you can just fill a board with them, and switch them in parallel. Keeps the ESR low, which is a requirement.

The monsters used larger caps, 680 uF each. My boss often visited executory sales and bought components and machinery. These caps (he had a number of crates full of them) sat on the shelves for a year before I decided to do something with them. Beautiful Siemens stuff. Very low ESR, large cap. Nevertheless, I did say "huge array" which was exactly that. Two boards (one for each set of lamps) filled with them, each board 1 by 1.5 meters, which dictated the size of the case. As I remember these caps were about 5 centimeters diameter, and something like 12 centimeters high, so - guessing - you could stack around 280 of them on a board, which sounds right.

All problems I had related to heat. The 750 and 1500 W-s models had a habit of melting their main wire. On typical stages one uses a lot of extension-wires, and its power consumption could be high enough to heat the extension to the point the insulation came dripping off, without blowing a fuse. Had to lower the amount of energy per flash at higher rates. The protective window in front was another problem area. Poly-carbonate covers work fine, but a single fingerprint absorbs enough IR to melt a hole in the cover. Glass won't melt, but shatters if dirty. Don't allow anything near it. Colored paper will catch fire within seconds, at max rate. Always use it to flash at a wall, never let the public look into such a bright flash.

The biggest used four larger tubes, flashing two by two, but charge-times were too long to make it usable as a real strobe. It was used to flash the ceiling of a large stadium. I considered it to be useless. I never solved the problems it had, like eating its eight, expensive, diodes (>$40 each) for lunch. It sucked dips in the mains, big enough to cause digital equipment to fail. Imagine all the effects of the audio-boys resetting after each flash. I kept it running for a few months, but when the edges of the window caught fire I scrapped it. I modified one off the triggers for the small strobe (750 and 1500 w-S) to allow multiple units.

I found a note in the same binder with a capacitor-free design for a strobe. The smallest Xenon tube made by Philips has a burning voltage low enough to start it on 220V. With a suitable choke and a diode in series it will burn - after ignition - for the rest of the half-cycle. The diode makes sure it dies when the polarity reverses. (Residual ionization will make it re-ignite without the diode) The choke will keep it from aggravating the utility-companies. I wonder if anyone knows a trick to enhance ionization. Fully ionized it has a burning-voltage of 50 Volts, but even after the 4 kV pulse it needs 200 Volts to get started. Only tricks I know are the 'normal' starter-pulse, microwave pulses, radioactivity and laser-pulses. Only the first one is acceptable with audiences around. It probably won't work with 110 V mains.

(From: Tomi H. Engdahl (then@cc.hut.fi).)

A friend of mine has around a 3 kW disco stroboscope. (It is really 3 kW as it blows a 230 V, 10 A fuse at full power. And you can guess that it is quite bright!) That stroboscope seems to be taking quite heavy (few tens of amperes) of current for one half wave when it flashes. The firing angle is controlled by the internal brightness control (dimmer).

What it looked inside on quick glance it seemed to have a heavy thyristor, rectifier, heavy line filter, one coil in series with the tube, the tube itself, and the triggering electronics.

(From: Sam.)

On 110 VAC you're out of luck if no caps are allowed and you don't want to use a stepup transformer. In any case, what you end up with is more of an arc lamp than a flashlamp since the current is limited to a few amps as opposed to 10s or 100s of A for even a tiny strobe.

Recycled Defibrillator as Capacitor Charger

The following may come in handy when building that next high speed high power strobe or pulsed laser.

WARNING: Defibrillators are at least as good at stopping beating hearts as restarting misbehaving ones. The charge in their energy storage capacitor (typically 300 to 400 Joules) is enough to kill a half dozen healthy adults instantly. The operating voltage (up to 5 kV) doesn't respect common wire insulation and can jump 1/4" or more in air. There are no second chances.

(From: Steve Roberts (osteven@akrobiz.com).)

Older defibrillators are now showing up as inexpensive surplus because their ancient edmark waveform is being replaced with newer computer controlled biphasic waveforms.

So what do you get in a typical edmark waveform defibrillator:

1. Switching HV supply up to 5 kV with programmable shutoff voltage.
2. 32 uF Maxwell energy storage capacitor rated at 5 to 6 kV.
3. 47 mH inductor rated for the above cap's current.
4. A high pressure gas (SF6?) or BIG vacuum glass relay.
5. A second smaller vacuum relay.
6. A 50 ohm resistor for bleeding the cap and simulating a patient's chest.
7. Usually a vectorscope with an amber phosphor CRT and a GM20 or similar galvanometer if the unit has a chart recorder.

Notes: The relay is usually a 5 kV 50 A DPDT which has a short across one set of contacts to protect the patient. The other set of contacts goes to the capacitor common leads and to the patient via the paddles. So, presto! - apply 12 volts to the relay and you get up to 360 joules dumped into the victim or patient via the inductor to control the waveform. A patient's chest is assumed to be about 50 ohms impedance via the conductive cream to the paddles so the test circuit monitors what happens when the second smaller relay dumps the cap into the 50 ohm air cooled test resistor. The cap is also dumped during power-down.

I can't overstress the absolute need for safety when handling a 33 uF 5 kV capacitor. Newer defibrillators have a MOSFET H-bridge for bipolar switching and only go to two kV with smaller caps.

- Back to Items of Interest Sub-Table of Contents.

Xenon Pressure in Typical Flashtubes

The following was prompted by my observation that many small flashtubes are not glass sealed but use a frit (sort of a solder for glass) or possibly even an Epoxy seal. However, at the relatively high xenon pressure (see below), leakage should be of little consequence even over a long period of time. As long as the sealing material can handle the heat during operation, even Epoxy should be fine.

(From: Don Klipstein (don@misty.com or klipstei@netaxs.com).)

I actually busted some smaller flashtubes in a cup of vegetable oil to get an idea of the xenon pressure! In the Radio Shack U-shaped tubes, the pressure is about 80 Torr. In a smaller cheap linear tube with the electrodes 19 mm. apart, the pressure is about 180 Torr. In at least one version of the tiny tubes often used in cheap and disposable cameras, the pressure is about 450 to 500 Torr. Most other small camera flashtubes are 100 to 300 Torr.

In many medium and large flashtubes, the pressure seems to be around 80 Torr, except one I have seems to have a little less - maybe 60 Torr. This was for three different professional photoflash tubes, a larger version of the popular U-shaped strobe tube, and a large photocopier flashtube. I estimated the pressure in these by passing a few milliamps through them from a neon sign transformer (operated at reduced voltage) and commparing the appearance of the discharge to that in tubes of known pressue.

Larger photographic flashtubes - mostly around 80 to 200 Torr:

- Norman FT-6 - lowish, 70 Torr (?).
- Spedotron MW8QW/14540 - looks like about 80 Torr.
- Photogenic C4-5 - looks like about 80 Torr.
- Lumedyne 090Q - higher, 120 to 160 Torr???.
- A sealed beam aviation strobe, NSN 6240-01-006-1260 - higher, around 200 (?). There is a slight trend for narrower tubes to have higher pressure and larger tubing diameter tubes to have lower pressure.

EG&G, Electro-Optics Division 35 Congress St Salem MA uses a standard pressure of 450 Torr in their superduper linear flashtubes, but won't hesitate to use a custom pressure at customer's request.

BIG Strobe from Fluorescent Tube?

From a posting on the USENET newsgroup sci.electronics.misc:

> "I had an interesting idea. Get a small (2 watt) fluorescent tube, wrap several turns of wire round it, connect ends of tube to xenon strobe outputs, connect wire to HV trigger connection, switch it on. As far as I can tell, this would make one hell of a bright strobe! Any ideas???"

Depending on the voltage and size of the tube, you may not need trigger - it will break down at lower voltage than xenon tube. For your 2 W tube, this is a certainty.

It will also only likely work for one or at most a few flashes unless you use a much smaller capacitor. What happens is the filaments disintegrate. Fluorescent tubes are NOT designed for the high peak current of a strobe type circuit with a large energy storage capacitor. Go much beyond their normal ratings of a few hundred mA and they will fail.

Been there, done that. I once powered an 8 foot fluorescent tube from a six volt lantern battery pulse circuit and stepup transformer - and even such a large tube was destroyed after a few flashes. But the flashes WERE pretty bright. :-)

(From: Don Klipstein (don@misty.com or klipstei@netaxs.com).)

It is not as bright as xenon. Also, triggering characteristics will change as strobe duty changes the condition of the electrodes, also as temperature changes and mercury vapor concentration changes. I've tried it - the fluorescent tube changes too much with temperature and past history of strobe use.

One more thing: A strobing fluorescent tube is more conductive than a xenon tube, which means more of the energy stored in the energy storage capacitor is used to heat the capacitor, and less is dissipated in the tube. But enough is dissipated into the tube to beat up the electrodes!

(From: Craig Douglas (blackspear@hotmail.com).)

You can very successfully flash banks of fluorescent lamps by running a continuous low current through the lamps and increasing the current (the lamps appear off, but are actually still lit). This works well in the electric sign industry.

The same principle is used to flash standard incandescent bulbs, without the bulbs blowing continually. It is the spike in initial power that blows the filament, running a low current continually through to keep the filament warm minimizes stress on the filament which stops it from blowing.

(From: Sam.)

It should be noted that this will not increase lamp life significantly in normal operation but may extend it by a few percent.

Strobe Parts Sources

Sub-Table of Contents

- Back to Strobe Parts Sources Sub-Table of Contents.

New and Surplus Parts

Common electronic components can be obtained from any large distributor. Even Radio Shack may have what you are looking for. However, many do not list any xenon flashlamps or trigger transformers.

1. Mouser Electronics, 1-800-346-6873. General electronics parts including trigger transformers, magnet wire, rechargeable batteries, laser diodes, photodiodes, much more.

   Mouser stocks a few xenon flashlamps and trigger transformers suitable for both small and medium power strobes.

2. Dalbani, 1-800-325-2264. Excellent Japanese semiconductor source, VCR parts, other consumer electronics, car stereo, CATV).

   Dalbani's current catalog lists a few types of xenon flashtubes - some of relatively high capacity (100s of W-s). Their selection used to be much larger. My guess is that they acquired someone else's inventory and have been selling this off without replenishing it.

3. Radio Shack stocks a couple of pricey strobe lights as well as a small xenon flash lamp. At least you can just walk over to your neighborhood store!

4. All Electronics, 1-818-904-0524. Large selection of surplus and new electronics and hobbyist items.

   A flashtube, trigger coil, and a more complete camera flash assembly are listed in their catalog.

5. Electronic Goldmine, 1-602-451-9495 or 1-800-445-0697.

   Some strobe kits, flashtubes, reflectors, flashtube-reflector combos, a trigger coil, a quench tube (!!), two different inverter transformers, and two complete strobe schematics, one of which is a 12 volt strobe using one of these transformers.

   The also sell small flashtubes by the bushel :-) about 1.2 inches long (~30 mm) by .15 inch (~3.5 mm) diameter. These cost 49 cents each, or 100 for $25. So, if you are planning on building your own New Year's Times Square celebration sphere, these may be ideal! These were offered in 1996 and may no longer be available but should be worth an inquiry.

6. (From: Gary M. Reese (greese@comteck.com).)

   High power capacitors (like 450 uf at 500 volts) and other strobe parts may be had though the list of strobe service centers at Lumedyne.

   However, it should be remembered that they are repair centers and do not normally sell parts at retail. I have ordered a capacitor like the one mentioned above from one them at a cost of $26.00 plus $3.50 S&H.

   (What this means is that (1) their prices may be quite high and (2) they may not be eager to sell to the public. --- sam)

7. (From: Scott Tilton (stilton@execpc.com).)

   The original Strobotac flashtubes were made by EG&G Optoelectronics. They used a FX6-A. I believe they now supply a FX7-A as a replacement. You can reach them at 1-800-950-3441.

   You might also try Quad Tech, which still manufactures the General Radio 1531AB, and other General Radio stroboscopes. They can supply spare parts. You can reach them at 1-800-253-1230.

Additional information including part numbers and minimum order amounts is available at Don's Where to Get Xenon Flashes/Strobes and Parts page.

- Back to Strobe Parts Sources Sub-Table of Contents.

Previously Owned and Recycled Parts

1. Garage sales (and the like), flea markets, thrift stores. These are often good sources for cameras with a built-in electronic flash, photographic strobes, and other similar equipment. Your (or your Aunt Minnie's) attic or basement may even hold some of these treasures!

   The going rate for a typical cheap flash camera is generally $.50 to $1 at a garage sale or flea market. While these may in fact still work, they often use 110 size film so you won't feel too badly about gutting them for the flash unit or its parts.

   Although in principle the capacitor may deform after a long period of non-use, I have yet to see any real trouble having picked up over 2 dozen cameras and strobes from these sources. None of these have had any actual defective components (though a couple had bad connections or broken wires). My last acquisition was a completely functional variable rate stroboscope for $2.

2. Photo processing labs who accept disposable flash cameras may just throw the carcasses away after extracting the film. These may be available for the asking. Unfortunately for our needs, I have heard that the reusable parts are now being recycled. :-(

   (From: Scott Johnston (sj@thor.iac.net).)

Complete working strobe circuits are available for *free* at photo developing places (not K-mart, but the expensive places that actually do the developing in-house). When they develop film from those cheap weekend disposable cameras (you know, the kind that are made out of plastic and cardboard?), they rip out the film and throw away the camera housing. The disposables with flashes have a complete xenon strobe circuit (triggered by a tiny little switch on wire leads) powered by a single AA (1.5v) alkaline battery. Recently, I called the local photo developer, asked if they could save some of the kind with flashes, and a few days later I picked up a pile of 12 complete flash units, with almost unused AA batteries in all of them! Really fun, although I discovered quickly that the capacitors in those things don't have bleeder resistors...

(From: Alfred C. Erpel (aerpel@ptd.net).)

I was picking up my Halloween party photos from the 1 Hour Photo place at my local drug store and I noticed a trash box full of thrown out single use cameras, empty 35mm spools and plastic containers. I asked if I could have the entire box.

When I got home I found I had 27 cameras with usable flash units and most of the AA batteries were still good. My wife got the plastic containers for her Girl Scouts crafts. The inside of used Kodak film canisters contains a nifty spool which may make a useful bobbin for some types of coils.

Watch out for residual charge on the flash capacitor when you disassemble these! Also, observe the mechanics carefully because, although I'm not certain about this yet, it seems that some of the cameras are designed to purposely disable the flash circuitry by mechanically breaking an existing connection when the board is removed. Obviously this could be restored if you see where it is.

No doubt some places won't give you their trash (afraid of the potential for liability), but it can't hurt to ask.

- Back to Strobe Parts Sources Sub-Table of Contents.

Flashlamp and Arc Lamp Manufacturers and References

Here are some of the major suppliers. Many also have a variety of useful technical information either on their Web sites or available in print.

- Perkin Elmer (used to be EG&G Electro Optics
  35 Congress St.
  Salem, MA 01970
  Phone: 1-800-775-6786

  Information is available for driving flashlamps (and other topics) in the Perkin Elmer (formerly EG&G) Technical Library. However, much of the product and technical info that used to be on the EG&G Web site is no longer present but this material is available on the Perkin Elmer CDROM, which includes complete product specifications and technical papers. The CDROM is accessed using your normal Web browser. Some flashlamp info is also available at Polytec PI France - Department Electro-Optique.

- Heraeus Noblelight, Inc.
  2150 Northmont Parkway

Duluth, GA 30096
Phone: 1-770-418-0707

General technical information on flashlamps and arc lamps may be accessed via their Laser Lamps Download Page.

- ILC Technology Inc.
399 West Java Drive
Sunnyvale, CA 94089
Phone: 1-800-347-2474

  Some very complete technical notes on driving and triggering of flashlamps has been published by ILC Technology (now part of Perkin Elmer). Some of these include:

  - Technical Bulletin #1: "An Introduction to Flashlamps".
  - Technical Bulletin #2: "A Guide to Flashlamps for Pulsed Solid State Lasers".
  - Technical Bulletin #3: "An Overview of Flashlamps and CW Arc Lamps".
  - (No publication number): "Linear Flashlamps".

  These were originally published around 1986 so there may be newer versions. As far as I know, they are not currently on-line but should be available in print by contacting ILC.

- Xenon Corporation
20 Commerce Way
Woburn, MA 01801
Phone: 1-800-XENONXL

Electronic Flash Problems and Solutions

Sub-Table of Contents

- Back to Electronic Flash Problems and Solutions Sub-Table of Contents.

Electronic Flash Problems

A variety of failures are possible with electronic flash units. Much of the circuitry is similar for battery/AC adapter and line powered units but the power supplies in particular do differ substantially.

Most common problems are likely to be failures of the power supply, bad connections, dried up or deformed energy storage or other electrolytic capacitor(s), and physical damage to the to the flashtube or other components.

Problems Unique to Battery or AC Adapter Powered Electronic Flash Units

- Power source - dead or weak batteries or defective charging circuit, incorrect or bad AC adapter, worn power switch, or bad or corroded connections.

  Symptoms: unit is totally dead, intermittent, or has excessively long cycle time.

  Test and/or replace batteries. Determine if batteries are being charged. Check continuity of power switch or interlock and inspect for corroded battery contacts and bad connections or cold solder joints on the circuit board.

- Power inverter - blown chopper transistor, bad transformer, other defective components.

  Symptoms: unit is totally dead or loads down power source when switched on (or at all times with some compact cameras). No high pitched audible whine when charging the capacitor. Regulator failure may result in excess voltage on the flashtube and spontaneous triggering or failure of the energy storage capacitor or other components.

  Test main chopper transistor for shorts and opens. This is the most likely failure. There is no easy way to test the transformer and the other components rarely fail. Check for bad connections.

Problems Unique to AC Line Powered Electronic Flash Units

WARNING: Line powered units often do not include a power transformer. Therefore, none of the circuitry is isolated from the AC line. Read, understand, and follow the safety guidelines for working on line powered equipment. Use an isolation transformer while troubleshooting. However, realize that this will NOT protect you from the charge on the large high voltage power supply and energy storage capacitors. Take all appropriate precautions.

- Power source - dead outlet or incorrect line voltage.

  Symptoms: unit is totally dead, operates poorly, catches fire, or blows up. Spontaneous triggering may be the result of a regulator failure or running on a too high line voltage (if the unit survives).

  Test outlet with a lamp or circuit tester. Check line voltage setting on flash unit (if it is not too late!).

- Power supply - bad line cord or power switch, blown fuse, defective rectifiers or capacitors in voltage doubler, defective components, or bad connections.

Symptoms: unit is totally dead or fuse blows. Excessive cycle time.

Test fuse. If blown check for shorted components like rectifiers and capacitors in the power supply. If fuse is ok, test continuity of line cord, power switch, and other input components and wiring. Check rectifiers for opens and the capacitors for opens or reduced value.

Problems Common to All Electronic Flash Units

WARNING: the amount of charge contained in the energy storage capacitor may be enough to kill - especially with larger AC line powered flash units and high power studio equipment. Read and follow all safety guidelines with respect to high voltage high power equipment. Discharge the energy storage capacitors fully (see the section: Safe Discharging of Capacitors in Electronic Flash Units) and then measure to double check that they are totally flat before touching anything. Don't assume that triggering a flash does this for you (especially for automatic units). For added insurance, clip a wire across the capacitor terminals while doing any work inside the unit. Better to blow a fuse than you if you should forget to remove it.

- Energy storage capacitor - dried up or shorted, leaky or needs to be 'reformed'.

  Symptoms: reduced light output and unusually short cycle time may indicate a dried up capacitor. Heavy loading of power source with low frequency or weak audible whine may indicate a shorted capacitor. Excessively long cycle time may mean that the capacitor has too much leakage or needs to be reformed.

  Test for shorts and value. Substitute another capacitor of similar or smaller uF rating and at least equal voltage rating if available.

  Cycling the unit at full power several times should reform a capacitor that has deteriorated due to lack of use. If the flash intensity and cycle time do not return to normal after a dozen or so full intensity flashes, the capacitor may need to be replaced or there may be some other problem with the power supply.

- Trigger circuit - bad trigger capacitor, trigger transformer, SCR (if used), or other components.

  Symptoms: energy storage capacitor charges as indicated by the audible inverter whine changing frequency increasing in pitch until ready light comes on (if it does) but pressing shutter release or manual test button has no effect. Spontaneous triggering may be a result of a component breaking down or an intermittent short circuit.

  Test for voltage on the trigger capacitor and continuity of the trigger transformer windings. Confirm that the energy storage capacitor is indeed fully charged with a voltmeter.

- Ready light - bad LED or neon bulb, resistor, zener, or bad connections.

  Symptoms: flash works normally but no indication from ready light. Or, ready light on all the time or prematurely.

  Test for voltage on the LED or neon bulb and work backwards to its voltage supply - either the trigger or energy storage capacitor or inverter trans- former. In the latter case (where load detection is used instead of simple voltage monitoring) there may be AC across the lamp so a DC measurement may be deceptive.)

- Trigger initiator - shutter contacts or cable.

Symptoms: manual test button will fire flash but shutter release has no effect.

Test for shutter contact closure, clean hot shoe contacts (if relevant), inspect and test for bad connections, test or swap cable, clean shutter contacts (right, good luck). Try an alternate way of triggering the flash like a cable instead of a the hot shoe.

- Xenon tube - broken or leaky.

  Symptoms: energy storage and trigger capacitors charges to proper voltage but the manual test button does not fire the flash even though you can hear the tick that indicates that the trigger circuit is discharging.

  Some xenon tubes have "getters", which are silver or dark silver coatings of a highly reactive metal, deposited on the inner surface of the flashtube at one or sometimes both ends. Less frequently, a getter may be found on a metal surface such as one of the electrodes inside the tube, but not on the tubing inner surface. The getter "gets" any traces of air or water vapor in the flashtube. If a flashtube with a getter is broken or leaky, the getter will be corroded into a powdery gray-white form. If you know there is a getter and it is corroded badly, the flashtube is no good. Please note that unrelated glass discoloration or staining that resembles corroded getters can occur in a heavily used or moderately abused flashtube that still works.

  Inspect the flashtube for physical damage. Substitute another similar or somewhat larger (but not smaller) flashtube. A neon bulb can be put across the trigger transformer output and ground to see if it flashes when you press the manual test button shutter release. This won't determine if the trigger voltage is high enough but will provide an indication that most of the trigger circuitry is operating.

Electronic Flash Dead After Long Time in Storage

The unit may be totally dead or take so long to charge that you give up.

For rechargeable units, try charging for the recommended time (24 hours if you don't know what it is). Then, check the battery voltage. If it does not indicate full charge (roughly 1.2 x n for NiCds, 2 x n for lead-acid where n is the number of cells), then the battery is likely expired and will need to be replaced.

Even for testing, don't just remove the bad rechargeable batteries - replace them. They may be required to provide filtering for the power supply even when running off the AC line or adapter.

For units with disposable batteries, of course try a fresh set but first thoroughly clean the battery contacts.

See the sections on batteries.

The energy storage capacitor will tend to 'deform' resulting in high leakage and reduced capacity after long non-use. However, you should still be able to hear the high pitched whine of the inverter.

Where the unit shows no sign of life on batteries or AC, check for dirty switch contacts and bad internal connections. Electrolytic capacitors in the power supply and inverter may have deteriorated as well.

If the unit simply takes a long time to charge, cycling it a dozen times should restore an energy storage capacitor that is has deformed but is salvageable. This is probably safe for the energy storage capacitor as the power source is current limited. However, there is no way of telling if continuous operation with the excessive load of the leaky energy storage capacitor will overheat power supply or inverter components.

Flashlamp Failure Behavior and Causes

(Portions from: Don Klipstein (don@misty.com).)

When a flashlamp fails, it may do so quietly or with a bang.

Generally, only laser pump flashlamps or similar ones with a lot of flash energy for their size will likely die spectacularly. When lower power flashlamps such as those used in small to medium size photographic strobes crack, they tend to stay in one piece or sometimes break apart surprisingly quietly.

- A hairline crack would enable air to enter resulting in a flashlamp that doesn't work but might remain intact, at least to casual handling. This is more common than spectacular failure.

- A crazed flashlamp may crack or break into two pieces when fired.

- A high mileage lamp may show discoloring, mostly around the area of the cathode.

- Low quality or old flashtubes may have traces of air in them due to imperfect seals. Oxygen and water vapor will make the flashlamp more difficult to fire. In a high power lamp where the electrodes get hot enough to react with any oxygen or water vapor, oxides can form and collect on the inner surface of the tube, resulting in a powdery discoloration. I have seen a whole batch of older camera flashes with leaky flashtubes with varying ability to fire.

As for failure modes due to abuse:

- Too much energy on a cheap glass flashtube - they just crack. 10 times too much and what they usually do is just crack all over and fall apart easily, but maybe they could explode. You may hear the tube crackling during the roughly two seconds after such a fatal flash. One that I had broke into two pieces and with no bang nor even a loud pop with about 3 times its rated energy.

- With moderately excessive energy the first big flash is not fatal. But a discolored area of the tubing will get hotter than an adjacent clear area during a subsequent flash, and this can crack the tubing. I once abused a flashtube this way (with about three times its maximum rated energy), and the first flash caused discoloration and the second flash cracked the tube around one edge of the discoloration.

- Excessive flash energy to quartz flashtubes with lower xenon pressure such as most photocopier and higher power photoflash lamps will usually just discolor them at an unacceptably high rate if the voltage is not also excessive. Seals could fail however. Obviously, there is some amount of energy that will cause the lamp to crack, break, explode, or melt or do a combination of these things.

- Excessive average power input to a cheap glass flashtube will cause it to crack, often not doing so until after some discoloration develops.

- Excessive average power input to a quartz flashtube usually causes accelerated discoloration or risks the seals, but if you're lucky nothing bad happens until the quartz tubing gets soft enough to slowly, slightly give way (900-1000 degrees C or hotter) and then cracks from stresses.

- High power quartz lamps that heat up to a few hundred degrees C or hotter should be clean. Ash, salts, and alkalis will slowly leach into hot quartz and cause stresses that may make the tubing crack.

- With too much voltage while pushing limits of energy or average power the flashtube may crack more easily from higher heating of the glass by UV.

- Exceeding some combination of voltage and flash energy will cause "wall ablation" - in which traces of the tubing material is vaporized. This happens from exceeding some combination of total flash energy and peak flash power. The vapor is mostly silicon dioxide and it will decompose in the hot xenon arc. The resulting oxygen will make the flashtube harder to fire. The tubing will also discolor or sometimes just get cloudy, usually unevenly if flash energy is low and voltage is extremely high. In high power flashlamps where the electrodes get hot enough to react with the free oxygen, powdery oxide can form and collect on the inner surface of the tube. But this process will remove some of the oxygen and can restore ease of firing the flashtube.

- Reverse polarity on a polarity-sensitive flashtube will sometimes impair flashing but usually not. Tube discoloration will occur more easily and may cover more of the tube more easily. But not all flashtubes are polarity sensitive.

Transformer Replacement in Electronic Flash Units

While not as common a problem as many people believe (the hardest to find part must be at fault, right?!), the transformers in electronic flashes do fail occasionally, probably due to faulty manufacturing - damaged fine wire in the secondary which eventually breaks or a shorted secondary from arcing through an insulation layer.

Line voltage transformers: Most AC line powered flash units don't have any transformer so this isn't general a problem. For those that do (higher speed or other special types of strobes), it shouldn't be difficult to match up the secondary voltage and find a standard replacement that will be acceptable. These may be cobbled together from the power transformers for vacuum tube equipment (yes, they can still be found), small isolation transformers with multiple windings, and possibly the addition of some additional lower voltage windings in buck or boost phase to adjust the output voltage.

For safety reasons, I don't recommend attempting to repair transformers connected to the AC line, though this may be a possibility if all else fails.

Inverter transformers in battery powered flash units:

There is virtually no chance of successfully repairing any of these. The secondary winding uses wire so fine that it's almost impossible to even handle it. With a decent coil winding machine, a new spool of #45 or so wire, proper insulating tape (these are wound in 10 to 20 separate layers), and a few days of patience, it can be done but doesn't rank up there on my "fun things to do list". :) Furthermore, it's almost certain the core got destroyed in attempts to get at the windings. Thus, replacement is the only viable option.

There is NO chance of getting one of these from an electronics distributor as they are all custom. Since it's almost a certainty that the original manufacturer will have little interest in selling you a new one, salvage from other flash units is the best hope. These can be $1 garage sale specials (other 35 mm, 126, or similar cameras), disposable camera flashes, or shoe mounted units, depending on the physical size and energy (guide number) rating of your broken flash. The main problem will be the number of turns on the primary. If you can match those up by adding or removing turns to your replacement, there is a good chance it will work since they all seem to have roughly the same number of secondary turns (probably around 1,600 to 2,000). Even if the primary is buried, you can still add turns on top of the secondary in the appropriate direction to adjust the total net turns. Once its running, adding or removing an additional turn or two may be needed to tweak the output voltage.

Another option is to transplant the entire inverter if one can be found that operates on the same input (battery) voltage. I've done this successfully. without problems. See "Repair Brief #100: Minox ME1 Electronic Flash for Minox B Camera - Dead" in the document: Sam's Repair Briefs - Complete: 1 to 100.

Trigger transformers: Fortunately, these are fairly standard. Just match up the input voltage and select one that has an adequate output voltage for your strobe - 4 to 5 kV for most small strobes should work. The only remaining thing that needs to be determined is the wiring polarity. While the strobe may work with either polarity of the trigger pulse, one may result in reliable operation. Electronics distributors like DigiKey and Mouser should have a suitable replacement if a garage sale or disposable camera isn't handy.

Xenon Strobe Design

Sub-Table of Contents

- Back to Xenon Strobe Design Sub-Table of Contents.

General Strobe Circuit Design

In addition to what is covered in this document, various circuits and design guidelines are available at: Don's Xenon Flash and Strobe Page.

Among the features that may be found there are:

- How to build your own trigger coil.
- A repetitive trigger circuit.
- Various parts sources including the use of Radio Shack stuff.
- Guidelines for estimate voltages and energy levels for flashtubes.

More details can be found on Don's General Xenon Flash and Strobe Design Guidelines Page which also includes some basic design equations.

Don's site is constantly evolving so more interesting articles will likely appear in the future.

See the section: Flashlamp and Arc Lamp Manufacturers and References for links to specifications as well as externsive technical information and application/design notes.

Specifications for the 1300 series linear flashlamps can also be found in the chapter on solid state lasers in Sam's Laser FAQ.

Design of Small Strobes

Here are some general guidelines for the design of a small (5-20 W-s) battery or line operated strobe.

Most small flashlamps will operate on about 300 V (some as low as 250 - or less). If the flashlamp voltage is too low, the tube may not fire reliably or at all. If the flashlamp voltage is too high, spontaneous firing or damage and/or shortened flashlamp life due to excessive current may be the result. For power, you will need one of the following:

1. An inverter putting out about 300 VDC from your battery. Some of the cheap disposable cameras use as little as 1.5 V but don't expect too much battery life. There are zillions of simple inverter designs that will work using either discrete transistors or ICs with some minimal external components. The easiest way to obtain the inverter is to rip one out of a dead camera. Try garage sales, flea markets, thrift stores, or your Aunt Patty's attic. Typical cost for a cheap pocket camera from these sources is $.50 to $2. I don't know what your Aunt charges. Otherwise, you can build one easily. The only difficult part is finding a suitable transformer. They are easy to wind but don't expect great efficiency unless extreme care is taken in the design. For designing IC based DC-DC converters, check out companies like Maxim and Linear Technology. These generally only require minimal external components like capacitors, diodes, and an inductor or two - but often no transformers.

   WARNING: If left charging for longer than needed to get the ready light to come on, the actual voltage on the energy storage capacitor may approach 400 V with some of these cameras! Take even more care.

2. A line operated voltage doubler for 110 VAC (just a rectifier for 220 VAC). When the peak voltage of the AC line is considered, these supplies will provide about 300-320 VDC. Common 1N4005/6/7 silicon rectifiers and small (e.g., 16 uF) 250 V electrolytics can be used for the doubler. Include a surge limiting resistor of about 22 ohms in the common as well as a current limiting resistor in the output (before the energy storage capacitor) to allow the flashlamp arc to quench (e.g., 100-1000 ohms). A line fuse, power switch, and power indicator are also essential. Warning: this is a non-isolated line operated power supply - see safety guidelines. Do not connect triggering circuit directly - use capacitive or transformer coupling for safety.

The rest of the items can be basically the same with eithr power source.

1. An energy storage capacitor. A 200 uF capacitor charged to 320 V will give you 1/2*C*V*V = 10 W-s. Xenon flashlamps are rated in terms of both maximum flash energy and maximum average power (as well as others but for small strobe units - under 25 W-s or so - these are the most critical). These ratings should not be exceeded. For example, a tube rated at 20 W-s flash energy and 5 W average power could be flashed at most once every 4 seconds at a 20 W-s level or at most once every second at a 5 W-s level. Use a smaller capacitor for more frequent flashing. While photoflash rated capacitors are desirable, you should be able to get away with any good quality electrolytic for this type of modest power application. Note that the typical pocket camera flash uses a 100-400 uF capacitor and puts out quite a lot of light.

2. A trigger circuit. This is usually a HV pulse transformer into whose primary you discharge a small capacitor - .1 uF at 100 to 300 V is typical. The high voltage secondary is designed to put out 4 to 10 kV depending on flashlamp size and type. If the voltage of the trigger pulse is too low, the flashlamp may not fire or may fire erratically. If the trigger voltage is too high, there may be arcing to the flashlamp electrodes or other components resulting in possible damage. The trigger output is connected with a short wire to an electrode (wire, foil, or metal reflector) that is in close proximity to the xenon tube. The high voltage pulse ionizes the xenon gas mixture allowing the storage capacitor to discharge through it. Trigger transformers are available from places like Mouser Electronics. These can also be constructed relatively easily. See: How to build your own trigger coil. Although not very compact, a TV or monitor flyback or automotive ignition coil will also work as a trigger transformer.

   An SCR can be substituted for physical switch contacts where electronic control of the trigger is desired. For the battery powered unit, there is no issue of line isolation and the cathode of the SCR can be tied directly to the ground of your logic circuits. However, with the line operated strobe, isolation is essential for safety - use capacitor or transformer coupling, or an optoisolator.

Strobe Design Parameters

The common photographic strobe is not really designed for very short flash duration. While a typical electronic flash is much much shorter than one of those antique flash bulbs, it is still long compared to what is possible. Typical flash duration for a full power flash is under a millisecond with the range of automatic units going down to 20 microseconds or less for a minimum energy flash. One of those antique flash bulbs, on the other hand, had a flash duration of between 5 and 20 milliseconds. For most common photography, 1 millisecond or less is for all intents and purposes, instantaneous. However, if you want to freeze the blades of a rotating turbine or stop bullet in flight, even 20 microseconds is way too long.

Some of the highest speed photographs using the light source to control exposure have been taken with spark gaps operating at many kV resulting in flash durations as low as fractions of microseconds. Even higher speed photography is possible using electronic image tubes. The first instants of conventional or nuclear detonations have been captured using this type of technology.

For more information on high speed photography, see the classic works by Harold E. ("Doc") Edgerton. The following are just some general comments:

Several design parameters influence flash intensity, duration, and maximum repeat rate. However, the relationships are not linear as a flashlamp is a gas discharge device with complex nonlinear resistance characteristics. It is necessary to consult the flashlamp manufacturer's data sheets to do any detailed design.

1. Voltage. For a given energy, flash duration varies inversely with flash lamp voltage. The higher the voltage, the shorter the flash.

2. Capacitor size in uF. Total flash light output is proportional to the energy storage capacitor uF rating. However, both the peak intensity and the flash duration will increase with a larger capacitor.

3. Impedance of discharge path. Since the circuit when triggered is basically a capacitor discharging into a low impedance load, both the duration and peak intensity are affected. In addition, for higher capacity strobes especially, controlling this impedance is critical to achieving optimal light output as well as maximizing the life of the flash lamp. Excessive peak discharge current as well as reverse current due to overshoot and ringing reduces flash lamp life through damage to the electrodes. Too much instantaneous current and the flashlamp may explode.

4. Flashlamp design. The diameter, length, material, gas pressure, and electrode construction, etc. all affect the performance and power handling capabilities.

5. Cooling. Convection, forced air, and liquid (water or oil) cooling may be used. Dramatically higher average power is possible using liquid flow cooling if the flash lamp design will permit this.

Some Guidelines for Designing Small Xenon Strobes

Flashlamp manufacturers publish very detailed data sheets for their products. For high power strobe design, all this information is essential. However, when building small strobe units (under 20 W-s), my general rules-of-thumb are:

1. Use a 250 to 350 V power supply for the energy storage capacitor. Depending on your application, this can be a battery or AC adapter powered inverter, transformer/rectifier power supply, a line operated voltage doubler for 110 VAC or a simple line rectifier and filter capacitor for 220 VAC.

2. Use a trigger transformer capable of 4 to 5 kV or more pulse output. The actual output trigger pulse voltage can be controlled by the voltage on the trigger capacitor. This is usually obtained from a voltage divider off of the energy storage capacitor. Too low and it won't flash reliably. Too high and arcing to nearby components may occur.

3. Follow the flashlamp manufacturer's ratings for maximum flash energy and average power. If you ripped the flashlamp out of something like a pocket camera, limit your flash energy to that provided by the capacitor contained in the unit or 10 W-s per inch of flashlamp length if the capacitor value is unknown. Limit the average power to this maximum energy every five seconds or the actual minimum full power cycle time if this known.

4. Use a photoflash rated capacitor if available but any good quality capacitor will probably work fine. No inductor is needed for these low power applications. For a 320 V power supply, flash energy is just about 5 W-s per 100 uF of energy storage capacitor rating.

5. Keep lead lengths between the energy storage capacitor and the flashlamp reasonably short (a few inches is fine). Minimize the length of the wire from the trigger transformer and make sure that it is well insulated and not in proximity to any other components.

6. Make sure human contact with all line connected and high voltage components is impossible during operation or at any time when a charge is present on the power supply or energy storage capacitors - by packaging everything in a plastic or grounded metal box, for example.

7. Always use capacitor, transformer, or optical isolation when triggering line powered strobe units from low voltage logic circuits or anything that a human may contact. This is recommended in general as it will assure that no high power transients find their way back into sensitive electronic circuits.

8. Don't neglect the essential power switch, fuse(s), and indicator lights. For logic controlled or computerized strobes, a mechanical test button using a hard set of contacts (i.e., across the SCR) is highly desirable.

The guidelines above will adequately handle typical small to medium size strobes - perhaps to 50 W-s or so depending on the extent to which the flashlamp maximum energy specifications exceed the power input you are using and the characteristics of other circuit components.

For higher power strobes, it is essential that appropriate flashlamps are used with photoflash rated capacitors. A series inductor - matched to the flashlamp, capacitor, and voltage - is critical to preserving the life of some flashlamps (perhaps beyond one flash!) and achieving maximum flash intensity. The flashlamp manufacturer's datasheets are probably the best source of this information. Also see the section: Super High Power (Laser Pump) Strobe Circuit.

The series inductor is often needed for laser pumping applications and other applications where the quantity of energy and/or the peak current are particularly great for the size of the flashtube.

For additional design information, see the section: Flashlamp and Arc Lamp Manufacturers and References as well as the chapters on solid state lasers in Sam's Laser FAQ.

Strobe Light Output Test Circuit

(Portions from: Don Klipstein (don@misty.com).) Where you are designing a strobe requiring a specific pulse shape and/or duration, it is desirable to have a way of measuring its output. If you have an oscilloscope (almost any will do), the following can't be beat for simplicity and cost - total component complement is a green LED (hooked up backwards to act as a photodiode) and a 3.3K Ohm resistor! I assume a red or other color LED would work just as well but haven't tried one.

```
    +5 to +15 VDC o--------|<|--------+----------o Scope input
                        Green LED     |
                     (Note polarity)  /
                                      \ 3.3K
                                      /
                                      \
                                      |
           Common o-------------------+------------o Scope Ground
```

The response of this circuit is quite decent, easily showing the shape of the light pulse in strobes with pulse durations in the 10s of microseconds. Voltage is proportional to light intensity as long as it doesn't approach the value of the power supply voltage (so there is still some bias on the LED turned photodiode).

Note that even with the power supply removed and the inputs shorted together, there is a photovoltaic response to light, but it quickly saturates and may give a false indication of the shape of the light pulse.

Identifying the Cathode and Anode of the Flashtube

If there is any doubt as to the polarity of a flashtube you are using in a new design, the following will help to confirm proper direction - running a flashtube with reverse polarity will adversely affect performance and life.

(From: Don Klipstein (don@misty.com or klipstei@netaxs.com).)

1. Any red markings or "+" markings indicate the anode.

2. With no markings but electrodes of unequal size, the larger one is the cathode.

3. If both ends look identical but the trigger electrode is closer to one electrode, or more coupled to one electrode, then that electrode is the cathode.

4. If the tube looks symmetric except for having a getter at only one end, it is probably preferable to make the getter end the cathode, especially if any getter material exists on the electrode itself. Any vaporized getter metal forms positive ions easily, and will be attracted to the cathode. Metal vapor released around the anode is more likely to condense all over the tube and discolor it.

5. If both ends of the flashtube look alike except for one electrode being shinier and with rounded edges, then the shiny electrode with rounded edges is the anode, and the steel-gray (tungsten) sharply cylindrical one is the cathode.

Transformers for Low Voltage Powered Strobe Inverters

It is usually not possible to determine all parameters of the inverter transformer when reverse engineering pocket camera strobes.

(The following is from: Kevin Horton (khorton@tech.iupui.edu))

This is *always* the kicker. I have devoting heavy amounts of time into figuring out how these transformers work. They are very, very special. *nothing* else will work in their place, or if it does, it'll be woefully inefficient. They are usually .4" or so cubed, but may be larger. The gap on the core seems to be pretty critical- it limits the overall current that the circuit will draw. In one particular strobe I disassembled, they had a 100 pf cap coming from the output of the HV winding directly tied to the base of the drive transistor! I finally figured out why: it controlled the frequency vs voltage of the oscillator, hence giving it more current as it was completing a charging cycle!

I've disassembled many of these small transformers. Unlike most ferrite transformers, these are usually held together by dipping them in wax, rather than varnish. Some transformers have the primaries wound on the core, while others have it on the outside. I haven't figured out exactly why this is. However, one one transformer I took apart, the feedback and drive windings were wound on the core; bifilar. The feedback was 11 turns, while the primary was 10. Both were #24. On top of that was thousands of turns of #40 or so wire.

It seems that the small sizes play a part in the efficiency of these transformers; since the magnetic field is contained in such a small core area, the losses are small.

Comments on Voltage Multipliers

To obtain 300 VDC from the 115 VAC line requires a voltage doubler; 450 VDC requires a tripler. This also applies to the use of alternative power sources with the following caveats:

- When using a 12V to 115 VAC inverter to provide the input to voltage multiplier circuits, cheap units produce a squarewave output with 115 V peak (since the RMS and peak value of a squarewave are the same). Therefore, the circuit will take this value and multiply it by 2 or 3 (or whatever) rather than the peak of a sinusoid (which is 1.4 times greater). Thus, a tripler will be needed to obtain 300 VDC when using one of these inverters rather than a doubler in the case of normal line input.

- Driving these circuits from a gasoline powered generator should not be a problem unless its voltage becomes excessive - in which case the flashes may not be coming only from the xenon tube! Such a unit (actually probably an alternator) should produce a decent sinusoid unless it is actually a low voltage generator and inverter (as above).

There are several considerations with respect to the design of these circuits. Capacitor size (uF value and voltage rating) is the one that generally has the most impact on performance and cost.

Depending on the circuit, the required voltage rating may be anywhere from the peak of the AC waveform to the maximum output voltage of the circuit (both with a safety factor). Using the highest value will always be safe and not that expensive for modest size capacitors.

For the capacitance value:

- If too small, output power will be inadequate. Damage can even result if one or more electrolytic capacitors becomes reverse biased under heavy load.

- If too large, cost will be excessive and performance will not improve significantly beyond a certain uF value.

For a classic voltage doubler, the main consideration is the ripple (as determined by capacitor uF value and load) and what the diodes and current limiting resistor can provide. This is because the caps in this case are really just filtering opposite sides of the half wave rectifiers. (Where they are then charging another larger cap (via some isolation diodes) but no series resistance, this may get somewhat messier.)

However, for anything with more stages or stages arranged where some of the capacitors are effectively in series with the output, analysis can become interesting (translation: I am not about to attempt it here!).

In these cases, the impedance of the capacitors at the line frequency (60 Hz in the U.S.) will affect the power available before the output drops and/or has excessive ripple.

My very rough rule of thumb just treats the impedance of the capacitors like a series resistance. Then, I would select the capacitor value so that this resistance is small compared to the needs of the circuit.

A 1 uF capacitor has an impedance (magnitude) of about 2.65K ohms at 60 Hz. A 10 uF cap is 265 ohms. The 22 uF capacitors in the tripler described in the section: Higher Power Photoflash with SCR Trigger have an impedance of about 120 ohms. Consider a load of 100 W at 350 VDC (average - which would be a high power strobe indeed). The load resistance is then: R = V*V/P = 1.22 K. Since this is large compared to the capacitor impedance - even if all capacitors are assumed to be in series - I wouldn't expect very much improvement with the use of larger capacitors.

Keep in mind that this is an edge of the envelope calculation so a factor of 2 (or 20) either way is possible (and likely!).

The ESR (Effective Series Resistance) of smaller electrolytic capacitors is also higher. This may result in excessive heat dissipation in the capacitor. There is also a 'ripple current' rating for capacitors which should not be exceeded. However, if your capacitors are from Radio Shack, this particular specification is probably not available :-).

A surge limiting resistor on the line input should be provided to limit the peak current through the diodes and capacitors.

Once a particular circuit has been constructed, test it under a dummy load which simulates the expected average power. If the output voltage drops excessively and/or there is too much ripple, try increasing the capacitor uF values (not all of them may need to be changed.) Check the waveform on each capacitor with a scope (you MUST use an isolation transformer for this!). The voltage must NEVER go negative for an electrolytic capacitor. Feel the capacitors for evidence of excessive heating.

Also see the section: Voltage Doubler Design Considerations.

Voltage Doubler Design Considerations

> "I have a problem. I am using a standard voltage doubler (2 diodes, 2 capacitors) in a strobe circuit. The doubler consists of two 4.7 uF 450 V caps and two 1N4005 diodes. The timing circuit is a neon-bulb relaxation oscillator that triggers an SCR, which in turn dumps a .1 uF cap into a trigger coil to fire the flashtube. The flashtube gets a 47 uF cap discharged through it, which equals about 2.5 watt-seconds.
>
> The problem is that the 4.7 uF doubler capacitors overheat and fail! The doubler voltage is 325 volts with no load, so a 450 V rating should be adequate. Should I be using more capacitance for these?"

(From: J. M. Woodgate (jmwa@thenet.co.uk).)

Well, you really haven't given enough information. The problem is likely to be that you are exceeding the ripple current rating of the caps. I guess that you are running the neon and SCR from the doubler and your neon takes a thump of current when it fires, even if you have set the duty cycle down so that the average current is low. Higher value capacitors usually do have a higher ripple-current rating. But first you need to find how much ripple-current you are producing, and this depends on the cap. value (at least to some extent). Very roughly, the ripple current is pi times the DC current, and you should look at the load current waveform with a scope and take the maximum value as the DC value, to be sure of not over-running the capacitors.

Why the Trigger Transformer Should be Next to the Flashlamp

(Portions from: Don Klipstein (don@Misty.com).)

When constructing systems where the size of the flashhead is critical and/or where the flashhead(s) are to be remotely located relative to the controller, one might be tempted to keep all the electronics with the controller.

While the energy storage capacitor(s) can be centrally located, this is not recommended for the trigger transformers as it is the risetime or dV/dt of the high voltage pulse that ionizes the gas and any length of wire - even if it is adequately insulated - will add capacitance - a few dozen pF may prevent reliable triggering.

Generally, the best approach is to locate the trigger transformer, its capacitor and associated charging resistors, and the trigger SCR (if used) in the flashhead.

- The main tube's resistance is nonlinear and varies during the flash and is frequently as low as about an ohm.

  This determines the minimum size of the wiring between the energy storage capacitor and flashhead(s) since its resistance should be low compared to this - say .1 ohm or less. For very long runs, the wiring inductance may also be a factor.

  Care must be taken if using multiconductor cables to assure that cross coupling from the high discharge current pulse(s) doesn't result in false triggering where multiple flashheads or other circuits are involved that aren't supposed to be activated simultaneously.

- The stray capacitance over the length of a long trigger line can load down the peak voltage of the trigger pulse. Things may work better if you keep the trigger transformer close to the flashtube.

  The typical trigger capacitor is only about .022 uF. The turns ratio of the trigger transformer is often about 13-plus, and has been known to exceed 20. Divide .022 uF by the square of the turns ratio, and this is the maximum capacitive load which will probably get a majority of the normal trigger pulse voltage. So you may want the stray capacitance of the high voltage trigger line to maybe not exceed maybe 150 pF or possibly as low as 60 pF! And that is optimistically! If you run the trigger wire along other wires or close to grounded or even remotely coupled-to-ground conductive surfaces, you can get this much capacitance in just a few feet (or maybe a meter) of wire. In the unlikely event you can run the trigger wire through the middle of the air with nothing nearby, you may get OK results with a few times this distance.

  If the trigger capacitor is larger, you can get more distance without loading down the peak trigger voltage too much - but there may still be bugs! If you try increasing the trigger capacitor, you risk blowing up/out parts of the trigger circuit. And just to sometimes put the odds against you for use of a long trigger line - the stray capacitance can slow down the risetime of the trigger pulse. Sometimes fast risetime is essential for the trigger pulse to get enough peak current through the tube to make the xenon conductive enough to flash at the main voltage. Sometimes not and you may get away with things...

I really recommend keeping the trigger transformer really close to the flashtube, even if this necessitates extra wires to the flash head. And a long wire between the trigger transformer and the trigger capacitor may have enough stray inductance to mess things up - you may want to keep the entire trigger circuit close to the flashtube if it is at all feasible to do so!

Inverters in Series to Boost Voltage

As noted in the section: High Speed (Short Flash Duration) Strobes, higher voltage on the xenon flashtube will reduce flash duration, all other factors being equal.

The compact inverters in pocket and disposable cameras and externally mounted flash units will charge an energy storage capacitor to about 300 to 320 VDC. What if you need more? Yes, it is possible to wire several of these in series.

- To avoid a meltdown, the high voltage side of the inverters must be isolated (this is often not the case) or rewired to be isolated if they are to share a power source (battery pack or AC adapter).
- For the special case of just two inverters, only the node between the two energy storage capacitors must be shared.
- If run off isolated and well insulated power supplies (e.g., individual AA battery packs!), then this type of isolation doesn't matter but you better be careful what you touch!

Depending on which of these schemes is used, there could be a substantial fraction of the total output voltage between the secondary and primary of one or more of the inverter transformers. Given that these sorts of inverters are already designed to within an inch of of their lives with respect to arcing over even when used in the normal fashion, I don't know how far you can push this before the inverter transformer insulation breaks down.

The trigger circuit can be one of those associated with any of the inverters or a totally separate unit.

A Discussion of Triggering and Other Design Issues

Here is an example of what one person did using inverters in series (see the section: (Inverters in Series to Boost Voltage) and some non-conventional trigger experiments:

(Replies from: Andreas Nowatzyk (agn@acm.org) and Sam).

(From: Local Echo (localecho@aol.com).)

> "Yesterday, I hooked a small photoflash tube desoldered from a discarded photoflash unit to a power supply of 1.2 kV (Also using parts from photoflash units (I used 4 small Fuji disposables), mainly the inverters- the trigger capacitors were placed where the normal discharge capacitors were.). I noticed that at this voltage it would sometimes trigger on it's own, so I carefully adjusted things to conditions just before this happens. What's interesting is that I was able to trigger the tube with the trigger electrode (An alligator clip connected to a trigger transformer) up to 5 cm away from the center of the tube's wall. I was even able to trigger one with only 235 V across it even when the trigger pulse was

> generated from a separate circuit with no return path. (Though, the separate one was not able to trigger the tube at distances greater than .5 mm away from the tube's wall.) Also, it seems that the orientation of the trigger electrode makes a huge difference (Such as being parallel or perpendicular to the discharge path). Why is this? (I have a few ideas, but I don't wish to bias any answers.)"

(From: Sam.)

Interesting.... Realize you are running that tube at roughly 4 times its normal energy so don't be surprised if it explodes.>>

(From: Local Echo.)

> "Yes, that was one thing I was worried about so I made sure the capacitance connected to the tubes was very low (is only .0025 uF). The arc is bright, but well confined."

(From: Andreas Nowatzyk.)

The energy is = 1/2 * C * U^2, so a much smaller capacitor at a higher voltage can have less discharge energy.

(From: Sam.)

The closer the tube voltage is to its breakdown voltage, the less trigger energy you need. So, at 1.2kV, you are on the hairy edge.

(From: LocalEcho.)

> "Are the dynamics different from that of a tube not on the borderline (Such as commutation time, for instance)?"

(From: Andreas Nowatzyk.)

Yes, pulse duration will be shorter. I experimented with flash tubes from disposable cameras for the purpose of generating short light pulses. Under normal operating conditions (electrolytic capacitor at 300V), the typical pulse duration was about 5msec. With 0.05 uF at 4 kV (low inductance, HV capacitor), pulse duration is down to 0.9 us.

Unfortunately, there is a downside to short pulses: they create a shock wave inside the tube that erodes it slowly. Micro-cracks are formed and eventually the envelope shatters. The tubes from disposable cameras lasted 20 minutes on average when pulsed at 25 flashes a second (with proper cooling).

This can be avoided with a pulse forming network, typically consisting of a series inductor and a diode to avoid ringing. However, that causes much longer pulses, say 250 us.

(From: Local Echo.)

> "One other neat thing a friend noticed is that the trigger transformer isn't necessary at this point. We were able to trigger it by bridging a wire from one of the electrodes (In this case, the cathode) to the center of the tube. Eventually, the tube would become unresponsive (after about 20 or so discharges). So, still operating on the assumption that it's a capacitive effect, we used the anode connection instead. Instead of the multiple or fragmented arcs we normally saw, the discharge was very uniform (and

> occupied the entire volume of the tube). This seldom happened after that except an occasional arc of non-uniform density. This entire sequence can be repeated over and over. Also, the plasma seems to avoid the general area of the trigger electrode at times."

(From: Andreas.)

Since the trigger pulse is capacitively coupled into the tube, instabilities about the trigger arise from charge that is deposited on the surface of the fused silica envelope. Hence a larger pulse with fast rise times is desirable to minimize jitter and get a reliable trigger. Because of this problem, flash tubes for strobe applications use internal trigger electrodes and large tubes - say for pumping a laser - are triggered via a trigger pulse superimposed on the discharge voltage.

(From: Sam.)

Since the idea is to ionize the xenon gas in the tube, it orientation would be critical especially as you move further away.>>

(From: Local Echo.)

> "Which orientation would be best? (It seems to be perpendicular to the arc, but I could somehow be introducing bias.) Speaking of bias in a different sense, in certain schematics there are provisions for biasing the trigger electrode. I wish I knew more about it."

(From: Andreas.)

The trigger electrode is more effective if the capacitance between it and the plasma discharge path is maximized. Larger tubes tend to have trigger electrodes that consist of a small wire that is wrapped along most of the envelope. This provides a path for an initial discharge that is "fueled" by discharging the linear capacitor that is formed between the electrode, the silica wall and the discharge column. A DC bias generally doesn't do anything because *clean* fused silica is a good isolator. Things change when the tube is dirty or very hot.

(From: Sam.)

The fact that it isn't connected to a return is quite reasonable - with those sharp pulses, there is enough stray capacitance between the tube electrodes and your trigger circuit to create an adequate return.>>

(From: Local Echo.)

> "I thought about that and I'm assuming that is correct. Although the trigger electrode was about 5 cm away from the tube's wall, the transformer is located about 4 cm from even that. Is the capacitance still significant?"

(From: Andreas.)

Hard to tell. Under these conditions, you should take the phase of the moon into account. Basically, any electrostatic disturbance can cause the discharge, as well as natural radioactivity: A tube that is run very close to its breakdown voltage becomes a crude Geiger-counter and can trigger by any change in the electrostatic environment. Note that the breakdown voltage will change a lot depending on the tube temperature, the charge that has accumulated on the envelope from prior discharges and erosion of sharp features of the electrodes of a new tube. For example, a new tube from a disposable camera can trigger a 2 kV. After running it for a while, you may find that it needs 5 kV.

Adjustable Energy Strobes

Automatic flashes using quench tubes and thyristors have been discussed elsewhere. Modifying a commercial automatic flash to provide adjustable flash output/duration may be as simple covering the sensor (e.g., putting it on manual mode) and installing a variable resistor across the sensor. The resistor value and other Details would depend on the particular model.

But what about providing fixed, but selectable, flash energies? Over a range of perhaps 2:1 to 4:1 in flash energy, the input voltage to the flashlamp can be used to control flash energy. This range would be between the minimum voltage specification for the flashlamp and the self-triggering spec. However, this range can be extended by simply having a small fixed capacitor (call it C1) to maintain the required voltage for reliable triggering of the flashlamp backed by a much larger capacitor (or capacitor bank, call it C2) whose voltage can be varied to control the flash energy. The two capacitors are separated by a high current diode. Once triggered, C1 provides the initial discharge current to the lamp. As the voltage drops, current starts flowing from C2 and continues to do so until the voltage on the flashlamp drops below the maintaining voltage (usually about 50 V) with no inductance in the circuit. This simple approach can work over a very wide range of repeatable flash energies. There are only two catches:

- One is the high current diode required between C1 and C2 to allow C1 to charge to a higher voltage than C2 (from a separate supply feed). Peak flashlamp current will be several hundred AMPS and the diode needs to handle this without exploding. However, diodes with single cycle peak currents in this range aren't unusual or particularly expensive.

- The other is that as with any scheme where the flashlamp peak current changes with flash energy, the color temperature of the flash will also vary being somewhat more yellow at low energies and somewhat more blue at higher energies.

Integrated Circuits for Strobe Chargers

Although most of the circuits shown here and used in electronic flash and strobe circuits have used discrete components for the high voltage generation, it is, of course possible to apply many of the literally hundreds of switchmode power supply ICs to this task. As these, and the required support components, come down in price, the elegantly simple designs of the past will probably disappear.

For example, see the Linear Technology Design Note 303: Photoflash Capacitor Charger with Automatic Refresh. This uses the LT3420, an IC designed specifically for photoflash applications, in a simple flyback converter to charge capacitors to 320 V from a 1.8 to 10 VDC source. While the lowest input voltage is too high for operation on a single cell battery and requires 2.5 to 5 VDC source for the chip itself, it would be suitable for most pocket camera applications. Digital control of charging is built in.

Special Design Considerations

Techniques for Boosting the Repetition Rate of Small Strobes

Cycle time on commercial electronic flash units is typically 1 to 10 seconds depending on design and the battery's state of charge. How can this be improved without overstressing the circuitry?

Without redesigning the inverter circuit for higher power and using a larger flashtube, the only variable you have to play with is the size of the energy storage capacitor:

- Cycle/charge time will be proportional to its uF rating.

- Flash energy will be proportional to its uF rating.

- Light output will be proportional to flash energy.

- Perceived brightness will be a sub-linear function (not a proportional one) of flash energy. A simple approximation is flash energy raised to the .5 power (square root).

Thus, depending on your needs, reducing flash energy may still result in adequate brightness. For example, cutting the uF rating of the energy storage capacitor to 1/4th of its original value will still result in about 1/2 the perceived brightness (not 1/4 the brightness). An easy way to do this is to put two identical flash caps in series (no equalizing resistors are needed). However, if you need the same intensity (i.e., to use the same F-stop), then the distance between the flash and the subject will have to be reduced by half in this case

Since power dissipation is still limited by the inverter, the flashtube should not overheat. The only concern is that the trigger capacitor has enough time to charge up - check its time constant and reduce its charging resistor if necessary to assure that the voltage on the trigger capacitor is high enough (close to what it would be for the unmodified circuit).

What you DON'T want to do is use a higher voltage on the input. That would almost certainly blow the inverter transistor (either immediately or from overheating) and/or the transformer, energy storage capacitor, or flashtube.

Where reducing the size of the energy storage capacitor is not adequate, here are some guidelines for more extensive redesign:

(From: Don Klipstein (don@misty.com or klipstei@netaxs.com).)

1. For faster flash rates, you want lower energy levels to avoid overheating the flashtube. The smaller U-shaped tubes may take about 5 watts of average power at faster flash rates, and about 4 watts at really fast flash rates. This means you probably want a flash energy under 1 W-s. The efficiency is also lower at lower energy levels, giving you more heat and less light. With lower energy levels (under about 2 W-s or so with a smaller U-shaped tube), the tube works better with unusually high voltages near or even above 400 volts. You would also use less capacitance, to get your desired flash energy with a higher voltage. You will probably have better flash extinguishing with more voltage and less capacitance.

2. Add an inductor in series with the power feed into the energy storage capacitor. This makes the capacitor hardly recharge at all for a few milliseconds, allowing the flashtube to extinguish.

   A 15 watt fluorescent lamp choke ballast will probably work for this. This goes in series with the power feed to the capacitor, not in series with the flashtube. CAUTION: This inductor may cause a voltage overshoot of the energy storage capacitor - probably to your favor if the capacitor can take the extra voltage.

   By my quick calculations, such a choke is order of 1 to 2 Henries of inductance so you could use an actual inductor if you have one handy. You won't beat the price though - a 15 W ballast is about $3.

Use two capacitors, with the inductor between their positive terminals, if the power feed requires a capacitor load. The first capacitor can be the larger value original energy storage capacitor. The second capacitor will be the low uF value one used for flashing, and will need to withstand extra voltage.

Caution: While it may be possible to totally eliminate (or greatly reduce size of) the series resistor in if you use an inductor, there is a chance of a meltdown if for some reason the arc didn't quench as might happen if the flashtube overheated - an inductor eventually looks like a short circuit to the power line while a resistor still has resistance :-). Make sure you have it fused!

For a typical variable rate stroboscope circuit, see the section: Welch Scientific Model 2153C Stroboscope.

Due to the drop in efficiency, trying to use this approach to create a continuous-appearing light source isn't worthwhile. It is easy to reduce the energy to a level that is safe to repeat 60 times a second, but a usual cheap glass flashtube will not be especially bright - almost certainly dimmer than a halogen lamp consuming the same amount of power. There may also be a slight "flicker" effect from the discharge being "sparklike" instead of uniformly filling the tube, and taking a different path through the tube on each flash.

High Speed (Short Flash Duration) Strobes

The typical integrated or camera mounted electronic flash unit has a flash duration of under 1 ms at full power. This is short compared to a flash bulb and adequate for most common photographic applications. However, when attempting to freeze high speed machinery or other rapid action, this may be way too long.

All other factors being equal, flash duration is roughly proportional to the size - uF rating - of the energy storage capacitor.

Where lower flash energy is acceptable and/or the strobe can be moved closer to the subject and/or faster film can be used, the normal energy storage capacitor in your electronic flash can be replaced with one that is smaller. Flash duration and energy will then be reduced in proportion to the ratio of the capacitor's uF ratings.

Using a higher voltage will enable the uF rating of the capacitor to be decreased and still achieve the same total light output - the required uF (and flash duration) goes down as 1 / (V * V). Of course, since the same energy is involved, the physical size of the capacitor doesn't change much. There is no free lunch :-).

For example, the typical small electronic flash unit uses a capacitor voltage of about 300 V. Designing a strobe with a 3 kV energy storage capacitor will permit its uF rating and flash duration to be cut by a factor of 100!

High voltage flashtubes and capacitors must be used but the basic principles of operation of these strobes are unchanged. Power to charge the capacitors can be provided by a line operated transformer or high frequency inverter either directly using a rectifier or doubler, or diode-capacitor voltage multiplier. For ideas, see the chapters on helium neon lasers in Sam's Laser FAQ as the operating voltage requirements for HeNe lasers are similar. Where fast cycle time is not critical or your required flash energy is modest, one of the sample circuits may be acceptable.

Those pictures of bullets in flight were likely made with air spark gap light sources with 10s of kV on the energy storage capacitors resulting in flash durations in the microsecond range.

Lengthening the Duration of a Flash

If you long for the blur of a real flash bulb, this may be for you!

In some cases, simply adding an inductor in series with the flash tube can provide some increase in flash duration. However, where you want 20 ms instead of less than 1 ms, this is not going to work. If the inductor is too small it won't do much of anything. Once it starts to have an effect, the effect will be to simply cut off the flash.

What should work better (and I have not tried this) is to add a high current constant current driver between the capacitor and the tube. For example, assuming a small flash with say 500 uF at 300 V results in roughly a 200 A peak current assuming a 1 ms flash duration. This is an equivalent resistance of about 1.5 ohms! To extend the flash duration to 20 ms requires dropping the current to 10 A.

One way to do this is with a constant current series regulator set for 10A:

```
                +-------+         R1
  +300 o---+----|-    |-|---------/\/\------+-----------+
           |    +-------+         1         |           |
           |       FL1                      |           |
 Main      |                           +-----------+     |
 Energy + _|_ C1                       | Constant  |   +_|_ C2
 Storage  --- 500uF                    | Current   |    --- 10uF
 Capacitor |  350V                     | Regulator |   - |  350V
           |                           +-----------+     |
           |                                |           |
           |                                |           |
Return o---+--------------------------------+-----------+
```

The use of a high frequency switchmode (buck) converter will almost certainly be necessary unless you have some really HUGE transistors floating around in your junk box. The problem isn't the voltage or current rating - a common BUT12A would meet these requirements - but rather maximum power and SOA (Safe Operating Region). Peak power dissipation in a linear regulator would be about 2,500 W!

C1 provides a sink for the flash tube current until the regulator can start up. It may be necessary to play with their values to achieve reliable operation. An alternative is to bias the transistor from a separate power source prior to triggering.

Also see the section: Driving Continuous Output Xenon Arc Lamps.

Details are left as an exercise for the student :-).

Another alternative that may be adequate for some applications is to split the single high intensity short duration flash normally provided by a standard strobe circuit into multiple lower energy flashes spread over a longer time.

As a starting point, consider the schematic of an energy conserving flash like the unit described in the section: Vivitar Auto/Thyristor 292 Energy Conserving Automatic Flash. Bypass the light sensor to control flash intensity directly. I guestimate that on a single charge of the energy storage capacitor, you should be able to get 10 or so short flashes spread over, say, 20 ms, at 50 percent efficiency. Depending on your needs, the discrete nature of these multiple flashes may be a problem - or a feature :-).

Driving Continuous Output Xenon Arc Lamps

These approaches can probably be applied to regular xenon flash lamps as well. See the section: Lengthening the Duration of a Flash.

(From: (macy@global.california.com).)

Take a look at the Xenon arc tubes made by ILC of Sunnyvale which is used in lighting those invasive tiny little arterial cameras. The light comes from a xenon arc tube and is transferred down the arteries via fiber optics.

I believe ILC used to provide these tubes on the open market (may still be) through Edmund Scientific, but they were too difficult for the general hobbyists and the market was zilch.

As I recall, they fire at around 300-400 volts and then the arc sustains at something like 20 volts 10-20 Amps or such. The drivers for these consist of the lower voltage high power drive with a transformer winding in series with the output lead (capable of the high current). The high voltage would "spark plug" the arc until it fired, then the low power supply sustained the arc producing *very* bright, pure light.

You could make such a driver where a lower voltage cap stores horrendous energy and use a "tickler" drive to fire the arc. Probably even get away with using the shorter duration arc you now have.

This tube is made for constant high power. The arc electrodes are mounted inside a cylinder shape about 1 1/4 inch diameter by 1 1/2 inch length. The electrodes are mounted along the axis of the cylinder with a parabola reflecting cup and tripod mounting of the outgoing electrode (to not block the light much)

The whole thing is clamped for heat exchange and electrical contact.

Originally, the "bulb" was used for headlights on tanks because they survive shock so well. [I'd heard some guy put a row on top his 4 W sport and when he turned them on, he could see 2 miles down the road. - makes a good story but I can't confirm it.]

Sometime in the 70's I met the man at Eimac (division of Varian) who invented the tube and he was looking for other applications. He had mounted it inside a 16mm projector to make a brighter, cooler light source. You could actually freeze the frame without having to dim because there was so little infrared in the light energy.

It is bright. I saw a movie being projected overhead on a 16 foot screen in a drafting room and you could watch the movie easily! Plus the colors made for a beautiful rendition of the film.

He saw this as a great potential market, until ..well the tube's light is so potent that it makes ozone and the ozone would "eat" up the aluminum parts on the projectors in 2 to 6 months. so that idea died.

At least it finally found its way into a very useful application - medical.

Strobe Design for Multiple Flashing

These are often seen in safety related applications - warning lights, for example, where a typical cycle might be two flashes .2 seconds apart with a .8 second dead time.

Here is one approach to designing a strobe that will double (or multiple) flash from a battery powered inverter of limited capacity.

Charge a large buffer storage capacitor from the DC-DC converter, then have its output feed a smaller flash energy storage capacitor through a resistor small enough to give you a fast recharge but large enough to allow the flashlamp arc to quench.

Building the DC-DC converter is pretty easy and you should be able to make it run off of a battery without any problem. You can use a simple power oscillator feeding a home-wound step-up transformer. With the energy buffer, the inverter only needs to satisfy the average power requirements of the multi-flash cycle. See the section: General Strobe Circuit Design.

For example, a small unit using a 100 uF 330 V capacitor for the flash could use a 1000 uF cap. for buffer storage separated by a 250 ohm power resistor. That would provide a 100 ms or so cycle time. The 1000 uF cap provides a reservoir between the relatively low power DC-DC converter and the tube as long as you do not flash too quickly - faster than your DC-DC converter can keep up.

This should be much easier than trying to interrupt the 10s-100s of amperes of current flowing in the tube during the flash.

Strobe Systems with Multiple Flashheads

Have you seen the 'new' ball used for the New Year's celebration on top of the tower in Times Square? Is uses something like 144 computer controlled xenon lamps. Sort of gives you something to strive for!

Several approaches can be taken in designing such systems depending on the needs:

- If only one flashlamp is to fire at any given time, a single energy storage capacitor can be shared by multiple flashlamps assuming the distance between it and any flashlamp is not excessive (probablyless than a couple of feet).

- Where multiple flashlamps may fire in an arbitrary sequence (but the average rate is known), each flashlamp can be connected to its own energy storage capacitor fed through a current limiting resistor from one high capacity power supply.

- If the maximum rate for each flashlamp is known, each head can have have its own independent inverter. For example, the flash units from disposable pocket cameras can be modified with beefed up heatsinks for the chopper transistor, suitably sized energy storage capacitors, and remote triggering capability.

Hybrid systems using a combination of these techniques are also possible.

In all cases, each flashlamp must have its own trigger transformer and it should be mounted in the flashhead near the xenon tube. See the section: Why the Trigger Transformer Should be Next to the Flashlamp.

An optoisolated SCR can then be controlled from a logic level signal - the output of a PC's parallel port or a dedicated bus. For long runs, use Schmitt Trigger gates or differential line drivers/receivers to prevent false triggering due to interference from the high voltage and high current pulses associated with each flashlamp's firing.

Multiple Xenon Tubes in Series/Parallel

For some applications, it might be desirable to use a bunch of small xenon tubes rather than a single large one. This might be the case if you happened to inherit a bucket load of someone's excess inventory. :) Or, the physical constraints of whatever you are building are better satisfied with many small tubes. This could be a single series string, a single parallel arrangement, or a parallel set of series strings.

Of course, it might be possible to use individual flash heads (e.g., from disposable cameras) each with their own electronics. However, sharing a single large energy storage capacitor and trigger circuit could be much more compact, efficient, and cost effective.

For series connections, the voltages add so you will need the energy storage capacitor to charge to n times the individual flashtube ratings (typically around 300 V for camera flashes). Problems with this approach are that with the higher voltage, peaks currents can be much higher than with normal designs and some means may be needed (e.g., series inductor) to limit this.

For parallel connections, the voltage is unchanged but some means must be provided to equalize the currents among the tubes. This usually means some low value resistors in series with each tube or series string of tubes. Since they are have a negative resistance, the tube that triggers earliest may end up with all the current and explode! Also, triggering must be 100 percent reliable else the tubes that end up triggering will see all the current and likewise, may be damaged or destroyed.

In both cases, a much larger trigger transformer or multiple trigger units will be needed. An automotive ignition coil might be appropriate for the single trigger approach.

I would try to avoid these sorts of setups unless there is no other choice. With the parallel one, in particular, too many things can go wrong and power will be wasted in the equalizing resistors.

Strobe Voltage Considerations

There are a variety of issues that determine the selection of the voltage used across the flashtube. Here are just a few:

(Portions from: Don Klipstein (don@misty.com or klipstei@netaxs.com).)

1. Other factors being equal, higher voltage results in shorter flash duration for a given energy.

2. Higher voltage should be very slightly more efficient since there is a fairly constant voltage left on the capacitor after the flash unless an actual pulse forming network (including inductance) is included to fully discharge through the lamp. For a typical small flashtube, this is about 50 V.

3. The length (and other characteristics) of the flashtube determines the maximum voltage before it will self-trigger. Thus, size and cost of compact flash units are limiting factors.

4. Higher voltage energy storage capacitors (above 450 to 500 V) must be made from multiple lower voltage caps in series with equalizing components. This adds complexity and cost, and decreases reliability.

5. Another factor to consider: Internal resistance of the capacitors. Typically, this becomes significant with flash durations shorter than a millisecond. Internal resistance is usually less with axial lead electrolytics such as Sprague's TVA series than with "radial" lead electrolytics.

6. Higher voltage results in a slightly higher color temperature and usually disfavors the major bunch of IR spectral lines around 820 to 1000 nm. Disfavoring these lines results in higher efficiency.

7. Any given flashtube has a minimum capacitance to get a good continuous spectrum. Lower capacitance results in a line spectrum unless the voltage is too low for good efficiency anyway. This "critical capacitance" is not a sharp limit, but does not seem to vary with voltage.

8. There is some upper limit to voltage, since exceeding some combination of peak power and total energy causes some of the flashtube wall to vaporize. This is called "wall ablation". I will have to dig out some of my still-packed literature to find out (numerically) what this limit is.

Converting a Pocket Camera Strobe into a Repeating Strobe

The little inverter in those units cannot put out enough power to charge the normal energy storage capacitor any faster. It is quite easy to replace the inverter with a voltage doubler off the AC line (with a current limiting resistor! Warning: non-isolated power supply). Using a smaller energy storage capacitor would also permit a much higher flash rate at reduced brightness and this would prolong the life of the flashtube as well.

With too high a repetition rate at high power, the problem is heat dissipation in the tube. Above a flash rate of once every couple of seconds, your poor little tube will degrade fairly quickly and it may not turn off properly as well due to overheating of the electrodes.

It will probably be necessary to use an SCR instead of a set of switch contacts to allow triggering from a 555 timer or other logic level input. For a basic constant frequency strobe, a relaxation oscillator using a unijunction transistor or neon lamp, an astable multivibrator built from a couple of general purpose transistors, or a counter operated from the AC line zero crossings or a crystal oscillator would be perfectly adequate.

However, a very simple repeating trigger can be made from a motor driven cam operated microswitch. Using a variable speed motor would implement a basic adjustable frequency stroboscope with no additional electronic components.

For a simple electronic modification:

(From: William "Chops" Westfield (billw@cisco.com).)

> "In fact, some types of disposable (or other) camera electronic flash units can be converted to repetitive flashers (not quite a strobe, but useful as a safety-beacon sort of thing) by connecting a couple neon bulbs or a 130 V (or better) 'Sidac' or diac across the existing trigger contacts. This is a nice trivial modification."

The resistance of the trigger capacitor charging circuit will affect the repetition rate and the RC time constant must be long enough for the main energy storage capacitor to charge to a high enough voltage for the xenon tube to fire reliably. Details are left to the student :-).

However, I wonder about flashtube life if the original energy storage capacitor is used. So, you might want to replace it with a smaller one if adequate for your needs.

In any case, if you retain the inverter, use an AC adapter or other power supply instead of batteries for testing at least. Otherwise, let me know which battery company's stock I should buy!

I've added the following little circuit to a Kodak MAX type disposable flash after replacing the original 160 uF energy storage capacitor (C2) with a 5 uF, 400 V motor run type (5 uF was selected because I had that value in my junk box).

It's obviously not nearly as bright as the original (1/36th the energy) but is quite adequate for attention getting, a safety beacon, etc. The repetition rate is adjustable from about 1 to 5 flashes per second with the component values shown. Many variations are possible.

Please refer to the Kodak MAX Flash Unit Schematic for connection information.

    C2+ o----+-------------+-----------+------------------------+
```

This forms a relaxation oscillator using the NE2 neon lamp as the trigger device. If you have higher value resistors, C4 could be reduced to a smaller uF value to get the same flash rate. A somewhat higher repeat rate may be possible. Without modifying any other parts of the Kodak MAX circuit, the charge button (S1) has to be pressed to start the unit. Where the flash rate is at least 1 Hz, S1 can be the original momentary pushbutton. However, if you want a slower flash rate, there is enough leakage to to cause the voltage on the trigger circuit to decrease too much between flashes (recall the much smaller C2 resulting in a proportionally shorter time constant) so the flashing may stop. Higher value resistors for R4, R5, and R6 would help, or replacing S1 with a toggle switch will force the inverter to run as needed to top off the charge (but will help eat more batteries in the process!).

It may be necessary to experiment with component values since at low speed, the circuit as shown is critically dependent on the breakdown voltage of the neon lamp (about 90 V for an NE2). To increase the time constant of the decay of the C2 voltage between flashes, the 3.9M resistor (R3) feeding the ready light (IL1) can be removed. This results in slightly more overshoot when the inverter charges C2 but it appears to be within safe limits. The ready light then only comes on for a second or so when the inverter cuts off and the decay of C2 voltage between flashes is only dependent on component leakage and the resistance of your external circuit.

CAUTION: DO NOT remove IL1 itself and note that the end of R3 connected to D2 also acts as a via on the printed circuit board and must NOT be removed (or a wire should be put in its place). Else, there is no regulation and the voltage probably climbs to a point where something explodes. :(

So, to implement this enhancement on a Kodak MAX type flash (most others are quite similar):

1. After discharging the existing energy storage capacitor, C2 (!!), remove it and attach red and black wires to its positive and negative pads.

2. Solder a different color wire to the solder pad of S2 which goes to the trigger transformer.

3. Solder a remote on/off switch in place of or in parallel with S1. For flash rates of less than 1 Hz, a momentary switch can be used - to start, press and hold until the first flash occurs. Stop by removing power. Else, short across S1 and use a separate SPST switch to control power.

4. Construct the circuit above on a piece of perforated or prototyping board and attach the C2+, C2-, and S2 wires. CAUTION: Note polarity - for the Kodak MAX design, common is positive (red) on the HV side.

At 1 or 2 flashes per second, the inverter transistor gets warm but not hot after a few minutes using 5 uF for C2. At higher rates, it does get rather toasty - a clip-on heatsink would be advisable. The flashlamp should tolerate an average power of a few watts - with 5 uF for C2, it is a only about 1.25 W at 5 Hz. I don't know about long term reliability of the overall system or how much larger C2 can be made while running at the same speed.

If you have a handy source of low voltage DC, you could use a real 555 timer to trigger the Triac and not have to deal with multi-megaohm resistors! For other options for inverter control and triggering, see the section: Digital Control of the Kodak MAX Flash Unit.

For an even simpler modification resulting in a fixed-rate repeating strobe, see Don's Hack Kodak MAX to Strobe Page. To make this variable, replace R2 with a series combination of a fixed resistor (to limit current) and a pot for speed adjustment. As above, for faster repeat rates, the uF rating of the main energy storage cap will need to be reduced.

Repeating Strobe Trigger Generators

Here are two simple circuits for generating a continuously repeating strobe trigger.

It is assumed that the power supply and xenon tube can handle the average power requirements for the minimum desired cycle time.

Inadequate energy storage capacitor charging power will result in erratic or reduced intensity flashing. Excessive heating caused by too high a repeat rate may lead to damage to circuit components and/or the flashlamp or may result in the arc not quenching properly between flashes.

Inadequate trigger charging power (RC time constant too long) will result in missed or erratic triggering.

Repeating Trigger Using 555 Timer

This is a common 555 timer operated in astable mode. For a detailed description of the circuit operation, see the 555 timer datasheet any databook which includes the 555 timer chip.

Component values have been selected to cover a range of about 1 to 10 seconds between flashes.

```

    GND o---+---+-----+--------+
```

Trigger-N can drive an optoisolator (LED cathode, anode via current limiting resistor to Vcc), can be capacitively coupled to SCR gate (fire on rising edge), put through pulse transformer, etc.

Repeating Trigger Using Neon Tube (Indicator Lamp)

This is a simple relaxation oscillator using a common NE2 neon indicator lamp. As drawn, the repeat rate should be adjustable from about 0.1 to 10 Hz. Adjust component values for your particular needs. (Note: use of audio taper potentiometer would help to linearize the adjustment range.)

Relaxation Oscillator Operation

The neon indicator, NT1, is a negative resistance device. It becomes conductive when the voltage across it exceeds about 90 V but then only requires about 60 V to maintain conduction. This circuit has an RC network formed by R1, R2, and C1. C1 charges through R1 and the repeat rate adjustment potentiometer, R2. When its voltage exceeds the NE2 breakdown voltage, C1 discharges through NT1 resulting on a pulse on R3 coupled by C2 to the gate of SCR1. The SCR fires and discharges the trigger capacitor (not shown) into the trigger transformer of the strobe firing circuit.

Once the voltage across NT1 has decreased below about 60 V, it turns off and the cycle repeats. Since the voltage across NT1 is swinging between about 60 and 90 V (out of 150 VDC total), the repeat frequency should be between 4 and 5 times 1/(RC). It is assumed that SCR1 (Out+/-) takes the place of the shutter contacts, is the SCR, or in parallel with the SCR shown in the strobe circuits shown elsewhere in this document.

For other values of VPP between about 100 and 300 V, adjust resistance values appropriately.

Note that C3* and C4* are essential to provide safety isolation for line powered strobes.

Please note that the characteristics of neon lamps sometimes change with age, temperature, and use. The SCR should have a sensitive gate since some neon lamps do not reliably conduct more than a few milliamps when they ionize in a relaxation oscillator.

- Back to Nifty Strobe Circuits and Notes Sub-Table of Contents.

Optoisolated Remote Trigger from low Voltage Logic or Signal

Here is a circuit for an optoisolated trigger interface. This will permit control of line-connected (non-isolated) strobes from logic or other lower voltage signals. This is probably the safest way to deal with the isolation and safety issues as the insulation resistance of typical optoisolators is several kV (7.5 kV for the specific part shown). Also see the next section for a specific application of a similar circuit.

Another important reason to consider this approach is to assure reliable triggering in an electrically noisy environment. Such interference may be external (e.g., power cables, digital busses) or internal. Even where there are only two flashtubes, the current pulse when one of these fires could falsely trigger the other. Minimizing the length of sensitive trigger wiring and low pass filtering the trigger signals (i.e., RCs on the input to the SCR) will help. However, the best way to prevent false triggering is to use light rather than electrical signals to trigger the flash heads. Instead of running long wires with low level signals, use individual fiber optic cables for each channel between its LED and photodetector (rather than an opto-isolator) in the circuit below. Such a design will even be immune to the EMP resulting from a nuclear blast - should you care :-).

This basic design would be suitable for a wide variety of applications requiring microprocessor, PIC, or PC control. A multiheaded strobe pulsing to a musical beat (high power color organ) could be implemented by triggering several strobe units from an audio amp's speaker output via audio filters of various cutoff or bandpass frequencies.

Optoisolated Remote Trigger Operation

The input signal may be DC coupled resulting is a high level triggering the strobe or AC coupled resulting in a positive edge trigger. R1 provides current limiting to the optoisolator's LED and R2 minimizes any possibility of electrical noise turning on the optoisolator. Change the values of R1 and R2 for a different input voltage range. D2 provides reverse voltage protection for the LED.

For VPP greater than 10 V, the voltage divider formed by R3 and R4 charges C2 to about 5 V. This is the most common case where VPP is derived from the strobe power supply and is typically 300 V. The time constant for this RC network is under 5 ms so it will not affect high speed repeat operation. C2 assures that there will be enough current from the optoisolator to trigger SCR1 even with the high value resistor which may be used for R3 to minimize power dissipation with a large VPP. For a VPP of less than 10 V, the circuit can be simplified to just a current limiting resistor (leave out R4).

When current flows through OPTO1's LED, it turns on the phototransistor which allows C2 to discharge into the gate of SCR1 which is connected to the trigger capacitor and transformer of the flashlamp firing circuit (not shown).

To minimize the possibility of false triggering, locate the optoisolator circuit in close proximity to the SCR. R5 and C3 are included to reduce the SCR's sensitivity to any electrical noise pickup as well.

VPP must be a positive DC voltage referenced to the terminal Out-. In most cases, this will be the energy storage capacitor's positive terminal. Adapter Circuit for Low Voltage Camera to High Voltage Flash

Optoisolated Adapter for Older Flash Units to Low Voltage Cameras

(From: Brian L. Zimmerman (blz@home.com).)

Many electronic flash units can have a very high voltage between the trigger contacts that are shorted to trigger the flash. For example, the trigger voltage of the "Digi-Slave" DSF-1s flash unit being sold in 2001 for use with digital cameras (See for example, Slave Flash Products) measures 218 V fully charged. This would be dangerous to use on many modern electronic cameras such as Canon digital cameras which specify no more than 6 V.

This design adapts such a high voltage flash for use on a low voltage camera by using an optocoupler to electronically isolate the camera's contacts from the high voltage. It can then be triggered by the camera using the 6 volt supply from the flash unit's batteries, but also works at a lower voltage. The use of a triac optocoupler has the added advantages of using fewer parts than other optocoupler designs and can use the power from the flash's trigger circuit to fire the SCR switch instead of a separate power source.

The adapter circuit can be inserted into the lines inside the flash unit going between the flash trigger circuit and the flash unit's contacts as shown below. Since there are only 4 small parts in this circuit, there is a good chance that you can build it right into the available space inside the flash unit's case.

(WARNING: High voltage precautions apply here - be sure to safely discharge all capacitors!)

```

Parts list

1. SCR1: SCR, 400V, 6A, (RS#276-1020, $1.29, TIC106D, etc.).
2. OPTO1: Triac optocoupler (MOC3010, RS#276-134, $1.99)
3. R1: 330 ohm Resistor.
4. R2: 5.6k ohm Resistor.

RS# indicates Radio Shack part numbers. Total cost (October, 2001) is $3.75.

Operation

The camera shutter shorts the hot-shoe contacts, causing current to flow from the 6V battery through the IR-emitting diode at pins 1 & 2 of the OptoTriac. The current is transferred via light pulse which switches on the triac at pins 4 and 6 of the OptoTriac which is powered by the voltage from the flash trigger circuit. Current flows into the gate of the SCR, switching it on and causing discharge of the flash trigger through the anode and cathode of the SCR. The 330 ohm resistor (R1) limits the current through the hot-shoe to about 18 mA, and the 5.6k ohm resistor (R2) limits the current through the triac to about 40 mA. You may need to use a different value for R2 for your particular flash and SCR, since this is based on a 218 V trigger voltage. The triac can handle a larger current (1.2 A peak), but SCR's typically only use a small gate current for triggering.

Note

The circuit with component values shown seems to work reliably (at least so far) for this particular combination of Canon digital camera and slave flash. Others may be quite different. Some info can be found at Kevin Bjorke's: Non-Canon Strobe Page with a List of Trigger Voltages. Just knowing the trigger voltage isn't really enough information as it doesn't imply anything about the available current. Adding an input buffer using a transistor or CMOS gate would eliminate this as a concern.

SCRs and triacs should be driven hard when they are controlling high current sources to make sure they turn on quickly and minimize time where they are passing significant current with a significant voltage drop. The optotriac's output is current limited so this isn't much of an issue. However, the SCR discharges the trigger capacitor through the trigger transformer and this could amount to several A switched in a few microseconds. A gate current 10 to 20 times the minimum spec in the datasheet is recommended so long as this doesn't exceed the maximum rating in the datasheet. In any case, the worst that will happen is that the SCR will fail or become unreliable after running with marginal gate drive - no great loss considering its cost.

Optically Activated Strobe Circuits

Light Beam Triggered Strobe Circuit

Here, the intention is to trigger a strobe should a light beam be interrupted or completed. Any of the electronic flash schematics can be modified for this purpose. This approach can also be used to implement a slave flash. However, for such a high intensity application, a Light Activated SCR (LASCR) would be suitable and result in a simpler circuit (as in 1 component). However, LASCRs may be harder to find.

Any light source with sufficient spectral content for the selected photodiode can be used to generate the beam including an incandescent lamp, visible or IR (light) emitting diode (LED/IR LED/IRED), or a visible or IR laser diode. A small convex lens will greatly increase the range of any of these light sources. For a slave flash trigger aimed at the main flash, a lens may or may not be needed depending on the energy of the main flash and its distance from the sensor.

The circuit below should work for the detector. Its output may need to be put through one (light beam completed or slave flash) or two (light beam interrupted) inverting Schmitt Trigger gates (e.g., 74LS14) to clean up its output and provide the proper polarity. It should be AC coupled to the gate of an SCR. The SCR will substitute for the camera's X-sync contacts and fire the strobe. Note that if this is a line operated unit, capacitor (or transformer) coupling is essential for providing the very important line isolation barrier absolutely required for safety.

For the case where the strobe is supposed to fire when the light beam is interrupted, when the light beam is unbroken, the photodiode is illuminated providing current to keep the transistor on and its output is low. When the beam is broken, the output goes high, is cleaned up by the Schmitt Trigger gates creating a rising edge to provide a pulse to trigger the SCR.

Any common IR or visible photodiode can be used for PD1. Sources include optoisolators, photosensors from dead VCRs, and optomechanical computer mice. IR photodiodes are usually sensitive to visible light and vice-versa so it may not be necessary to match source and detector precisely.

Notes on Light Beam Triggered Strobe Circuit

1. CAUTION: Capacitors provide needed isolation barrier for line connected electronic flash units. Make sure they have adequate specifications.

2. For detecting a light beam being completed or for use as a slave flash trigger, logical inversion is needed. Therefore, use an inverting Schmitt Trigger or a single 74LS14 inverter.

3. For detecting a light beam being interrupted, no inversion is needed. Therefore, use a non-inverting Schmitt Trigger or a pair of 74LS14 inverters in series.

Simple Slave Flash Triggering

Here are a pair of really simple approaches to firing a slave flash unit from the light output of a master flash:

(From: David T Bupp (dtbradio@dtbradio.com).)

Here's one idea that I've used quite successfully to make a slave flash: Take a miniature (or standard-size if desired) green or yellow LED, and mount it directly into the front of the existing camera flash unit (I mounted mine at the lower right corner of the plastic cover plate by drilling a tiny hole just big enough to fit the body of the LED up to the flange). I then coupled the positive side of the LED to the base lead of a general purpose NPN transistor, and coupled the negative side of the LED to the emitter lead of the transistor. I used the transistor in an inverting full-on/full-off switch configuration with a 1K resistor from my positive supply (5-12 VDC) to the collector lead. I then used the collector lead to trigger the timing cycle on a 555 monostable timer circuit set for 1 ms pulse output, and coupled that pulse output into a triac-based opto-coupler and a separate triac to fire the strobe's trigger transformer when a flash was detected on the camera's built-in flash unit. Although the setup is rudimentary at best, it works very well, and has been quite reliable as far as triggering goes.

(From: Gordon Couger (gcouger@provalue.net).)

I used one solar cell and one triac (or SCR) to create a slave flash that works great indoors. The solar cell positive output simply drives the gate of the triac directly. The triac is used in place of the shutter contacts. No batteries required. :)

Some solar cells and some flash units may need current limiting resistors, and bypass capacitors are a must. But I was annoyed and in a hurry. Adding an RC network to drive the triac may be needed to prevent triggering from ambient illumination in some cases.

Additional comments at: Quick and VERY DIRTY Slave Flash for CoolPix 995.

Triggering a Slave Flash from a Dual Flash Camera

Many newer cameras (film and digital) activate the flash twice for each picture; once for red-eye reduction (which may or may not actually use the electronic flash itself) and the second time to take the shot. Where it is desired to use a slave fill flash, it may fire uselessly on the first burst of light. However, there is an easy solution if the slave can be electronically triggered. Use the trailing edge of the light pulse (the positive edge of the output at ST2 in the circuit above) to trigger a monostable whose output is low-ANDed (the NOR gate shown below) with its input. The output of the NOR gate can trigger the SCR as shown or drive an opto-SCR or opto-triac to trigger the slave flash. The first flash won't get through because the monostable won't be activated until it goes away. Select the pulse width for the monostable to be longer than the time between the dual flashes.

Kevin's Super Strobomatic

(The following is from: Kevin Horton (khorton@tech.iupui.edu))

I'm building a super strobe bar! It has 8 strobe tubes under computer control. (Actually a PIC processor, but hey, computer is a computer. I have all the stuff done except the control section, and I only have 2 of the 8 strobe units done due to the fact that I haven't found any more cheap cameras at the thrift store! (One Saturday morning's worth of garage sales and flea markets would remedy that! --- sam).

It runs on 12 V, at up to 6 A, and can fire the tubes at a rate of about 8-10 times per second. The storage cap is a 210 uf, 330 V model; it gets to about 250 V to 300 V before firing; depending on how long it has had to charge. Because of this high speed, the tubes get shall we say, a little warm. (Well, maybe a lot warm --- sam). I have it set up at the moment driving two alternating 5 W-s tubes. I'm pumping them quite a bit too hard, as the electrodes start to glow after oh, about 5 seconds or so of continuous use. I know, a high class problem, indeed! My final assembly will have 8 tubes spaced about 8 inches apart on a 2x4, with a Plexiglass U-shaped enclosure with a nice 12 V fan blowing air through one end of the channel to cool the inverter and the tubes. Stay tuned.

The following schematics provide some details of this design:

- Inverter - High power 12 V to 300 V inverter for high repeat rate medium power strobes: inverter.gif.
- Trigger - Opto-isolated logic level trigger for general electronic flash and strobe applications: trigger.gif.

Tiny Tiny Inverter Design

(The following is from: Kevin Horton (khorton@tech.iupui.edu))

I have developed a cool little transformer circuit that seems to be very efficient. I built this inverter as tiny as I could make it. It runs off of 3V, and charges up a little 1 uf 250V cap all the way up in about 30 seconds; drawing about 5 to 8 mA in the process. The numbers by the windings tell the number of turns. The primary and feedback windings are #28, while the secondary is #46. Yes, #46! (Apparently, you can buy wire down (up?) to size #60 - less than .000350 inches in diameter! Check out MWS Wire Industries if you are really curious about fine wire.) I could hardly tell what gauge it was being almost too small to measure with my micrometer! It may have bee #44 or #45, but at these sizes, who knows? I used a trigger transformer for the wire. I used all the wire on it, to be exact; it all *just* fit on the little bobbin. The primary went on the core first, then the secondary, and finally the feedback winding. This order is very important. I used a ferrite bobbin and corresponding ferrite 'ring' that fit on it. The whole shebang was less than 1 cm in diameter, and about 3-5 mm high! I gave it a coat of wax to seal things up, and made the inverter circuit with surface-mount parts, which I then waxed onto the top. There are two wires in, and two wires out. It's enough to run a neon fairly brightly at 1.2 V, with a 3 ma current draw.

Super Simple Inverter

This circuit will generate over 400 VDC from a 12 VDC, 2.5 A power supply or an auto or marine battery. While size, weight, and efficiency are nothing to write home about - in fact, they are quite pitiful - all components are readily available (even from Radio Shack) and construction is very straightforward. No custom coils or transformers are required. If wired correctly, it will work.

Output depends on input voltage. Adjust for your application. With the component values given, it will generate over 400 V from a 12 V supply and charge a 200 uF capacitor to 300 V in under 5 seconds.

```

Notes on Super Simple Inverter

1. Construction can take any convenient form - perf board, minibox, etc. Make sure the output connections are well insulated.

2. C1 must be nonpolarized type - not an electrolytic.

3. D1 provides a return path for the base drive and prevents significant reverse voltage on the B-E junction. Any 1 A or greater silicon diode should be fine.

4. C2 is shown as typical energy storage capacitor for strobe applications.

5. D2 should be a high speed (fast recovery) rectifier. However, for testing, a 1N4007 should work well enough. R2 limits surge current through D2.

6. The polarity of the input with respect to the output leads is important. Select for maximum voltage by interchanging the black output wires.

7. Mount Q1 (2N3055) on a heat sink if continuous operation is desired. It will get warm. Any general purpose NPN power transistor should work. For PNP types, reverse the the polarities of the power supply and D1, and interchange one set of leads.

8. Some experimentation with component values may improve performance for your application.

9. When testing, use a variable power supply so you get a feel for how much output voltage is produced for each input voltage. Component values are not critical but behavior under varying input/output voltage and load conditions will be affected by R1 and C1 (and the gain of your particular transistor).

10. WARNING: Output is high voltage and dangerous even without large energy storage capacitor. With one, it can be lethal. Take appropriate precautions.

11. For your less intense applications, a fluorescent lamp can be powered directly from the secondary (without any other components) in place of a flash lamp! This works reasonably well with a T5-13W or T8-15W bulb but Q1 does get quite hot so use a good heat sink.

12.

Ultra-Compact 350 V Capacitor Charger

This pair of circuits, shown in Ultra-Compact 350 V Capacitor Charger, is based on the inverter transformer found in the flash units from disposable pocket cameras. They use only 4 required components in addition to the transformer, battery, and energy storage capacitor. See Photo of Ultra-Compact 350 V Capacitor Charger for an example of the compact construction (shown sitting on a U.S. dime). While not quite the simplest possible design, the inverter transformer only needs to have drive and HV output windings, no feedback winding or tap. Thus, it is likely that the transformer from almost any pocket camera flash unit can be used, or one can be relatively easily constructed. See the section: "Ultra-Compact 350 V Capacitor Charger" in the document: Various Schematics and Diagrams for more details.

- Back to Nifty Strobe Circuits and Notes Sub-Table of Contents.

Radio Shack Low Power Strobe

This circuit was printed on the back of the Radio Shack trigger coil blister pack. It is suitable for various stroboscopic, signaling, engine timing, scientific, and other similar (relatively) low intensity applications.

The power supply for this strobe can be either a voltage doubler operating from the AC line (caution - no isolation) or a battery powered inverter. An isolated SCR trigger circuit can be easily substituted for the firing button. See the sample circuits elsewhere in this document.

(Original schematic provided by Robert Bullock (robert_bullock@pobox.tbe.com).)

Applied Voltage (+V): 200 to 300 VDC

Parts list:

C1 - Energy storage capacitor. 2 to 20 uF, 400 V.
C2 - Trigger capacitor. 0.0022 uF, 400 V.
R1 - 250 ohm 2 W.
R2 - 47K ohm 1\2 W.
R3 - 150K OHM 1\2 W.
S1 - Firing switch. SPST momentary pushbutton.
T1 - Trigger coil (transformer), 4 kV, Radio Shack 272-1146.
FL1 - Flashlamp, Radio Shack 272-1145.

Note: I could not find the trigger coil (RS part number 272-1146) in the latest Radio Shack Catalog - the flashlamp was there - so I do not know if it is still available from them. However, I don't see any reason why R2 and R3 cannot be combined into one resistor (at R2's location - 200K, 1W) permitting the use of a trigger transformer with a single terminal for the drive and HV return (more common) should the one from Radio Shack be unavailable.

Digital Control of the Kodak MAX Flash Unit

Sub-Table of Contents

- Back to Digital Control of the Kodak MAX Flash Unit Sub-Table of Contents.

Description of MAX Modifications

Additional circuitry has been added to permit digital (e.g., TTL, CMOS, PIC, etc.) control of the Kodak MAX flash unit (see the section: Photoflash Circuit from Kodak Disposable 35mm Pocket Camera 2. This allows these dirt cheap or free flash units to be used for all sorts of other applications.

While it may be possible to construct the additional circuitry on the original MAX circuit board (there is quite a bit of free space), for my prototype, I added a mezzanine board held in place with an insulating treaded spacer. Even so, I ended up adding a few parts (like the triac and its drive components) to the back of the PCB. The battery clips were also removed and an external battery holder was added. However, for testing, I used the power supply described in the section: "1.5 V Alkaline Cell Eliminator" in the document: Various Schematics and Diagrams. The total cost of the modifications is about $2 (most of this being for the triac).

Note that for the simplified case of just trigger the MAX or similar flash unit electronically, the triac and associated components would easily fit on the existing circuit board. For instructions on disassembling Kodak MAX cameras, see Don's Hack Kodak MAX to Strobe Page.

Modified MAX I/O Specifications

Here are descriptions of the control and status signals:

- OPR-H: This logic signal controls the inverter:
  - RUN: (TTL High, 2 to 5 V) -> Inverter starts and runs but may be overridden by the OFF signal or built-in 300 V limiter.
  - CRUISE: (Open, Hi-Z or Tri-Stated) -> No Change. Inverter will continue running or remain off as determined by previous state. Note: The unit will also automatically recharge if fired with OPR open or tri-stated and Switching from OFF to CRUISE seems to start up the inverter - a high value resistor to ground may inhibit this 'feature'.)
  - STOP: (TTL Low, 0 to .4 V) -> Inverter stops. Note: Low must be .4 V or less while sinking 15 mA to guarantee off. Use OFF-H to force shutdown if your driving logic can't handle this.
- OFF-H: This logic signal disables the inverter regardless of state of OPR.
- FIRE-P: This pulse signal will trigger the flash on either edge with a sufficiently powerful driver (assuming the energy storage capacitor is charged). The driving output must be able to sink or source at least 15 mA to guarantee reliable firing (depending on whether you want a negative or positive or either edge trigger In order to prevent possible damage to the triac, Q6, it is important that this line be driven hard so assure that Q6 is never turned only partially on. A diode (D10) can be added in series with the gate of appropriate direction to select which edge is used for triggering. For testing, I just substituted a jumper for D10.
- READY-L: This output can be used as either a digital indication of full charge or an analog monitor of the energy storage capacitor (C1) voltage in the approximate range of 305 to 310 VDC.
  - As a digital status signal, READY goes low when the voltage on C1 reaches about 310 V. READY will remain active for a couple of seconds after the inverter cuts out. Therefore, to assure full charge, the inverter should be turned on prior to triggering flash until READY becomes active. Or, leave OPR active and the inverter will run every few seconds for a fraction of a second to maintain full charge.

    Note: READY changes relatively slowly - it does not have a sharp edge. If this is a problem for the type of logic being used for control, READY should be buffered with a Schmitt Trigger gate (e.g., 74LS14).

- As an analog feedback signal, READY actually tracks C1's voltage between roughly 305 and 310 VDC (READY goes from 5 V to 0 V over this range). Therefore, if precise control of the flash energy is desired, READY can be fed to an A/D or voltage comparator. The voltage on C1 can then be trimmed by pulsing OPR.

Modified MAX Circuit Operation

Please refer to the Modified MAX Flash Unit Schematic for the following discussion.

WARNING: The energy storage capacitor, C1, will retain a potentially lethal charge for quite a while. The time constant is greater than 6 minutes (via neon ready light, IL1, and 3.9M resistor, R8) down to about 200 V. Below this voltage (when IL1 turns off), there is essentially no discharge path other than the very small leakage of C1 and Q6. Take care!

The circuit changes were designed to take advantage of the way the MAX operated as part of the camera and to minimize rework to its printed circuit board. Where a new board is to be fabbed, the latter is not an issue but it turned out that this approach was still more-or-less optimal. See the section: Modified MAX PCB Layout.

Operation of the OPR signal for RUN and CRUISE is analogous to the original charge push-button of the MAX camera: A TTL high is the same as pressing the button while OPEN is like releasing the button. The addition of a diode (D8) allows a solid TTL low or ground to such enough current out of the drive circuit to kill inverter oscillation.

The OFF signal drives the base of Q5 which similarly shorts out the drive to stop oscillation.

The FIRE signal is capacitively coupled to the gate of the triac, Q6, to discharge the trigger capacitor, C3. This is exactly analogous to the way the original shutter contacts worked.

An additional circuit, very similar to that of the 300 V limiter, was added for the READY status signal. Its input is derived from the energy storage capacitor through the same high voltage neon bulb (IL1) and zener (ZD2) so it turns on at around 300 V. It was found necessary to add a sneak path prevention diode, D9, to block voltage making its way in from the TTL supply and restarting the inverter even if OPR was open.

Clamp diodes have been included on all signal lines. This is sort of insurance to prevent any glitch pulses generated at the time the flash is triggered from feeding back to the logic. I do not know if these are really needed at any time but 1N4148s are cheap enough!

Modified MAX Options and Precautions

The original MAX flash design charges C1 to slightly over 310 V based on the combination of the 110 V zener (ZD1) and the 200 V neon ready light (IL1). IL1 can be replaced with a zener diode if desired to change this value. However, I wouldn't recommend going too much higher without also using a C1 of greater voltage rating. The inverter itself will top out at about 350 VDC on C1 (with a nominal 1.5 V input) but its transformer may fail if pushed by more than even a small amount. Who knows? :)

As noted, with OPR set HIGH, the inverter will run as needed to maintain full charge. This means a few tenths of a second burst every few seconds. If R3, the load resistor for the Ready light (IL1), were removed, the charge would decay even slower. However, I am not sure of the implications for regulation without IL1 - the neon bulb would actually go off and on which may represent substantial hysteresis. However, this scheme should definitely work if IL1 were replaced with a 200 V zener.

Modified MAX Test Circuit

To test the modified MAX, I made up a simple set of switches and used a hex inverter (7404) for input buffers and to drive a the READY LED.

- OPR-H: SPDT center off toggle switch selecting +5 (RUN), open (CRUISE), or Gnd (STOP).
- OFF-H: Pushbutton to Gnd (with pullup) buffered by inverter.
- FIRE-P: Pushbutton to Gnd (with pullup) buffered by inverter.
- READY-L: Two inverters in series drive LED through 220 ohm resistor to +5.

For a more 'high-tech' approach, use a PIC or the parallel port of your PC.

Modified MAX PCB Layout

A printed circuit board layout is also available. The entire double sided circuit board is 2.2" x 1.6". Power can be provided by the built-in AA size battery holder (which may be removed by snapping along the score lines) or via an external 1.5 V power supply.

The layout may be viewed as a GIF file (draft quality) as: mmaxpcb.gif.

A complete PCB artwork package may be downloaded in standard (full resolution 1:1) Gerber PCB format (zipped) as: mmaxgrb.zip.

The Gerber files include the solder side copper, soldermask, top silkscreen, component side copper, and drill control artwork. The original printed circuit board CAD files and netlist (in Tango PCB format) are provided so that the circuit layout can be modified or imported to another system if desired. (Note: I don't guarantee that the parts *values* in the Tango PCB file are accurate - go by the schematic.) The text file 'mmax.doc' (in mmaxgrb.zip) describes the file contents in more detail.

Retrofitting Older Cameras for Electronic Flash

Sub-Table of Contents

- Back to Retrofitting Older Cameras for Electronic Flash Sub-Table of Contents.

Whatever Happened to All Those Flashbulbs?

In what some would call 'the good old days', it was common to carry around a bag full of flashbulbs to provide photographic illumination. These were a pain to use, resulted in disposal issues, and were somewhat hazardous when used 'according the label directions' - exploding flash bulbs were common.

Of course, in the truly good old days, they had those exposed palettes with flash powder. They were really good at starting fires....

Individual flashbulbs were single use sources of light containing a wad of fine magnesium (or other active metal) wool with an electric or mechanical trigger. These produced an intense white light of relatively long duration (perhaps 40 ms as compared to 1 ms or less for an electronic flash).

With the march of technology individual flash bulbs gave way to to flashcubes, flashbars, and other multi-use source of light (at least for the weekend camera bug - the professional photographer still needed the higher power of individual bulbs),

While the electronic flash has been used professionally for at least 40 years, it is only within the last 10 years or so that all but the least expensive camera comes with a built-in electronic flash as standard equipment.

However, some people still would like to continue to use their older equipment for which no low cost electronic flash upgrade may exist. The information in this chapter is directed toward these die-hards. While written specifically for replacement of the Polaroid SX-70 Flashbar, little or no modification should be needed to interface to nearly any camera or lamp holder originally designed for electrically triggered flash bulbs.

The remainder of this chapter is based on material from: George Holderied (holderied@ubaclu.unibas.ch).) His web page: The Hacker's Guide to the SX-70 provides all sorts of useful information including more details on the flashbar retrofit described below.

- Back to Retrofitting Older Cameras for Electronic Flash Sub-Table of Contents.

Flashbar Eliminator for SX-70 Polaroid Cameras

I have built a flashbar eliminator. It works fine with my Polaroid SX-70. As they stop selling flashbars in the US, it may be interesting for Polaroid fans to build an interface for common electronic flashes.

The flashbar contains five glass bulbs on each side that are filled with magnesium wool in an oxygen atmosphere. The magnesium is ignited by an electric pulse. The glass bulbs are plastic coated to prevent them from exploding. There is also an outer plastic wall which is another safety shield and corrects the light color.

The flashbar is contacted from the front (active) side.

```
+-----------------------------+
|   A    A    A    A    A     |
|   1    2    3    4    5     |  <- Flashbulbs
|   U    U    U    U    U     |
+-----------------------------+
          H123456                 <- Contacts
```

The wider contact (H) to the left shorts two contacts in the camera to indicate the presence of a flashbar. Contacts 1, 2 and 3 go each to one side of the bulbs 1, 2 and 3. Contact 4 is the common contact that goes to one side of each bulb. Contacts 5 and 6 go each to one side of the bulbs 5 and 6.

The flashbar wiring is shown below:

```
(4)o---+-----+-----+-----+------+
       |     |     |     |      |
     (B1)  (B2)  (B3)  (B4)   (B5)
       |     |     |     |      |
       |     |     |     |      |
      (1)   (2)   (3)   (5)    (6)
```

There are no electronics in the flashbar. The camera knows which bulb has been fired by measuring the resistance across the bulb. A good bulb has a resistance of a couple of ohms whereas a dead one has almost infinite resistance.

Replacing a Flashbar with an Electronic Flash

There are several reasons to use an electronic flash instead of the flashbars:

- Flashbars cost about US$4 and are becoming harder to obtain.
- They end up in the garbage.
- Bulb flashes, due to their longer duration, cause a dark spot in your field of view if looked into, that lasts for several minutes.

You can easily find cheap electronic flashes that replace flashbars.

A used one should not cost more than two flashbars. However, if you already have an electronic flash that you want to use instead of the bars, you need an interface.

Flashbars have a fixed light output that reaches to a distance of about 3 meters (10 feet). The SX-70 exposure control is based on the focused distance. The camera's maximal aperture (f-stop) is 8. It is recommended to use an electronic flash with the same light output as a flashbar. That flash would have a guide number of 75 (9,5 feet * 8), or a metric Leitzahl of ca. 25 (3.2 meters * 8) at 150 ASA.

Flashbar Eliminator Interface

A flashbar-compatible camera outputs an electric pulse of about 4V at 1.5A. However, an electronic flash has a voltage of about 250 V between the trigger contacts that are shorted to trigger the flash.

The interface is based on the general optoisolated remote trigger from a low voltage logic or signal. See the section: [Optoisolated Remote Trigger from Low Voltage Logic or Signal].

Flashbar Eliminator Schematic

             Optocoupler                /       _|_ |
              4N33 typ.              1K \ 100pF --- |
                                        /        |  |
                                        |        |  |
                                        +--------+--+-------o Flash trigger (-)
```

Flashbar Eliminator Operation

The 3.5 Ohm resistor tells the camera that there is a unused flashbulb in between the contacts 4 and 3. The 22 ohm resistor limits the current through the coupler's LED.

On the output side an electrolytic cap (2.2 uF) is charged from the flash's trigger voltage to 6.3 V. This voltage is limited by a zener diode. When triggered, the coupler's phototransistor discharges the capacitor into the thyristor's gate and fires the thyristor and thus the flash.

The whole circuit easily fits into an empty flashbar.

Schematics for Pocket Camera and Externally Mounted Compact Flash Units

Sub-Table of Contents

---

* Back to Schematics for Pocket Camera and Externally Mounted Compact Flash Units Sub-Table of Contents.

General Description of Battery Powered Flash Units

These range from the tiny units inside pocket camers to larger, more powerful hot shoe or remotely mounted units. They all run on battery power and some also operate from the AC line. (See the section: Flash Circuits from Disposable or 'Single Use' Cameras for an introduction to those types specifically.)

The typical power input is between 2.4 V (from a pair of NiCd cells) to 6 V from 4 AA Alkalines or a Lithium battery. The DC-DC inverter produces around 300 VDC using some form of a blocking oscillator forward or flyback converter. High performance units include automatic exposure (external or TTL - Through The Lens). Some are quite sophisticated with microcomputer control. Since the only source of schematics I know of for these things is by reverse engineering the circuits, don't expect to see too many of the fancy variety in this chapter as these very quickly become too complicated and difficult to trace. There IS a limit as to how far I will go :-). However, contributions are always welcome!

If you are going to be experimenting with any of these in a serious way, I would recommend constructing a power supply to replace the batteries as their appetite for power is quite large. See the section: "1.5 V Alkaline Cell Eliminator" in the document: Various Schematics and Diagrams for a suitable circuit (just a transformer/rectifier/filter/IC regulator) since this basic design can easily be modified for whatever voltage is needed.

Here are some additional comments:

(From: Malcolm Watts (M.J.Watts@massey.ac.nz).)

I was browsing through this circuit collection when I came across the disposable camera flash circuits. I *think* from what I read that some areas of operation are still a bit of a mystery to some. Some years ago, I analyzed such circuits and have the following comments which you may find useful.

The inverter is basically a forward converter. As noted, it delivers energy to the capacitor on the power stroke. Note that the cap charging current is also the transistor base current and this gives it a power-on- demand characteristic. The inverter will not operate if the pri:sec turns ratio of the transformer is such that the base current is reduced below that which causes the transistor to go into saturation. In other words, the step-up ratio of the circuit is beta-limited. I should stress that the term "beta" is used loosely since the transistor current gain varies with collector current. Using a darlington to boost the transistor current gain is not an option in the low voltage supply version since the output stage of a Darlington cannot saturate and is limited by a B-E drop which subtracts from the battery voltage and wastes power with the high primary current demand. The best transistors to use are those with as low a Vcesat as you can find and also have as high a current gain as possible. See the section: Malcohm's Flashgun Charger for info and schematics of a relatively fast charging unit I built awhile ago.

Flash Units from Cheap Pocket Cameras

Photoflash Circuit from Keystone Pocket Camera

This schematic was traced from an electronic flash unit removed from an inexpensive pocket camera, a Keystone model XR308. Other Keystone models are similar. Errors in transcription are possible.

Note that the ready light is not in the usual place monitoring the energy storage capacitor voltage. It operates on the principle that once nearly full charge is reached and the inverter is not being heavily loaded, enough drive voltage is available from an auxiliary winding on the inverter transformer to light the LED. It is also interesting that the trigger circuit dumps charge into the trigger capacitor instead of the other way around but the effect is the same.

```

   |                         |
   +-------------------------+
```

Keystone Everflash Flash Operation

1. The inverter boosts the battery voltage to about 300 V. This is rectified by D1 and charges the energy storage capacitor, C1.

2. The LED, IL1, signals ready by once C1 is nearly fully charged.

3. Pressing the shutter closes S2 which charges C2 from C1 through T2 generating a high voltage pulse (4 to 5 kV) which ionizes the xenon gas in the flashlamp, FL1.

4. The energy storage capacitor discharges through the flashlamp.

Keystone Everflash Flash Notes

1. The inverter transformer winding resistances measured with a Radio Shack DMM. Primary resistance was below .1 ohms.

2.
```
       |                          |           |
   ---+--- are connected;    ---|--- and ------- are NOT connected.
       |                          |           |
```

- Back to Schematics for Pocket Camera and Externally Mounted Compact Flash Units Sub-Table of Contents.

Photoflash Circuit from Kodak Pocket Camera

This schematic was traced from an electronic flash unit removed from an inexpensive Kodak pocket camera, specifically an Ektralite 10 (uses size 110 film, remember that?). Errors in transcription are possible:

- Kodak Ektralite 10 Camera Flash Unit in GIF format.

Designs similar to this are used by a wide variety of small photoflash units.

Note that the chopper transistor for this particular model is a PNP *germanium* type! This tells you something about the age of this thing!

Kodak Ektralite 10 Flash Operation

1. The inverter boosts the battery voltage to about 300 V. This is rectified by D1 and charges the energy storage capacitor, C2.
2. The trigger capacitor, C3, charges through R3 and T2.
3. The neon bulb, IL1, signals ready by flashing at about 6 Hz.
4. Pressing the shutter closes S2 which discharges C3 through T2 generating a high voltage pulse (4 to 5 kV) which ionizes the xenon gas in the flashlamp, FL1.
5. The energy storage capacitor discharges through the flashlamp.

Kodak Ektralite 10 Flash Notes

1. Transistor was unmarked but ECG12 should be a suitable choice.
2. Resistances of T1 measured with Radio Shack DMM.
3. The power switch, S1, disconnects both the supply to the inverter and the return for the trigger to prevent accidental triggering with power off.
4.
```
       |                          |           |
   ---+--- are connected;    ---|--- and ------- are NOT connected.
```

* Back to Schematics for Pocket Camera and Externally Mounted Compact Flash Units Sub-Table of Contents.

Flash Circuits from Disposable or 'Single Use' Cameras

For between $8 (basic model) and $16 (with electronic flash) these cameras pack quite a bit of technology into a package that you can take to the beach without worrying about expensive photo gear. And, they take remarkably good pictures (considering) for something make mostly of plastic including the lens.

The manufacturers like Kodak call them 'single use' cameras. I am calling them 'disposables' since this is what very often happens as the recycling incentives are not high enough and many/most are simply discarded - which is great for the experimenter since it is often possible to obtain the complete camera (minus aunt Sally's baby pictures) free for the asking from camera shops and one-hour photo places as long as the the lawyers (should the people in charge fear liability from charged capacitors and such) don't get wind of this. :-)

The circuits are all quite similar to those of other battery powered flash units except that these run on a single 1.5 V AA Alkaline cell (another bonus for salvage since the battery is usually very usable as well).

For experimentation, I recommend constructing a power supply to replace the AA cell since while a 24 exposure roll of film may not drain one of these, an afternoon's tinkering will easily go through a several. In addition, as the battery is depleted, the cycle time will increase. See the section: "1.5 V Alkaline Cell Eliminator" in the document: Various Schematics and Diagrams for a suitable circuit.

---

* Back to Schematics for Pocket Camera and Externally Mounted Compact Flash Units Sub-Table of Contents.

Photoflash Circuit from Kodak Disposable 35mm Pocket Camera 1

This schematic was traced from an electronic flash unit removed from a Kodak disposable 'Funsaver with Flash' pocket camera.

Thanks to Bill Kennedy (hue@node1.frontiernet.net) for performing the reverse engineering. I then redid the schematic to match the style of the very similar one described in the section: Photoflash Circuit from Kodak Disposable 35mm Pocket Camera 2. The transformer windings number of turns and wire size were estimated based on that circuit as well which I completely disassembled down to the cores!

* Kodak Funsaver Flash Unit in GIF format.

I have also reverse engineered the flash in a Far East (probably) clone of this camera. The only obvious differences seem to be: C1 omitted, R1 = 200 ohms, R2 = 4.7M. Operation is essentially identical. Apparently, some component values may also differ slightly even on genuine Kodak units.

Kodak Funsaver Flash Operation

1. Pressing the 'charge' button (S1) enables base drive to the inverter transistor (Q1, 2SD965). The inverter boosts the battery voltage to about 300 V. This is rectified by D1 (1N4007) and charges the energy storage capacitor, (C2, 160 uF, 330 V).

2. The trigger capacitor, C3, charges through R2.

3. The neon bulb, IL1, signals ready by flashing at about a 5 Hz rate.

4. Pressing the shutter closes S2 (fire) which discharges C3 through T2 generating a high voltage pulse (4 to 5 kV) which ionizes the xenon gas in the flashlamp, FL1.

5. The energy storage capacitor discharges through the flashlamp.

Note that the battery is never actually disconnected from the inverter. Thus, a failure (shorted) of Q1 would result in draining the battery and potential overheating - I do not know if this has ever happened!

WARNING: If left on charge for longer than needed to get the ready light to come on OR if run on greater than 1.5 V, the actual voltage on the energy storage capacitor can be much greater than the nominal 300 V. It is not known at what point the capacitor or other components blow up but needless to say, this becomes even more dangerous!

- Back to Schematics for Pocket Camera and Externally Mounted Compact Flash Units Sub-Table of Contents.

Photoflash Circuit from Kodak Disposable 35 mm Pocket Camera 2

This schematic was traced from an electronic flash unit removed from a Kodak 'MAX' disposable pocket camera. The basic circuit is virtually identical to the one described in the section: Photoflash Circuit from Kodak Disposable 35mm Pocket Camera 1 for the Kodak Funsaver with Flash camera. However, recall the warning about running for too long or on too high a voltage? Well, the Kodak MAX circuit has added a voltage limiter (regulator) which disables the inverter when the voltage on the energy storage capacitor (C1) exceeds about 300 VDC. It is only necessary to press and release the 'charge' button since it continues to run until fully charged and holding the 'charge' button in all day would do no harm since the regulator cuts it off! In addition, this unit automatically recharges after firing.

- Schematic of Kodak MAX Flash Unit.
- Photo of Kodak MAX Flash Unit with parts labeled.

For instructions on disassembling Kodak MAX cameras, see Don's Hack Kodak MAX to Strobe Page.

All newer Kodak disposable cameras including the "Funsaver Sure Flash" appear to use a similar, if not identical, circuit. Apparently, "ADVANTIX" flash units (at least some of them) use a pair of AAA cells instead of the single AA so some modifications had to have been made. And, later revisions of the MAX flash have gone to surface mount components (though I don't think the circuit has changed much). I haven't yet seen any of these circuits up close and personal. :)

It is easy to make modification to this basic circuit to provide other voltages for other applications from a 1.5 V Alkaline cell. For example, a simplified version was tested which generates about 4 to 5 V:

- Mini Power Supply Based on MAX Flash Inverter.

See the section: "Up to 350 VDC Inverter from 1.5 V Alkaline Cell" of the document: Various Schematics and Diagrams for details of these modifications.

(From: Source unknown)

After cracking open several Kodak Max cameras, I noticed that some had slight changes in circuit design. First, the 2SD879/2SD965 was replaced with a 2SA1585. Second, the zener had been replaced with a 330 volt MOV. The inverter transformer was smaller than usual. All resistors were SMD. There were three SMD transistors on the underside of the board labeled A6AU, 5DZ, and 1AM. I have not attempted to reverse-engineer yet.

(From: Sam)

Oh well, someday I'll have to find and dissect one of these. It sounds like some significant changes were made - possibly a totally different design with the 2SA1585 being a PNP transistor instead of the NPN variety that were used previously.

Kodak MAX Flash Operation

1. Momentarily pressing the 'charge' button (S1) enables base drive to the inverter transistor (Q1, 2SD965) via the emitter follower, Q2. The inverter boosts the battery voltage to in excess of 300 V (see note 3). The output of T1 is rectified by D1 (unmarked but presumably similar to a 1N4007) and charges the energy storage capacitor, (C2, 160 uF, 330 V).

   Inverter frequency starts at about 5 kHz with C2 completely discharged and increases to about 11 kHz just before cutoff.

2. The trigger capacitor, C3, charges through R2.

3. The neon bulb, IL1, signals ready when the voltage on C2 exceeds about 275 VDC. In addition, the current flowing through IL1 results in a voltage drop across R3 exceeds the rating of the zener diode (110 V), D2, Q3 disables base drive to Q1 and the inverter shuts off - around 300 VDC. This simple limiter can easily be designed into any inverter driven strobe circuit.

   The MPS2111 (Q3) is a PNP transistor which has an internal resistor network in its base-emitter circuit. These devices are sometimes called 'digital transistors' since they can be used as simple buffers or inverters without additional input components. The values of the series and shunt resistors are both 10K for this particular part. Special thanks to Paul Grohe (grohe@galaxy.nsc.com) for locating a datasheet for the MPS2111. However, a common 2N3906 PNP transistor DOES seem to work in place of this unusual device!

   While I am calling IL1 a neon bulb since it looks like a sort of a runt (shortened) version of the ubiquitous NE2, in order to operate as described above, its on-state voltage drop must be around 190 to 200 V - not the usual 60 V or so one would expect from an NE2. I confirmed this by measuring across one of these bulbs connected to C2 via a 1M resistor.

4. Pressing the shutter closes S2 (fire) which discharges C3 through T2 generating a high voltage pulse (4 to 5 kV) which ionizes the xenon gas in the flashlamp, FL1.

5. The energy storage capacitor discharges through the flashlamp. The inverter automatically restarts to recharge C2 after firing.

Kodak MAX Flash Transformer Construction

Since I acquired a bunch of these flash assemblies, I didn't feel too guilty about destroying the inverter transformer, T1, and the trigger transformer, T2, on one unit to determine their precise construction.

1. T1 consists of a pair of ferrite E-cores each measuring approximately .4025" x .219" x .187" (WxHxD). The center leg and outer legs are each .096" x .187" and .06" x .187" respectively. There are no core gaps. The plastic bobbin fits over the center leg and has 1,750 turns (give or take a few) of #45 AWG wire for the HV secondary. (Apparently, you can buy wire down (up?) to size #60 - less than .000350 inches in diameter! Check out MWS Wire Industries if you are really curious about fine wire - #45 is nothing to write home about!) This is wound first as one clump - distributed back and forth to create a fairly uniform layer without lumps. There were no separators as are often found in high frequency transformers to divide high mileage windings. After a layer of plastic tape, the primary consists of 6 turns of #25 AWG wire. A final layer of tape and there you have it! The entire inverter transformer fits in a cube less than .5" on a side.

   Since there is no core gap, this inverter does NOT operate in flyback mode but rather as a simple blocking oscillator with a stepup transformer. Therefore, I would predict the maximum voltage (if the limiting circuit were disabled) to be determined (in an ideal world) roughly by the turns ratio of T1 times the battery voltage (minus Q1's saturation voltage) or: 1750/6 * (1.5 - .3) or about 350 V for a fresh AA cell. This was confirmed on another unit by measuring the amplitude of the primary and secondary waveforms on T1 while operating with D1 removed.

2. T2 consists of a linear ferrite core, about .065" square by .265" long and a plastic bobbin with 12 turns of #33 AWG wire, insulating tape, and about 450 turns of #45 AWG wire on top of this, followed by more tape. The entire trigger transformer is about .210" x .210" x .275".

   Note: Some samples of these units appear to lack the ferrite core and are somewhat fatter. I haven't dissected any of these yet.

Transformers like T1 and T2 could be built at home if you have a coil winding machine. Otherwise, I would expect it to be quite frustrating since the #45 AWG or finer wire is so thin and fragile. The tensile strength of #45 wire is already significantly less than that of a human hair! But why bother since they can be salvaged easily enough! However, this information should help should modifications be desired.

Kodak MAX Flash Notes

1. Minor component differences may be found in samples of this unit. For example, Q1 may be a 2SD879 or 2SD1146 instead of the 2SD965 shown.

2. Some versions of this flash apparently have a 120 uF instead of 160 uF capacitor for C2. I wonder if the film speed and/or lens aperture are different in these cameras since the flash energy is only about 2/3 as much as with the 160 uF capacitor.

3. Extra precautions must be taken when experimenting with these circuits since they automatically recharge without pressing any buttons! Take care.

Flash Units from Fuji Disposable Cameras

These are basically basic (1) and deluxe (2) versions of the same circuit from various models of Fuji disposable cameras. Virtually the same circuit board and physical arrangement are used though they aren't quite interchangeable.

The basic one requires that the charge button be held in until the ready light comes on and has a smaller energy storage capacitor (100 uF compared to 160 uF):

- Schematic of Fuji Flash Unit 1.

The deluxe flash seems to be functionally similar to the one used in the Kodak MAX and other newer Kodak disposable cameras. However, it is much more complex and yet smaller since the 'smart' circuitry is mostly surface mount (SMT) on the back of the printed wiring board. Except for 3 resistors, the SMT components are all related to the deluxe features.

- Schematic of Fuji Flash Unit 2.
- Photo of Fuji Flash Unit 2 with parts labeled.

(The photo of the basic flash would be virtually identical to this one except for the lack of all the SMT circuitry and 3 resistors on the top of the board.)

Instead of the sweet simplicity of the Kodak units, the Fuji flash uses extra parts to provide the feedback to keep the inverter running without keeping the 'charge' switch depressed. The cutoff when fully charged appears to operate similarly to the Kodak flash but with a 300 V zener instead of the combination of 110 V zener and 200 V discharge lamp combination that it used.

Except for the drive winding, the transformer specifications were estimated based on circuit similarities to the Kodak flash units. The 6 turn drive winding is visible and wound bifilar fashion with a pair of #26 AWG wires.

Like the Kodak MAX, this unit uses some strange transistors - all the more difficult to identify because they are surface mount parts. I believe, again thanks to Paul Grohe (grohe@galaxy.nsc.com), that these have internal resistors. Specifically, Q2 (marked 6E) has a series base resistor of 47K and Q3 (marked 6D) has series and shunt resistors of 47K and 10K respectively.

Flash Circuits from Externally Mounted Flash Units

Electronic Flash Model ME1 for Minox B

This is a three-part unit for one of those teeny-tiny Minox spy cameras :-). The flash head itself is about as big as the entire camera with the power supply and charging adapter being somewhat larger. Actually, the power supply is a lot larger. I don't suppose spies generally like to use electronic flash in covert operations too often anyhow!

The inverter is of conventional design but, due to its age of at least 30 years (purchased in 1968), somewhat larger than is typical of modern strobes. In fact, compared to a modern disposable camera, the capacitor charging circuitry occupies about 8 times the volume and probably at much lower efficiency! (Also available in GIF format as [Minox ME1 Inverter and Energy Storage Capacitors].)

Note: The BAY90 rectifiers cross to 1000 V, 2.5 A general purpose diodes.

No, that is not a typo - 1,950 turns of #46 (!!) wire in 7 layers (6 of 300 turns each and the first was 150 turns) for the Output winding! I counted every single turn because the Output winding was open and I was hoping to locate the break. Not likely! It was somewhere in the middle and the wire was so fine that it broke about 50 times while unwinding - so it could have been any one of those! (See the section: [Conversion of Minox ME1 Flash to Use a Modern Inverter] to find out how I repaired this unit.) The ferrite double E-core is about 1 inch on a side with each leg being 1/4 inch square. There were no core gaps.

The Flash Intensity switch, S2, selects between 12 W-s and 24 W-s. There are actually three positions. Apparently, you are supposed to pause in the middle one called "Hold 1 Sec" when switching between power levels for at least 1 second (surprise, surprise!) to allow the capacitor voltages to equalize! I would assume that the reason for this is to prevent damage to the switch contacts.

The flash head is separate from the power supply and appears to be very much like any of the other strobes. However, note the adjustment for the ready light!

I was not willing to completely disassemble this unit so some of the actual components and wiring were guessed (also available in GIF format as Minox ME1 Ready and Trigger Circuits).

The wall adapter/charger provides both the current to charge the 2 cell NiCd battery and a high voltage AC output (CCAC) to power the flash when plugged into an outlet regardless of the state of the batteries. When operating from the wall adapter, D1 and D2 in the power supply unit in conjunction with C4 form a voltage doubler that takes the 130 VAC (>80 V peak) output of the adapter and produces over 300 VDC to charge the energy storage capacitors (also available in GIF format as Minox ME1 AC Line Circuitry).

Note that unlike many modern designs, the flash will work on AC as long as the Output winding of the inverter transformer is intact and the HV rectifiers are good. The condition of the remainder of the circuitry including the inverter itself and battery is irrelevant !

Conversion of Minox ME1 Flash to Use a Modern Inverter

As a result of the inverter transformer having an open secondary, I was forced to improvise in order to repair a Minox ME1 flash unit. The result was a unit that appears to be every bit as good and possibly even has a faster cycle time and a greater number of shots per charge - only time will tell for sure.

There were several requirements to locate a compatible inverter:

- It runs on a pair of NiCd cells totaling 2.4 V so the circuitry out of a disposable camera is not appropriate, being designed for 1.5 V operation.

- The inverter may need to run continuously. For this reason as well, the disposable camera solution is unacceptable since they usually are activated by a push button and may only be designed for short duty cycle operation.

- AC operation must not be affected.

- The circuitry must fit in the case.

Checking the schematics for each of the other battery powered flash units in this chapter, it seemed that the one described in the section: Photoflash Circuit from Keystone Pocket Camera might work if it could accommodate the 2.4 V NiCd rather than 3.0 V Alkaline battery it expects. I would expect this to be the case since Alkaline voltage is not really constant at 3.0 V but drops gradually as they are used up (NiCd voltage is nearly constant until the charge is exhausted). Therefore, it probably should work down to about 2.0 V (but with longer cycle time). And, the lower effective series resistance of NiCds would partially offset the lower initial voltage. I have a couple of the Keystone units so it is easy to try.

A simple test jumpering 4 wires confirmed functionality. The actual inverter portion of the Keystone flash occupies a volume of about 1" x 1-1/4" x 3/4" or just slightly more than that of the original dead inverter transformer! Some quick action with a hacksaw and nibbling tool resulted in a cute little circuit board that could be tucked into the available space. Some electrical tape assured that there would be no nasty short circuits. The chopper transistor was left exposed so any heat from it would have somewhere to go.

The excised circuit was attached to the positive terminal of the battery, the negative (center) at the switch, and the two secondary leads of the inverter transformer, taking care to get the polarities correct (the waveform out of the inverter is asymmetric and it would not work well if reversed). Except for T1 (dead) and C2 which I removed, all other components were left in place since they shouldn't affect anything.

It seems to work fine on both power settings and on battery or AC. The voltage on the energy storage capacitors stabilizes at about 315 to 325 VDC in all cases. The battery charges fine. What more can you ask? :-)

At first, I thought there was one slight problem: When plugged into an AC outlet with the power switch in the 'on' position (meaning the inverter is also running - the flash operates from AC with this switch off), I was afraid the voltage will eventually climb beyond the safe limits of the capacitors. Then, about 3 AM the next morning I realized there was a missing plastic piece to prevent the switch from being moved into the 'on' position with the adapter plugged in (or vice-versa).

- Back to Schematics for Pocket Camera and Externally Mounted Compact Flash Units Sub-Table of Contents.

Vivitar Auto 253 Electronic Flash circuit

The Vivitar Auto 253 is a typical small inexpensive automatic electronic flash. As is typical of these designs, the flashlamp is paralleled with a quenchtube. This is a small discharge tube that looks something like an oversized neon indicator light (but probably xenon filled). The quenchtube is triggered at a time after the main flashlamp fires which is determined by the light reflected from the subject and terminates the flash when adequate exposure has been achieved. The actual trigger circuit using an SCR to pulse a trigger transformer applying a 4 to 5 kV pulse to a foil wrapping on the quenchtube. Typical flash duration for small automatic electronic flash units vary from about 1/50,000 second for a minimum energy (closeup) flash to 1/1000 second for a maximum energy (distant subject or manual) flash.

The power supply portion of this unit is interesting as well. It can operate on either AC (220 V, it would seem from the circuit) or a 9 V battery. For AC, a simple half wave rectifier produces about 320 VDC needed by the flashlamp. On DC, it uses an inverter that operates on a 9 V battery rather than the 3 V which is typical of many cheap pocket cameras. This results in a fairly rapid cycle time of about 2 seconds.

The ready light looks like an ordinary NE2 neon bulb but must have a different gas mixture as it does not turn on until nearly full charge is reached on the energy storage capacitor. There appears to be no voltage divider. In addition, there is another lamp that provides a nice green illumination for the flash 'computer' dial. This looks like a neon indicator lamp but with an internal phosphor coating.

I have observed the spectrum of these things. I have seen two different gas fills in these that emit UV that makes the green-glowing phosphor do its stuff. One bulb type about the size of an NE-2H uses a mixture of neon and xenon. GE made those things (I don't know if anyone else ever did), which are called NE-2G lamps. The other type, a much smaller one that I found in Radio Shack's 272-708 green neon "cartridge", uses a mixture of neon and krypton. (Don Klipstein (don@misty.com or klipstei@netaxs.com).)

The Vivitar schematic is split into two parts with FL1, C1, and L1 duplicated to improve readability.

Vivitar Auto 253 Power Supply Operation

1. DC 9 V: The inverter boosts the battery voltage to about 300 V. This is rectified by D1/D2 and charges the energy storage capacitor, C1, through the inductor, L1.

   AC 220 V: The line input is rectified by D3 and D1 resulting in about 320 V peak which charges the energy storage capacitor, C1, through the inductor, L1.

2. The trigger capacitor, C2, charges through R3, R4, and T2.

3. The neon bulb, IL1, signals ready by glowing when the energy storage capacitor is nearly fully charged.

4. Pressing the shutter closes S2 which discharges C2 through T2 generating a high voltage pulse (4 to 5 kV) which ionizes the xenon gas in the flashlamp, FL1.

5. The energy storage capacitor discharges through L1 and the flashlamp.

Vivitar Auto 253 Exposure Control Operation

The power inputs, X and Y, may come from the Vivitar Auto 253 power supply circuit (above), other battery/AC adapter powered inverter, or other AC line operated power supply.

1. Quench trigger capacitor, C7, charges from energy storage capacitor, C1, through voltage divider formed by R7 and R8.
2. Flashlamp is triggered by 4 to 5 kV pulse from main trigger transformer, T2 (not shown) when shutter contacts close.
3. Because of series inductor, L1, voltage across flashlamp drops abruptly when current starts flowing. (Note: I am calling this an inductor - from appearance only - as it is unmarked. It may just be a small high current resistor).
4. This negative step is coupled by C6 to cathode of the quench trigger thyristor, SCR1. The anode-to-cathode voltage does not change but the cathode becomes negative with respect to the energy storage capacitor negative (common) terminal which feeds the gate circuit.
5. CDS light sensor, LS1, R8, and C9 form an RC network with a time constant inversely proportional to the light reflected off of the subject. Voltage on SCR1's gate increases as C9 charges.
6. When enough light has been detected indicating proper exposure, SCR1 is triggered dumping C7 through quench trigger transformer. Resulting 4 to 5 kV pulse ionizes (xenon) gas in quenchtube.
7. The quenchtube has a lower voltage drop than the flashlamp and thus bypasses any charge remaining on C1 around FL1 terminating the light output.

Vivitar Auto 253 General Notes

1. Cycle time is independent of flash duration as energy storage capacitor is always discharged nearly fully by either flashlamp or quenchtube.

2. Components in automatic exposure circuit denoted with * are duplicated from power supply section to improve readability of schematic.

3. Part numbers are consistent with the Vivitar Auto 292 schematic but have no correlation with actual Vivitar designations.

4.

Vivitar Auto/Thyristor 292 Energy Conserving Automatic Flash

An energy conserving electronic automatic flash only uses as much energy from the energy storage capacitor as is needed for the particular photographic situation base on light reflected from the scene. This is in contrast to lower cost units (like the circuit shown in the section: Vivitar Auto 253 Electronic Flash Circuit) that simply dump the excess charge. With these, closeups use the same amount of the battery's capacity and require the same recycle time as long distance shots. With an energy conserving flash, battery life is greatly extended and recovery from low power flashes is instantaneous.

Although I did not totally reverse engineer this unit - not being willing to sacrifice my Vivitar 292 as I might never be able to get it back together after analysis - the construction is not what you would call modular - I was able to determine some of its basic operating principles.

There is an SCR - it looks like a regular SCR - in *series* with the negative lead of the xenon flashlamp. The SCR part number is Mitsubishi CR3DZ-8. I was not able to locate this part in my databooks bat based on the ECG Semiconductor Master Replacement Guide, similar devices are normal SCRs - typically 8 A at 400 V which would be suitable since these can pass short very high current (250 A) pulses without damage.

There is also a quenchtube. This is fired based on light returning from the scene to turn the SCR *off*. I believe that this is done by discharging a separate capacitor in reverse across the main SCR thus driving it into cutoff long enough for the flashtube to extinguish.

Other designs may use a small SCR in place of the quenchtube to apply reverse voltage to the main SCR. Alternatively, a Gate TurnOff (GTO) thyristor or high power Insulated Gate Bipolar Transistor (IGBT) may be used in place of the main SCR. GTO devices are designed for this type of application and requires only a modest gate pulse to switch them off. However, they aren't that common. I've see the IGBT used in one design but don't have specs for it. However, a peak surge rating of hundreds of AMPS will be required.

What I surmise is that operation of the Vivitar 292 is basically similar to that of the smaller Vivitar 253 automatic flash unit (see the section: Vivitar Auto 253 Electronic Flash Circuit (the circuitry on the photosensor board looks nearly identical) except that instead of the quenchtube dumping the entire charge on the energy storage capacitor, it is used to interrupt the current to the flashtube in mid-stride by turning off the SCR. The Vivitar engineers were probably able to add this energy conserving feature to the simpler 253-type strobe with minimal redesign of other parts of the auto exposure circuit.

Electronic flash units which incorporate manually selectable power levels can use a similar design. Instead of the light sensor triggering the quenchtube/thyristor, this would be accomplished with a timing or power measuring circuit.

If anyone has one of these or similar energy saving automatic flash units they would be willing to donate to the cause, I would fully reverse engineer the design and add it to this document.

Vivitar Auto/Thyristor 292 Exposure Control Circuit

This is what I expect the auto exposure portion of the Vivitar Auto/Thyristor 292 to be like. As noted, I have not fully reverse engineered this design.

Some part values have been estimated. I have assumed that the actual exposure determining and quench tube firing circuits are identical and have used part numbers from the Vivitar Auto 253 (which, of course, were also arbitrarily chosen).

The inverter and main power circuits are not shown but should be understood to be similar - but of higher energy capacity - to those of the smaller Vivitar electronic flash units.

Vivitar Auto/Thyristor 292 Exposure Control Operation

The power inputs, X and Y, may come from the a circuit similar to the Vivitar Auto 253 power supply circuit (but of higher power probably), other battery/AC adapter powered inverter, or other AC line operated power supply.

1. Quench trigger capacitor, C7, charges from energy storage capacitor, C1, through voltage divider formed by R7 and R8. SCR shutoff capacitor, C11 charges from C1 through R11 and R12.

2. When shutter contacts close, a pulse is applied to the trigger of the main SCR (SCR2, or it is already triggered on continuously while the main filter capacitor is charged). Flashlamp is triggered by 4 to 5 kV pulse from main trigger transformer, T2 (not shown). Note: SCR2 must be turned on before flashlamp is triggered.

3. Because of series inductor, L1, voltage across flashlamp drops abruptly when current starts flowing.

4. This negative step is coupled by C6 to cathode of the quench trigger thyristor, SCR1. The anode-to-cathode voltage does not change but the cathode becomes negative with respect to the energy storage capacitor negative (common) terminal which feeds the gate circuit.

5. CDS light sensor, LS1, R8, and C9 form an RC network with a time constant inversely proportional to the light reflected off of the subject. Voltage on SCR1's gate increases as C9 charges.

6. When enough light has been detected indicating proper exposure, SCR1 is triggered dumping C7 through quench trigger transformer. Resulting 4 to 5 kV pulse ionizes (xenon) gas in quenchtube.

7. The quenchtube has a discharges C11 applying a voltage pulse in reverse across SCR2. This biases the SCR in cutoff long enough for the flashlamp to extinguish. Very little energy is lost.

Vivitar Auto/Thyristor 292 General Notes

1. Cycle time is a function of actual amount of light required for each shot. It is possible to fire off a half dozen or more low power shots without any recycle delay.

2. The values of components denoted with * have been estimated (i.e., guessed).

3. Part numbers are consistent with the Vivitar Auto 253 schematic but have no correlation with actual Vivitar designations.

4.

Other Battery Powered Camera Flash Circuits

Photoflash/Strobe Circuit Using IC 1

This is the circuit board for some sort of flash or strobe application. These are/were available from Electronic Goldmine single for $1 or in 8-packs for $5. There is no energy storage capacitor or flashlamp, only the inverter and trigger circuit. From their main page, go to "Products", then "Strobe Items". It would be under "Micro Strobe Brains" unless sold out. Photos of the unit can be found in:

- Photo of Flash Circuit Using IC 1 - Top View
- Photo of Flash Circuit Using IC 1 - Bottom View

I originally thought this cute circuit was from a disposable camera but now rather doubt it as will become clear below.

The part of the circuit I am reasonably confident of is shown in:

- Flash Circuit Using IC 1

Don't take the cap values or number of turns on the transformer too seriously. They are basically guesses based on other flash circuits or what seems reasonable. However, the turns-ratio (as determined by driving the transformer out-of-circuit with a function generator) is around 1:10 - not the 1:100 or 1:200 of a typical flash running on 1.5 V. Another interesting thing is the use of an SCR for the trigger. This would imply the desire to be triggered by something other than simple shutter contacts. So, I suspect this was for some sort of pocket camera, but not a disposable type. Of course, it might not have been a camera flash at all but some other sort of strobe application.

I have attempted to power it and experiment with the unidentified wires attached to the IC. However, I wasn't able to determine anything conclusive. Pulling pin 6 to BATT+ through a current limiting resistor seemed to have something to do with turning the inverter on (thus the pin designation, IE-Inverter Enable) but I could never get a 120 uF photoflash capacitor to charge to any significant voltage, though a 0.22 uF cap would occasionally charge to 200 or 300 V very quickly. It wasn't consistent though. And then the IC let its smoke out so further experiments will have to wait until I have more confidence in what I'm doing. :(:)

If anyone can provide any information that would help resolve these mysteries, please contact me via the Sci.Electronics.Repair FAQ Email Links Page

Malcohm's Flashgun Charger

(From: Malcolm Watts (m.j.watts@massey.ac.nz).)

I built a 40 J flash and slave for my camera about 15 years ago using a variation of the basic inverter circuit which also delivers to the cap any energy left in the core at the end of the forward stroke. The transistors I used were BD438 and the supply was a 12 V 6 amp-hour Gel cell lead-acid battery. The circuit variation requires the inclusion of several extra diodes to steer what little core energy there is to the output capacitor (you end up with a bridge arrangement). All diodes I used are ultra-fast recovery types (UF4007). My units charge a 450 uF cap to 400+ volts in about 3 seconds from a good battery. The caps I used are low-ESR types designed for SMPS applications.

See Malcohm's Flashgun Charger.

Schematics for Line Powered Flashes and Strobes

Sub-Table of Contents

- Back to Schematics for Line Powered Flashes and Strobes Sub-Table of Contents.

General Description of Line Powered Flash Units

These units are usually (but not always) more powerful than those operating from small battery packs. Most use doubler or tripler attached directly to the AC line and are therefore NOT isolated - and even more DANGEROUS to troubleshoot than their smaller cousins! The first one is the only commercial unit in this category so far and does use a stepup transformer rather than a non-isolated voltage multiplier.

Honeywell Prox-O-Lite Flash Unit

This is a two piece AC line powered flash. It can power 1 or 2 flash heads at the same time (subject to certain energy restrictions on the Main and Aux jacks). The flash head I have uses a ring shaped flashlamp and mounts around the camera lens to provide shadow-free illumination.

- Get the schematic for HWPL1 in PDF format: [HWPL1-SCH].

The rectified output of a stepup transformer is applied to an SCR-based regulator which will maintain about 400 V on the energy storage capacitors. The regulator is somewhat peculiar and I'm not sure I copied the circuit correctly. :)

To provide Low (L), Medium (M), and High (H) energy levels, there are 3 energy storage capacitors of 56, 70, and 374 uF. These correspond to approximately 4.5, 5.5, and 30 w-s (Joules) at 400 V and are used in combination to provide 4.5 (L), 10 (M), or 40 (H) w-s to the Main flash head; or 30 (L), 30 (M), or 40 (H) w-s to the Aux flash head. (Yes, L and M are the same energy for the Aux jack.) Both flash heads can be used simultaneously as long as the energy isn't set for High. A single switch with high current contacts selects the L, M, or H energy levels (so must be the same setting for Main and Aux).

The ring flashlamp in the flash head is about 3-1/16" OD made of 4 mm tubing. However, the circuit should drive any common flashlamp that can handle the 40 w-s maximum energy.

Medium Power Photoflash Circuit

Here is a sample schematic for a typical line operated medium power electronic flash unit. Cycle time is under 1 second.

```

Medium Power Photoflash Operation

1. The doubler consisting of D1, D2, C1, and C2, boosts the AC line voltage to about 320 V. This charges the energy storage capacitor, C3 through R2. R1 limits inrush current to the doubler.

2. The trigger capacitor, C4, charges through R3, R5, and T2.

3. The neon bulb, IL1, signals ready by coming on when C3 is charged to about 270 V.

4. Pressing the shutter closes S2 which discharges C4 through T2 generating a high voltage pulse (4 to 5 kV) which ionizes the xenon gas in the flashlamp, FL1.

5. The energy storage capacitor discharges through the flashlamp. R2 limits current from doubler to allow flashlamp arc to quench.

Medium Power Photoflash Notes

1. CAUTION: Line operated power supply is not isolated - use with care. Fuse and power-on indicator not shown. * R3 and R5 provide protection from line for trigger circuit - do not remove!

2. Flash energy is about 20 W-s. Adjust component values for desired application.

3. For rapid cycle times, make sure flashlamp is rated for adequate average power dissipation (e.g., 25 W for 1 second repeat). Forced air cooling may be required for sustained operation at full power.

4. Trigger transformer, T2, available from places like Digikey and Mouser.

5. Shutter contacts, S2, may be replaced with SCR for electronic control of flash trigger.

6.

Higher Power Photoflash with SCR Trigger

Here is a sample schematic for a typical line operated moderately high power electronic flash unit. The power supply uses a tripler to generate approximately 420 V for the energy storage capacitor.

An SCR allows a safely isolated logic or sensor signal to easily trigger the strobe.

Cycle time is under 2 seconds.

Higher Power Photoflash with SCR Trigger Operation

1. The tripler consisting of D1, D2, D3, C1, and C2, boosts the AC line voltage to about 420 V. This charges the energy storage capacitor, C3 through R2. R1 limits inrush current to the tripler.

2. The trigger capacitor, C4, charges through R3 and T2.

3. The neon bulb, IL1, signals ready by coming on when C3 is charged to about 360 V.

4. Applying a positive edge between Trigger + and - turns on the SCR which discharges C4 through T2 generating a high voltage pulse (5 to 8 kV) which ionizes the xenon gas in the flashlamp, FL1.

5. The energy storage capacitor discharges through the flashlamp. R2 limits current from doubler to allow flashlamp arc to quench.

Higher Power Photoflash with SCR Trigger Notes

1. CAUTION: Line operated power supply is not isolated - use with care. Fuse and power-on indicator not shown. * C5 and C6 provides protection from the line for trigger circuit - do not remove! As an added safety

precaution, the use of an optoisolator or optoisolated SCR is recommended for the trigger circuit.

2. Flash energy is about 45 W-s. Adjust component values for desired application.
3. For rapid cycle times, make sure flashlamp is rated for adequate average power dissipation (e.g., 50 W for 1 second repeat). Forced air cooling may be required for sustained operation at full power.
4. Trigger transformer, T2, available from places like Digikey and Mouser.
5.

Super High Power (Laser Pump) Strobe Operation

1. Power transformer, T1, in conjunction with D1, D2, and C1-C4, provides 1.7 kV DC. The power supply doubler capacitors are also used as the energy storage capacitors. Resistors, R1-R4, equalize the voltage drops across the series capacitors to compensate for slight differences in leakage resistance. R5 and R6 limit inrush current and charge rate.

2. The trigger capacitor, C5, charges through T2 from the voltage divider formed by R7 and R8.

3. Ready light and capacitor bank voltage monitoring circuits are not shown.

4. Applying a 5 V signal to the Fire input turns on SCR1 dumping C5 into the primary of the trigger transformer, T2. This generates a 30 kV pulse which ionizes the xenon gas in the flashlamp, FL1.

5. The energy storage capacitor bank discharges through L1 and FL1.

Super High Power (Laser Pump) Strobe Notes

1. WARNING: If you thought line operated equipment was dangerous, this is much much worse. The power transformer output is enough to kill. Once doubled and stored in the capacitor bank, it is LETHAL. The total energy storage is about 1300 W-s (this is not a typo!). Based on one estimate, this is enough energy to KILL 20 adult humans simultaneously with the power supply unplugged from the AC line - and still have some juice left over. TAKE EXTREME CARE!

2. Fuse, power switch, power-on light, and all other absolutely essential safety interlocks and indicators are not shown. R1-R4 do act as bleeder resistors and will discharge the capacitor bank to safe levels in about 10 MINUTES. However, don't depend on these. Resistors can fail. Use the capacitor discharge tool and indicator.

3. The power transformer from a tube type (old) TV set would probably be suitable for T1. Microwave oven high voltage rectifiers may be used for D1 and D2. A high power xenon tube like this requires a 30+ kV trigger pulse. Those little tiny trigger transformers will NOT work. Capacitors, C1-C4, must be rated for photoflash rapid discharge.

4. High power strobes require special flashlamps - anything from a pocket camera or electronic flash will explode into a mass of molten bits of glass and metal. This design is derived from one using a tube from EG&G, Electro-Optics Division (Salem, Massachusetts, 35 Congress St., Salem, MA 01970, (508)745-3200. They produce a complete line of xenon strobe and continuous output lamps. Another division of EG&G produces most of the xenon flashtubes used in disposable cameras in the world.) Even a properly specified flashlamp may explode - operate only behind protective shielding. Flashlamp cooling must be adequate for desired cycle time.

5. L1 helps to shape the discharge current pulse. For some high power strobe designs, a series inductor is essential to optimize power output and prevent damage to the flashlamp due to excessively high current and negative voltage (undershoot resulting in reverse current). A damping factor of .8 is generally recommended. The 25 uH value is just an estimate - L1 must be calculated for each combination of energy storage capacitor value, voltage, and the impedance characteristics of the specific flashlamp to be used.

6. If you are serious about constructing a high energy strobe system (and your life and accident insurance is fully paid), consider some advanced reading first. The flashlamp manufacturer's datasheets and application notes will prove essential. The following is one example of possible sources of general design information:

   (From: Bill Reuber (breuber@mail.wcl.on.ca).)

   I have found this to be useful:

   > Solid State Laser Engineering (revised)
   > Springer-Verlag Heidelberg, New York
   > ISBN 3-540-18747-2 or 0-387-18747-2

   They have chapters on many aspects of laser system design including pulse forming networks for flashlamp systems.

7. Flash energy is about 1300 W-s. For a typical flash duration of 250 uS, this is an equivalent power input to the flashlamp of 5.2 MW! Adjust component values for the desired application.

8. DO NOT even think about staring at the flashlamp when fired. The peak light output is equivalent to at least 500,000 - 100 W light bulbs! Even when averaged over the 1/40th of a second typical response of the human eye, this is still more than 5,000 - 100 W light bulbs. (Note: this estimate takes into account the increased luminous efficiency of xenon flashlamps compared to incandescent light bulbs.)

9. Make sure all optical components - especially the flashlamp - are cleaned with isopropyl alcohol and a lint free cloth to remove all traces of contaminants.

10.

```

Timing Light Operation

1. D1 and C1 form a half wave doubler which produces a waveform across D1 which is approximately a sinusoid with a p-p voltage of 2*1.414*VRMS of the line or about 320 V. (The peaks will get squashed with a significant load).

2. C2 charges from this through D2 to about 300 V. The flashlamp fires when triggered by the HV pulse from the #1 spark plug connection. Note: this requires a direct connection, not an inductive pickup. CAUTION:

Excessive trigger voltage could puncture the glass of the flashlamp or cause other damage if the trigger electrode isn't formed in such a way that a discharge to ground will happen first! I don't recall how this device was configured - probably with a metal reflector.

3. I would think that there will be some beating of the charging and flash for high rpms but the timing will be accurate. In other words, it will not fire for every rotation of the crankshaft since C2 cannot recover quickly enough but will flash at the proper instant when C2 has charged to a sufficient voltage. (This is probably by design - otherwise, the flashlamp would overheat very quickly at high rpms.)

Welch Scientific Model 2153C Stroboscope

Here is a schematic for a typical line operated variable rate stroboscope. This unit is from Welch Scientific - Model 2153C Stroboscope. These things typically gather dust in the dusty dark corners of high school physics labs. :-)

Its uses include the visualization of moving parts as well as rotation speed or frequency determination of rotating or vibrating machinery.

Specifications:

```
 Flash energy   - .1 W-s.
 Low range      - 1.6 to 20 pps (96 to 1200 rpm).
 High range     - 8 to 120 pps (480 to 6000 rpm).
 Flash duration - approximately 10 uS.

                D1   D2       L1 ======         R1              Flashlamp

```

Welch Scientific Model 2153C Stroboscope Operation

1. The power supply consisting of T1, D1, D2, C1, and L1, develops about 650 V. This charges the energy storage capacitor, C3 through R1.

   The trigger capacitor, C4 (X1 range) or C4||C5 (X5 range), charges through the frequency (speed) control network consisting of R2, R3, R4, R5, and R6. The main (user) control is R3 which provides roughly a 12:1 range.

2. When the voltage on the Diac, D3, exceeds about 175 V, D3 changes to the conductive state - it becomes a short circuit. This discharges the trigger capacitor(s) through T2 generating a high voltage pulse (4 to 5 kV) which ionizes the xenon gas in the flashlamp, FL1.

3. The energy storage capacitor discharges through the flashlamp.

4. The energy storage capacitor and trigger capacitor(s) recharge and the cycle repeats. The inductor, L1, prevents the voltage across the energy storage capacitor from increasing too quickly for a few critical milliseconds just after the tube fires to enable the arc to reliably extinguish at high repetition rates.

Welch Scientific Model 2153C Stroboscope Notes

1. Power switch, S1, and fuse, F1, not shown.

2. Flash duration is minimized by using the small (.5 uF) but high voltage energy storage capacitor.

3.

High Speed Logic Triggered Strobe 1

Basic Description of HSS1

This is a short pulse strobe originally designed by Don Klipstein don@misty.com and myself (Sam) for a special application requiring a very short flash duration (under 50 microseconds), triggering from a logic level input, and portability. It will operate from a 12 to 18 VDC power supply with a cycle time of less than 3 seconds for the 36 uF energy storage capacitor charged to 900 V (15 J). The capacitor voltage is actively regulated with the inverter running as required to maintain full charge. Current consumption (at 12 VDC input) is around 1 A while charging and averages less than 50 mA (in periodic 1 A pulses) while idling. To reduce idle current consumption to near zero, the inverter may be controlled and monitored via the system logic.

The specified flashlamp (8538 from Mouser is a wide bore U-shaped unit suitable for medium power photographic applications. However, this same circuit can be used for a laser pump by replacing the inductor and flashlamp with PFN1/SSY1 or another suitable set of components.

The inverter section could also be used with minor modifications to charge the capacitor(s) for a normal photographic strobe operating at 300 to 500 V. Simply replace R15 with a jumper and modify R14 to produce the desired regulated voltage. Note that many not-quite-so-small flashtubes work best at a lot more than 300 volts. For example, the three largest Mouser tubes have nominal anode voltage of 400 to 450 volts and they will probably do well with even a little more, especially with flash energy well below the limit. Thus HSS1 would also be suitable for these or as an adjustable general purpose capacitor charger.

HSS1 Schematics

- Get the schematic for HSS1 in PDF format: HSS1-SCH.

HSS1 consists of the inverter, pulse forming network (energy storage capacitor, inductor, and flashlamp), and trigger circuit.

The inverter consists of a CMOS TLC555 timer and IGBT (Insulated Gate Bipolar Transistor). The IGBT is driven like a MOSFET but has output characteristics more like that of a bipolar transistor - the best of both worlds. The output voltage is monitored by one section of an LM339 quad voltage comparator and shuts off the oscillator once full charge is reached. With the components values for the voltage divider resistors (R14,R15,R17,R18) shown, this is approximately 900 V. The circuit should work for voltages up to 1 kV or more by changing the value of the parallel combination of R17||R18. As the voltage decays due to leakage through the trigger circuit and voltage monitor, the oscillator will come on briefly at periodic intervals to top off the charge. With some minor changes, the idling current could be substantially reduced.

The other sections of the LM339 are wired as buffers to accept an inverter ENABLE signal, provide a (low going) READY output signal, and drive a READY LED. The ENABLE input and READY output allow the control logic to turn on the inverter on demand (which is fine for the intended application). (But the internal voltage limiter cannot be overridden.) This reduces the idle current consumption substantially.

One beauty of this inverter design is the super simple transformer requiring a grand total of 32 turns of wire. Yes, you read correctly, not the hundreds or thousands of turns you might have expected! :) I didn't believe it the first time I saw the transformer description either. It takes advantage of the flyback pulse generated when the chopper IGBT turns off boosted by the 1:1 autotransformer.

The trigger circuit consists of an opto-triac driving a 10 A SCR which dumps a 0.082 uF capacitor charged to about 300 V through the trigger transformer. For manual triggering, these components could be replaced with a pushbutton switch.

The PFN (Pulse Forming Network) as shown was designed to optimally drive the 8358 flashlamp with a 15 J input at less than 50 us. The inverter itself really doesn't care what is used for the PFN except that as designed it charges to 900 V and how long it will take to charge the energy storage capacitor. This one was designed based on a Ko value for the flashlamp of around 12.

Note that the 36 uF, 1 kV energy storage capacitor (C1) is quite special - I call it the "magic yellow cap". It has a very low ESR (about 24 milliohms) and high peak current capability (at least 800 A). Substituting a series or series/parallel combination of photoflash (electrolytic) capacitors will not result in nearly as short a flash duration or peak light output. The flash will be 2 to 3 times as long and the total output light energy will also be much less because much of the electrical energy will be dissipated inside the much higher ESR capacitors. The typical ESR for a 120 uF, 330 V photoflash capacitor is 0.3 ohms - over 10 times that of the magic yellow cap. Of course, they are also about 25 times cheaper! The magic yellow cap appears physically identical to one found in the laser pump PFN1. It is a custom capacitor from Cornell-Dubilier but I don't think it is listed on their Web site.

The PFN inductor, L1, is just 7 turns of #14 AWG insulated stranded wire in a single layer on a 1.5" diameter form. A toilet paper roll works fine. :)

The diode across the flashlamp (D1) is just insurance. There really should be no reverse voltage across the flashlamp given the critically damped design of the PFN.

The HSS1 Inverter Transformer

The wonderfully simple transformer consists of two E cores of the "older" Ferroxcube part number E375-3C81 (or even previous to that E375-3C8) and the modern Philips Components part number E34/14/9-3C81. The half gap (paper thickness) is two pieces of regular copy paper which should be about 0.2 mm. The bobbin is old Ferroxcube part number E375pcB1-12 and Philips Components part number CPH-E34/14/9-1512. I got them from Eastern Components, 1-800-642-0518.

Gapped versions of this core may be available. If both halves are gapped, specify 0.2 mm. If you get a gapped piece paired with an ungapped piece then the gapped one should be 0.4 mm.

The primary and secondary are each 16 turns of insulated #20 AWG hookup wire, but wire size is not critical and the secondary could easily be #22. Magnet wire is fine with adequate insulation between layers and between the secondary and the core (3C8 and related ferrite materials are slightly conductive!), and as thick as #18 should easily fit.

- Back to Schematics for Miscellaneous Xenon Flash Devices Sub-Table of Contents.

Variable Intensity Variable Frequency Stroboscope

This circuit is designed to provide a variety of options in terms of repetition rate, flash intensity, and various repeat and triggering modes.

- Get the schematic for STROBEX in PDF format: STROBEX-SCH.

The design includes:

1. Line operated voltage doubler power supply. A low voltage inverter could be easily substituted if desired. See the sections starting with: Schematics for Pocket Camera and Externally Mounted Compact Flash Units as well as the document: Various Schematics and Diagrams for a variety of possibilities.

2. Power transformer operated low voltage logic supply.

3. Variable frequency repeat mode controlled by 555 timer.

4. Optoisolated external trigger input.

5. Selectable flash intensities of .2, 2, and 20 W-s.

6. Autorepeat speeds from .05 to 100 Hz (though obviously, the flashlamp will not operate at all intensities for these entire ranges.)

Parts of this circuit have been built and tested but the entire unit is not complete. Maybe someday.

- Back to Schematics for Miscellaneous Xenon Flash Devices Sub-Table of Contents.

Other Strobe Circuits

12 V Powered Ignition Timing Light

This schematic was provided by Jan Hamer.

Here is a timing light circuit that is powered from the 12 V battery in the car (or whatever) rather than the AC line. Ignition Timing Strobe uses a 2 transistor multivibrator with a pair of 2N3053 buffers driving a 240 V to 12 VCT transformer in reverse to charge a 0.1 uF (100 nF) energy storage capacitor. Triggering is via an external electrode connected to the #1 spark plug. CAUTION: Excessive voltage on the trigger electrode could conceivably puncture the glass of the flashlamp or do other damage. The trigger electrode must be arranged in such a way that a discharge will take place harmlessly to ground before this happens.

Flashing Alarm Beacon

This schematic was provided by Jan Hamer.

Flashing Alarm Beacon is a simple line powered fixed rate xenon flasher. It appears to be set for about 5 flashes/per second as drawn. Obviously, it would be easier to change this rate by selecting different values for the 750K resistor through which the trigger timing capacitor is charged.

Note that the 47 uF main energy storage capacitor may be too large for a typical small flashlamp resulting in relatively short life due to excessive power dissipation if nothing else. The flash energy is about 2 w-s so at 5 flashes/per second this becomes 10 W.

Sam's Strobe FAQ Components

HTML, Diagrams, Photos, and Schematics

For contact info, please see the Sci.Electronics.Repair FAQ Email Links Page.

Introduction

This is a complete list of the files which constitute the Sam's Strobe FAQ (Official name: Notes on the Troubleshooting and Repair of Electronic Flash Units and Strobe Lights - and - Design Guidelines, Useful Circuits, and Schematics).

Note: There are *zillions* of additional diagrams and schematics included within the HTML files themselves. Those that are listed here are only the ones that are in .pdf, .gif, .jpg, or other graphics or compressed format.

Sam's Strobe FAQ Components

  - Photo of Flash Circuit Using IC 1 - Top View (flshic1t.jpg).
  - Photo of Flash Circuit Using IC 1 - Bottom View (flshic1b.jpg).
  - Flash Circuit Using IC 1 (flashic1.gif).
  - Malcohm's Flashgun Charger (mflinv1.gif).

- Honeywell Prox-O-Lite Flash Unit (hwpl1sch.pdf).

- Variable Intensity Variable Frequency Stroboscope (strobex.pdf).

- HSS1 - High Speed Logic Triggered Strobe 1 (hss1sch.pdf).

- Ignition Timing Strobe (timnglt1.gif).
- Flashing Alarm Beacon (beacon1.gif).

Warning Signs and Icons :-)

- Electrical Safety Warning Sign (Shock.gif).

- Sci.Electronics.Repair FAQ Icon (Browser, serfaq.gif).

- Laser (HeNe Tube) FAQ Icon (Browser, laserfaq.gif)

- Silicon Sam's Technology Resource Icon (Browser, sstr.gif).

Silicon Sam's Technology Resource

Local Installation

Version 1.53

For contact info, please see the Sci.Electronics.Repair FAQ Email Links Page.

Table of Contents

Introduction

This document outlines the installation procedure to create a local browser accssible copy of Silicon Sam's Technology Resource - the complete set of Repair and Information Guides that I have authored. It consists of a set of HTML files and associated schematics, diagrams, and photographs.

Note: Some of these documents (the large electronics and appliance repair guides) are not as nicely formatted as those at the Sci.Electronics.Repair FAQ sites - which you may prefer to view on-line. However, the ugly ones may be more recent versions.

Basic Installation

Important: all-faqs.zip does not include laserfaq.zip (Sam's Laser FAQ). This must be downloaded separately. The following assumes a first time install of SSTR.

- See Home and Mirror Site Locations to identify a site with a ZIPPED version of SSTR.

- Download all-faqs.zip into a new directory (or the same directory as Sam's Laser FAQ) and decompress it (unix unzip or DOS PKUNZIP):

    - Extract all files: unzip all-faqs
    - Extract selected files: unzip (or PKUNZIP) -x all-faqs file1 file2 ...
    - Directory of all-faqs: unzip (or PKUNZIP) -v all-faqs

  (Answer 'yes' or 'all' to any duplicate file queries.)

  The files "faqfil.htm", "cdfaqfil.htm", (and "laserfil.htm" if Sam's Laser FAQ was downloaded and decompressed) contain a summary of all the HTML, photos, diagrams, and schematics which constitute this release.

- When "sammenu.htm" is accessed using a Web browser, everything may be viewed directly. If you want the entry point to be to a short file located elsewhere, move "faqsam.htm" to the desired dirrectory and modify its links to point to the directory where you have put all the text and graphics files.

- Your browser needs to be configured properly to make sense of the many ASCII diagrams, schematics, and tables. See the document: Suggested Browser Settings for font and other related information.

- If you are not planning to have Sam's Laser FAQ loaded locally but would like the laser related links to be live, edit "sammenu.htm" and replace the text strings: "lasersam.htm", "laserfil.htm", and "laserpic/laesrpic.htm", with links to files of the same names in the SSTR directory at one of the sites found in "samsites.htm".

I routinely test all of this on both Unix (Sun OS/Solaris) and DOS under Win95/Win98. Please let me know if there are any problems.

Icons and Links

A set of icons are included for linking to Silicon Sam's Technology Resource or the full Sci.Electronics.Repair FAQ from you own Web pages (sstr.gif or serfaq.gif, 64 x 64 pixels) and from Windows (sstr.ico or serfaq.ico, 32 x 32 pixels). For example:

- To create a link to SSTR from an existing Web page, use a text or HTML editor to add the following lines to it:

  ```
  <li><a href="sammenu.htm">SSTR Main ToC</a>  <a href="sammenu.htm">
    <img WIDTH=64 HEIGHT=64 src="sstr.gif" alt="SSTR" align=middle
    border=0></a> - Comprehensive Repair Guides, FAQs, Testing Info,
    Assorted Schematics, etc.
  ```

  This will add the SSTR icon and create hot links to the SSTR Main Table of Contents as long as it is in the same directory with an appearance similar to this:

  - SSTR Main ToC - Comprehensive Repair Guides, FAQs, Testing Info, Assorted Schematics, etc.

  Edit as appropriate for your complete path if located elsewhere or to link to the S.E.R FAQ.

- If you are running Win95 or Win98 (I don't know if this works for Win3.1x), the .ico format icon files can be used when accessing SSTR or the full S.E.R FAQ from a folder or the desktop.

  To add a link from the Win95 desktop directly to the Silicon Sam's Technology Resource main menu, via Netscape, surf over to your copy of "sammenu.htm" and press and hold the left mouse button while dragging the local "Main Menu" or its icon hot link to the desktop. Create a shortcut there and then edit its properties to use the icon of your choice! (You can do the same thing with any of the other hot links instead if you do not intend to maintain a local copy of these documents.)

- Back to SSTR Install Table of Contents.
- Go (back) to Home and Mirror Site Locations.

Introduction

Reducing the Clutter in Land Fills

The purpose of this document is to prevent land fills from becoming filled. :-)

Many dead appliances, and consumer electronic and computer equipment contain parts and subassemblies which are not only neat and interesting, but useful for various experiments and projects.

- I bet you tossed that big heavy slow 5-1/4" hard drive in the garbage when you upgraded, didn't you? Admit it! Did you know that if it was a high performance drive, it contained several of the most powerful permanent magnets you would ever be likely to find anywhere? And, they would have been free!
- That big old microwave oven? Too bad. More magnets, nice high voltage power transformer, rectifier, capacitor. Electronic or mechanical timer, fans, other motors, etc.
- What about that dot matrix printer? Too bad - at least two stepper motors, a nice power supply, and various other electronic and mechanical components.
- More steppers in floppy drives. Also, probably a regulated speed pancake motor.
- Old TV or monitor? Another mistake. The high voltage power supply was probably good for 12 to 30 kVDC at 1 or 2 mA. This is useful for many high voltage experiments, plasma globes, negative ion and ozone generators, bug disintegrators, starters for really LARGE HeNe lasers, etc.

There will be several types of information:

1. Where to obtain a particular type of part like a powerful magnet.
2. What dead consumer electronics, computer equipment, and appliances yield in the way of useful parts.
3. Unconventional uses for subsystems or common replacement parts or modules from such equipment.

Safety Considerations

The devices, equipment, circuits, and other gadgets described in this document may be dangerous. Much of it deals with potentially lethal voltages. Getting electrocuted could ruin your whole day.

Before thinking about experimenting with anything using or producing high voltages or connected to the AC line - even opening up a disposable camera that may have been laying around gathering dust (the capacitor can still be charged - arggh!), see the document: Safety Guidelines for High Voltage and/or

Line Powered Equipment. A large percentage of equipment that is perfectly safe from the outside has dangers lurking inside. In addition to electrical dangers, there might be sharp sheet metal, wound up springs, powerful magnets, and other potential risks to your outer surface integrity like CRT implosion - just to name a few. Something that looks innocent can really ruin your entire day!

For really high voltage equipment, also see: Tesla Coils Safety Information.

Places to Obtain Sacrificial Equipment

So, where do you find the equipment from which to remove parts other than your basement, your attic, or those of your relatives or friends? Consider garage, yard, tag, estate, and other sales; thrift stores (which may even have a 'free' table); junk, salvage, and surplus yards (including those run by the Department of Defense!), the town dump and other landfills if they let you take things away, trash rooms of high rise apartment complexes, the curb on pickup day, college campuses around the end of the Spring term, and any other place where perfectly good equipment gets tossed in this throw-away society!

Of course, don't overlook high tech flea markets as well as ham and computer fests. Regular flea markets are usually overpriced (where do you think they get the stuff??) but sometimes you will be able to negotiate a great price because they have no idea of what they are selling!

Yes, we are a strange bunch. :-)

- Back to Sam's Gadget FAQ Table of Contents.

Neat Magnets

Sources of Extremely Powerful Magnets

Two excellent sources of magnets are described below. These are at least as strong as the more well known speaker types, possibly much stronger, and generally easier to remove:

- Microwave oven magnetron tubes. Go to your local appliance repair shop and ask - they just toss bad ones. Each one has two ring shaped ferrite magnets about 2-1/4" in diameter with a 7/8" hole, magnetized N-S on the faces.

  Surplus places typically charge $3 to $6 each for one of these magnets.

  Note: A few older magnetrons used AlNiCo magnet assemblies or even possibly electromagnets which are not nearly as interesting. However, you probably won't see any of these.

- Large hard disk drives - especially full height 5-1/4" high performance types - e.g., Seagate

WREN series or Micropolous boat anchors (the rare earth magnets in these are wicked). The magnets in small drives are even stronger but are, well, much smaller. :-) A typical size for a large drive is about 1" x 1-1/4" by 1/2". Since almost no one wants such large slow drives anymore, they are often found at swap meets or yard sales for next to nothing. These magnets are a few thousand Gauss compared to 10 to 15 K Gauss (1 to 1.5 Tesla) for a medical MRI scanner (of course, the field of the MRI scanner's superconducting magnet is uniform over a volume of several cubic FEET! The disk drive magnet's field decays quickly as you move away from it.)

Surplus places may charge $12 or more for ONE of the magnets from a large disk drive (there are typically 2 to 6 such magnets in a disk drive)!

I have a monolithic clump of 40 or 50 of the magnets from full height 5-1/4" SCSI drives. I figure there is a black hole growing inside but haven't dared to look. :) The only way I was able put the clump together with minimal damage to flesh was by using a hard wood ramp to gently guide each new magnet into place. I haven't figured out how I'll ever get them apart though!

Here is a quick easy experiment to try with these powerful magnets: Slide one such magnet over a thick aluminum plate. What do you feel? Or, let a 1/8" x 2" x 12" aluminum plate drop through the intact yoke from a Seagate WREN series 5-1/4" full height hard drive positioner. What happens? Why? What material might produce an even more pronounced effect? Why?

For more things to do with these neat magnets, see: Neodymiumarium.

CAUTION: Both these types are powerful and will squash flesh as they suck all the bits off of your magnetic media! I am not kidding about the part about squashed flesh - with some you actually need a small crowbar to pry the assembly apart!

You will find that some of these magnets are painted. This provides some resistance to chipping though this material may be on the verge of flaking off or has already done so in spots. In any case, I further recommend that you add additional layers of a tough enamel (e.g., Rustoleum) or the plastic/rubber dip used to coat tool handles. Otherwise, chipping damage (at least) will result all too easily and the chips are just as powerful as the rest of the magnet.

Additional Disclaimer: I will not be responsible when your spouse or parents come home to find the microwave or PC missing some key components and as dead as a brick!

(From: Terry Sanford (tsanford@nf.sympatico.ca).)

Magnets salvaged from scrapped computer drives are strong!

- We use them to hold old blankets that cover a vintage car stored in garage.
- Useful for finding nail locations in plasterboard walls. Strong magnet will 'stick' to wall at the nail location. better than those weak magnet 'dippy indicator' things! You can leave magnet parked on

the nearest nail head after each use!

- Use magnet to pick up wrench/spanner dropped off boat wharf into ten feet of sea water! Also fished wrench out from under patio deck other day; main problem was finagling wrench through the gap between the deck boards. Used bent coat hangar which kept sticking to the magnet; darn!

- Also you can 'feel' if current is actually flowing to an electrical appliance by holding a strong magnet next to the wiring! It detects 'flow' not the presence of voltage.

PS: After WWII, strong horseshoe ex radar magnetron magnets were sold surplus for about two and sixpence each. Someone took his into a pub on way home and everyone had a great time with it until people starting checking their (then magnetic) watches. He wasn't too popular after that I can tell you!

Other Sources of Fairly Powerful Magnets

The following are other possibilities. However, they are not likely to be nearly as strong!

- Spent laser printer toner cartridges where the entire developer assembly is part of the cartridge (e.g., EPS-2 for Canon engines). These include a page-width ferrite magnet. However, expect to make a mess disassembling the cartridge as there will still be considerable toner remaining inside.

  WARNING: The toner is a possible health hazard. A good dust mask should be used while working on these. Also, do not vacuum what remains - static can set off a dust explosion - use wet rags or paper towels to clean up the mess! The coating on the photosensitive drum may also be a hazardous material.

- Loudspeakers.

  - Smaller or older speakers use AlNiCo type magnets which are usually in the form of a cylinder (about as tall as it is wide). AlNiCo is an extremely hard metal alloy.

    AlNiCo magnets are not as powerful as ferrite or rare earth types and are easily demagnetized (but just as easily remagnetized). Passing a stack of these through the center hole of a strong ferrite magnet will increase their strength dramatically - until they are separated from each other!

  - Modern loudspeakers use ring shaped ceramic ferrite magnets (similar to those in a microwave oven magnetron - see the section: Neat Magnets) glued to the pole piece (yoke) assembly within which the voice coil moves. The ferrite is extremely hard but very brittle so care must be used to extract these from the yoke assembly - see the section: Disassembling Loudspeakers to Get at the Magnets.

- Permanent magnet stepper and servo motors. These will use ferrite or rare earth magnets usually in strange shapes. Note: Removing the magnets may result in partial demagnetization (reduction in magnetic strength) as the rotor is part of the magnetic circuit. Therefore, I do not recommend this source. There is generally no practical way of remagnetizing the strange shapes involved.

- Optical (laser) pickups from CD players, CDROM drives, and other optical data storage devices. These may have some very tiny, but strong, rare earth magnets in the focus and tracking actuator. However, it seems a shame to sacrifice the beautiful mechanics in such a device just to get the magnets! CAUTION: Tiny magnets even more fragile than bigger ones!

Disassembling Loudspeakers to Get at the Magnets

For small speakers with AlNiCo type magnets (the magnets usually look like metal cylinders), careful prying with a sturdy screwdriver will usually break the adhesive bond and/or free them from the yoke assembly. Note: Use the proper tool for the job - not your dad's prized screwdrivers!) Unlike the ceramic magnets described below, AlNiCo types are metal and quite sturdy.

(From: Arie de Muynck (ademu@pi.net).)

For the normal black ceramic ring shaped magnets (and likely for some Ticonal 'iron colored') the trick is: heat the complete assembly slowly using a paint-stripper gun, or in an oven (thermal, not microwave!). The glue will weaken and with a screwdriver you can SLOWLY work them loose. Protect your fingers with an old cloth. Never apply too much force, the ceramic would chip or break.

Do not overheat them above the so-called Curie temperature or the magnet will loose it's power irreversibly. That temp depends on the material but should be way above the 120 C or so to soften the glue. If you want to experiment with this effect: use a piece of iron attracted towards a magnet, heat the iron with a flame and above a rather sharply defined temperature it will not be attracted anymore. The effect is used in some Weller soldering irons to stabilize the temp.

Note that the force of a bare ceramic magnet is not as strong as you might expect, the magnetic lines of the large area of the ring have to be bundled and guided though iron to a narrow gap to provide a proper magnetic field.

How do I Make a Harddrive Motor Spin?

You are tempted - those spindle motors that are part of the same large old clunky harddrives that yield really powerful magnets look like they would be perfect in that next robotics project if only you could figure out what all those darn wires were for!

(From: Bob Weiss (bweiss@carroll.com).)

These motors are usually brushless DC, and can be a pain to figure out. Windings are usually 3-phase wye. DC power applied to center tap of wye, and ends of windings go to output transistors/fets in the driver. Driven by 3 pulse trains 120 degrees apart. Other leads are for hall effect sensors that measure rotor position and time the drive pulses to the relative positions of the rotor magnets and stator coils. Not an easy driver to build from discretes! Some motors contain all the driver electronics, and only require +12VDC and a TTL enable signal to run. The Disc drive you took them out of will contain appropriate parts to build a controller, probably a driver chip from SGS or Sprague UCN series. Look up the chip in a databook for suggested circuitry. Best way to learn this field is reverse engineering!

High Voltage Power Supplies from Dead Equipment

You are Surrounded by HV Equipment!

There are a surprisingly large number of types of common consumer electronics equipment and appliances which employ high voltage in one form or another:

- TVs, monitors, and computer terminals all contain a source of high voltage for the CRT. Depending on the particular model, up to 30 kVDC or more at 1 to 2 mA will be available assuming the deflection/HV subsystem of your sacrificial equipment is in operating condition. However, you cannot (or at least should not) just string HV wires from the back of the family's 35 inch TV to your lab. :-)

    - How much circuitry you actually need (and what you will have to add) depends on design but figure on the mainboard with the deflection drive and flyback, and probably the yoke (to keep the system properly tuned though this may not be essential).

      Some capacitance on the HV output may be needed as well (though the ones I have tried were happy enough with just the stray capacitance of the wiring). Originally, the CRT envelope provided this capacitance.

      See the section: Why the Yoke is Needed to Keep the Horizontal Deflection System Happy.

    - Power will either be the AC line (WARNING: Very dangerous) or a DC supply (typically 12 to 24 VDC). They will usually operate on somewhat lower input voltages with correspondingly reduced output.

    - A 555 timer based oscillator or other horizontal sync source may be needed as well if the system doesn't free-run at close to the normal horizontal scan rate. This is probably easier where the guts came from a monitor or terminal (since a separate TTL compatible horizontal drive input is likely to be available) but it should be possible to fake out a TV as well.

    - Depending on design, these may require signals like 'HV Enable' and/or a feedback or reference voltage to operate properly.

    - Small B/W TVs, mono computer monitors, and computer terminals will provide about 12 to 15 kV.

    - Large B/W TVs and Color TVs and monitors will provide 15 to 30 kV. Even more from projection sets!

    - Some larger high performance color monitors may have a separate self contained HV module. One particular type (found in a 19 inch workstation monitor) is rated at 25 kV, 1.1 mA (and produces several other voltages) from a 26 VDC, 2.5 A power supply. However, by tweaking some internal pots, over 30 kV is available. See the section: High Voltage Power Supply Module from Monitronix EZ Series Monitors for one example.

  One key advantage of using predesigned circuitry is that you are less likely to destroy power transistors and other expensive parts - and I have blown my unfair share. :-(

  See the section: Sam's Super-Starter(tm) for a specific example of this kludge, um, err, approach for starting large HeNe laser tubes. :-)

- The high voltage power supplies from plasma globes, electrostatic dust precipitators, photocopiers and laser printers, bug zappers, negative ion and ozone generators, electric fences, cattle prods, electric chairs, and other 'common' equipment may be pressed into service for your applications.

  Since these HV generators are not combined with anything else, they are likely to be self contained modules and very easily used by themselves.

  However, available current from some of these sources is generally less than from TVs or monitors. Details are left to the highly motivated student. :-)

    - Plasma globes: Pulsed (not rectified or filtered) 10 to 15 kV.

    - Electrostatic dust precipitators: 5 to 10 kVDC.

    - Photocopiers and laser printers: Two outputs at 5 or 6 kVDC.

    - Bug zappers: 10 kV???.

CAUTION: Since these power supplies were designed for a specific purpose under specific operating conditions, their behavior when confronted with overloads or short circuits on the output will depend on their design. It may not be pretty - as in they may blow up! Take care to avoid such events and/or add suitable protection in the form of fast acting fuses and current limiting to the switching transistor.

Note about X-rays: Improper use of these sorts of devices may result in shock or electrocution, but at least you will not be irradiated at the same time unless you connect them to a something which includes a vacuum. In order to produce measurable X-ray radiation, electrons must be accelerated to high velocity and strike a heavy metal target. A high vacuum such as in a CRT or other vacuum tube (valve) is best but there may be some X-ray production from a low pressure gas filled tube. There is virtually none in sparks or arcs at normal atmospheric pressure. However, there will be UV and ozone which are both hazardous.

Sam's Super-Starter(tm)

This would be called a kludge by some, a Rube Goldberg by others. But, hey, as still others would say: "If it works, use it!". The original application was for starting LARGE HeNe laser tubes but there can be many other uses.

The entire horizontal deflection and high voltage sections of a long obsolete and lonely ASCII video display terminal were pressed into service for starting larger HeNe tubes. A source of about 12 VDC at 1.5 A is needed for power and a 555 timer based oscillator is needed to provide the fake horizontal sync:

- The deflection circuitry was all on one corner of relatively small board (about 3 x 6 inches). The flyback transformer is a plug-in unit. I left the other circuitry (vertical, video) in place since it is not powered by the same supply and therefore is pretty inert. However, if you want to recycle the parts.....

- The horizontal deflection yoke is needed to 'tune' the system - performance is much better with it installed. This wart looks a bit strange but is the easiest way to avoid modifying the design. See the section: Why the Yoke is Needed to Keep the Horizontal Deflection System Happy for more info.

- Horizontal drive is provided by a 555 timer in astable mode running at about 16 kHz (the original horizontal deflection rate of the terminal). A 10K ohm pot allows me to fine tune this for maximum HV output.

  Well, it turns out there was an unused spot on the board ready made for this circuit (well almost, at least there was a pattern for a spare 8 pin DIP! So, once the thing was basically working, I built the oscillator onto the board to reduce the clutter!

- Power requirements are modest - 10 to 15 VDC at just over 1 A. Over this range, the output varies between about 10 and 15 kV (what a coincidence!). Input down to about 5 VDC produces correspondingly reduced output but the circuit is not particularly stable over this lower range of voltages.)

I guarantee that "Sam's super-starter(tm)" - or its big brother, "Sam's hyper-starter(tm)" using parts from a color TV or monitor - will start ANY HeNe tube that can possibly be started! These also make nice self contained HV sources for other experiments. :-)

Why the Yoke is Needed to Keep the Horizontal Deflection System Happy

If you unplug the yoke (even if there is no interlock), while the system may still work to some extent but performance will be poor. High voltage will be reduced and parts may overheat (and possibly blow up).

(From: Jeroen Stessen (Jeroen.Stessen@philips.com).)

Of course that doesn't work. The flyback capacitor is tuned for the presence of both inductances: line transformer and deflection coil. If you remove the deflection coil then the remaining primary transformer inductance is about 5 times as large. So, rule-of-thumb, you would have to decrease the flyback capacitor by a factor of approximate 5. But that's not all:

Without the deflection coil, a lot less current runs through the horizontal output transistor. So, in all likelihood, it will now be overdriven. So you need to reduce the base drive. But that's not all:

If you remove the picture tube capacitance and the deflection coil then all peak energy demand must be delivered from the primary winding of the line transformer. Even the shortest peak load will cause saturation. The parallel deflection coil will at least lend some temporary energy, and the picture tube capacitance does an even better job. A good high-voltage source without the benefit of a deflection coil is more expensive...

If you *must* get rid of the 'ugly' deflection coil, then you may want to replace it with an equivalent 'pretty' coil. But:

- It must be able to carry the peak current without saturation (a deflection coil has such a huge air gap that it can not possibly ever saturate, but a smaller coil can).
- It must have a low enough dissipation so you might have to wind it with litz-like wire (multi-stranded isolated), do not underestimate the losses in high-frequency coils, mostly due to skin- and proximity-effect.
- Yes, it can be done, good luck.

And you might want to add a discrete high-voltage capacitor. How to isolate the wiring (corona discharge!) is left as an exercise to the reader... (We pot them in convenient blocks).

High Voltage Power Supply Module from Monitronix EZ Series Monitors

This is a self contained module (separate from the deflection circuitry) which makes it very convenient for your HV projects.

It is fully enclosed in an aluminum case about 1-7/8" x 6" x 5" with a 9 pin connector for the low voltage wiring and thick red wires with HV connectors - suction cup and Alden type - for the CRT 2nd anode and focus voltage respectively.

- Manufacturer: Toyo, Corp., Japan
- Model: HVP-1208A1-26L.
- Input: 26 V, 2.5 A max.
- Outputs:
  - High Voltage: 25 kVDC, 1.1 mA
  - Focus: 4.5 to 7.65 kVDC, 15 uA
  - G2: 200 to 1000 VDC, 5 uA
  - AUX: -200 VDC, .5 mA

There are 8 pins installed on the 9 pin connector of which 6 were used. I wonder if the other 2 have any function other than spacing off the G2 voltage.

```
   ___________
  /           \
 (  o3  o6  o9 |
  >            |  View of connector on case.
 (  o2  o5  o8 |
  >            |
 (  o1  o4  o7 |
  \___________/
```

- Pin 1 - G1: -200 VDC (-184 VDC measured), white or yellow.
- Pin 2 - DC+ in: 26 VDC, 2.5 A max, green or brown.
- Pin 3 - Power Gnd, black.
- Pin 4 - Shield Gnd, bare or black.
- Pin 5 - NC.
- Pin 6 - NC.
- Pin 7 - Enable (low) TTL, orange.
- Pin 8 - NC.
- Pin 9 - G2 (+200 to +1000 VDC), red.

I assume the NCs are truly not connected to anything and simply serve as clearance for the up to 1000 V G2.

In addition to the Focus and G2 pots, there is an unmarked adjustment accessible via a hole in the case. At first, this appeared to have no effect on any output.

When I opened the case, 2 additional pots come into view. While I do not really know their exact function, by advancing them clockwise, the HV could be boosted significantly. With both fully clockwise, the externally accessible control will vary the HV between about 27 and 32 kVDC regulated (only HV probe meter load).

- Back to Sam's Gadget FAQ Table of Contents.

High Voltage Transformers

Types of HV Transformers and Where to Get Them

There are many types of transformers capable of generating high voltages for hobbyist type projects. Some operate from the AC line directly while others require an interrupter or solid state high frequency driver.

- Neon sign or luminous tube transformers (same thing): 10 to 15 kV at 15 to 60 mA, current limited. Some may be higher. There are also smaller ones.

  Current limited means that the transformer will deliver the rated current (Io) into a short circuit and produce the rated voltage (Vo) with no load. In between, it is designed to produce a somewhat constant current up to a substantial fraction of its no-load output voltage. This is somewhat similar to being in series with a resistor equal to n*Vo/Io (where n may be 2 or 3 or more) over this range but implemented without silicon as the magnetic design of the core and windings with no extra power dissipation. (It isn't really this straightforward but will serve as a first approximation.) Therefore, a short circuit on the output will not blow a fuse or trip a breaker (though the transformer will overheat if left this way for too long).

  Sources: Your local sign shop, demolition company, or salvage yard. New: $100 or more. Used: $5 to $50 or free.

  Both iron (an actual transformer) and electronic (high frequency inverter) types are available. The iron types are more robust and will survive repeated abuse that may destroy the others but they are heavy.

  WARNING: Though current limited, the available current from neon sign transformers - especially the larger ones - is far into the range where lethal consequences are likely under the wrong circumstances.

  (From: Jason Freeburg (egraffiti@iname.com).)

  > "A used neon sign transformer should not cost more than $20 or so. Find a neon shop in your area. They usually have the used ones stacked up somewhere and will sell cheap. The 60 mA models are usually somewhat cheaper than the 30 mA type if

you buy them used from a neon shop because they are really too hot (e.g., provide too much current) for running neon and they cause staining and premature burnouts. It all depends on the particular shop you go to. I don't suggest buying new for something like this, the performance will be the same but the price much higher. A new 15 kV, 60 mA transformer lists for about $80.

BTW, the best name to look for in neon sign transformers is France. These things are ruggedly built like and will take a lot of abuse without dying. The name to avoid is Actown - their transformers are wimpy and usually don't deliver the rated current."

- Oil burner ignition transformers: 8 to 10 kV at 10 to 25 mA, current limited. (See description for neon sign transformers, above.)

  Sources: Your local HVAC contractor probably for the asking as the ignition transformers are thrown out along with old oil burners when they are replaced. Of course, you will probably have to take the entire icky smelling disgusting burner assembly as part of the deal. :-) However, there is will be a nice motor and small oil pump in there as well. ;-)

  WARNING: Though current limited, the available current from oil burner ignition transformers is still more than enough to kill under the wrong circumstances.

Both neon sign and oil burner ignition transformer generally have centertapped secondaries connected to the case - which MUST be grounded (via a three wire cord and properly wired outlet) for SAFETY. Therefore, it is generally not possible to construct a totally isolated HV power supplie with these devices.

- Microwave oven high voltage transformers: 1.5 to 3 kV at 0.25 to 0.5 AMPS.

  Sources: Dead microwave ovens (the transformer is rarely the problem). Try your local appliance repair shop. However, you will probably have to cart away the entire oven - but other useful parts inside. :-) See the section: Dangerous (or Useful) Parts in a Dead Microwave Oven.

  WARNING: The electrocution danger from microwave oven transformers cannot be overemphasized. They are not current limited, and even if they were, could be instantly lethal given the least excuse for a suitable path through your body since the rated current is a substantial fraction of an AMP at several thousand volts. Normally, one end of the high voltage secondary is bonded to the core - which must be grounded for safety. However, it may be possible to disconnect this and construct an isolated HV power supply (which will be only marginally less dangerous).

- Automotive ignition coils: 25 to 75 kV (depending on model) at low current.

  Sources: Your 1997 Honda. Just kidding. :-) Auto repair shops or parts stores, salvage yards.

WARNING: While unlikely to be lethal, the HV output of an ignition coil can still result in a seriously unpleasant shock and possible collateral damage.

- Flyback transformers from TVs, monitors, computer terminals, or other HV power supplies. Little teeny ones in CRT based camcorder viewfinders and older Watchman TVs. Output from less than 3 kV to over 30 kV at 1 to 2 mA depending on model. Most include a high voltage rectifier though some may use an external one or voltage multiplier (also a useful and neat device).

  For many hobbyist uses, the only portion of the flyback that is important will be the high voltage winding (and rectifier, if present). It is a simple matter to add your own drive and feedback windings on the flyback core. This eliminates the uncertainty of determining the number of turns and wire size for the existing windings.

  Sources: CRT based equipment tossed for failures NOT caused by a defective flyback. However, sometimes even a bad flyback can be used for HV projects. This will be the case if the problem is:

  - Shorted primary windings. With some flybacks, the primary windings are on a separate bobbin and can be removed. Even when buried, they can sometimes be extracted without affecting the HV winding (just don't lose the HV return!).

  - External arcing due to cracks or pin-holes. Try coating with RTV silicone or HV sealer (allow ample time to dry completely). Plastic electrical tape may work temporarily at least. Note: Try to get the type of RTV that is non-acidic. The normal kind (that smells like viniger when curing) may be corrosive to the wiring. However, I haven't seen problems with this.

  - Breakdown in focus/screen network. This section may be removable with a hacksaw or small chisel! Then, insulate the exposed HV terminals as above.

  - Shorted HV rectifier (rare). Just add an external HV rectifier if needed.

    If you really want AC, this is an advantage! In fact, it might be possible to deliberately short the HV rectifier where you want an AC source by passing excessive (DC) current through it and/or violating its PIV rating (but that may be tough as other parts are likely to fail first!).

  - Broken or cracked core. Substitute the core from another flyback or glue or clamp the pieces together (broken edges in close contact). Don't lose the mylar/plastic spacers and replace them (if needed) when the repair is complete!

  No one actually buys flyback transformers for experimentation!

  WARNING: Flyback transformers are capable of producing shocking experiences. However, when run at high frequencies, your first hint of bodily damage may be via your sense of smell -

from burning flesh. Keep clear!

Note: Ignition coils and flyback transformers can generate very high voltages but must be driven by a pulsed or high frequency drive circuit. These cannot be plugged into the wall socket directly!

Also see the section: Driving Automotive Ignition Coils and Similar Devices.

Basic Ignition Coil Circuit

For a description of how an ignition coil generates high voltage and some math, see the section: Driving Automotive Ignition Coils and Similar Devices. The circuit below is about the simplest possible and easily generates 25 kV using the 12 VDC output of a surplus PC power supply:

```
                           T1 +-------o HV Out
              Rb       Bat ||(
+12 o--------/\/\--------+ ||(
                          )||( Ignition Coil
                          )||(
             Cp           )||(
        +----||---+----+-+    +-+
        |         |    |        |
        | S1 _|_  |    +--------+
Gnd o---+----o o--+
           Points
```

- T1 is one of those round metal can ignition coils widely used in automobiles when there were actual points. If you have a modern one, that should work also as long as there isn't other 'stuff' inside.

- Rb is a current limiting ballast resistor. I used the nichrome element from a defunct waffle baker but an auto headlight or any other high power resistor will work just as well. The nice thing about the heating element is that it is easily adjustable by just moving a crocodile clip lead.

- Cp is essential - not just to protect the switch contacts ('points') but to provide a buffer so that current flow isn't interrupted so suddenly that a low voltage arc forms across the switch contacts. Without Cp, there will be next to no HV output. Think of it this way: without Cp, as the points open, the inductive kick-back from T1 results in an arc forming across the switch contacts. This is relatively low voltage and essentially kills any output from the coil. With Cp present, current continues to flow into Cp until the contacts have opened wide enough that they no longer arc and a high voltage can build up (probably a couple hundred volts). The accompanying field collapse results in a nice juicy spark from the ignition coil! See additional comments below.

  I used a .1 uF, 400 V capacitor for Cp. You can try smaller capacitors (but at least the same voltage). Too small, however, and that annoying arcing will return and you will barely be able to light a tiny neon indicator lamp!

- S1, the switch ('points') should be a 'fast break' variety - not a knife switch. The faster the contacts move apart (and the better the insulating medium is if it isn't air), the smaller Cp can be and still result in reliable operation. Smaller Cp should result in higher output voltage. Just touching some wires was erratic - a large pushbutton 'micro-switch' was much better. Of course, using a power transistor and 555 timer to drive it would be even more way cool. :) See the "Adjustable High Voltage Power Supply" in the document: Various Schematics and Diagrams. It can easily be adapted to use an ignition coil instead of its flyback transformer.

- The power supply was a no-name far-East 200 W unit for a PC clone. You will likely need a load on the +5 to keep it happy - an automotive headlight works well. The second half of a dual-beam headlight can be used for Rb (though you may want to go to a lower value and it isn't adjustable like the heating element, above).

I was able to obtain a 1 inch spark from each button release using about 2 ohms for Rb. If you build an interrupter/buzzer or a mechanical doohickey (technical term) to operate the points, you will get a nice steady stream of fat juicy sparks. Just take care - contact with one isn't going to be an experience you will want to repeat.

(From: Jonathan Bromley (jsebromley@brookes.ac.uk).)

The voltage across the coil is L*dI/dt. Voltage across the coil HT winding is the same, but larger by a factor of (turns ratio) which is typically 50 to 100 in ordinary car coils.

When the points are closed, the coil current will progressively increase because the full battery supply appears across the primary. This will incidentally put around 1kV across the secondary, not enough to jump the gaps in spark plug and distributor. The points dwell time (or the behaviour of the electronic points-substitute controller) will be such as to allow the coil current to reach some sensible value.

When the points open, if no capacitor then current would instantaneously collapse to zero giving a very high coil voltage (huge dI/dt). But this happens JUST AT THE MOMENT THE POINTS OPEN, when the points gap is tiny. So the high coil voltage will immediately strike an arc at the points as they open. This provides a fairly low-resistance path which will be sustained as the points open further. dI/dt is therefore not so big after all, just enough to maintain the few tens of volts across the points arc. Therefore, not enough voltage on the HT winding to fire the proper spark, and all the stored energy in the coil goes into the arc at the points.

So, the (rather small) capacitor is there to allow the coil current to continue to flow, without a big voltage appearing across the points initially. Basically this C is there to give the points time to open before the coil primary voltage reaches its peak value of a few hundred volts. The C is chosen to resonate with the L of the primary so that the peak voltage is delayed just long enough so that the points are open wide enough that the 500V primary voltage DOESN'T arc across them, but the 50*500V = 25kV secondary voltage DOES jump the plug/distributor gaps. It's therefore the breakdown voltage of the plug/distributor gap that controls the highest voltage reached across the points. Typically this will not be high enough to allow much of the coil's energy to be transferred into the capacitor. Any energy that _is_ stored in the capacitor will eventually find its way into the spark by the reverse- current mechanism that you describe - the spark current will oscillate for a while. But the oscillations are fairly heavily damped by the loss of energy into the spark.

The story is slightly more complex in reality because of finite resistance of the coil windings and their distributed capacitance, but this simplified account is not too far from the truth.

(From: George Nole (gnole@brisbane.dialix.com.au).)

In the operation of the Kettering ignition system three clearly defined stages or phases can be identified.

1. Points closed.
2. Points open, but no gas discharge or spark has been initiated.
3. As per (2) but discharge has occurred.

Before proceeding with an analysis, a few notes on the ignition coil. The ignition coil is a transformer with very high leakage inductance. This because the core of the coil is not a closed magnetic circuit, but a straight piece with both ends open. The turns ratio is of the order of 100 or so. Recent measurements on a 6V coil revealed primary inductance with secondary open -no discharge- of 4mH, and with the secondary loaded -gas discharge- of 1mH. These values vary considerably from coil to coil.

Now the analysis which you can do yourself. Don't take my word.

1. With the points closed a current flows and energy is stored in the inductor (primary inductance).

2. When the points open, the circuit consists of a capacitor or condenser in series with the inductor. The other terminal of the capacitor is connected to chassis, and so is the other terminal of inductor via the ignition switch and the car battery.

   This forms a series resonant circuit of finite Q with energy stored in the inductor, and will start to oscillate. The voltage across the inductor -and the capacitor- will be much higher than the voltage across the series resonant circuit and in practice it is of the order of a few hundred volts. This is important because, with a transformer ratio of -say- 100 and a secondary requirement of 20kV, the primary voltage has to be 200V.

3. Before the oscillation can reach the first peak the gas discharge commences and the inductance changes to that of the leakage value, with a quenched oscillation continuing at a higher frequency than the frequency before the spark.

End of analysis.

What would happen if you tried to start the car without a condenser? If you do the experiment, please let me know the result.

Driving Automotive Ignition Coils and Similar Devices

From a posting on one of the sci.electronics newsgroups:

> "I have some questions about automotive ignition coils. I'm referring to the cylindrical "universal" type which has two 12 V terminals and one HV terminal in the center of the cap.
>
> What is the typical peak output voltage and current?
>
> What is the maximum average power input that such a coil can tolerate? I'm aware that the cross-sectional area of a transformer core dictates power handling capability. Judging from the skinny core in a spark coil, I'd place the maximum continuous duty input at around 50 watts. Am I in the ball park on this?
>
> Is there an optimum pulse rate?
>
> Do ignition coils employ any sort of current limiting?
>
> Do "high-performance" coils with 45-75kv outputs offer significant increases in output power, or just higher voltage?"

(From: jfreitag@gsosun1.gso.uri.edu (John Freitag).)

First, be aware that the coil does not act as a transformer as such, even so called "Hot Coils" have only a 1:100 turns ratio which would give only 1,200 volts from a transformer. If you were to energize the coil with an AC voltage like you would with a transformer this is what you would get. An automobile ignition is more properly referred to as an "induction coil" Its output voltage is defined, not by the turns ratio but rather by the differential equation:

```
V = L di/dt
```

Where:

- V is the output voltage
- L is the inductance in Henrys
- di/dt is the rate of change of current flow as the field collapses in the coil.

V into an open circuit, will essentially rise until a spark jumps. When the air ionizes and the spark occurs the remaining energy in the coil sustains the spark.

Hot coils have a heavier primary so that they can pass more current, hence a higher di/dt.

The maximum pulse rate is determined by the time taken for the current to build when the points close (due to L it rises slowly until it reaches a steady state) and the time for the field to collapse when the points open. (the voltage to generate the spark occurs only after the points open and the field is collapsing)

I have never thought about the power in the spark but I suppose it would be:

P = (L di/dt)^2 / R where P is the power in watts and R is the total resistance of the coil secondary, the plug wire and the ionized spark gap. (Some Professor of EE is welcome to comment here).

As for current limiting, many coils employ a series resistor in the primary which limits current and is shorted out during starting.

(From: Mark Kinsler (kinsler@froggy.frognet.net).)

I use a 12 volt battery and it works pretty well. Probably the best high voltage power supply for careless amateurs is the one I designed, which could be found on my Web page if I knew how to do schematics but I don't. But it's simple enough.

I've been driving my old 12 V coil (bought as a replacement for the one in my Econoline but never used) through a buzzer-type interrupter made from an old relay. I put a capacitor across the contacts for good luck, and for the most part it works pretty well. It'll give me about a 1/2" spark, which is all I need for my illegal spark transmitter and the spark plug in my famous "One Stroke Engine" demonstration. However, it yields some amusing effects, to wit: blue sparks dancing around on the battery lead and the battery itself, extremely strange noises, copious production of ozone, and the occasional puff of smoke. I have the whole mess mounted inside a plastic 2-liter cola bottle. On the advice of my friend Dewey King, who restores old gas engines from oil rigs, I've purchased a Chrysler ballast resistor to put in series with the battery and thus keep the coil healthy.

All you need to do is make a trip to the local auto junkyard:

Buy a used but fairly viable car battery, an old-fashioned ignition coil (i.e., before electronic ignition came out in the '70's), an ignition condenser (capacitor) from out of a dead distributor, and the heaviest 12 volt spdt relay you can get from Radio Shack. DPDT is okay, too.

1. Figure out how to connect the relay so it buzzes.

2. Connect the capacitor across the contacts

3. Connect the primary winding of the ignition coil in parallel with the relay coil.

If you do this right, the relay contacts will give a pulsating current through the ignition coil primary.

You'll get a several hundred Hz, 12,000 V between the secondary (the central tower of the coil) and ground. It'll give you a big surprise but it won't kill you unless you're pretty determined to do yourself in.

I've found that only a car battery has sufficiently low internal resistance to run the thing: my big old bench power supply won't do it. So keep a trickle charger on the battery. It seems capable of giving a 3 cm or so arc depending on conditions.

(From: Pamela Hughes (phughes@omnilinx.net).)

I did something like that only it plugged into the wall. Don't remember the circuit but it was a 33 uF, 630 VAC mercury vapor ballast cap connected to a rectifier in a linear fashion (much like using a cap for an AC resistor only the rectifier prevented bidirectional current flow...). This was connected to an 800 V, 6 A SCR and a neon lamp for a diac in a trigger circuit. Adjusted the trigger point so the scr would fire at a certain point in the AC cycle and discharge the cap through the primary of an ignition coil. If you adjusted the trigger point right, you could get about 3" to 4" sparks. Connected that to a 40 kV TV rectifier and a cap made from a window and some aluminum foil and to a 2" spark gap. Wouldn't fire unless something was placed in the spark gap, but then it went off with a bang that would put any bug zapper to shame.

BTW, I took the ignition coil apart, disconnected the common lead connecting the primary and secondary and then used the secondary and core for a giant sense coil for monitoring changes in magnetic fields... thing would make the volt meter jump if you brought a magnet anywhere close to it, but mostly it just fluctuated with atmospheric effects like lightning.

(From: Pierre Joubert joubertp@icon.co.za).)

1. Use a monostable-based circuit which gives the maximum 'on' time for current in the coil. As revs go up, many older systems produce reduced spark energy simply because the rate of rise of current in the coil prevents full current from being reached before the current has to be switched off.

2. Use one of the coils which is designed to operate normally with a series resistance, which is conventionally bypassed during cranking to help get a better spark on the reduced battery voltage. But instead, limit the current in the coil to a safe value by setting a current limit around the switch transistor. This prevents the coil overheating (which it would if you used it without the resistor in a conventional system.

3. Look around for the 'best' coil you can find; you might find a better match to your needs by using a coil from a different model or even make of car. If you know the R and approximate L you can model the current buildup and estimate the energy available. Generally the more energy the better, assuming that the transformation ratios of most coils are roughly the same, which was true way back when.

(From: Scott Stephens (Scott2@mediaone.net).)

I have characterized a 'typical' car coil, and found it rings best around 1 kHz with the steel core in, and around 8 kHz with it out (no capacitive load on secondary). As you can imagine, leakage (coupling) get worse without the core out, but Q is a little better. Q is under 10, more like around 4. The secondary is around 20 Henries (core in) and 4 H with it out, and primary is around 5 mH. Step up ratio is around 60. My thermal guestimate said continuous power should be under 300 watts in oil. Disappointing.

Mark's Comments on High Voltage Lab Conditions

(From: Mark Kinsler (kinsler@frognet.net).)

So how do you make your high-voltage laboratory safe? Well, you just assume that anything you build is likely to catch fire and/or arc over, and design your lab space accordingly. Stay out of the way of capacitor strings, though when these blow up the shrapnel is generally pretty harmless. I've gotten stung by exploding carbon resistors, but again, it's no big deal if you're well away from them. In general, take the same precautions with high-voltage or high-current components that you would with small fireworks: avoid flammable environments and stay well away from them. If all else fails, take the stuff outside.

My advisor at Mississippi State University observed that if you never damage any equipment and you don't have fairly catastrophic failures, you're probably not doing any research. That helped justify the 6" crater I blew in the concrete lab floor (a record that still stands--his crater was only 4", though there were several of them produced at once.)

Discharge Display Gizmos

Plasma Globes

A 'plasma globe' is one of those things sold at Radio Shack and gift shops which have a glass sphere containing a partial vacuum sitting on a power supply base which is a high frequency inverter. The pressure is such that the discharge tends to take place in streamers rather than as a diffuse glow. The resulting display is supposed to be neat, nifty, interesting, etc. When you place your hand(s) on the globe, the patterns of the discharge inside change.

Recent Sci-Fi movies and TV series seem to have latched onto plasma globes as high-tech replacements for the old-fashioned Jacobs Ladder. :-) (E.g., certain episodes of "Star Trek the Next Generation" and "Star Trek Voyager".)

One such product is called "Eye of the Storm".

It should be possible to construct these gadgets with salvaged flyback transformers, power transistors, and a few other miscellaneous parts using a large clear light bulb - good or bad, doesn't matter - for the discharge globe (However, I don't know how good these actually are for this purpose).

Of course, purists will insist on fabricating their own globe (and official ones can also be purchased at exorbitant prices as well).

As far as I know, these will work with just regular air (though the expensive ones no doubt have fancy and very noble gasses!) and the vacuum is not that high so a refrigeration compressor should be fine.

See The Electronic Bell Jar vacuum technology articles for info on using refrigeration compressors as vacuum pumps.

However, since large clear light bulbs may also be satisfactory (though I don't which ones to recommend), there is may be no need to mess with a vacuum equipment. :-) And, of course, you have a wide selection of inexpensive types to use for experiments, and dropping one or blowing it up isn't a disaster!

Excitation is usually from a high frequency flyback transformer based inverter producing 12 to 15 kV AC at around 10 kHz. Its HV terminal attaches to the internal (center) electrode of the globe or light bulb. The HV return is grounded. Ionization of the gas mixture results from the current flowing due to capacitive coupling through the glass.

For a power source, either the "Simple High Voltage Generator" or "Adjustable High Voltage Power Supply" would be suitable. See the document: Sam's Schematic Collection - Various Schematics and Diagrams for circuit ideas.

However, note that its output must be AC so there must not be any internal HV rectifier in the flyback transformer (which may be hard to find these days since most flybacks have internal rectifiers). (If a flyback with an internal rectifier is used, the globe will just charge up like a capacitor which is pretty boring after a few milliseconds!)

(From: Don Klipstein (don@misty.com).)

As for common gas fills, Radio Shack's "Illuma Storm" sure looks like neon and xenon. I have seen others that had neon-krypton or neon-xenon-krypton. I have seen one in a science museum that looked like plain argon. Other lightning display type things with brighter basically white sparks have xenon.

(Portions from: Steve Quest (Squest@mariner.cris.com).)

A $20 air conditioner repair hand-pump is fine. If the colors of plain air are not 'pretty' enough, let me recommend what is used in commercial units: a mixture of low pressure argon and neon. If you want to be extra fancy, try all the inert gasses, or a mixture of them all, helium, neon, argon, krypton, xenon, radon. :) Of course, radon may not be safe/legal, or even available. You could just toss a chunk of radium into the globe, it will generate the daughter isotope Rn(222) thus slowly, over time, enhance the color of the gas mixture. Just a thought.

The power supply needs to be dielectrically isolated (using the glass as the dielectric), otherwise you'd have direct emission from the metal, and it would be more of a light bulb than streaks of color. Plus, people touching it would feel a tingle while the dielectrically isolated is less likely to shock. What this means is that a direct connection to the filament lead wires is not that great as you really want glass in between the driving source the center as well as the outside globe.

- If you are making your own 'globe', one way to do this is to fuse a glass test tube into the center and coat its interior with conductive paint. This then becomes the center electrode.

- For a light bulb (which isn't really recommended anyhow), you can try to use the filament directly or cut the lead wires as close to the glass as possible and insulate them with RTV or HV putty. Then coat the remainder of the interior of the glass filament support structure with conductive paint to use as the center electrode.

If you cannot locate a suitable flyback, wind your own. Tesla-style air core transformers work. :)

However, I would highly recommend using a commercial flyback! You just need to find one without an internal rectifier. To wind your own flyback requires several thousand turns of super fine wire in 50 to 100 nicely formed layers with the whole thing potted in Epoxy for insulation. Not a fun project.

(From: John Drake (jdrake_deja@deja.com).)

Here is a simple trick:

1. Find some clear light bulbs. Burnt out ones are fine. Any size will do, from a small turn signal light for a car, to a head lamp for a car, to whatever.

2. Attach any Tesla coil output or other low current high voltage source in the 10 to 100 kV range to one of the filament leads. Leave the other lead alone.

3. Turn on the power and watch. Touch with your hand, if you dare. Plenty of lightning in a jar. Eventually, the lightning will poke a hole in the glass, and let the air in. Game over. Get another bulb.

The guy who patented the plasma globe, William Parker (aka Sparks), primarily concentrated on using really interesting blends of gasses and certain frequencies of AC voltage to produce really unusual discharges. For example, it was common to see a kind where an orange lightning bolt had a white tip on it, and a control would let you change the length of the white tip. Other mixes of gasses produced lightning that had a "kinkyness" control -- you could make a bolt very twisty or very straight with a slider control. Check out **U.S. Patent #4754199: Self Contained Gas Discharge Device.** Suitably obscure, huh? :) (The US Patent & Trademark Office currently has a search facility with free access to complete text and graphics.)

Sparks patented his device, and overseas companies literally ripped off the patent wholesale. (Most of the $49 plasma globes you see use his exact circuit from the patent, including a couple of unnecessary parts, etc.) He was trying to get some money out of the whole thing, but I don't know if he ever did or will. Alas.

Of course, if you are just going to make plasma globes and not sell them, you aren't necessarily violating the patents. The underlying idea was well known for a long time before Sparks patented his "globe with controls".

If you want to make your own globes, you can make them lightning compatible by either just sucking the air out, or sucking the air out then adding gas in. Common gasses to use are argon, neon, and krypton. Helium might work (haven't tried), and it's easy to get and use; you can replace the air in the bulb with helium since it's lighter than air.

Lum(n)glass Lightning Plates

There are the disk shaped displays that have random electrical discharges radiating from center to edge and are sold in science/novelty stores in various styles and sizes. Unfortunately, Star Trek Voyager has latched onto these 20th century gizmos as somehow being beneficial to the Borg regeneration cycle - or perhaps they just got a good deal from some antique dealer or on the 24th century equivalent of eBay! :)

A basic description can be found in **U.S. Patent #5383295: Luminous Display Device.** The abstract reads:

> "A luminous display device which includes a fused assembly of three flat members, behind the first of which a chamber partly defined by an opening in the second of said members is formed, a quantity of beads and an ionizable gas being disposed in said chamber, a source of high frequency voltage being connected to an electrode through an opening in the third of said members to form myriad discharge paths throughout said chamber."

For the diagrams, you have to view the patent on-line. In non-patentspeak, the device consists of a sandwich of two glass plates and a spacer ring. It appears as though constructing one of these at home might be possible. A neon sign type electrode in the center of the bottom disk is fed from an RF source probably similar to the high frequency flyback based power supply used for a plasma globe. This will typically be several kV at a couple of mA, at frequency of 20 to 50 kHz or higher. There is no return electrode - the capacitance between the ionized gas and ground provides the return path. However, the physical discharge chamber will certainly more difficult to fabricate. A fairly decent vacuum is also required - the patent claims 15 microns. This requires at least a two stage mechanical pump.

By adjusting the voltage and frequency, using gasses (other than air), phosphor type materials on the beads, colored beads and/or glass, higher or lower pressure, and other changes in drive or construction, the size, color, character, and dynamics of the resulting display to be varied over a wide range.

I would suggest making the assembly out of a pair of pieces of plate glass (though even Lucite/Plexiglas might work - it shouldn't get hot during operation). The plates don't even need to be circular though this isn't really difficult with a glass cutter and template. The outer ring which serves to space the glass plates and also to seal the chamber may be the greatest challenge if made of glass. The space is filled with glass beads, or frit, which, in conjunction with the outer ring, also prevents the thing from imploding. Drilling the hole in the center of the bottom plate for the electrode can be done with some abrasive and a tile or glass bit.

The patent describes a construction method that fuses the entire assembly together at high temperature. This may not be needed unless you intend to seal the device permanently (and even then, a good two-part Epoxy will likely be adequate).

Cheap Sources of Magnet Wire

It has been suggested that transformers, inductors, and TV/monitor deflection coils are inexpensive or free sources of magnet wire. This may be OK for antennas or similar applications where the insulation isn't critical. However, unwinding those coils may result in damaged insulation as the wire is peeled apart since they tend to be impregnated with varnish. This makes the wire unsuitable for winding new coils. Unless, you have a way of dissolving the varnish without destroying the insulation, the risk of a random shorted turn or two (or many) buried beneath several thousand nice separate ones isn't worth it!

However, a nice source of fine magnet wire is relays and solenoids - many have very fine wire - #40 for example - and miles of it (well thousands of feet at lest). These are very often not varnished so they unwind easily (just don't let them unwind all over your junk drawer!).

- Back to Sam's Gadget FAQ Table of Contents.

Ideas for Things to do with High Voltage

(From: Robert Michaels (rrr@crush.wwnet.net).)

- Jacobs Ladder, Tesla Coil, CO2 and other home-built lasers, ersatz plasma globe(s) from clear light bulbs; investigate (or at least observe) spark and spark-gap behavior between electrodes made of various materials; Use of spark as an ignition source - for igniting paper, black powder, flash powder, firecrackers. combustible liquids, gases and mixtures of gases; with a rectifier (few bucks from surplus places) - DC phenomena, electrostatic precipitator

- If you have a vacuum pump in that "well-stocked workbench" collection, and you get hold of a rectifier, you are set to investigate all sorts of high-voltage discharge phenomena in partial vacuum and/or reduced pressure - that could keep me amused for weeks.

- Spark travel and propagation over surfaces (kind of a sub-set of my earlier suggestion about spark phenomena in general).

- Flame phenomena: Flames are highly ionized (hence, charged) and react in various ways to high voltages applied to them in one way or another.

- Spark-gap transmitter: Revisit the very earliest days of of radio by duplicating on a small scale the work of Hertz, Marconi, Fessenden, et. al. (Note that the operation of a spark-gap transmitter is unlawful in most jurisdictions - but - if you keep the power way down; use a small antenna; work in the dead of night; and keep transmissions *very* brief -

- High-voltage and photography: Great opportunity to combine two hobbies. Lictenberg Figures and Kirlian photography. There are also Kerr cell shutters, and microflash - both for ultra- brief bullet-stopping photographic exposures. There is also X-ray flash and microflash (for a photo of a bullet actually entering and traveling inside of - whatever - a block of wood -- a side of beef).

- I guess I may as well mentioned X-rays. Of course you need a small X-ray tube. Some of us have been successful in finding, begging, borrowing, such. They can of course be bought - but usually we claim to have no money. :) 10 kV (actually 14.14-kV peak) gives rather soft (but still usable) X-rays, which brings me to:

- Voltage multipliers, impulse generators (a la Marx, Cockcroft-Walton, and many others). You need rectifiers and (homemade perhaps) capacitors. Multiplications of 3X and 4X are attainable without too much effort, 6x, 7x maybe achievable.

- Kissing-cousin to spark-gap radio transmitters is the singing-arc. Although it is an arc phenomena rather than a spark phenomena, you can use your transformer all the same to good advantage. A singing- arc circuit is essentially the same as that for a spark-gap radio transmitter except it is tuned for audio frequencies. (You can imagine the rest).

- There's always Van DeGraaff Generators - the kind charged by an external high voltage power supply. Of course you need a rectifier to get the DC required.

- Crystal phenomena: Certain crystals, such as those of Potassium Chloride, develop what are called color centers when exposed to prolonged, intense, high-voltage fields (and for that matter to strong x-rays as well).

- There is also X-ray crystallography to be investigated when you get that X-ray tube. Fortunately it does not require much power or hardness from the X-rays/tubes. Investigators have spent an entire career in this field alone - it ought to keep you occupied for at least a couple of weekends.

- Plant growth: Are you any kind of a gardener, whether inside or out? Plants are greatly influenced by the presense of an electric field - AC, DC, positive polarity, negative polarity - hey each have their effects. (Watch your fingers as you do the watering!)

- Ozone generation. Be careful. Ozone is considerably more toxic than many realize. It's approximately the same as hydrogen cyanide (HCN). Fortunately Ozone has a much stronger aroma in small concentrations.

- Back to Sam's Gadget FAQ Table of Contents.

Dangerous (or Useful) Parts in a Dead Microwave Oven

A microwave oven with its power cord cut or removed AND its high voltage capacitor safely discharged is an inanimate object. There are no particularly hazardous parts inside. Of course, heavy transformers can smash your feet and sharp sheet metal can cut flesh. And, the magnets in the magnetron may erase your diskettes or mess up the colors on your TV.

Some may feel there is nothing of interest inside a microwave oven. I would counter that anything unfamiliar can be of immense educational value to children of all ages. With appropriate supervision, an investigation of the inside of a deceased microwave oven can be very interesting.

However, before you cannibalize your old oven, consider that many of the parts are interchangeable and may be useful should your *new* oven ever need repair!

For the hobbiest, there are, in fact, some useful devices inside:

- Motors - cooling fan and turntable (if used). These usually operate on 115 VAC but some may use low voltage DC. They can easily be adapted to other uses.

- Controller and touchpad - digital timer, relay and/or triac control of the AC power. See the section: Using the Control Panel from Defunct Microwave Oven as an Electronic Timer.

- Interlock switches - 3 or more high current microswitches.

- Heavy duty power cord, fuse holder, thermal protector, other miscellaneous parts.

- High voltage components (VERY DANGEROUS if powered) - Typical HV transformer (1,500 to 2,500 VRMS, 0.5 A - see the section: Microwave Oven Transformers), HV rectifier (12 to 15 kV PRV, 0.5 A), and HV capacitor (approximately 1 uF, up to 1,500 to 2,500 VAC (4,200 to 7,000

VDC).

- Magnetron - there are some nifty powerful magnets as part of the assembly. Take appropriate precautions to protect your credit cards, diskettes, and mechanical wristwatches. See the section: Neat Magnets and the document: Notes on the Troubleshooting and Repair of Microwave Ovens for more info.

DOUBLE WARNING: Do not even think about powering the magnetron once you have removed any parts or altered anything mechanical in the oven. Dangerous microwave leakage is possible.

Microwave Oven Transformers

The high voltage transformers from discarded microwave ovens can be put to many useful purposes. Ther are LARGE and can easily handle a kW or more, And due to their construction with separate and distinct windings for the 115 VAC primary, filament, and HV, are much more easily modified compared to typical power transformers with all the windings on top of one-another.

However, these transformers are designed with the bare minimum of copper so without a load, they still draw several amps from the power line. Therefore, they are most suitable for applications where a heavy sustained load is involved - not for that isolation transformer used mostly for testing (20 W) laptop switchmode power supplies! Figure things like arc or spot welding, battery charging, shaker table drivers, aluminum ring levitation (remember that science museum demo?), and other low voltage high current experiments. I am not recommending these for your 1 kW class A audio amp because of they are not generally rated for continuous duty and tend to hum - but you could try especially if you add some cooling.

Note that very few microwave oven failures are due to transformer problems. And, even those that are, likely mean that the HV or filament windings are to blame - neither of which you will likely be using (unless you want the 1.5 to 2.5 kVRMS at 0.5 A or so they put out).

Aside from the dead microwave oven(s) you may have around the house and your friends' and relatives' houses, try the local dump and repair shops - but you may have to convince them that you know what you are doing and of course be willing to haul away the entire carcass, not just the transformer!

WARNING: The intact microwave oven transformer is extremely dangerous when powered. (When not powered, about all it can do is smash your foot.) That 1.5 to 2.5 kVRMS at 0.5 A or more is an instantly deadly combination. Take extreme care if you have any idea about using the transformer without modifications. In addition, since it is so LARGE, any windings you add are also going to be capable of high current and could quite easily end up arc welding or burning things you didn't intend!

Assuming you are not using the HV or filament windings, the first step is to remove them. The filament winding is only 2 to 3 turns of heavy wire and easily extracted. However, the HV winding is likely to require the services of one or more of the following: a chisel, hacksaw, ax, blowtorch, heavy cutters, drill. (And, make sure your accident insurance is paid up for the required trip to the ER to stitch up your hand afterwards.)

Once these windings are gone, there is plenty of core area to wind your own new ones.

- Confirm that the primary is good. Power the transformer at normal line voltage and make sure it doesn't draw excessive current. As noted above, with no load, a few amps due to magnetizing current and core saturation is normal. However, it shouldn't trip your 15 A line fuse!

- Determine the V/turn rating. This is likely to be around 1 V/turn for the typical design which uses just enough copper to prevent excessive overhating. Just wrap 10 turns of insulated wire on the core, power up the primary at normal line voltage, and measure the voltage across your 10 turn secondary with a multimeter. Divide this by 10 to determine the V/turn rating.

- For each secondary, determine the wire size you will need based on your current requirements. A rough guideline would be to keep the total heat dissipation for the secondary to under 25 W. As an example, suppose you want 25 VRMS at 40 A. Then, R needs to be less than .015 ohms. Assuming a 1 V/turn transformer with an average turn length of 10 inches (36 feet of wire), this results in a wire size of at least #6 AWG (or 4 'strands' of #12 AWG wire). Fatter wire won't hurt if it will fit.

- Wrap the core with insulating tape. For light duty use, this can simply be plastic electrical tape. However, proper transformer insulating material should be used for serious applications.

- Wind your secondary or secondaries. For maximum fill, the use of proper magnet wire - even special square wire - is desirable. However, for a couple of turns here and there, any insulated wire of suitable size will do. For extended operation, make sure the insulation is rated for high temperature use.

Using the Control Panel from Defunct Microwave Oven as an Electronic Timer

It is usually possible to remove just the touchpad and controller board to use as a stand-alone timer with a switched output. Be careful when disconnecting the touchpanel as the printed flex cable is fragile. With many models, the touchpanel (membrane touchpad) needs to be peeled off of the front plastic panel or the entire assembly can be removed intact.

The output will control a 10 to 15 A AC load using its built in relay or triac (though these may be mounted separately in the oven). Note that power on a microwave oven is regulated by slow pulse width modulation - order of a 30 second cycle if this matters. If it uses a triac, the triac is NOT phase angle controlled - just switched on or off.

- Back to Sam's Gadget FAQ Table of Contents.

The Zap in Scripto Lighters and Gas Grill Ignitors

Some types of disposable lighters contain a piezo electric element (instead of a flint and wheel) which generates a spark to ignite the butane gas. Pressing down on the activator drives an escapement which results in a bar hitting the piezo element.

The result is several thousand volts on demand with its output available at a couple of terminals. This can be used to trigger xenon tubes or even to start helium neon lasers (with the addition of a pair of high voltage diodes to form a charge pump). Or as a prod for small cattle, but I didn't say that. :-) For a discussion of the HeNe laser application, see the document: Sam's Laser FAQ.

Detaching the piezo assembly only requires bending back and removing the sheet metal shroud at the top of the lighter. The entire piezo unit then just pops out.

Gas grill ignitors are similar - and even more powerful. These are available as replacement parts at your local home center or appliance store. (Don't steal the one from the family gas grill - your dad won't be happy.) Ditto for piezo matches. Once the gas is used up in these, you're the only one who will want them anyhow. :)

- Back to Sam's Gadget FAQ Table of Contents.

Useful Parts in a Battery Powered Electronic Flash

These units are found in both pocket cameras (regular 35 mm, older 110 or 126, as well as disposable 'single use' types), and external flash units. Larger, more sophisticated models will have proportionately larger components but the basic circuits are very similar.

For information on how these things work, see the document: Sam's Strobe FAQ - Notes on the Troubleshooting and Repair of Electronic Flash Units and Strobe Lights which also includes many many sample circuits. Two popular designs from Kodak disposable camera flashes are:

- Kodak Funsaver with Flash Schematic.
- Kodak MAX Flash Schematic and Photo. Many newer Kodak disposable cameras including the "Funsaver Sure Flash" appear to use a similar if not identical circuit though some parts may be surface mount. I've heard that some APS (Advanced Photo System) "ADVANTIX" are powered by a pair of AAA cells instead of the single AA used in most other units, so their design may differ somewhat but I haven't disassembled one of those as yet.

For detailed instructions on disassembling the Kodak MAX camera to safely remove the flash unit and some simple modifications, see Don's Hack Kodak MAX to Strobe Page. Details on other cameras will differ but this information should alert you as to what to avoid touching.

WARNING: The energy storage capacitor in even the tiny flash from a disposable camera may hold a painful, if not lethal, charge for days or longer. Always remove the battery first and then make sure to check and, if necessary, safely discharge this large capacitor before touching anything!

The major parts present in all units include:

- Chopper transistor - high gain power transistor to drive the inverter. For pocket cameras, typical part numbers are: 2SD965, 2SD879, 2SD1960, etc. These are low voltage (20 to 40 V) NPN (though some may use PNP), high current (e.g., 5 A), with Hfes in the 400 to 600 range.

- Inverter transformer - Generates the 300+ VDC to charge the energy storage capacitor. Includes a primary drive winding of 5 to 15 turns, similar feedback winding (maybe), and 1,000 to 2,000 turn high voltage secondary.

- Energy storage capacitor - 120 to 500 uF or more, 330 to 400 V, photoflash rated (rapid discharge) electrolytic. Note: These usually do not have a high temperature rating - 55 DegreesC typical. WARNING: Can be lethal if even partially charged!

- Neon (normal or 200 V breakdown) or other ready indicator.

- Trigger transformer - generates a 4 to 8 kV pulse to fire the xenon tube from a small 150 to 300 V capacitor discharge. Includes a primary of about 12 turns, secondary of 350 to 450 turns.

- Xenon flashtube - usually between 1 and 2 inches in length. These require a 300 to 400 V energy storage capacitor, 4 to 8 kV trigger, and can handle 10 to 30 W-s flash energy.

And, in the disposable cameras, there is likely to be a very nearly fresh Alkaline cell unless the place you obtained them from knew this and beat you to it! :)

Automatic types will have additional components including the following:

- Quenchtube - looks like an oversize neon light bulb but filled with xenon and triggered in a similar way to the main flashtube.

- Trigger transformer for the quenchtube - similar to the main trigger transformer.

- Thyristor (SCR) - in series with the flashtube used in energy conserving automatic flash unitsx.

- Photosensor - used to read light reflected from scene to set exposure.

There will also be a variety of other small electronic components possibly including fancy microchips in TTL (Through The Lens) programmable units.

Note: To remove individual components without destroying either the PCB or the component, you must use a proper desoldering technique. If too much heat is used for too long, I've heard that the HV winding inside the transformer may become detached which renders it useless. And, the PCB will certainly be damaged. I generally use a desoldering pump like Solda-Pullet(tm), (not the cheap short one) but this can still damage the fine PCB traces. The use of copper braid with rosin like Solder Wick(tm) may be gentler.

Also see the document: Sam's Schematic Collection - Various Schematics and Diagrams for possible useful modifications to inverters like the one from the Kodak MAX Flash.

- Back to Sam's Gadget FAQ Table of Contents.

Useful Parts in a Non-Working VCR

- Motors: 1 to 6 motors of various types. Mostly these are cheap DC permanent magnet motors but the main capstan motor may be a high quality brushless type with electronic control on-board. The video drum motor is likely three phase with its own controller.

- Power supply: Outputs various voltages and may be used intact but will always contain useful components like transistors and diodes, transformer(s), and large capacitors.

- Tuner. Whether you can make this work without the rest of the VCR is problematic but worth a try.

- RF modulator. This usually accepts a DC voltage for power, a control voltage to select TV/VCR, and will output on channel 3 or 4.

- IR receiver module (for remote control). It is usually possible to power this from a DC supply (5 or 12 VDC typical) to convert the IR signal from remote controls (probably not just the one that came with the VCR) to a logic level output.

- Miscellaneous electronic components including crystals, delay lines, video and audio ICs, pots, connectors, etc.

What can you build with it? One can never tell! :-)

---

Useful Parts in a CD, DVD, LaserDisc, or Other Optical Disc/k Device

All of these devices are basically need to perform similar functions though the specific implementation can differ considerably. Usually, the older the equipment, the more good stuff it yields. Modern CD and DVD drives have almost everything laser and optics related in a little tiny optical pickup block which may not be easy to disassemble. However, 20 year old CD players have much larger optical assemblies with larger numbers of distinct parts. All CD players, CDROM drives, and other common optical storage devices use infra-red laser diodes usually around 780 nm. For all intents and purposes, this is invisible and they make truly lousy laser pointers. DVD players are so new that few cast-offs are available but they, at least, use visible red (635 to 650 nm) laser diodes. Really old LaserDisc players use red helium-neon lasers (actually appears orange-red, 632.8 nm) with possibly even separate focus and tracking mirrors on galvo-like devices which can be easily converted into a simple laser show.

* The laser itself - For really old LaserDisc players, this is a helium-neon gas laser tube (probably linearly polarized) and high voltage power supply. All the others use diode lasers which require current limited drivers to prevent instant destruction. The output power of these lasers is usually less than 5 mW except for writeable optical drives which may go up to 30 mW (but IR) or more.

* Optics - May include lenses, mirrors, beam splitters, 1/4 wave plates, diffraction gratings, and other unidentified optical elements. Depending on the application, these may be optimized for the laser's wavelength. Thus, an IR mirror may actually look more or less transparent. The objective lens and/or other mirrors may be on electromagnetic positioning devices.

* Motors - For spindle, sled movement, drawer open/close, etc. Some are common DC permanent magnet types while the spindle motor may be a brushless DC type. Some CDROM and other use storage drives linear motors to directly position the optical pickup sled.

* Mechanical parts - Gears, racks, rails, pulleys, belts, etc.

* Power supply components - Transformer, regulator(s), transistors, capacitors, etc.

* Other electronic components - Microswitches, opto-interrupters, solenoids, etc. Ironically, the high-tech chips are probably not work unsoldering. :(

See the documents: "Notes on the Troubleshooting and Repair of CD Players and CDROM Drives" and "Notes on the Troubleshooting and Repair of Optical Disc Players and Optical Data Storage Drives" for information on how this equipment works.

WARNING: In addition to electrical and mechanical dangers, the laser may emit levels of visible or invisible radiation that is potentially harmful to vision.

There is much more info on their laser and optics [Sam's Laser FAQ].

Wayne's Notes on Salvaging Parts from Pioneer LaserDisc Players (From: Equinox (eso@pacific.com).)

I have taken apart several of Pioneers old video disc units, I cannot remember the model #'s right now.

The units I had contained the following items that I found of value and kept. Yours should be the same or similar, as all units that I took apart, internally were very similar.

- The laser - A bare HeNe laser tube producing a red beam rated at 1 mW or less, about 8 "long.
- The laser power supply - A small circuit board with a flyback transformer with obvious high voltage white rubbery wires going to the laser tube.
- Large transformer - The laser power supply gets it's input voltage from the main stepdown/up transformer of the entire system. it put out around 700 VAC to work the laser power supply, as well as the analog and digital DC voltages for the rest of the player. Keep it! Your laser power supply board may be useless without it.
- Small X-Y galvo - Dual voice coil assembly to deflect the beam. (In some models, this may be similar/identical to Meredith's GAL-2.)
- Small diffraction grating in round brass housing producing 3 beams if I remember correctly.
- Beam splitter, 2 adjustable mirrors, photo detector and preamp, other optics.
- Voice coil actuated focusing assembly - This looks like a speaker magnet with a hollow center with a lens. It sort of looks like a mechanical eyeball from the top - Used to focus the beam on the disc.
- DC motor with analog tach output - drove the disc Small geared down DC motor - found near and controls the assembly that houses the optics controlling the translation of the beam/optics across the disc.

Disassemble the unit with care. Be careful if you start cutting wires, as the laser power supply has DC control voltages used to enable/disable high voltage output of the laser supply. It may also have other DC voltages used to assist in HV generation. Count the wires coming off of the board and follow and note where they go. You need to know the DC voltages on these wires.

With care and the forethought that you are working with 110 VAC, 700 VAC and more than a kV for the laser, you can measure the voltages in, and enable/disable the safety interlock and see which line it triggers. The interlock switches (2?) were a metal tab activated switch in the back of the lid, and I think part of the latch gizmo near the front of the system had one.

(From: Chris Hoaglin (choaglin@aol.com).)

Inside Maxoptix magneto-optical drives, there are quite a few small mirrors, lenses, beam splitters, etc. The models I've taken apart have been the Tahiti II model. These drives also have a very nice actuator. The laser diode isn't even on the part which emits the beam against the disc, it's mounted on the frame of the drive and reflected against the disc by a mirror mounted on the bottom of the part that moves back and forth. The actuator assembly might be useful for experimentation as well, since It's very sturdy (It rides on two metal shafts and has small metal wheels which keep in contact with the shafts). It has a coil and magnet arrangement on each side. All the optics are on small removable mounts as well, so they'd be easy to put to other uses. I believe the wavelength being used is IR, but they might work for visible stuff as well.

How and where to find them: The drive is a full height 5.25" drive. Looks a bit like an ESDI drive, except for the slot on the front to insert the MO disk, of course. A good place to look for them might be places which do data storage, or use workstations (DEC, Sun, etc.) I don't think they're used much on the PC platform.

Also, I noticed today while reading Lasers and Optronics that several outfits are offering OEM modules which incorporate 400 nm diodes. Sooner or later people will start scrapping equipment that uses them, although probably not for a few years.

- Back to Sam's Gadget FAQ Table of Contents.

Useful Parts in a Laser Printer or Laser Fax

All modern laser printers use IR diode lasers of 5 to 30 mW maximum output. Very old laser printers used helium-neon lasers but these are even rarer than HeNe laser based LaserDisc players. However, if you do find one, there will likely also be an Acousto-Optic Modulator (AOM) and driver since directly controlling HeNe lasers at high speed isn't feasible - don't neglect these very desirable components!

- Laser - Usually semiconductor laser diode mounted in assembly with collimating lens and other optics. Its output is a nearly parallel beam 1 or 2 mm in diameter.

- Laser diode driver - Usually a circuit board in close proximity to the laser diode which provides power and modulation capability. Reverse engineering and luck may be required to figure out how to use it.

- Thermo-electric cooler - I don't know how common this is but some laser printers have/had a nice little Peltier device to maintain the laser diode at a constant temperature. There would be an electronics board associated with the actual device.

- Multifaceted scanner - A polygonal mirror (usually metal coated) on a high quality brushless DC motor. The constant speed controller may be a part of the motor assembly with only a few interface signals to power and run it.

- Objective lenses - 2 or 3 lenses that look cylindrical may actually be just relatively thin sections of normal lenses or anamorphic with different focal lengths in the two axis. Due to their shape, they may be of questionable utility for other purposes.

- Mirrors - 1 or 2 long strip mirrors that may be metal coated (with a copper tinge for IR laser printers) or dichroic coated. Note that while these appear to be planar, they may in fact have a slight curvature along the narrow axis. The dichroic types may be of very high (laser resonator) quality but if frosted on the opposite surface, of limited utility since any transmitted beam is dispersed.

- Fiber optic sensor - Canon engines have this situated at the one end of the scan line to detect the beam and provide a time reference.

- Motors - In addition to the scanner, there will be a main AC line driven for paper movement. There will also be 1 or 2 fans.

- Mechanical parts - rollers, gears, pulleys, clutches, bearings, you name it - lot's of useful stuff.

- HV power supply - Usually a self-contained module which generates the corona voltages. Up to 6 kV or more but microamps of current.

- LV power supply components - Depending on whether a switchmode or linear power supply is used, there could be a variety of useful parts and possibly the complete power supply as a separate unit.

- Toner/Developer - There will be a long, moderately powerful magnet associated with the toner distribution system, probably inside an aluminum cylinder. The toner cartridge or built-in mechanism will also include other useful parts but is extremely icky and messy to disassemble.

- Fuser lamp and power supply - Quartz halogen lamp and triac controlled power supply with temperature sensor.

- Other electronic components - Again, the high-tech parts may be less useful than the simple things. :)

- Fax machine components (where applicable) - Include a cold cathode fluorescent lamp for the light source and linear CCD image sensor with associated electronics.

I'm sure I've missed some major parts.

See the document: "Notes on the Troubleshooting and Repair of Printers and Photocopiers" for information on how this equipment works as well as warnings and precautions with respect to the hazards of toner dust.

WARNING: In addition to electrical and mechanical dangers, the laser may emit levels of visible or invisible radiation that is potentially harmful to vision.

There is much more info on their laser and optics Sam's Laser FAQ.

- Back to Sam's Gadget FAQ Table of Contents.

Useful Parts in a Photocopier

There are mostly similar to laser printers, above. However, instead of a laser, the light source is usually a halogen or high intensity fluorescent lamp. Most other parts are similar and similar precautions with respect to toner apply. Copiers are likely to use toner cartridges having the various components such as the photosensitive drum, toner reservoir, and developer as separate units. Thus, they are more likely to have gobs of messy toner all over the interior when you finally get your hands on them!

Items in place of the laser of a laser printer include:

- Light source - a linear quartz halogen lamp is most likely. Some may use a special fluorescent lamp instead. In either case, the needed power supply or ballast will be included - don't miss it!
- Optics - Several mirrors and a high quality objective lens. The large tempered glass plate on which the material to be copied sits is also useful.
- Additional mechanical parts - Include those for paper selection and sorting, two sided copying, and so forth.

See the section: Useful Parts in a Laser Printer or Laser FAX for more information.

- Back to Sam's Gadget FAQ Table of Contents.

Useful Parts in a Barcode Scanner

The types mostly likely to show up surplus are helium-neon laser based supermarket checkout scanners that have been replaced by more modern diode laser based equipment but are probably still operational.

Looking through the glass of the scanner, it may appear that all sorts of stuff is arranged at random. However, this is not the case. :) For more information on how barcode scanners operate, see the chapter: "Laser Instruments and Applications" in Sam's Laser FAQ.

- Laser - The source of the beam is either a low power helium-neon (HeNe) or diode laser. Older (and larger) scanners tended to use HeNe lasers. However, size alone is no sure indication until you get to very small (6 inch cubes or hand-held wands) which are almost always based on diode lasers (if they use a laser at all). A better test is to check the color of the beam - the light from HeNe laser based scanners appears orange-red (632.8 nm) while that from diode laser based scanners tends to be a deep red from the 670 nm wavelength which is less expensive (but just as effective). Just explain that you are doing scientific research when the people in the white coats come to take you away for staring into the scanner! :)

    - HeNe lasers are typically 1 to 3 mW (mostly near 1 mW) using tubes between 5 and 10 inches in length. The tube will probably be mounted on brackets and will be easily replaceable. Some scanners use HeNe tubes with larger than diffraction limited divergence to simplify the optical system down the line. Where an external lens is actually glued to the output mirror of the HeNe tube, it can probably be removed with a suitable solvent or heat leaving a low divergence tube. See the chapter: "The Home-Built Laser Assembly and Power Supply" chapter of Sam's Laser FAQ for more details. Or, simply locate the collimating lens that is present in the scanner or one of your own and use that to adjust the divergence as desired.

      The HeNe laser power supply may be a self-contained 'brick' or built onto the mainboard.

    - Diode lasers are typically 670 nm (deep red) with 5 mW maximum output. A collimating lens and possibly some other optics will be part of the diode laser assembly.

      The laser diode driver circuit will be in close proximity to the laser diode itself and may be on a separate board. However, it is most likely part of the mainboard. and difficult to determine correct use without a schematic.

- Variable attenuator - A graded density filter may be present immediately following the laser's output to adjust the beam intensity to compensate for variations in laser power (mostly for HeNe lasers - diode lasers will have a pot for this purpose).

- Turning mirror(s) - There may be one or more high quality planar first surface or dichroic mirrors to direct the beam. Their mount will probably be adjustable in X and Y to some extent.

- Main objective combo - This consists of a large (probably plastic molded) convex lens with a hole in its center in which a prism, mirror, and/or lens may be inset.

  The components of the this part can generally be separated to use individually using a combination of brute force and solvents. For example, to remove the lens and prism from the combo in the Orien 300, a pad of tissue paper is inserted in the hole followed by a wooden dowel that just fits. A couple of whacks to the dowel with a small hammer while holding the assembly should result in the prism/lens popping free. They can then be separated by soaking in acetone.

WARNING: Acetone and its vapors are flammable and toxic.

CAUTION: Acetone will also damage many plastics including most likely, the large plastic lens, so don't let it contact that or other plastic optical components.

- Multifaceted rotating mirror - The collimated outgoing is deflected by a 3 to 6 facet polygonal mirror directly driven by a speed regulated brushless DC motor. The motor/scanner assembly is generally a separate module in older equipment requiring only DC power and an enable signal to run. However, newer ones may be mounted directly on the mainboard.

  Unlike those in a laser printer, the mirror facets are large since they have to reflect the diffuse return beam as well as the tiny spot of the outgoing beam. They are fabricated as individual mirrors glued to a cast metal wheel type affair and are all set at slightly different angles so that each rotation of the mirror wheel results in scan lines at 3 to 6 slightly different locations depending on the number of facets.

- Multiple planar mirrors - These are usually decent quality aluminized first surface mirrors and could find all sorts of other uses. Although generally shaped as strange 4 sided polygons, they can be subdivided into more useful sizes using a glass cutter from the rear or a water-cooled diamond cutoff wheel.

- Photodetector - A silicon photodiode, often of moderate area (typically 2x2 mm, good for a laser power meter) There may be an additional focusing lens and/or red ambient light blocking filter associated with the photodetector.

- Electronic components - Include a microprocessor, RS232 or other interface, etc. However, these may not be very useful for other purposes.

- Power supply - Depending on the model, these may plug directly into the AC line or be powered from a wall adapter.

DISCLAIMER

Careless troubleshooting of a microwave oven can result in death or worse. Experienced technicians have met their maker as a result of a momentary lapse of judgement while testing an oven with the cover removed. Microwave ovens are without a doubt, the most deadly type of consumer electronic equipment in wide spread use.

The power supplies for even the smallest microwave ovens operate at extremely lethal voltage and current levels. Do not attempt to troubleshoot, repair, or modify such equipment without understanding and following ALL of the relevant safety guidelines for high voltage and/or line connected electrical and electronic systems.

We will not be responsible for damage to equipment, your ego, county wide power outages, spontaneously generated mini (or larger) black holes, planetary disruptions, or personal injury or worse that may result from the use of this material.

- Back to Microwave Oven Repair FAQ Table of Contents.

Introduction

Radar Range anyone?

Remember when you actually had to use the real oven to defrost a TV dinner? Think back - way back - before VCRs, before PCs (and yes, before Apple computers as well), almost before dinosaurs, it would seem. There was a time when the term 'nuke' was not used for anything other than bombs and power reactors.

For a long time, there was controversy as to whether microwave ovens were safe - in terms of microwave emissions and molecular damage to the food. Whether these issues have been resolved or just brushed aside is not totally clear. Nonetheless, the microwave oven has taken its place in virtually every kitchen on the planet. Connoisseurs of fine dining will turn up their collective noses at the thought of using a microwave oven for much beyond boiling water - if that. However, it is difficult to deny the convenience and cooking speed that is provided by this relatively simple appliance.

Microwave ovens are extremely reliable devices. There is a good chance that your oven will operate for 10 years or more without requiring repairs of any kind - and at performance levels indistinguishable from when it was first taken out of the box. Unlike other consumer electronics where a new model is introduced every 20 minutes - some even have useful improvements - the microwave oven has not changed substantially in the last 20 years. Cooking is cooking. Touchpads are now nearly universal because they are cheaper to manufacture than mechanical timers (and also more convenient). However, an old microwave oven will heat foods just as well as a brand new one.

This document provides maintenance and repair information applicable to most of the microwave ovens in existence. It will enable you to quickly determine the likely cause and estimate the cost of parts. You will be able to make an informed decision as to whether a new oven is the better alternative. With minor exceptions, specific manufacturers and models will not be covered as there are so many variations that such a treatment would require a huge and very detailed text. Rather, the most common problems will be addressed and enough basic principles of operation will be provided to enable you to narrow the problem down and likely determine a course of action for repair. In many cases, you will be able to do what is required for a fraction of the cost that would be charged by a repair center - or - be able to revive something that would otherwise have gone into the dumpster or continued in its present occupation as a door stop or foot rest.

Should you still not be able to find a solution, you will have learned a great deal and be able to ask appropriate questions and supply relevant information if you decide to post to sci.electronics.repair. In any case, you will have the satisfaction of knowing you did as much as you could before taking it in for professional repair. You will be able to decide if it is worth the cost of a repair as well. With your new-found knowledge, you will have the upper hand and will not easily be snowed by a dishonest or incompetent technician.

On-line microwave oven repair database

Microtech maintains a web site with a large amount of information on microwave oven repair including an on-line Tech Tips Database with hundreds of solutions to common problem for many models of microwave ovens. There are also an extensive list of microwave oven related links to other interesting sites (including this document!). The comprehensive Safety Info is a must read as well. Not entirely coincidentally, I assume, some of its wording appears remarkably familiar! Microtech also offers instructional videos and books on microwave oven and VCR repair.

It is quite possible your problem is already covered at the Microtech site. In that case, you can greatly simplify your troubleshooting or at least confirm a diagnosis before ordering parts. My only reservation with respect to tech tips databases in general - this has nothing to do with Microtech in particular - is that symptoms can sometimes be deceiving and a solution that works in one instance may not apply to your specific problem. Therefore, an understanding of the hows and whys of the equipment along with some good old fashioned testing is highly desirable to minimize the risk of replacing parts that turn out not to be bad.

Jim Bryant's Microwave Ovens page is another site worth visiting. While he deals mostly with models in the UK, he will answer questions via email and includes links to many USA microwave oven manufacturers and parts suppliers.

Expert system for microwave oven fault diagnosis

The MIDES (Microwave Oven Diagnosis Expert System) site represents an interesting and possibly useful approach for isolating the cause of many common failures. It will take you through a customized step-by-step procedure based on your symptoms (and specific microwave oven model in some cases) and the results of its suggested tests. For the novice, this may be an effective way of obtaining a solution quickly as long as you follow the extremely important safety information provided by MIDES (or this document). You will not be forced to acknowledge that you have read, understood, and followed their safety precautions and warnings before performing each test.

The simplest problems

- Bad interlocks switches or door misalignment causing fuses to blow or no operation when the start button is pressed. Locate and replace defective switches and/or realign door.

- Arcing in oven chamber: clean oven chamber and waveguide thoroughly. Replace carbonized or damaged waveguide cover. Smooth rough metal edges. Touch up the interior paint.

- Blown fuse due to power surge or old age: Replace fuse. On rare occasions, the main fuse may even be intermittent causing very strange symptoms.

- An MOV, probably on the controller, may have shorted due to a power surge blowing the controller fuse. Remove remains of MOV, replace fuse and test, replace MOV for future surge protection.

- Erratic touchpad operation due to spill - let touchpad dry out for a week.

- Bugs in the works - the controller circuit board is a nice warm safe cozy place to raise a family.....

More detailed explanations are provided elsewhere in this document.

Repair or replace?

With small to medium size microwave ovens going for $60-100 it hardly makes sense to spend $60 to have one repaired. Even full size microwave ovens with full featured touchpanel can be had for under $200. Thus, replacement should be considered seriously before sinking a large investment into an older oven.

However, if you can do the repair yourself, the equation changes dramatically as your parts costs will be 1/2 to 1/4 of what a professional will charge and of course your time is free. The educational aspects may also be appealing. You will learn a lot in the process. Many problems can be solved quickly and inexpensively. Fixing an old microwave for the dorm room may just make sense after all.

- Back to Microwave Oven Repair FAQ Table of Contents.

Installation and Preventive Maintenance

Microwave oven installation and use

To assure safety and convenient, follow these recommendations:

- Read your users manual from cover to cover especially if this is your first microwave. What a concept! If nothing else, you may discover that your oven has features you were not aware were even possible. In any case, there may be requirements or suggestions that are specific to your model and will enable you to get the most performance from your new microwave.

- Select a stand-alone unit rather than a built-in if possible. It will be cheaper to buy, cheaper and easier to service, and possibly more reliable since ventilation and adjacent heat producing appliances will not be as much of a factor.

- Select a convenient location - easy access and not too high or too low. This is particularly important if the door of the oven opens down instead of to the left side (only a few models are built this way, however).

- Put the microwave oven on its own dedicated 3 wire grounded circuit. Temporary use of a 3 to 2 prong adapter is acceptable only if the outlet box is properly grounded to begin with (BX, Romex, or conduit with ground) AND the adapter's ground wire or terminal is securely attached to the outlet box ground screw.

  Make sure the outlet is in good condition in either case. Check that the plug (or adapter) fits tightly and that there is no appreciable heating of the outlet during use of the microwave oven. If there is, spread the metal strips of each of the prongs apart if possible and/or replace the outlet.

  A grounded outlet is essential for safety. Microwave ovens are high power devices and a separate circuit will eliminate nuisance fuse blowing or circuit breaker tripping when multiple appliances are being used at the same time. It will also minimize the possibility of Radio Frequency Interference (RFI) between it and any electronic equipment which might be on the same circuit. A GFCI is not needed as long as the outlet is properly grounded and may result in nuisance tripping with some microwave ovens.

  Inexpensice outlet testers are available at hardware stores, home centers, and electrical parts distributors, to confirm that the outlet is properly wired and grounded.

- Allow adequate ventilation - do not push it up against the wall or wedge it under a tight fitting wall cabinet (or inside one for that matter!). Leave at least 2 inches on all sides and top if possible.

- Do not let children use the microwave oven unless properly supervised. It is very easy to cause a fire through the use of excessive times or power settings. Even something as simple as microwave popcorn can explode and/or catch fire if heated for too long - e.g., 5 minutes instead of my precisely determined 3:41 on high :-).

Microwave oven maintenance

Most people do not do anything to maintain a microwave oven. While not much is needed, regular cleaning at least will avoid potentially expensive repairs in the future:

- Clean the interior of the oven chamber after use with a damp cloth and some detergent if necessary. Built up food deposits can eventually carbonize resulting in sparks, arcs, heating, and damage to the mica waveguide cover and interior paint - as well as potentially more serious damage to the magnetron. If there is any chance of food deposits having made their way above the waveguide cover in the roof of the chamber, remove the waveguide cover and thoroughly clean inside the waveguide as well.

- Clean the exterior of the cabinet and touchpad in a similar manner. DO NOT use a spray where any can find its way inside through the door latch or ventilation holes, or a dripping wet cloth. Be especially careful around the area of the touchpad since liquid can seep underneath resulting in unresponsive or stuck buttons or erratic operation. Do not use strong solvents (though a bit of isopropyl alcohol is fine if needed to remove sticky residue from unwanted labels, for example).

- Inspect the cord and plug for physical damage and to make sure the plug is secure and tight in the outlet - particularly if the unit is installed inside a cabinet (yes, I know it is difficult to get at but I warned you about that!). Heat, especially from a combination microwave/convection oven or from other heat producing appliances can damage the plug and/or cord. If there is evidence of overheating at the outlet itself, the outlet (and possibly the plug as well) should be replaced.

- Periodically check for built up dust and dirt around the ventilation holes or grills. Clean them up and use a vacuum cleaner to suck up loose dust. Keeping the ventilation free will minimize the chance of overheating.

- Listen for any unusual sounds coming from inside the oven. While these appliances are not exactly quiet, grinding, squealing, scraping, or other noises - especially if they were not there when the oven was new - may indicate the need for some more extensive maintenance like belt replacement or motor lubrication. Attending to these minor problems now may prevent major repairs in the future.

- Keep your kitchen clean. Yes, I know, this isn't exactly microwave specific but cockroaches and other uninvited guests might just like to take up residence inside the electronics bay of the oven on the nice warm controller circuit board or its neighborhood and they aren't generally the tidiest folks in the world.

  If it is too late and you have a recurring problem of cockroaches getting inside the electronics bay, tell them to get lost and then put window screen over the vents (or wherever they are entering). Such an open mesh should not affect the cooling of the electronic components significantly. However, the mesh will likely clog up more quickly than the original louvers so make sure it is cleaned regularly. If possible, clean up whatever is attracting the unwanted tenants (and anything they may have left behind including their eggs!!). WARNING: See the section: SAFETY before going inside.

CAUTION: Do not spray anything into the holes where the door latch is inserted or anywhere around the touchpad as this can result in internal short circuits and costly damage - or anywhere else inside, for that matter. If you do this by accident, immediately unplug the oven and let it dry out for a day or two.

How long does microwave energy hang around?

You have probably been warned by your mother: "Wait a few seconds (or minutes) after the beep for all the microwaves to disappear". There is no scientific basis for such a recommendation. Once the beep has sounded (or the door has opened), it is safe. This is because:

1. There is no such thing as residual microwave radiation from a microwave oven - it is either being produced or is non-existent.

2. There is little energy storage in the microwave generator compared to the amount being used. The typical high voltage capacitor - the only component that can store energy - has a capacity of less than 15 W-s (Watt-seconds) even for the largest ovens. Power consumption is typically 800 to 1500 W depending on oven size. Therefore, the capacitor will be fully drained in much less than .1 second - long before the beep has ended or the door has cleared the front panel. (Based on the numbers, above, for a 1500 W oven with a capacitor storing 15 W-s, it is more like .01 seconds!)

   WARNING: This only applies to a *working* microwave oven! If there is no heat, the magnetron may not be drawing any current from the HV power supply and the HV capacitor can remain charged for a long time. In this case, there is a very real risk of potentially lethal electrical shock even after several minutes or more of being unplugged! See the section: SAFETY if you will be troubleshooting a microwave oven.

- Back to Microwave Oven Repair FAQ Table of Contents.

Microwave Oven Troubleshooting

SAFETY

The following applies to microwave oven troubleshooting - once the cabinet cover is removed. There is also safety information on proper use of the oven in subsequent sections, below.

Please see Typical Microwave Oven Electronics Bay for parts identification.

WARNING! WARNING! WARNING! WARNING! WARNING! WARNING! WARNING! WARNING!

Microwave ovens are probably the most dangerous of consumer appliances to service. Very high voltages (up to 5000 V) at potentially very high currents (AMPs) are present when operating - deadly combination. These dangers do not go away even when unplugged as there is an energy storage device - a high voltage capacitor - that can retain a dangerous charge for a long time. If you have the slightest doubts about your knowledge and abilities to deal with these hazards, replace the oven or have it professionally repaired.

Careless troubleshooting of a microwave oven can not only can fry you from high voltages at relatively high currents but can microwave irradiate you as well. When you remove the metal cover of the microwave oven you expose yourself to dangerous - potentially lethal - electrical connections. You may also be exposed to potentially harmful levels of microwave emissions if you run the oven with the cover off and there is damage or misalignment to the waveguide to the oven chamber.

There is a high voltage capacitor in the microwave generator. Always ensure that it is totally discharged before even thinking about touching or probing anything in the high voltage power circuits. See the troubleshooting sections later in this document.

To prevent the possibility of extremely dangerous electric shock, unplug the oven from the AC outlet before removing the cover and do not plug it in to operate it with the cover off if at all possible. If you must probe live, remove the connections to the magnetron (see below) to prevent the inadvertent generation of microwaves except when this is absolutely needed during troubleshooting. Discharge the high voltage capacitor (with the oven unplugged) and then use clip leads to make any connections before you plug it in and apply power. Then after removing power and unplugging the oven discharge the HV capacitor once again.

WARNING: Experienced technicians have been electrocuted deader than a brick from even careful probing of the HV circuits of a powered microwave oven. Therefore, I highly recommend avoiding any probing of the HV circuits - nearly everything can be determined by inspection and component tests with the oven unplugged.

The microwave oven circuitry is especially hazardous because the return for the high voltage is the chassis - it is not isolated. In addition, the HV may exceed 5000 V peak with a continuous current rating of over .25 AMP at 50/60 Hz - the continuous power rating of the HV transformer may exceed 1500 W with short term availability of much greater power. Always observe high voltage protocol.

Safety guidelines

These guidelines are to protect you from potentially deadly electrical shock hazards as well as the equipment from accidental damage.

Note that the danger to you is not only in your body providing a conducting path, particularly through your heart. Any involuntary muscle contractions caused by a shock, while perhaps harmless in themselves, may cause collateral damage - there are many sharp edges inside this type of equipment as well as other electrically live parts you may contact accidentally.

The purpose of this set of guidelines is not to frighten you but rather to make you aware of the appropriate precautions. Repair of TVs, monitors, microwave ovens, and other consumer and industrial equipment can be both rewarding and economical. Just be sure that it is also safe!

- Don't work alone - in the event of an emergency another person's presence may be essential.

- Always keep one hand in your pocket when anywhere around a powered line-connected or high voltage system.

- Wear rubber bottom shoes or sneakers.

- Don't wear any jewelry or other articles that could accidentally contact circuitry and conduct current, or get caught in moving parts.

- Set up your work area away from possible grounds that you may accidentally contact.

- Know your equipment: TVs and monitors may use parts of the metal chassis as ground return yet the chassis may be electrically live with respect to the earth ground of the AC line. Microwave ovens use the chassis as ground return for the high voltage. In addition, do not assume that the chassis is a suitable ground for your test equipment!

- If circuit boards need to be removed from their mountings, put insulating material between the boards and anything they may short to. Hold them in place with string or electrical tape. Prop them up with insulation sticks - plastic or wood.

- If you need to probe, solder, or otherwise touch circuits with power off, discharge (across) large power supply filter capacitors with a 25 W or greater resistor of 5 to 50 ohms/V approximate value.

  For the microwave oven in particular, use a 25K to 100K 25 W resistor with a secure clip lead to the chassis. Mount the resistor on the end of a well insulated stick. Touch each of the capacitor terminals to the non-grounded end of the resistor for several seconds. Then, to be doubly sure that the capacitor if fully discharged, short across its terminals with the blade of a well insulated screwdriver. I also recommend leaving a clip lead shorting across the capacitor terminals while working as added insurance. At most, you will blow a fuse if you should forget to remove it when powering up the microwave.

- Connect/disconnect any test leads with the equipment unpowered and unplugged. Use clip leads or solder temporary wires to reach cramped locations or difficult to access locations.

- If you must probe live, put electrical tape over all but the last 1/16" of the test probes to avoid the possibility of an accidental short which could cause damage to various components. Clip the reference end of the meter or scope to the appropriate ground return so that you need to only probe with one hand.

- Perform as many tests as possible with power off and the equipment unplugged. For example, the semiconductors in the power supply section of a TV or monitor can be tested for short circuits with an ohmmeter.

- Use an isolation transformer if there is any chance of contacting line connected circuits. A Variac(tm) is not an isolation transformer! (See the next section with regards to isolation transformers and microwave ovens.) The use of a GFCI (Ground Fault Circuit Interrupter) protected outlet is a good idea but will not protect you from shock from many points in a line connected TV or monitor, or the high voltage side of a microwave oven, for example. A circuit breaker is too slow and insensitive to provide any protection for you or in many cases, your equipment. A GFCI may, however, prevent your scope probe ground from smoking should you accidentally connect an earth grounded scope to a live chassis.

- Don't attempt repair work when you are tired. Not only will you be more careless, but your primary diagnostic tool - deductive reasoning - will not be operating at full capacity.

- Finally, never assume anything without checking it out for yourself! Don't take shortcuts!

As noted, a GFCI (Ground Fault Circuit Interrupter) will NOT protect you from the high voltage since the secondary of the HV transformer is providing this current and any current drawn off of the secondary to ground will not be detected by the GFCI. However, use of a GFCI is desirable to minimize the risk of a shock from the line portions of the circuitry if you don't have an isolation transformer.

An isolation transformer is even limited value as well since the chassis IS the HV return and is a large very tempting place to touch, lean on, or brush up against.

And, of course, none of these devices will protect fools from themselves!

Take extreme care whenever working with the cover off of a microwave oven.

Isolation transformers and microwave ovens

There's little point to using an isolation transformer with a microwave for testing the high voltage circuitry. It would have to be HUGE due to the high power nature of a microwave oven and since the high voltage return is the chassis which is grounded, it won't be terribly useful as noted above. However, an isolation transformer can and should be used to test the primary side circuitry if necessary including interlocks, motors, triac/relay, etc. Disconnect the HV transformer to eliminate the possibility of high voltage shock and to reduce the load.

Actually, the best policy is to NEVER EVER attempt to measure anything in the HV section while the oven is powered - it's almost never needed in any case. Failures are usually easily found by performing test with the oven unplugged. If you insist on making live measurements, connect the meter before power is applied and disconnect or move its probes only after power is removed AND the HV cap has been discharged (even if the meter catches fire or explodes!). Qualified service people have been electrocuted using proper test equipment on microwave ovens!

Troubleshooting tips

Many problems have simple solutions. Don't immediately assume that your problem is some combination of esoteric complex convoluted failures. For a microwave oven, there may be a defective door interlock switch or just a tired fuse.

If you get stuck, sleep on it. Sometimes, just letting the problem bounce around in your head will lead to a different more successful approach or solution. Don't work when you are really tired - it is both dangerous (particularly with microwave ovens) and mostly non-productive (or possibly destructive - very destructive).

If you need to remove the cover or other disassembly, make notes of which screw went where - they may not all be identical. More notes is better than less.

Pill bottles, film canisters, and plastic ice cube trays come in handy for sorting and storing screws and other small parts after disassembly.

Select a work area which is well lighted and where dropped parts can be located - not on a deep pile shag rug. Something like a large plastic tray with a slight lip may come in handy as it prevents small parts from rolling off of the work table. The best location will also be relatively dust free and allow you to suspend your troubleshooting to eat or sleep or think without having to pile everything into a cardboard box for storage.

A basic set of high quality hand tools will be all you need to work on a microwave oven. These do not need to be really expensive but poor quality tools are worse than useless and can cause damage. Stanley or Craftsman are fine. Needed tools include a selection of Philips and straight blade screwdrivers, needlenose pliers, wire cutters and wire strippers.

A medium power soldering iron and rosin core solder (never never use acid core solder or the stuff for sweating copper pipes on electronic equipment) will be needed if you should need to disconnect any soldered wires (on purpose or by accident) or replace soldered components.

However, most of the power components in microwave ovens use solderless connectors (lugs) and replacements usually come with these as well.

See the document: Troubleshooting and Repair of Consumer Electronics Equipment for additional info on soldering and rework techniques and other general information.

An assortment of solderless connectors (lugs and wirenuts) is handy when repairing the internal wiring. A crimping tool will be needed as well but the $4 variety is fine for occasional use.

Old dead microwaves can often be valuable source of hardware and sometimes even components like interlock switches and magnetrons as these components are often interchangeable. While not advocating being a pack rat, this does have its advantages at times.

Test equipment

Don't start with the electronic test equipment, start with some analytical thinking. Many problems associated with consumer electronic equipment do not require a schematic (though one may be useful). The majority of microwave oven problems are easily solved with at most a multimeter (DMM or VOM). You do not need an oscilloscope for microwave oven repair unless you end up trying to fix the logic in the controller - extremely unlikely.

A DMM or VOM is necessary for checking of power supply voltages (NOT the high voltage, however) and testing of interlock switches, fuses, wiring, and most of the components of the microwave generator. This does not need to be expensive but since you will be depending on its readings, reliability is important. Even a relatively inexpensive DMM from Radio Shack will be fine for most repair work. You will wonder how you ever lived without one! Cost: $25-50.

Other useful pieces of 'test equipment':

- A microwave leakage detector. Inexpensive types are readily available at home centers or by mail order. These are not super accurate or sensitive but are better than nothing. Also see the sections: "Microwave leakage meters" and "Simple microwave leak detectors".

- A microwave power detector. These can be purchased or you can make one from a small neon (NE2) or incandescent bulb with its lead wires twisted together. Sometimes these homemade solutions do not survive for long but will definitely confirm that microwave power is present inside the oven chamber. Note: always have a load inside the oven when testing - a cup of water is adequate.

- A thermometer (glass not metal) to monitor water temperature during power tests.

- High voltage probe (professional, not homemade!). However, this is only rarely actually required. Low voltage, resistance, or continuity checks will identify most problems. WARNING: the high voltage in a microwave oven is NEGATIVE (-) with respect to the chassis. Should you accidentally use the wrong test probe polarity with your meter, don't just interchange the probes = it may be last thing you ever do. Unplug the oven, discharge the HV capacitor, and only then change the connections.

There are special magnetron and microwave test instruments but unless you are in the business, these are unnecessary extravagances.

Safe discharging of the high voltage capacitor

It is essential - for your safety and to prevent damage to the device under test as well as your test equipment - that the large high voltage capacitor in the microwave generator be fully discharged before touching anything or making measurements. While these are supposed to include internal bleeder resistors, these can fail. In any case, several minutes may be required for the voltage to drop to negligible levels.

The technique I recommend is to use a high wattage resistor of about 5 to 50 ohms/V of the working voltage of the capacitor. This will prevent the arc-welding associated with screwdriver discharge but will have a short enough time constant so that the capacitor will drop to a low voltage in at most a few seconds (dependent of course on the RC time constant and its original voltage).

- For the high voltage capacitor in a microwave oven, use a 25 W or larger 100 K ohm resistor for your discharge widget with a clip lead to the chassis. The reason to use a large (high wattage) resistor is again not so much power dissipation as voltage holdoff. You don't want the HV zapping across the terminals of the resistor. Even better is to use a proper high voltage resistor rated for at least 5 kV. A series string of 10 to 20 1/2 W normal resistors in series can also be used.

- Clip the ground wire to an unpainted spot on the chassis. Use the discharge probe on each side of the capacitor in turn for a second or two. Since the time constant RC is about .1 second, this should drain the charge quickly and safely.

- Then, confirm with a WELL INSULATED screwdriver across the capacitor terminals. If there is a big spark, you will know that somehow, your original attempt was less than entirely successful. There is a very slight chance the capacitor could be damaged by the uncontrolled discharge but at least there will be no danger.

- Finally, it is a good idea to put a clip lead across the capacitor terminals just to be sure it stays fully discharged while you are working in the area. Yes, capacitors have been known to spontaneously regain some charge. At worst, you will blow the fuse upon powering up if you forget to remove it.

WARNING: DO NOT use a DMM for checking voltage on the capacitor unless you have a proper high voltage probe. If your discharging did not work, you may blow everything - including yourself.

A suitable discharge tool can be made as follows:

- Solder one end of the appropriate size resistor (100K ohms, 25W in this case) to a well insulated clip lead about 2 to 3 feet long. Don't just wrap it around - this connection must be secure for safety reasons.

- Solder the other end of the resistor to a well insulated contact point such as a 2 inch length of bare #14 copper wire mounted on the end of a 2 foot piece of PVC or Plexiglas rod which will act as an extension handle.

- Secure the resistor to the insulating rod with some plastic electrical tape.

This discharge tool will keep you safely clear of the danger area. The capacitor discharge indicator circuit described in the document: Capacitor Testing, Safe Discharging and Other Related Information can be built into the discharge tool if desired.

Again, always double check with a reliable high voltage meter or by shorting with an insulated screwdriver!

Reasons to use a resistor and not a screwdriver to discharge capacitors:

1. It will not destroy screwdrivers and capacitor terminals.

2. It will not damage the capacitor (due to the current pulse).

3. It will reduce your spouse's stress level in not having to hear those scary snaps and crackles.

Getting inside a microwave oven

You will void the warranty - at least in principle. There are usually no warranty seals on a microwave so unless you cause visible damage or mangle the screws or plastic, it is unlikely that this would be detected. You need to decide. A microwave still under warranty should probably be returned for warranty service for any covered problems except those with the most obvious and easy solutions.

Unplug the unit! Usually, the sheet metal cover over the top and sides is easily removed after unscrewing 8-16 philips head sheet metal screws. Most of these are on the back but a few may screw into the sides. They are not usually all the same! At least one of these includes a lockwasher to securely ground the cover to the case. Make note of any differences in screw types so they can be put back in the same place. The cover will then lift up and off. Note how fingers on the cover interlock with the main cabinet - these are critical to ensure prevention of microwave leakage after reassembly.

Please see Typical Microwave Oven Electronics Bay for parts identification. Not all ovens are this wide open. If yours is a compact unit, everything may be really squeezed together. :) Details will vary depending on manufacturer and model but most of the major components will look fairly similar to those depicted in the photo. Note that for this model, the oven lamp is actually inside the electronics bay right next to the high voltage on the magnetron filament - light bulb changing here is really best left to a professional if you would otherwise not go inside!

Discharge the high voltage capacitor as described in the section: Safe discharging of the high voltage capacitor before even thinking about touching anything.

A schematic showing all of the power generation components is usually glued to the inside of the cover. How much of the controller is included varies but is usually minimal.

Fortunately, all the parts in a microwave can be easily replaced and most of the parts for the microwave generator are readily available from places like MCM Electronics, Dalbani, and Premium Parts.

Reassemble in reverse order. Take particular care to avoid pinching any wires when reinstalling the cover. Fortunately, the inside of a microwave is wide open and this is not difficult. Make sure ALL of the metal fingers around the front edge engage properly with the front panel lip. This is critical to avoid microwave emissions should the waveguide or magnetron become physically damaged in any way. Confirm that the screws you removed go back in the proper locations, particularly the one that grounds the cover to the chassis.

Principles of Operation

Instant (2 minutes on HIGH) microwave oven theory

Please see Typical Microwave Oven Electronics Bay for parts identification.

A typical microwave oven uses between 500 and 1000 W of microwave energy at 2.45 GHz to heat the food. This heating is caused mainly by the vibration of the water molecules. Thus plastic, glass, or even paper containers will heat only through conduction from the hot food. There is little transfer of energy directly to these materials. This also means that the food does not need to be a conductor of electricity (try heating a cup of distilled water) and that electromagnetic induction (used elsewhere for high frequency non-contact heating) is not involved.

What is significant about 2.45 GHz? Not that much. Water molecules are not resonant at this frequency. A wide range of frequencies will work to heat water efficiently. 2.45 GHz was probably chosen for a number of other reasons including not interfering with existing EM spectrum assignments and convenience in implementation. In addition, the wavelength (about 5 inches) results in reasonable penetration of the microwave energy into the food. The 3 dB (half power) point is about 1 inch for liquid water - half the power is absorbed in the outer 1 inch of depth, another 1/4 of the power in the next inch, and so forth.

From: Barry L. Ornitz (ornitz@tricon.net).)

> "Industrial ovens still often operate at 915 MHz and other frequencies near 6 GHz are also used.
>
> Water has numerous resonances over the entire spectra range, but the lowest frequency resonance is the rotational resonance is around 24 GHz. Other resonances occur in the millimeter wave range through the infrared.

> For references, check books on microwave spectroscopy by Townes and Gordy."

Since the oven chamber cavity is a good reflector of microwaves, nearly all the energy generated by the oven is available to heat the food and heating speed is thus only dependent on the available power and how much food is being cooked. Ignoring losses through convection, the time to heat food is roughly proportional to its weight. Thus two cups of water will take around twice as long to bring to a boil as one.

Heating is not (as popularly assumed) from the inside out. The penetration depth of the microwave energy is a few cm so that the outside is cooked faster than the inside. However, unlike a conventional oven, the microwave energy does penetrate these few cm rather than being totally applied to the exterior of the food. The misconception may arise when sampling something like a pie filling just out of the microwave (or conventional oven for that matter). Since the pie can only cool from the outside, the interior filling will appear to be much hotter than the crust and will remain that way for a long time.

One very real effect that may occur with liquids is superheating. It is possible to heat a pure liquid like water to above its boiling point if there are no centers for bubbles to form such as dust specks or container imperfections. Such a superheated liquid may boil suddenly and violently upon removal from the oven with dangerous consequences. This can take place in a microwave since the heating is relatively uniform throughout the liquid. With a stovetop, heating is via conduction from the burner or coil and there will be ample opportunity for small bubbles to form on the bottom long before the entire volume has reached the boiling point.

Most metal objects should be excluded from a microwave oven as any sharp edges (areas of high electric field gradient) may create sparking or arcing which at the very least is a fire hazard. Microwave safe metal shelves will have nicely rounded corners.

A microwave oven should never be operated without anything inside as the microwave generator then has no load - all the energy bounces around inside an a great deal is reflected back to the source. This may cause expensive damage to the magnetron and other components.

Why don't microwaves leak out from through the glass?

> "I am trying to find out what the glass on a microwave consists of exactly. i have not been able to get a better answer than 'a wire mesh'. if you can help, i would greatly appreciate it."

There *is* a wire mesh embedded in the glass panel. Since the holes in the mesh are much much smaller than the wavelength of the 2.45 GHz microwaves (about 5 inches or 12.5 cm), it is essentially opaque to microwaves and essentially all the energy is reflected back into the oven cavity.

(From: Filip (I'll buy a vowel) Gieszczykiewicz (filipg@repairfaq.org).)

Greetings. Did you ever see a "mesh" satellite disk up close? You will note that it looks much like it's made out of simple wire mesh that you can get in a hardware store (in the USA, it's called "chicken fence" :-). The reason this works is that the wave that the dish picks up is longer than the hole in the mesh. Consider bouncing a tennis ball on the "wire mesh" in the microwave - it WOULD work because the ball is bigger than the holes. The wave in the microwave is about 2.5cm "long" ... as long as the holes are smaller than that (actually, you want them as small as possible - without affecting the "watching the food" - to minimize any stray and harmonic waves from escaping... like bouncing tennis and golf and ping-pong balls and marbles off the mesh - you want to catch all the possible sizes - yet still be able to see through it) they will not let anything out of the oven.

BTW, it's not really "glass" but rather a 'sandwich' of glass, from the outside, wire mesh (usually a sheet of metal which is either stamped or drilled with a hole pattern - like a color TV CRT mask!), and followed by a sheet of glass or plastic to make sure that food splatters and vapor condensation are easy to clean - imagine scraping the mesh!

How a microwave oven works

The operation of a microwave oven is really very simple. It consists of two parts: the controller and the microwave generator.

A schematic diagram of the microwave generating circuitry and portions of the controller is usually glued to the inside of the cover.

The controller is what times the cooking by turning the microwave energy on and off. Power level is determined by the ratio of on time to off time in a 10-30 second cycle.

The microwave generator takes AC line power. steps it up to a high voltage, and applies this to a special type of vacuum tube called a magnetron - little changed from its invention during World War II (for Radar).

Controller

The controller usually includes a microcomputer, though very inexpensive units may simply have a mechanical timer (which ironically, is probably more expensive to manufacture!). The controller runs the digital clock and cook timer; sets microwave power levels; runs the display; and in high performance ovens, monitors the moisture or temperature sensors.

Power level is set by pulse width control of the microwave generator usually with a cycle that lasts 10-30 seconds. For example, HIGH will be continuous on, MEDIUM may be 10 seconds on, 10 seconds off, and LOW may be 5 seconds on, 15 seconds off. The power ratios are not quite linear as there is a 1 to 3 second warmup period after microwave power is switched on.

The operating voltages for the controller usually are derived from a stepdown transformer. The controller activates the microwave generating circuitry using either a relay or triac.

Sensors

More sophisticated ovens may include various sensors. Most common are probes for temperature and moisture. A convection oven will include a temperature sensor above the oven chamber.

Since these sensors are exposed to the food or its vapors, failures of the sensor probes themselves are common.

Cooling fans

Since 30 to 50 percent of the power into a microwave oven is dissipated as heat in the Magnetron, cooling is extremely important. Always inspect the cooling fan/motor for dust and dirt and lubricate if necessary. A couple of drops of electric motor oil or 3-in-One will go a long way. If there are any belts, inspect for deterioration and replace if necessary.

An oven that shuts off after a few minutes of operation could have a cooling problem, a defective overtemperature thermostat, a bad magnetron, or is being operated from very high AC line voltage increasing power to the oven.

One interesting note: Since 30 to 50 percent of the power goes out the vents in the back as heat, a microwave oven is really only more efficient than conventional means such as a stovetop or gas or electric oven for heating small quantities of anything. With a normal oven or stovetop, wasted energy goes into heating the pot or oven, the air, and so on. However, this is relatively independent of the quantity of food and may be considered to be a fixed overhead. Therefore, there is a crossover point beyond which it is more efficient to use conventional heat than high tech microwaves.

Microwave generator

This is the subsystem that converts AC line power into microwave energy. It consists of 5 parts: high voltage transformer, rectifier diode, capacitor, magnetron, waveguide to oven chamber.

- High Voltage Transformer. Typically has a secondary of around 2,000 VRMS at 0.25 amp - more or less depending on the power rating of the oven. There will also be a low voltage winding for the Magnetron filament (3.3 V at 10 A is typical).

  You cannot miss this as it is the largest and heaviest component visible once the cover is removed. There will be a pair of quick-connect terminals for the AC input, a pair of leads for the Magnetron filament. and a single connection for the HV output. The HV return will be fastened directly to the transformer frame and thus the chassis.

  These transformers are designed with as little copper as possible. The primary for 115 VAC is typically only 120 turns of thick wire - thus about 1 turn per volt input and output (this is about 1/4th as many turns as in a "normal" power transformer. (It's usually possible to count the primary turns by examining how it is wound - no disassembly required!) So there would about 3 turns for the magnetron filament and 2080 turns for the high voltage winding for the transformer mentioned above. The reason they can get away with so few turns is that it operates fully loaded about 90 percent of the time but is still on the hairy edge of core saturation.

  There is also generally a "magnetic shunt" in the core of the transformer. This provides some current limiting, possibly to compensate for various magnetron load conditions. However, it's not enough to provide any reduction in the likelihood of electrocution should you come in contact with the HV winding!

- Rectifier - usually rated 12,000 to 15,000 PRV at around .5 amp. Most commonly, this will be rectangular or cylindrical, about .5 inch long with wire leads. Sometimes, it is a box bolted to the chassis. One end will be electrically connected to the chassis.

- Capacitor - .65 to 1.2 uF at a working voltage of around 2,000 VAC. Note that this use of 'working voltage' may be deceiving as the actual voltage on the capacitor may exceed this value during operation. The capacitor is metal cased with quick-connect terminals on top (one end). Always discharge the capacitor as described below before touching anything inside once the cover is removed.

- Magnetron - the microwave producing tube includes a heated filament cathode, multiple resonant cavities with a pair of permanent ceramic ring magnets to force the electron beams into helical orbits, and output antenna. The magnetron is most often box shaped with cooling fins in its midsection, the filament/HV connections on the bottom section, and the antenna (hidden by the waveguide) on top. Sometimes, it is cylindrical in shape but this is less common. The frequency of the microwaves is usually 2.45 GHz.

Magnetron construction and operation

The cavity magnetron was invented by the British before World War II. It is considered by many to be the invention most critical to the Allied victory in Europe.

The story goes that shortly after the War, a researcher at the Raytheon Corporation, Dr. Percy Spencer, was standing near one of the high power radar units and noticed that a candy bar in his shirt pocket had softened. In the typical 'I have to know why this happened' mentality of a true scientist, he decided to investigate further. The Amana Radarange and the entire future microwave oven industry were the result.

Here are two descriptions of magnetron construction. The first is what you will likely find if you go to a library and read about radar. (Some really old microwave ovens may use the classic design as well.) This is followed by my autopsy of a dead magnetron of the type that is probably in the microwave oven in your kitchen. (Items (1) to (6) in the following sections apply to each type while items (7) to (9) apply to both types.)

For more detailed information with some nice diagrams, see the articles at the Microtech Web Site. Topics include basic microwave theory as well as a complete discussion of microwave oven magnetron construction and principles of operation.

Magnetron construction - basic textbook description

This is the description you will find in any textbook on radar or microwave engineering. The original Amana Radarange and other early microwave ovens likely used this design as well.

1. A centrally located cylindrical electron emitting cathode. This is supplied with pulsed or continuous power of many thousands of volts (negative with respect to the anode.

2. A cylindrical anode block surrounding but separate and well insulated from the cathode.

3. Multiple cylindrical resonator cavities at a fixed radius from the cathode bored in the anode block. Channels link the cavities to the central area in which the cathode is located.

   The wavelength of the microwave energy is approximately 7.94 times the diameter of the cavities. (For the frequency of 2.45 GHz (12.4 cm) used in a microwave oven this would result in a cavity diameter of approximately .62" (15.7 mm).

4. An antenna pickup in one of the cylindrical cavities which couples the microwave energy to the waveguide.

5. The entire assembly is placed in a powerful magnetic field (several thousand Gauss compared to the Earth's magnetic field of about .5 Gauss). This is usually supplied by a permanent magnet though electromagnets have been also used. The original designs used huge somewhat horseshoe shaped permanent magnets which were among the most powerful of the day.

6. Cooling of the anode block must be provided by forced air, water, or oil since the microwave generation process is only about 60 to 75 percent efficient and these are often high power tubes (many kilowatts).

Magnetron construction - modern microwave oven

This description is specifically for the 2M214 (which I disassembled) or similar types used in the majority of medium-to-high power units. However, nearly all other magnetrons used in modern domestic microwave ovens should be very similar.

The item numbers are referenced to the diagram in the section: Cross section diagram of typical magnetron.

Also see this photo of the Typical Magnetron Anode and Resonant Structure. This is a view looking up through the anode cylinder from the filament end of the tube. See the text below for parts names and dimensions.

1. The filament and cathode are one in the same and made of solid tungsten wire, about .020" (.5 mm) diameter, formed in a helix with about 8 to 12 turns, 5/32" (4 mm) diameter and just over 3/8" (9.5 mm) in length. The cathode is coated with a material which is good for electron emission.

   Note: this coating is the only material contained in the microwave oven magnetron that might be at all hazardous. Beryllium, a toxic metal, may be used in large radar magnetrons but should not be present in the types found in domestic microwave ovens.

   The filament gets its power via a pair of high current RF chokes - a dozen or so turns of heavy wire on a ferrite core - to prevent microwave leakage back into the filament circuit and electronics bay of the oven. Typical filament power is 3.3 VAC at 10 A.

   The cathode is supplied with a pulsating negative voltage with a peak value of up to 5,000 V.

2. The anode is a cylinder made from .062" (1.5 mm) thick copper with an inside diameter of 1-3/8" (35 mm) and a length of about 1" (25.4 mm).

   Steel plates (which probably help to shape the magnetic field, see below) and thin steel covers (to which the filament and antenna insulators are sealed) are welded to the ends of the cylinder.

   The filament leads/supports enter through a cylindrical ceramic insulator sealed to the bottom cover and then pass through a hole in the bottom end plate.

3. Rather than cylindrical cavities (as you would find in most descriptions of radar magnetrons), there are a set of 10 copper vanes .062" (1.5 mm) thick and approximately 1/2" (12.7 mm) long by 3/8" (9.5 mm) wide. These are brazed or silver soldered to the inside wall of the cylinder facing inward leaving a 5/16" (8 mm) central area clear for the filament/cathode.

   Surrounding this space are the .062" (1.5 mm) thick edges of the 10 vanes with gaps of approximately .04" (1 mm) between them.

   Copper shorting rings at both ends near the center join alternating vanes. Thus, all the even numbered vanes are shorted to each other and all the odd numbered vanes are shorted to each other. Of course, all the rings are also all shorted at the outside where they are joined to the inner wall of the cylinder.

   This structure results in multiple resonant cavities which behave like sets of very high quality low loss L-C tuned circuits with a sharp peak at 2.45 GHz. At this high frequency, individual inductors and capacitors are not used. The inductance and capacitance are provided by the precise configuration and spacing of the copper vanes, shorting rings, and anode cylinder.

4. A connection is made near the middle of a single vane to act as the output power takeoff. It passes through a hole in the top end plate, exits the tube via a cylindrical ceramic insulator sealed to the top cover, and attaches to the pressed-on bu?ll-nose antenna cap.

5. The entire assembly is placed in a powerful magnetic field (several thousand Gauss compared to the Earth's magnetic field of about .5 Gauss). This is provided by a pair of ceramic ring magnets placed against the top and bottom covers of the anode cylinder. For the 2M214, these are about 2-1/8" (54 mm) OD, 1-13/16" (46 mm) ID, 1/2" (12.7 mm) thick.

6. A set of thin aluminum fins act as a heat sink for removing the significant amount of wasted heat produced by the microwave generation process since it is only about 60 to 75 percent efficient. These are press fit on the magnetron anode and also in contact with the magnetron case. There will always be a cooling fan to blow air through this assembly.

   The anode and magnetron case are at ground potential and connected to the chassis.

Magnetron construction - common features

The following items apply to all types of magnetrons.

7. The gap between the cathode and anode, and the resonant cavities, are all in a vacuum.

8. When powered, electrons stream from the cathode to the anode. The magnetic field forces them to travel in curved paths in bunches like the spokes of a wheel. The simplest way to describe what happens is that the electron bunches brush against the openings of the resonating cavities in the anode and excite microwave production in a way analogous to what happens when you blow across the top of a Coke bottle or through a whistle.

9. The frequency/wavelength of the microwaves is mostly determined by the size and shape of the resonating cavities - not by the magnetic field as is popularly thought. However, the strength of the magnetic field does affect the threshold voltage (the minimum anode voltage required for the magnetron to generate any microwaves), power output, and efficiency.

Cross section diagram of typical magnetron

The really extraordinary ASCII art below represents (or is supposed to represent) a cross section of the 2M214 type magnetron (not to scale) through the center as viewed from the side.

Microwave generator circuit diagram

Nearly all microwave ovens use basically the same design for the microwave generator. This has resulted in a relatively simple system manufactured at low cost.

The typical circuit is shown below. This is the sort of diagram you are likely to find pasted inside the metal cover. Only the power circuits are likely included (not the controller unless it is a simple motor driven timer) but since most problems will be in the microwave generator, this schematic may be all you need.

```
                                       || +------------------------+
                                       ||( 3.3 VAC, 10 A, typical  |
                         TP  Relay or  || +------------+------+FA F| Magnetron
            _ Fuse   I   __    Triac   ||              |    +-|----|-+
    o------- _---+---/ --  ----/ ----+ || +------||----+    | |_  _| |
                 |                    )||( HV Cap      |    |   \/   |
   AC           I \ I=Interlock       )||(           __|__  |   ___  |
  Line           |  TP=Thermal Prot.  )||( 2,000 VAC _\_/_  +----|:--+
    o------------+-------------------+ ||( .25 A       | HV      |'--> Micro-
                                       ||( typical     | Diode   |      waves
```

```
       (Controller not shown)         || +-----------+--------+
                                                    _|_
                                                     -  Chassis ground
```

Note the unusual circuit configuration - the magnetron is across the diode, not the capacitor as in a 'normal' power supply. What this means is that the peak voltage across the magnetron is the transformer secondary + the voltage across the capacitor, so the peaks will approach the peak-peak value of the transformer or nearly 5000 V in the example above. This is a half wave voltage doubler. The output waveform looks like a sinusoid with a p-p voltage equal to the p-p voltage of the transformer secondary with its positive peaks at chassis ground (no load). The peaks are negative with respect to the chassis. The negative peaks will get squashed somewhat under load. Take extreme care - up to 5000 V at AMPs available! WARNING: Never attempt to view this waveform on an oscilloscope unless you have a commercial high voltage probe and know how to use it safely!

The easiest way to analyze the half wave doubler operation is with the magnetron (temporarily) removed from the circuit. Then, it becomes a simple half wave rectifier/filter so far as the voltage acrtoss the capacitor is concerned - which will be approximately V(peak) = V(RMS) * 1.414 where V(RMS) is the output of the high voltage transformer. The voltage across the HV rectifier will then be: V(peak) + V where V is the waveform out of the transformer. The magnetron load, being across the HV diode, reduces the peak value of this somewhat - where most of its conduction takes place.

Note that there is a difference in the labels on the filament connections of the magnetron. Functionally, it probably doesn't matter which way they are connected. However, the typical schematic (as above) shows FA going to the node attached to the Anode of the HV diode, while F goes to the lone Filament terminal on the HV transformer.

WARNING: What this implies is that if the magnetron is not present or is not drawing power for some reason - like an open filament - up to V(peak) will still be present across the capacitor when power is removed. At the end of normal operation, some of this will likely be discharged immediately but will not likely go below about 2,000 V due to the load since the magnetron does not conduct at low voltages.

Other types of power supplies have been used in a few models - including high frequency inverters - but it is hard to beat the simplicity, low cost, and reliability of the half wave doubler configuration. See the section: High frequency inverter type HV power supplies.

There is also usually a bleeder resistor as part of the capacitor, not shown. HOWEVER: DO NOT ASSUME THAT THIS IS SUFFICIENT TO DISCHARGE THE CAPACITOR - ALWAYS DO THIS IF YOU NEED TO TOUCH ANYTHING IN THE MICROWAVE GENERATOR AFTER THE OVEN HAS BEEN POWERED. The bleeder may be defective and open as this does not effect operation of oven and/or the time constant may be long - minutes. Some ovens may not have a bleeder at all.

In addition, there will likely be an over-temperature thermostat - thermal protector - somewhere in the primary circuit, often bolted to the magnetron case. There may also be a thermal fuse or other protector physically elsewhere but in series with the primary to the high voltage transformer.

Other parts of the switched primary circuit include the oven interlock switches, cooling fan, turntable motor (if any), oven light, etc.

Interlock switches

Various door interlock switches prevent inadvertent generation of microwaves unless the door is closed completely. At least one of these will be directly in series with the transformer primary so that a short in the relay or triac cannot accidentally turn on the microwaves with the door open. The interlocks must be activated in the correct sequence when the door is closed or opened.

Interestingly, another interlock is set up to directly short the power line if it is activated in an incorrect sequence. The interlocks are designed so that if the door is correctly aligned, they will sequence correctly. Otherwise, a short will be put across the power line causing the fuse to blow forcing the oven to be serviced. This makes it more difficult for an ignorant consumer to just bypass the door interlocks should they fail or to run the oven with an open door as a room heater - and protects the manufacturer from lawsuits. (That interlock may be known as a "dummy switch" for obvious reasons and is often not even mentioned in the schematic/parts manifest.) Of course, should that switch ever actually be used, not only will the fuse blow, but the switch contacts will likely be damaged by the high initial current! This also means it probably wouldn't be a bad idea to replace the interlock switch which might have been affected if your oven fails with a blown fuse due to a door problem.

Failed door interlocks account for the majority of microwave oven problems - perhaps as high as 75 percent. This is not surprising considering that two of the three switches carry the full oven current - any deterioration of the contacts results in increased resistance leading to their heating and further deterioration. And, opening the door to interrupt a cook cycle results in arcing at the contacts. Complete meltdowns are not unusual! If any defective door switches are found, it is probably a good idea to replace all of them as long as the oven is already apart.

The typical door switches and their function:

- **Door Sensing**: Input to the microcontroller to indicate the state of the door.

- **Interlock Monitor**: Shorts out the AC line (and blows the main fuse) should the Primary Interlock not open due to incorrect sequencing of the door switches or a failed switch.

- **Primary Interlock**: In series with the high voltage (magnetron) power supply so cuts power when the door is open.

Note that if the Door Sensing switch should malfunction, peculiar behavior may occur (like the fan or turntable operating at the wrong time) but should never result in microwaves being generated with the door open.

Troubleshooting Guide

Instant troubleshooting chart - most common problems and possible causes

The following chart lists a variety of common problems and nearly all possible causes. Diagnostic procedures will then be needed to determine which actually apply. The 'possible causes' are listed in *approximate* order of likelihood. Most of these problems are covered in more detail elsewhere in this document.

While this chart lists many problems, it is does not cover everything that can go wrong. However, it can be a starting point for guiding your thinking in the proper direction. Even if not listed here, your particular problem may still be dealt with elsewhere in this document.

- Problem: Totally dead oven.
  Possible causes:

  1. No power to outlet (blown fuse or tripped breaker or GFCI).
  2. Blown main fuse - likely due to other problems.
  3. Open thermal protector or thermal fuse.
  4. Defective controller or its power supply.
  5. Clock needs to be set before other functions will operate (some models).

- Problem: No response to any buttons on touchpad.
  Possible causes:

  1. Door is not closed (some models).
  2. You waited to long (open and close door to wake it up).
  3. Controller is confused (pull plug for a minute or two to reset).
  4. Defective interlock switches.
  5. Faulty controller or its power supply.
  6. Touchpad or controller board contaminated by overenthusiastic cleaning.
  7. Defective/damaged touchpad.

- Problem: Oven runs when door is still open.
  Possible causes:

  1. Damaged interlock assembly.
  2. Cooling fans (only) running due to bad sensor or still warm.

- Problem: Oven starts on its own as soon as door is closed.
  Possible causes:

  1. Defective triac or relay.
  2. Controller is confused (pull plug for a minute or two to reset).
  3. Defective controller or its power supply.
  4. Touchpad or controller board contaminated by overenthusiastic cleaning.
  5. Defective/damaged touchpad.

- Problem: Oven works but display is blank.
  Possible causes:

  1. Defective controller or its power supply.
  2. Broken display panel.
  3. Oven needs to be reset (pull plug for a minute or two to reset).

- Problem: Whacked out controller or incorrect operation.
  Possible causes:

  1. Previous or multipart cook cycle not complete.

2. Controller is confused (pull plug for a minute or two to reset).
3. Defective controller or its power supply.
4. Touchpad or controller board contaminated by overenthusiastic cleaning.
5. Defective/damaged touchpad.
6. Defective sensor (particulalry covection/mirowave combos).

- Problem: Erratic behavior.
  Possible causes:

  1. Previous or multipart cook cycle not complete.
  2. Bad connections in controller or microwave generator.
  3. Faulty relay - primary (or HV side, much less commonly used).
  4. Defective controller or its power supply.
  5. Bad contacts/connections on mechanical timers. Intermittent fuse.
  6. Power surge at start of cook cycle confusing controller.
  7. Microwave (RF) leakage into electronics bay.

- Problem: Some keys on the touchpad do not function or perform the wrong action.
  Possible causes:

  1. Touchpad or controller board contaminated by overenthusiastic cleaning.
  2. Defective/damaged touchpad.
  3. Controller is confused (pull plug for a minute or two to reset).
  4. Faulty controller.

- Problem: Microwave oven does not respond to START button.
  Possible causes:

  1. Defective START button.
  2. Faulty interlock switches.
  3. Door is not securely closed.
  4. Faulty controller.
  5. You waited too long - open and close door to wake it up!

- Problem: No heat but otherwise normal operation.
  Possible causes:

  1. Blown fuse in HV transformer primary circuit or HV fuse (if used).
  2. Bad connections (particularly to magnetron filament).
  3. Open thermal protector or thermal fuse.
  4. Open HV capacitor, HV diode, HV transformer, or magnetron filament.
  5. Shorted HV diode, HV capacitor (will blow a fuse), or magnetron.
  6. Defective HV relay (not commonly used).

- Problem: Timer and light work but no heat, cooling fan, or turntable rotation.
  Possible causes:

  1. Defective (lower) door interlock switch or door not closing fully.
  2. Faulty relay or triac.

- Problem: Fuse blows when closing or opening door:
  Possible causes:

  1. Defective door interlock switchs.
  2. Misaligned door.

- Problem: Loud hum and/or burning smell when attempting to cook.
  Possible causes:

  1. Shorted HV diode, magnetron.
  2. Burnt carbonized food in or above oven chamber.
  3. Shorted winding in HV transformer.
  4. Frayed insulation on HV wiring.

- Problem: Arcing in or above oven chamber.
  Possible causes:

  1. Burnt carbonized food deposits.
  2. Exposed sharp metal edges.

- Problem: Fuse blows when initiating cook cycle.
  Possible causes:

  1. Defective interlock switches or misaligned door.
  2. Shorted HV capacitor.
  3. Shorted HV diode.
  4. Shorted magnetron (probably won't blow main fuse but HV fuse if used).
  5. Defective triac.
  6. Old age or power surges.
  7. Defective HV transformer.
  8. Short in wiring due to vibration or poor manufacturing.

- Problem: Fuse blows when microwave shuts off (during or at end of cook cycle).
  Possible causes:

  1. Defective triac (doesn't turn off properly).
  2. Defective relay.
  3. Shorting wires.

- Problem: Oven heats on high setting regardless of power setting.
  Possible causes:

  1. Faulty primary relay or triac or HV relay (not commonly used).
  2. Faulty controller.

- Problem: Oven immediately starts to cook when door is closed.
  Possible causes:

1. Shorted relay or triac.
2. Faulty controller.

- Problem: Oven heats but power seems low or erratic.
  Possible causes:

  1. Low line voltage.
  2. Magnetron with low emission.
  3. Faulty controller or set for wrong mode.
  4. Stirrer (or turntable) not working.
  5. Intermittent connections to magnetron filament or elsewhere.
  6. Faulty primary relay or triac or HV relay (not commonly used).

- Problem: Oven heats but shuts off randomly.
  Possible causes:

  1. Overheating due to blocked air vents or inoperative cooling fan.
  2. Overheating due to bad magnetron.
  3. Bad connections in controller or microwave generator.
  4. Faulty interlock switch or marginal door alignment.
  5. Faulty controller.
  6. Overheating due to extremely high line voltage.
  7. Stuck stirrer fan resulting hot spots detected by sensors.

- Problem: Oven makes (possibly erratic) buzzing noise when heating.
  Possible causes:

  1. Fan blades hitting support or shroud.
  2. Vibrating sheet metal.
  3. Vibrating transformer laminations.
  4. Turntable or stirrer hitting some debris.

- Problem: Oven light does not work.
  Possible causes:

  1. Burnt out bulb :-).
  2. Bad connections.

- Problem: Fans or turntables that do not work.
  Possible causes:

  1. Gummed up lubrication or bad motor bearing(s).
  2. Loose or broken belt.
  3. Bad motor.
  4. Bad thermostat.
  5. Bad connections.

What can go wrong

The most common problems occur in the microwave generating portion of the system, though the controller can be blown by a lightning strike or other power surge. Bad interlock switches probably account for the majority of microwave oven problems. Also, since the touchpad is exposed, there is a chance that it can get wet or damaged. If wet, a week or so of non-use may cure keys that don't work. If damaged, it will probably need to be replaced - this is straightforward if the part can be obtained, usually direct from the manufacturer. Unfortunately, it is an expensive part ($20-50 typical).

The interlock switches, being electromechanical can fail to complete the primary circuit on an oven which appears to operate normally with no blown fuses but no heat as well. Faulty interlocks or a misaligned door may result in the fuse blowing as described above due to the incorrect sequencing of the door interlock switches. Failed interlocks are considered to be the most common problems with microwave ovens, perhaps as high as 75% of all failures. See the section: Testing and replacing of interlock switches.

No adjustments should ever be required for a microwave oven and there are no screws to turn so don't look for any!

General system problems

The following problems are likely power or controller related and not in the microwave generator unless due to a blown fuse or bad/intermittent connections:

- Totally dead oven.
- No response to any buttons on touchpad
- Oven runs when door is still open.
- Oven starts on its own as soon as door is closed.
- Oven works but display is blank.
- Whacked out controller or incorrect operation.
- Erratic behavior.
- Some keys on the touchpad do not function or perform the wrong action.
- Microwave oven does not respond to START button.

First, unplug the microwave oven for a couple of minutes. Sometimes, the microcontroller will get into a whacko mode for some unknown reason - perhaps a power surge - and simply needs to be reset. The problem may never reoccur.

Note: when working on controller related problems, unplug the connection to the microwave generator (HV transformer primary) from the power relay or triac - it is often a separate connector. This will prevent any possible accidental generation of microwave energy as well as eliminating the high voltage (but not the AC line) shock hazard during servicing.

If this does not help, there is likely a problem with the controller circuitry or its power and you will have to get inside the oven.

Uninvited guests

Some cockroaches (or other lower life forms) may have taken up residence on the controller circuit board. It is warm, cozy, safe, and from their point of view makes an ideal habitat. If you got the microwave oven from a flea market, garage sale, the curb, a relative, or friend, or if your kitchen isn't the cleanest in the world, such visitors are quite possible. Creatures with six or more legs (well, some two legged varieties as well) are not known for their skills in the areas of housekeeping and personal hygiene.

Clean the circuit board and connectors thoroughly with water and then isopropyl alcohol. Dry completely. Inspect the circuit traces for corrosion or other damage. If there are any actual breaks, these will have be be jumpered with fine wire and then soldered. Hopefully, no electronic components were affected though there is always a slight possibility of other problems.

Totally dead oven

First, check power to the outlet using a lamp or radio you know works. The fuse or circuit breaker at your service panel may have blown/tripped due to an overload or fault in the microwave oven or some other appliance. You may just have too many appliances plugged into this circuit - microwave ovens are high current appliances and should be on a dedicated circuit if possible. If you attempt to run a heating appliance like a toaster or fryer at the same time, you *will* blow the fuse or trip the circuit breaker. A refrigerator should never be plugged into the same circuit for this reason as well - you really don't want it to be without power because of your popcorn!

If you find the fuse blown or circuit breaker tripped, unplug everything from the circuit to which the microwave is connected (keep in mind that other outlets may be fed from the same circuit). Replace the fuse or reset the circuit breaker. If the same thing happens again, you have a problem with the outlet or other wiring on the same branch circuit. If plugging in the microwave causes the fuse to blow or circuit breaker to trip immediately, there is a short circuit in the power cord or elsewhere.

The microwave oven may be powered from a GFCI outlet or downstream of one and the GFCI may have tripped. (Removing a broken oven lamp has been known to happen.) The GFCI outlet may not be in an obvious location but first check the countertop outlets. The tripped GFCI could be in the garage or almost anywhere else! Pushing the RESET button may be all that's needed.

Next, try to set the clock. With some ovens the screen will be totally blank following a power outage - there may be nothing wrong with it. Furthermore, some ovens will not allow you perform any cooking related actions until the clock is set to a valid time.

Assuming these are not your problems, a fuse has probably blown although a dead controller is a possibility.

If the main fuse is upstream of the controller, then any short circuit in the microwave generator will also disable the controller and display. If this is the case, then putting in a new fuse will enable the touchpad/display to function but may blow again as soon as a cook cycle is initiated if there is an actual fault in the microwave circuits.

Therefore, try a new fuse. If this blows immediately, there may be a short very near the line cord, in the controller, or a defective triac (if your oven uses a triac). Or, even a shorted oven lamp - remove and inspect the light bulb and socket.

If it does not blow, initiate a cook cycle (with a cup of water inside). If the oven now works, the fuse may simply have been tired of living. This is common.

If the fuse still blows immediately, confirm that the controller is operational by unplugging the microwave generator, power relay, and/or triac from the controller. If a new fuse does not now blow when a cook cycle is initiated - and it appears to operate normally - then one of the components in the microwave generator is defective (shorted). See the section: Microwave generator problems.

Some models have a thermal fuse as well and this may have failed for no reason or a cooling fan may not be working and the oven overheated (in which case it probably would have died while you were cooking something for an important guest - assuming you would use a microwave oven for such a thing!).

Other possible causes: bad controller power supply or bad controller chip.

Dead controller

The most common way that the controller circuitry can be harmed is by a power surge such as from a lightning strike. Hopefully, only components on the primary side of the power transformer will be affected.

- Check the primary of the power transformer - if it is open, there may be a fuse/thermal fuse underits outer insulation. If not, the transformer will need to be replaced. There is a good chance that the surge didn't propagate beyond the transformer and thus the rest of the controlled should be unaffected.

- In some cases, circuit board traces may have been vaporized (but repair may still be possible by simply jumpering across the crater). Some of these thin traces may be there specifically to act as fuses - and there may even be spares to use for just this situation!

- Assuming that the main fuse and power transformer primary checks out, then check the power supply for the controller next.

- As always, also check for bad solder connections.

If the controller power supply is working and there is still no sign of life (dead display and no response to buttons) the microcontroller chip or some other part may be bad. It could be a simple part like a capacitor or diode, but they would all need to be tested. At this point, a schematic of the controller board will be needed - often impossible to get - and replacement controller or even just the main chip may be nearly as expensive as a complete new oven.

No response to any buttons on touchpad

There can be many causes for this behavior (or lack of behavior):

- Door is not closed - on many ovens, there will be no response to any buttons - even setting the clock - unless the door is securely closed.

- You waited too long - some models (like Sharp) have a timeout. If you close the door but don't proceed to activate any functions with a couple of minutes, they will require you to open and close the door to reset their pathetic brains.

- Controller is confused - a power surge or random non-reproducible action of the universe may have resulted in the controller's program ending up in an infinite loop. Pull the plug for a minute or two to reset it.

- Defective interlock switches - this can result in the controller thinking the door is open and ignoring you.

- Faulty controller or its power supply - a power surge may have damaged the electronics. Other than checking for bad connections and obviously bad power supply components, diagnosing this will be tough without a schematic (and possibly much more).

- Touchpad or controller board contaminated by overenthusiastic cleaning - if you recently power washed the oven (or even if you only use some spray cleaner), some may have gotten inside and shorted out the touchpad or controller.

- Defective or damage touchpad - physical abuse is not a recommended technique for getting a microwave oven to cooperate. If there is any visible damage to the touchpad - the outer film is broken - it will probably need to be replaced.

Also see the section: Some of the keys on the touchpad do not function or perform the wrong action.

Oven runs when door is still open

WARNING: Needless to say, DO NOT operate the oven with the door open! While extremely unlikely, the microwave be generator could be running!

For microwaves to actually be generated with the door still open would require the failure of all 3 interlock switches. The only way this could really happen would be for the 'fingers' from the door that engage the interlocks to break off inside the oven keeping the interlocks engaged. In this case, the controller would think the door was always closed.

Where no such damage is evident, a failure of this type is extremely unlikely since power to the microwave generator passes through 2 of the 3 interlock switches. If both of these failed in the closed position, the third switch would have blown the fuse the last time the door was opened.

Another more benign possibility is that one or more fans are running as a result of either a defective sensor or normal operation to maintain air flow until all parts have cooled off.

Oven starts on its own as soon as door is closed

If the oven starts up as soon as the door is closed - regardless of whether a cook cycle has been selected, the cause could be a shorted triac or relay or a problem with the controller or touchpad.

First, unplug the oven for a couple of minutes to try to reset the controller.

If this doesn't help, put a cup of water into the oven and let it run for a minute to check for heating. (You could also note the normal sound change or slight dimming of lights that accompanies operation of the magnetron.) Much more must be enabled to actually power the magnetron so this might point more to the controller as being faulty but not always.

Also see the section: Whacked out controller or incorrect operation.

Oven works but totally dead display

If all functions work normally including heating but the display is blank (assuming you can issue them without being able to see the display), the problem is almost certainly in the controller or its power supply.

Try pulling the plug for a minute or two - for some reason the display portion of the controller may have been sent out to lunch by a power surge or alpha particle. It woudn't be the first time.

Check for bad connections between the display panel and the power supply and solder joints on the controller board.

With everything else operational, a bad microcontroller chip is not that likely but is still a possibility. If the oven was physically abused, the display panel may have fractured though it would take quite a bit of violence. In this case, more serious damage to the door seals may have resulted as well which would be a definite hazard.

Whacked out controller or incorrect operation

The following are some of the possible symptoms:

- All the display digits may have come on, EEEE or FFFF, or be displaying in Greek.
- The end-of-cooking cycle or keypress tone may be wailing away continuously. (By 'tone' I mean from the controller (not a low buzzing or humming when attempting to cook which would indicate a microwave generator power problem like a shorted magnetron).
- Pressing a button on the touchpad may result in a totally incorrect action such as entering the time resulting in the oven starting to cook. However, for the special case where pressing START results in erratic behavios, see the section: Erratic behavior.
- The oven may start cooking (or at least appear to) as soon as the door is closed. Pressing buttons on the touchpad may or may not have any effect. (This could also be a shorted triac or power relay).

First, try unplugging the oven for a couple of minutes - perhaps the controller is just confused due to a power surge, lightning strike or the EMP from a nearby nuclear detonation because it wanted attention.

If you recently cleaned the oven, some liquid may have accidentally gotten inside the touchpad or even the controller circuitry (though this is less likely). See the section: Some of the keys on the touchpad do not function or perform the wrong action.

If the oven seems to have a mind of its own - running a cycle you didn't think you programmed, are you sure a previous cook cycle was not interrupted and forgotten? Try to recreate the problem using a cup of water as a load.

Assuming this does not apply, it sounds like a controller problem - possibly just a power supply but could also be the controller chip. My guess is that unless you were to find some simple bad connections or an obvious problem with the controller's power supply, the cost to repair would be very high as the custom parts are likely only available from the manufacturer.

The controller's program may be corrupted (unlikely) but we have no real way of diagnosing this except by exclusion of all other possibilities. Depending on the model, some or all operations - even setting the clock - may be conditional on the door interlocks being closed, so these should be checked. Some ovens will not allow any actions to be performed if the door has been closed for more than a few minutes - open and close the door to reset.

A controller failure does little to predict the reliability of the rest of the oven. The microwave generator circuits could last a long time or fail tomorrow. The output of the magnetron tube may decrease slightly with use but there is no particular reason to expect it to fail any time soon. This and the other parts are easily replaceable.

However, unless this oven has a lot of fancy features, you can buy a replacement (depending on size) for $100-200 so it is probably not worth fixing unless it is something relatively simple and inexpensive.

Erratic behavior

There are three different situation:

- Whenever the oven performs unexpectedly both during setup and the cook cycle, suspect the controller power supply or bad connections.
- Where problems only occur when entering or during the cook cycle, suspect a power relay or mechanical timer (if used) with dirty or worn contacts, or (less likely) the power surge from energizing the microwave generator or microwave (RF) leakage into the electronics bay affecting the controller.
- However, if erratic simply means that it doesn't heat consistently, see the section: Oven heats but power seems low or erratic.

The filter capacitor(s) in the controller's power supply may be dried up or faulty. Check with a capacitor meter or substitute known good ones. Prod the logic board to see if the problem comes and goes. Reseat the flex cable connector to the touchpad.

For mechanical timers, the timing motor could be defective or require lubrication. The contacts could be dirty or worn. There may be bad connections or loose lugs.

The primary relay may have dirty or burnt contacts resulting in erratic operation. If the oven uses a HV relay for power control, this may be defective.

If the times and power levels appear on the display reliably but then become scrambled when entering the cook cycle or the oven behaves strangely in some other way when entering the cook cycle, there are several possibilies:

- The power surge caused by the cook cycle starting is resulting in changes to the settings or else the microcontroller is not interpreting them properly. This may be due to a faulty part of bad connections in the controller or elsewhere. As with intermittent problems, a thorough search for loose ground and other connections and bad solder joints may locate the source of the difficulty.
- Microwave (RF) leakage into the electronics bay due to an faulty joint between the magnetron and the waveguide or structure failure of the magnetron may be interfering with the operation of the microcontroller. Unless the oven was dropped or 'repaired' by an butcher, this sort of failure is unlikely. If you suspect either of these, inspect the integrety of the magnetron-waveguide joint and make sure the RF gasket is in place. Unfortunately, this is sometimes difficult to pinpoint because unless there is obvious mechanical damage, the 'problem' may disappear once the cover is removed for testing. See the section: Problems with internal microwave leakage.
- On rare occasions, the main fuse may become intermittent rather than failing completely. The surge or vibration of starting can jiggle the element open or closed. It is easy to try replacing it!

Problems with internal microwave leakage

(From: Charles Godard (cgodard@iamerica.net).)

I only service Amana's, but have serviced lot's of them over the years. I've only found a few that leaked with my expensive leak detector. The most memorable was the one with the leak that was due to the copper gasket that's between the magnetron tube and the cavity. I just reformed the gasket and reseated the magnetron and that fixed the leak.

The symptom was that the Touch Pad timer lights and indicators would change while the unit was cooking. I thought I had a timer problem. I took it apart and checked for loose solder joints and even cleaned the glass touch pad contacts.

For some reason that I don't remember now, I checked for radiation with the cover off the unit and found it extremely high.

It turned out that the radiation was affecting the controller.

From the outside, with the cover on, the unit didn't leak.

Long ago, I tried one of the cheapie detectors because one of my parts supply houses suggested it, and it detected leaks on everything. After that I shelled out the bucks and bought a real detector.

(From: Matthew Sekulic (goatboy@telusplanet.net).)

I have had a similar experience with a Sanyo, similar symptoms, but with the leakage from the spot welded waveguide inside the unit. Our calibration meter showed a two watt leakage, with none escaping the outer case when attached.

(My worst case of actual external leakage was from a misaligned door at .75 watts with the probe's styrofoam spacer placed against the door, of course dropping off to near zero a few inches away. My clue in was a spark between the waveguide and the case, when I was messing with the Controller PCB.)

Some of the keys on the touchpad do not function or perform the wrong action

Touchpads are normally quite reliable in the grand scheme of things but can fail as a result of physical damage (your spouse threw the roast at the oven), liquid contamination (from overzealous cleaning, for example), or for no reason at all.

Look carefully for any visible signs of damage or spills. The touchpads often use pressure sensitive resistive elements which are supposed to be sealed. However, any damage or just old age may permit spilled liquid to enter and short the sensors. A week or so of drying may cure these problems. If there is actual visible damage, it may be necessary to replace the touchpad unit, usually only available from the original manufacturer. Also, check the snap type connector where the touchpad flex-cable plugs into the controller board. Reseating this cable may cur a some keys dead problem.

Some people have reported at least temporary improvement by simple peeling the touch pad off of the front panel and flexing it back and forth a few times. Presumably, this dislodges some bit of contamination. I am skeptical as this could just be a side effect of a bad connection elsewhere.

With a little bit of effort (or perhaps a lot of effort), the internal circuitry of the touchpad can be determined. This may require peeling it off of the front panel). Then, use resistors to jumper the proper contacts on the flex cable connector to simulate key presses. This should permit the functions to be verified before a new touchpad is ordered.

Caution: unplug the microwave generator from the controller when doing this sort of experiment!

If the problem was the result of a spill into the touchpad, replacement will probably be needed.

However, if you have nothing to lose, and would dump it otherwise, remove the touchpad entirely and wash it in clean water in an effort to clear out any contamination, then do the same using high purity alcohol to drive out the water, and then dry it out thoroughly. This is a long shot but might work.

Microwave oven does not respond to START button

While all other functions operate normally including clock, cook time, and power setting, pressing START does nothing, including no relay action and the timer digits do not count down. It is as though the START button is being totally ignored. (However, if there is a momentary response but then the oven shuts off, see the section: Erratic behavior.

If there is an alternate way of activating the cook cycle, try it. For example, Sharp Carousel IIs have a 'Minute Plus' button which will cook for one minute on HIGH. Use this to confirm the basic controller logic and interlock circuitry. If it works, then the problem may indeed be a faulty START button. If it is also ignored, then there may be a bad interlock or some other problem with the controller.

Check for bad interlocks or interlocks that are not being properly activated.

Next confirm if possible that the START touch pad button is not itself faulty. If you can locate the matrix connections for this button, the resistance should go down dramatically (similar to the other buttons). See the section: Some of the keys on the touchpad do not function or perform the wrong action. The START button does, after all, sees quite a lot of action!

Assuming it is not the touch pad, it sounds like the controller is either not sensing the start command or refusing to cooperate for some reason - perhaps it thinks an interlock is open. Otherwise, the timer would start counting. Testing the relay or triac control signal will likely show that it is not there. Check that there are no missing power supply voltages for the controller and bad connection.

Microwave generator problems

Failures in the microwave generator can cause various symptoms including:

- No heat but otherwise normal operations.
- Fuse blows when closing or opening door.
- Loud hum and/or burning smell when attempting to cook.
- Arcing in or above oven chamber.
- Fuse blows when initiating cook cycle.
- Fuse blows when microwave shuts off (during or at end of cook cycle).

- Oven heats on high setting regardless of power setting.
- Oven immediately starts to cook when door is closed.
- Oven heats but power seems low or erratic.
- Oven heats but shuts off randomly.

Most of these are easy to diagnose and the required parts are readily available at reasonable prices.

No heat but otherwise normal operation

If the main power fuse is located in the primary of the high voltage transformer rather then at the line input, the clock and touchpad will work but the fuse will blow upon initiating a cook cycle. Or, if the fuse has already blown there will simply be no heating action once the cook cycle is started. There are other variations depending on whether the cooling fan, oven light, and so forth are located down stream of the fuse.

Some models may have a separate high voltage fuse. If this is blown, there will be no heating but no other symptoms. However, high voltage fuses are somewhat rare on domestic ovens.

A number of failures can result in the fuse NOT blowing but still no heat:

- Bad connections - these may be almost anywhere in the microwave generator or the primary circuit of the HV transformer. A common location is at the crimp connections to the magnetron filament as they are high current and can overheat and result in no or intermittent contact. See the section: See the section: Testing the magnetron.

- Open thermal protector - usually located on magnetron case. Test for continuity. It should read as a dead short - near zero ohms. See the section: Testing thermal protectors and thermal fuses.

- Open thermal fuse - some ovens have one of these in the primary circuit. It may be in either connection to the HV transformer or elsewhere. Test for continuity. It should read as a dead short - near zero ohms.

- Open HV capacitor - see the section: Testing the high voltage capacitor. A shorted HV capacitor would likely immediately blow the fuse.

- Open HV diode - see the section: Testing the high voltage diode.

- Open magnetron filament - This failure may also be due to loose, burnt, or deteriorated press (Fast-on) lugs for the filament connections and not an actual magnetron problem. See the section: Testing the magnetron.

- Open winding in HV transformer. See the section: Testing the high voltage transformer.

- Defective HV relay. A few models use a relay in the actual high voltage circuitry (rather than the primary) to regulate cooking power. This may have dirty or burnt contacts, a defective coil, or bad connections

- Shorted HV diode - see the section: Testing the high voltage diode.

- Short or other fault in the magnetron - see the section: Testing the magnetron.

* Short in certain portions of the HV wiring. See the section: Testing and repairing the wiring and connections.

A shorted HV diode, magnetron, or certain parts of the HV wiring would probably result in a loud hum from the HV transformer but will likely not blow the main fuse. (However, the HV fuse - not present on most domestic ovens - might blow.)

Depending on design, a number of other component failures could result in no heat as well including a defective relay or triac, interlock switch(s), and controller.

Timer and light work but no heat, cooling fan, or turntable rotation

This means the controller thinks the oven is working but the microwave generator AND motors aren't being powered. Note that these symptoms are subtly different than just having no heat and eliminates the actual components of the microwave generator from suspicion in most cases.

(From: Bonita Lee Geniac (bgen@wdl.net).)

When the timer counts down but nothing else works, 99% of the time the lower door switch is bad or else the door is not closing fully and the latch hooks are not depressing the upper and lower switches. There is also a slight possibility that the relay or triac on the control board is not closing but those usually do not result in these particular symptoms. Most of the microswitches used in recent production microwaves are very poor quality and the silicone lubrication used by some of the manufacturers migrates into the switch contact area and makes the switch fail even faster than it should.

Fuse blows when closing or opening door

This means that the main fuse in the microwave (or less commonly, the fuse or circuit breaker for the power outlet) pops when the microwave oven door is closed or opened. This may be erratic, occurring only 1 out of 10 times, for example.

The cause is almost certainly related to either the door interlock switches or the door itself. Marginal door alignment, broken 'fingers' which operate the switches, dislocated parts in the interlock mechanism, or a defective interlock switch may result in either consistent or erratic behavior of this type.

On some ovens, this can happen at any time regardless of the control panel settings or whether the oven is in the cook cycle or not. On others, it can only happen when interrupting the cook cycle by opening the door or when initiating the cook cycle from the front panel (if the switches are in the wrong state).

The rational for this basic design - some form of which is used in virtually all microwave ovens - is that a defect in the interlock switches or door alignment, which might result in dangerous microwave radiation leakage, will produce a hard permanent failure. This will prevent the oven from being used until it is inspected and repaired.

* As noted, one of the interlock switches is actually across the power line. If the switches are activated in the wrong sequence due to a misaligned door, that switch will not turn off before the other switches turn on shorting the power line. Similarly, if its contacts are welded closed, the power line will be shorted when the other switches close.

  See the section: Testing and replacing of interlock switches.

- Inspect the door, its mounting, and the plastic 'fingers' which operate the interlock switches as well. Again, if the sequence is not correct, the power line will be shorted blowing the fuse. If the oven was dropped, then such damage is quite likely. Look for broken or dislocated parts, warpage, and other indications of problems with the door and interlock mechanism Of course, if the oven was dropped, there could be much more extensive internal damage as well.

Loud hum and/or burning smell when attempting to cook

A loud abnormal hum is an indication of a short somewhere. The sound may originate from the HV transformer vibrating and/or from within the magnetron depending on cause. There may be a burnt odor associated with this behavior:

- Shorted HV diode - see the section: Testing the high voltage diode.

- Shorted magnetron (filament to anode) or other internal fault in the magnetron - see the section: Testing the magnetron. Arcing within the Magnetron case (visible through ventilation holes in the bottom section) is usually an indication of a bad magnetron.

- Other short resulting from frayed insulation or wires touching in the microwave generator.

- Shorted HV transformer - see the section: Testing the high voltage transformer.

- Short resulting from burnt on food (usually) in or around the waveguide. If the odor is coming from the oven chamber, see the section: Arcing in or above oven chamber.

The following procedure will quickly identify the most likely component if the problem is not food/spills/carbon related:

(Usually a loud hum is caused by a short in the HV transformer, HV diode, or magnetron. The other items listed below would likely blow the main fuse but possibly not always.)

(Portions from: Tony (tonyb@ramhb.co.nz).)

1. Discharge HV capacitor! (If there is a short it is doubtful if it has any charge but never hurts to be safe).

2. Remove one end of the lead from the HV capacitor to the transformer.

3. Start the oven.

    - Hum gone? If so, it is the HV circuitry, go to step 4.
    - If it still hums you probably have a faulty HV Transformer. (Not uncommon.)

4. Discharge the HV capacitor again, reconnect wire and disconnect the 2 wires to the magnetron.

5. Restart oven.

    - Hum Gone? If so, magnetron is shorted. Replace or get a new oven.

- Hum still there? If so, go to step 6.

6. You have either

   - Shorted HV capacitor,
   - Shorted HV Diode,
   - Shorted clamp diode across the HV Cap terminals (if one is present, about 30% of microwave ovens use these). (The oven will run 100% without this protection for the HV capacitor but it should be replaced if possible.)
   - Some older Panasonic ovens have a HV reed switch and these can also short but these are rare now because of the age.

Arcing in or above oven chamber

There is often a simple cause:

- Arcing in the oven chamber with a normal load (a cup of water, for example), often just indicates that a thorough cleaning of the oven chamber is needed, particularly around and inside/above the waveguide cover. Any food that gets trapped here will eventually burn and carbonize resulting in a focal point for further arcing. Usually, the waveguide cover is designed to be removable without taking the (cabinet) cover off of the oven. However, burnt food and carbon often make this difficult so that some disassembly will be required. See the sections: "SAFETY" and "Getting inside a microwave oven". Clean the waveguide cover and clean inside the waveguide as well. If the waveguide cover is broken or damaged seriously, a sheet of replacement material is available from places like MCM Electronics. Trim to fit with a pair of heavy duty scissors, metal snips, or a paper cutter. The oven will work fine without it but replacement will prevent contamination of the waveguide with food vapors or splatters which can lead to more expensive damage. Take extra care to cover all food (which you should do anyhow) until the waveguide cover is replaced.

- Any sharp metal edges may also result in arcing or sparking. However, the only way such damage could occur as part of the oven (not added knives or forks!) would be through physical abuse.

- If your oven uses a stirrer above the oven chamber (no turntable), it may be stuck. The result will be an uneven distribution of microwave energy and localized heating, arcing, and possibly melting plastic or metal.

- Flashing and sparking may also result from the stirrer/fan blades contacting the metal surrounding it due to the motor/bearings becoming loose or dislodged.

More on the waveguide cover and cleaning

That cover is made of an insulator transparent to microwaves, usually mica, not a metal. The material can be obtained from places like MCM Electronics which you then cut to size with a pair of scissors or a paper cutter.

First, completely clean below, above, inside, and whatever of the cover material is remaining. All traces of carbon and burnt on food must be removed. In particular, you need to clean inside the waveguide above the inside top of the oven as well.

Then run the oven (with the waveguide cover removed, if necessary) to verify that there are no other problems (there probably are none).

Sometimes, you need to remove the outside metal cover in order to remove the waveguide cover. There may be little plastic pins or snaps which tend to get gummed up with burnt food and may be difficult to pry off from inside the oven. If you do need to remove the metal cover, jot down the locations of each of the screws (they are not always all alike) and stay away from everything but the waveguide cover itself (especially the high voltage components!).

That waveguide cover is not essential to the operation of the oven but it does prevent food from entering the waveguide and getting trapped there.

Fuse blows when initiating cook cycle

The fuse may only blow when actually attempting to cook but depending on design, triacs and/or door switches may always be live and may result in a blown fuse at any time when plugged in or when the door is opened or closed.

The following can cause the fuse to blow (in approximate order of likelihood):

- Defective interlock switches or misaligned door. At least one of the interlock switches is across the power line and will blow the fuse if not activated in the correct sequence. See the sections: "Fuse blows when closing or opening door" and "Testing and replacing of interlock switches".
- Shorted HV capacitor. See the section: Testing the high voltage capacitor.
- Shorted HV diode (see note below). See the section: Testing the high voltage diode.
- Shorted magnetron (filament to anode - see note below). See the section: Testing the magnetron.
- Defective triac (shorted or partially shorted). See the section: Testing and replacing the triac.
- Old age or power surge. Fuses sometimes blow for no apparent reason.
- Defective HV transformer (shorted windings. See the section: Testing the high voltage transformer.
- Shorted wiring due to vibration or poor manufacturing quality. See the section: Testing and repairing the wiring and connections.

Note that a shorted magnetron or shorted HV diode - which you would think should blow the fuse - probably will not do so because current will be limited by the impedance of the HV capacitor (assuming it is not shorted as well). However, there will likely be a loud hum from the HV transformer as it strains under the excess load. Such a sound in conjunction with no heat is a likely symptom of a shorted magnetron or HV diode. If your oven has a separate high voltage fuse - somewhat rare in domestic ovens - it may certainly blow due to a fault in any of the HV components.

Fuses also die of old age. The types of fuses used in microwave ovens are subjected to a heavy load and you may find that all that is needed is to replace the fuse with one with equivalent ratings. (but check for shorts first). There could be an intermittent problem as well which will only show up at some random time in the future. A poorly timed power surge (as opposed to the well timed variety) could also weaken the fuse element resulting in eventual failure.

The fuses used in microwave ovens are usually ceramic 1-1/4" x 1/4" 15 or 20 A 250 V fast blow type. Replace with exactly the same type and rating.

Another possible cause of a blown fuse is a partially bad triac. Some ovens use a triac rather than a relay to control the main power to the high voltage transformer. One type of failure of a triac is for it to be totally shorted causing the oven to come on whenever the door is closed. Alternatively, the gate may be defective preventing the triac from ever turning on. A third, and most interesting possibility, is that one half of the triac is bad - shorted or open, or doesn't turn on or turn off reliably. Recall that a triac is in effect a pair of SCRs in parallel in opposite directions. If one side is defective, the main fuse will blow due to transformer core saturation since the triac will act as a rectifier and transformers really do not like DC.

See the chapter: "Testing and Replacement of Components" for more information on this and similar problems.

Fuse blows when microwave shuts off (during or at end of cook cycle)

This could be due to a number of faults including shorting wires or defective relay. However, a common cause that might not be obvious is that the triac used to switch power to the high voltage transformer is faulty. What is probably happening is that only one half of the triac (recall that a triac is controlled for both polarities of the line voltage/current) is turning off completely resulting in DC to the HV transformer, core saturation, and excessive current which blows the fuse. Drive to the triac could also be marginal but the bad triac is more likely.

Exactly how a bad relay could result in these symptoms unless it was actually arcing and shorting is unclear. However, there is anecdotal evidence to suggest that inspecting the relay contacts and cleaning them if necessary may cure it in some cases.

The following description applies directly to some GE and Hotpoint models. Modify it accordingly for your oven. Depending on model, the triac may be located on the control board or mounted directly on the chassis.

(From: John Gallawa (microtech@gallawa.com).)

I have seen exactly this problem; and I've seen it baffle many a repair shop. It is likely that the triac on the 'Power Control Board' is breaking down. This is a fairly common problem in GE and Hotpoint models that use this board.

You can usually confirm the problem by setting the oven to a lower power level, say "medium," and heat a cup of water. You will probably hear a 'thump!' each time the magnetron cycles on. This is an indication of a weakened triac.

Replace the triac (Q1) with either of the following: ECG 56010, or SK 10265. Finally, replace the line fuse, install the outer cover, and test the oven for proper operation.

The only other alternative is to replace the board. The cost used to be pretty reasonable, but now it's gotten expensive - probably about $80.00.

The triac is probably located beneath a red plastic guard on the power control board. Its designation is usually Q1.

(From: John Montalbano (jrmont@iquest.net).)

The microwave oven in my General Electric JHP65G002AD cooking center blew its 15 AMP fuse each time the timing cycle expired. Replacing the triac GE Part number WB27X5085 ($65.00 from GE) with a new NTE56014

($13.00) solved the problem.

(From: Les Bartel lbartel@veribest.com).)

I had the exact same symptoms on my GE microwave. I replaced the triac with a $3 15 amp off-the-shelf triac and it has been working for several years since.

See the chapter: "Testing and Replacement of Components" for more information on triac testing though replacement is probably the only sure test.

Oven heats on high setting regardless of power setting

Power levels in a microwave oven are controlled by cycling the microwave generator on and off with a variable duty cycle - kind of like slow pulse width modulation. For 'HIGH', it runs continuously; for low, it may run 10% on and 90% off; other settings are in between.

When the oven always seems to be stuck at high power, it is likely to be due to one of two possible causes - a faulty relay or Triac, or controller. The relay or triac may have failed in the on state. This will probably show up with ohmmeter tests (with the oven unplugged!) but not always.

Replacements should be readily available. If the problem is is the controller, it will be more difficult to diagnose as schematics for the controller are usually not readily available. However, it could be something simple like a bad connection or dirty connector.

Oven heats but power seems low or erratic

Some considerations are how old the oven is and did the problem happen suddenly or did it just gradually weaken over the years.

First, are you sure the problem is real? Perhaps you are just a little less patient than you used to be. Perform a water heating test or try to pop a bag of popcorn using you usual time setting. See the section: Testing the oven - the water heating test.

- If you are subject to brownouts or are running on your own generator, the line voltage may be low. Power output is quite sensitive to the AC input - there is no regulation. A 10% drop in line voltage is likely to reduce microwave power output by more than 20%.

- Magnetrons, like other vacuum tubes, can weaken with age and use. An oven that sees daily use may indeed weaken over the course of several years. It is unlikely that any other electronic components could change value in such a way as to significantly affect power output. However, a failure of the controller or sensor (if you have one) could result in short cycling.

  Testing on HIGH will eliminate this possibility. Make sure the magnetron is powered continuously and it is not cycling. You can often tell by listening for the relay clicks and/or by observing the oven light/other lights dimming as the magnetron kicks in. 50% power should result in approximately equal on and off times.

- If you run the oven on HIGH, can you tell if it is actually heating continuously or rather it thinks you want LOW? Many microwave ovens make a clicking sound as they use a relay to switch microwave power on and off - check if you can hear this. Alternatively, lights on the same circuit or the oven light may dim slightly when the magnetron kicks in. There should not be any cycling on HIGH - the microwave power should stay on continuously while it is cooking. If it is cycling, there may be a problem with the controller or you may unknowingly be in a low power mode - check it.

- Mechanical problems are also possible. Where a spinning paddle wheel is used to 'stir' the microwave energy (often where there is no turntable), its failure to rotate can result in hot and cold spots. Thus, you may see an unexplained variation in cooking times. The paddle is often accessible by unclipping a plastic cover above the oven cavity. Check for bearing failure, binding, broken or lose belt if direct driven, etc. Note that some are rotated by air flow from the cooling fan and require that cover to be in place to rotate. Therefore, it is not really possible to inspect for correct operation with the cover removed. However, you can put a microwave power indicator (NE2 neon light bulb with its leads twisted together) in the oven (with a cup of water for a load) and observe it through the window. You should see a periodic variation in intensity as the paddles do their job.

- There could be intermittent connections to the magnetron filament, thermal protector, or elsewhere. But, these would likely show up as erratic operation - no heat at all sometimes - not just a weak oven.

  Inspect and clean and tighten (if necessary) all connections in the microwave generator including the magnetron filament, HV transformer, HV Diode, HV capacitor, and thermal protector. Be sure to unplug the unit first and discharge the HV capacitor before touching anything!

- The thermal protector may be intermittent. Test by clipping a light bulb across it or monitoring with a multimeter on AC voltage. See the section: Testing thermal protectors and thermal fuses.

Oven heats but shuts off randomly

Everything operates normally, but the oven shuts off after varying amounts of time. This could be a faulty magnetron, bad cooling fan (or just built up dust and grime block ventilation grilles), bad thermal protector, faulty controller, some other intermittent component, or bad connections.

- If resetting it allows cooking to resume immediately, if even for a few seconds, I would not suspect the magnetron or thermal problem as no cool down time is required. It could be bad connections in the controller or elasewhere, a marginal door interlock switch, or a controller problem. Jiggle the door to see if this will cause it to shut off.

- If the magnetron was overheating, you would not be able to resume cooking until it cooled and the thermal protector reset. If it just stopped working (i.e., the filament opened), everything would appear normal but there would be no heating. If the magnetron were shorting, there would likely be a loud hum associated with the periods where there was no heat.

- If it is not possible to resume cooking for a few minutes indicating that something needs time to cool off, then the magnetron could be faulty but check for the obvious cooling problems first: blocked or dirty ventilation grill. Determine if the magnetron cooling fan is operating by listening for its sound or looking through the ventilation opening in the back of the oven. If it is not, there could be a broken or weak belt, gummed up or lack of lubrication, other mechanical problems, a bad motor, or bad connections.

- Extremely high power line voltage may also result in overheating on a poorly designed or oven where the components are marginal.

- Make sure the stirrer fan is turning normally. Should it gets stuck, some models may sense this and shut down/restart.

Oven makes (possibly erratic) buzzing noise when heating

Assuming operation is normal otherwise, this is most likely either a fan or other motor vibrating on its mounts, fan blades hitting something, or some sheet metal or the high voltage power transformer laminations vibrating. There may be something stuck under the turntable or above the waveguide cover interfering with the stirrer.

Something may have loosened up with age and use.

If the noise is caused be simple vibrations, no damage is likely to result. However, if the main cooling fan is on its way out and it stops or gets stuck, parts will overheat quite quickly at which point the oven will shut down (hopefully) and there could be damage to the magnetron or other components. Therefore, at least identifying the cause is probably a good idea.

The solution may be as simple as tightening a screw or weging a shim between two pieces of vibrating sheet metal.

Oven light does not work

If the oven light no longer works, believe it or not, a burned out light bulb is likely.

You would think that something like replacing a light bulb would be trivial and self evident. Unfortunately, not always so with microwave ovens. Light bulbs may be typically located in any of 3 places:

1. Oven chamber - it may be behind a mesh grill requiring a screw or snap to be removed. This is the easiest.

2. Rear - the bulb may be in a recessed compartment accessible by removing a screw or two on the back of the oven.

3. Inside - it may be behind a non-removable grille requiring the removal of the cover.

These are typically not your usual vanilla flavored appliance bulbs either.

Bad connections are also possible but not that likely.

Fans or turntables that do not work

There are up to 4 motors in a microwave oven:

- Magnetron cooling fan - always present.

- Mechanical timer (on inexpensive non-touchpanel or older units).

- Turntable.

- Convection air circulation (combo units only).

When any of these do not operate properly, the most likely causes are:

- Gummed up lubrication/dry bearings. Check for free rotation of the affected part(s). Clean and lubrication as needed. Also confirm that there are no other mechanical problems (e.g., turntable improperly installed).

- Loose or broken belt. Confirm that belt is properly installed. Test to determine if it is worn and flabby - stretch it by about 25%. It should return to its relaxed length instantly. Clean and/or replace if needed.

- Bad motor. Disconnect one wire and check for continuity with an ohmmeter. If open, winding is bad but check for break at terminal which you can resolder.

- Bad thermostat. Where a fan only runs when the oven is hot as in a microwave/convection oven, the thermostat or controller could also be at fault. Locate the thermostat and jumper across its terminals with power off. Plug the oven in and see if the fan now runs all the time or at least when the appropriate mode(s) are entered.

- Bad connections - trace wiring and check continuity (unplugged, capacitor discharge) to motor terminals.

Note that the opposite problem - a turntable and/or fan that runs *after* the cook cycle is completed may be normal for your oven. This is a "cool-down" function designed to allow the heat to equalize or possibly added by the company's legal department to reduce the number of lawsuits due to stupidity. :)

What to do if the door handle breaks off

Usually this happens at the places where the handle is screwed to the door.

I would NOT recommend making the repair in any manner that compromises the shielding properties of the door. (I have visions of someone using 1/2" stove bolts through the door and handle which would definitely be a bad idea). Anything that penetrates the door seal is a potential hazard - likely a very small one but it is not worth the risk.

Therefore, I would recommend staying with repairs that can be made totally externally unless there is no possibility of a change to the integrity of the door. For example, replacing the screws with similar sized screws that gripped better or using filler to reconstruct or strengthen the threaded holes would be acceptable.

Plastic is generally tough to glue where a strong bond is needed and where the joint is subject to abuse. However, depending on the type of plastic, one or more of the following may work: semiflexible adhesive like windshield sealer, plastic cement (the kind that fuses the plastic, not model cement), Duco cement, PVC (pipe) cement, or even superglue (though it seems not all brands are equally effective). Make sure the surfaces to be glued are perfectly clean (remove any residual library paste if you tried that!) and provide a means of clamping the pieces until the bond sets up (adhesive tape and/or rubber bands may be all you need). Consider providing some reinforcements around the joint (i.e., plastic splints or sisters depending on your profession) for added durability.

Replacement door handles and/or entire doors may be available from the manufacturer of the oven. Replacements for a few Panasonic models are even stocked by MCM Electronics (and no doubt other places as well).

(From: John Gallawa (microtech@gallawa.com).)

Here are the door disassembly instructions from the Amana service manual. Many others are similar:

1. Pry out the inner door trim with a small screwdriver on the latch side of the door.

2. Remove two screws securing the latch assembly and door handle to the outer panel (this may be all that's needed to replace the handle).

3. Remove six screws and release 4 spring fingers that secure the choke to the outer panel.

WARNING: A microwave leakage test must be performed any time a door is removed, replaced, disassembled, or adjusted for any reason.

Crack or other damage to door window

> "My microwave oven has a crack in the glass of its door. Is this safe to continue using or should I get it fixed? Will there be any radiation leakage?"

So you were throwing roasts at the oven again, huh? :-)

If the metal screen/mesh is behind and separate from the glass, there is no danger. In this case, the function of the glass is mostly cosmetic and a small crack should not be a problem.

However, if the screen is inside the glass and now broken as well, there could be microwave leakage. Even if it is not actually broken at this time, future failure is possible. Therefore, the glass panel or entire door should be replaced.

Also, any break large enough to allow something to touch the metal screen is a hazard because during cooking, there could be shock hazard due to microwaves inducing current in the screen. And, poking something metallic through the screen would make is susceptible to microwave pickup as well.

However, damage to the inner plastic is probably not a cause for concern as that is only there to keep the screen and inside of the door glass clean.

Repairing damage to the oven interior

If spilled food - solid or liquid - is not cleaned up soon after the oven is used, it will tend to harden and carbonize. Not only will this be much more difficult to remove, but hot spots may develop and result in possible sparking, arcing, and damage to the interior paint.

If this happens in the vicinity of the mica waveguide cover, it may be damaged as well. In addition, sometimes splatters may find their way above the waveguide cover and cause problems above the roof of the oven chamber in the waveguide.

Needless to say, clean up spills and food explosions as soon as possible. Not only will it be easier, the chance of future expensive problems will be minimized.

To prevent arcing and sparking, the interior needs to be smooth. Sharp edges and hard carbon in particular creates places where electric field gradients can become great enough to cause problems. Thus the warning not to use any metal utensils in a microwave.

Once damage occurs - paint blisters and peels, or totally hardened impossible to remove carbon deposits - more drastic action is called for:

- Assuming cleaning does not work on the carbon - even after repeated attempts, carefully scrape it off with a blunt knife or other suitable tool. This will probably damage the paint. Use fine sandpaper to completely smooth out the metal and feather the edges of the paint in the immediate area.

  Special microwave oven cavity paint is available but any common gloss enamel will work just as well (and costs about 1/10th as much). Use touch-up paint (with a small brush) or spray paint. The typical color is beige, almond, or some other form of off-white - just match it to your oven (if you care).

  Until you can obtain the paint, the oven will work fine but since the chamber is made of sheet steel, rust will set in eventually. So, do paint it.

- If the waveguide cover is damaged seriously - such that it no longer will prevent splatters from entering the waveguide, obtain replacement material, cut to fit. Leaving it larger than necessary is fine as well. Use a suitable bit in a hand drill to make holes in the mica for the mounting screws or plastic snaps.

  Alternatives to mica which can stand the elevated temperatures in a microwave oven may also be acceptable. Possible choices include plastic or fiberglass laminate but not all materials will allow microwaves to pass without some heating - check it out. Heat a cup of water and the candidate material on high for a couple of minutes. If the material doesn't heat up, it should be fine. Of course, it must also not have any metal coating (don't use a piece of one of those 'browning disks' :-). Mica is also non-flammable which is may not be the case with other materials.

- If the interior of the door is damaged seriously such that either it will not longer seal around the edge properly or that the mesh screening is breeched, a replacement will be required to assure continued safety with respect to minimizing microwave emissions.

Microwave oven cavity paint, waveguide cover mica sheets, and even some replacement doors are available from the parts suppliers listed at the end of this document. For most ovens, parts like doors will need to be obtained direct from the manufacturer, however.

Microwave/convection oven problems

In addition to the microwave components, these ovens also include an air circulating fan and an electric heating element as well as a temperature sensing themister. Any of these can fail.

- A convection oven which shuts down after a couple of minutes during the preheat cycle with the temperature display (if any) stuck at LOW (even though the oven is hot when opened) may have a bad thermistor temperature sensor.

- The overtemperature protection sensor (rather than the normal temperature sensor) is shutting the oven down. The termister will usually be accessible after removing the oven cover. It will be located centrally just above the oven ceiling duct or elsewhere in the convection air flow. It is a two terminal device that may look like a tiny resistor or diode and may be mounted on a metal header fastened with a couple of screws. Remove and test with an ohmmeter. An infinite reading means it is bad. As a test, jumper a 50 K ohm potentiometer in place of the thermistor. During preheat, as you lower the resistance of the pot you should see the temperature readout climb. The oven will then indicate READY when the simulated temperature exceeds the setpoint. Replacement thermistors are available from the oven manufacturer - about $20. Cheaper alternatives may be possible but you would need to know the exact specifications and it is probably impossible to obtain this information.

Also see the section:

- Sensor problems, below.

- If the convection preheat cycle never completes and the oven is cool when opened, then either the heating element is bad (test with an ohmmeter) or the relay controlling the heating element or the controller itself is bad. If the circulating fan runs off of the same relay and it is operating, then the problem must be the heating element.

- The heating element will be either a Calrod type (GE trade name?) which is a steel tube enclosing a Nichrome wire coil embedded in ceramic filler or a coiled Nichrome element strung between ceramic insulators. The former is probably only available from the oven manufacture, though it is worth trying an appliance parts distributor or a place like MCM electronics first. It may be possible to find a replacement Nichrome coil and form it to fit. Make sure the wire gauge and length are identical.

- The circulating fan is probably driven by a belt, which may break or deteriorate. Inspect the belt. If it is loose, cracked, or does not return to its normal length instantly after being stretched by 25% replace it. Check the fan motor and fan itself for adequate lubrication. Check the fan blades for corrosion and damage.

Sensor problems

Fancier microwave or microwave/convection ovens include various probes that can be used to shut off the oven when the food is supposedly done or maintain it at a preset temperature.

A problem with a sensor, controller, or wiring, may result in incorrect operation (never getting past 'preheat' or not terminating a cook cycle) or in a display of 'EEEE', 'FFFF', ERROR, or something similar:

(From: Wilton Itamoto (witam40231@aol.com).)

> "The 'FFFF' display is a common problem in older Panasonic convection ovens. The problem is the temperature sensor thermostat located on the top rear of the oven. This is the convection temp. sensor for the correct oven temperature. Replacing this open sensor will correct the problem."

When problems develop with these automatic features, the sensor and the probe cable are the primary suspects. However, it is possible that the electronic circuitry could also be affected by a damaged or defective probe unit.

- Check for bad connections where the probe plugs in as well as broken wires inside the cable particularly near the ends where it gets flexed.

- Temperature probes may use a thermistor similar to one that controls the convection portion of a microwave/convection oven. Steam/humidity probes may also behave similarly.

- If you have never tried the probe before, check your users manual. It may only be active in certain modes, etc.

The best test of the probe unit is to substitute a known good one. Of course, this is generally not convenient.

- There should be some resistance when measuring between the signal conductors of the probe cable. It may be high (hundreds of K ohms) but probably should not be open. A very low value (a few ohms or less) might indicate a short in the cable or sensor.

- See the section: Microwave/convection oven problems for a discussion of thermistors. Testing to determine if the controller is responding to the input from the sensor can be done in a similar manner except that access must be from inside the electronics bay while the oven is running (the probe normally plugs in inside the oven chamber). Substitute a fixed or variable resistor and see if you can get the oven to shut off (or stay on) as a function of resistance. CAUTION: Don't forget to put a cup of water in as a load if you are testing microwave operation.

If the resistor test determines that the controller is responding, than a bad probe unit is likely.

If the probe checks out or substituting a known good one makes no difference in behavior, look for corrosion or other deterioration of the socket in the oven chamber as well as bad connections. Faulty circuitry in the controller is also possible.

Testing and Replacement of Components

Please see Typical Microwave Oven Electronics Bay for parts identification.

Testing the oven - the water heating test

The precise number of degrees a known quantity of water increases in temperature for a known time and power level is a very accurate test of the actual useful microwave power. A couple of minutes with a cup of water and a thermometer will conclusively determine if your microwave oven is weak or you are just less patient (or the manufacturer of your frozen dinners has increased their weight - sure, fat chance of that!)

You can skip the heavy math below and jump right to the final result if you like. However, for those who are interested:

- 1 Calorie (C) will raise the temperature of 1 gram (g) of liquid water exactly 1 degree Centigrade (DegC) or 9/5 degree Fahrenheit (DegF).

- 1 Calorie is equal to 4.184 Joules (J) or 1 J = 0.239 C.

- 1 Watt (W) of power is 1 J/s or 1 kW is 1000 J/s.

- 1 cup is 8 fluid ounces (fl.oz.) which is 8 x 29.57 g/fl.oz. = 236.6 g. (For Avoirdupois ounces, use 28.35 g.)
- 1 minute equals 60 s (but you know this!).

Therefore, in one minute, a 1 kW microwave oven will raise the temperature of 1 cup of water by:

```
T(rise) = (60 s * 1000 J/s * 0.239C/J * (g * DegC)/C)/(236.6 g) = 60.6 °C.
```

Or, if your prefer Fahrenheit: 141 °F.

To account for estimated losses due to conduction, convection, and imperfect power transfer, I suggest using temperature rises of 57 DegC and 135 DegF.

Therefore, a very simple test is to place a measured cup of water in the microwave from the tap and measure its temperature before and after heating for exactly 1 minute on HIGH. Scale the expected temperature rise by the ratio of the microwave (not AC line) power of your oven compared to a 1 kW unit.

Or, from a Litton microwave handbook:

- Heat one Liter (L) of water on HIGH for 1 minute.
- Oven power = temperature rise in DegC multiplied by 70.

Use a plastic container rather than a glass one to minimize the needed energy loss to raise its temperature by conduction from the hot water. There will be some losses due to convection but this should not be that significant for these short tests. For the ultimate in accuracy (as these things go), put the water in a styrofoam cup, invert another styrofoam cup over it, and poke your thermometer through it.

(Note: if the water is boiling when it comes out - at 100 DegC or 212 DegF, then the test is invalid - use colder water or a shorter time.)

The intermediate power levels can be tested as well. The heating effect of a microwave oven is nearly linear. Thus, a cup of water should take nearly roughly twice as long to heat a specific number of degrees on 50% power or 3.3 times as long on 30% power as on full power. However, for low power tests, increasing the time to 2 minutes with 2 cups of water will result in more accurate measurements due to the long period pulse width power control use by microwave ovens which may have a cycle of up to 30 seconds.

Any significant discrepancy between your measurements and the specified microwave power levels - say more than 10 % on HIGH - may indicate a problem. (Due to conduction and convection losses as well as the time required to heat the filament of the magnetron for each on-cycle, the accuracies of the intermediate power level measurements may be slightly lower).

See the section: Oven heats but power seems low or erratic.

Testing the main fuse

Where the oven is dead or mostly dead, the main fuse is the place to start:

- UNPLUG THE OVEN and locate and remove the main fuse. It will usually be a 1" x 1-1/4" ABC ceramic type directly in-line with the Hot (black wire) of the power cord.

- Test it with an ohmmeter - the reading should be zero ohms.

    - If it is blown, suspect problems with the interlock switches, high voltage capacitor, or high voltage wiring.

    - If it is good but the oven makes a loud humming sound when you attempt to cook, suspect the magnetron or high voltage diode.

Testing and replacing of interlock switches

With the oven unplugged, put an ohmmeter across the AC input just before the interlocks (but beyond the power relay or triac if it precedes these). Open and close the door slowly several times - there should be no significant change in resistance and it should be more than a few ohms. If it approaches zero while opening or closing the door, the interlock switches and door alignment should be checked. (You may need to disconnect one side of the transformer primary since its resistance is a fraction of an ohm. Refer to the schematic pasted inside the cover.)

Replace with switches having a precisely identical fit and equal or better electrical specifications (terminal configuration, current rating). When removing the old switch make a note as to where each wire goes. Check the embossed marking on the old switch - don't depend on location as your replacement might just have a different arrangement. Make sure the new switch aligns correctly with the actuating mechanism and then check for correct electrical operation with an ohmmeter before applying power.

Making measurements inside microwave ovens

WARNING: In general, I DO NOT recommend making any sorts of measurements on the high voltage components of a live microwave oven. I only include this section for those who really want to know the details.

You may be temped to break out your Radio Shack DMM and start poking away inside a live microwave oven. DON'T! This isn't like a CD player! Most of the time, no measurements of any kind on the oven while it is operating will be needed to identify and correct the problem. However, where this is not the case, here are some guidelines to a long life:

WARNING: ALWAYS pull the plug and discharge the HV capacitor BEFORE doing anything inside! Never be tempted to make any changes of any kind while the oven is on - not even if your meter is being consumed by 5 foot flames! First, pull the plug and discharge the HV capacitor!

- High voltage - DON'T even think about this unless you have a proper high voltage probe or meter, or a proper microwave oven tester - AND KNOW HOW TO USE IT SAFELY. Even professionals have been killed performing measurements of this type using proper equipment! Luckily, current measurements can provide enough information to help make a diagnosis.

  WARNING: The high voltage components inside a microwave oven are at a NEGATIVE potential with respect to the chassis. DO NOT be tempted to interchange the probe and ground wire if you are using a high voltage probe on a meter with a POSITIVE input (e.g., for testing CRT HV) and no polarity switch! The ground cable doesn't have anywhere near the required insulation. Get the proper equipment!

One thing you can do relatively safely is to connect a Variac directly to the primary of the HV transformer. With this set at a MAXIMUM of 10 percent, the voltage on the filament terminals of the magnetron should read from -150 to -250 V with respect to the chassis. A scope can also be used if it has a proper 10:1 probe as long as you aren't tempted to turn up the Variac any higher! The scope waveform should be close to a sinusoid with its positive tips at 0 V. Such reduced voltage tests won't identify problems that only occur at full voltage, however.

- Magnetron current - Place a 10 ohm 10 watt resistor in series with the HV diode cathode and ground. Measure the voltage drop across this resistor. Sensitivity will be 10 V/A. Normal anode current is around 300 to 400 mA for a typical oven. This will be -3 to -4 VDC across the 10 ohm resistor with respect to chassis ground. SET EVERYTHING UP AND THEN STAND BACK and don't forget to DISCHARGE the HV capacitor after making the measurement:

    - If it is around this range, the magnetron is probably fine.

    - If it is very low or 0, magnetron is bad or HV is not working. Note that a shorted as well as open magnetron also results in no current. If the magnetron is shorted, it bypasses all current to ground. If the magnetron is open, the HV capacitor charges up and then there is no more current through the HV diode (but there will be an initial transient).

    - If it is much too high (whether fuse blows or not), capacitor is shorted.

(From: Michael Caplan (cy173@freenet.carleton.ca).)

A properly conducting magnetron will load down the HV power supply. If the magnetron is non-conducting, the voltage remains high.

The power supply will produce 3,500 to 4,000 volts DC, or more, open circuit (as when the oven is first turned on and the magnetron filament/cathode is not fully heated). With full conduction by the magnetron, the HV drops to between 1,800 and 2,100 V. Weak magnetrons conduct somewhat, but the HV remains well above the 2,100 V. (The voltages vary with design and model, but the magnitude of the change is the key.)

I check the HV using my 30 kV HV probe with a DMM, measuring between the magnetron filament connectors (either one) or at another equivalent point, and case ground. (Again, depends on the circuit, but I think this is a common configuration.) The HV at the magnetron filament is negative to ground.

Testing the high voltage components

WARNING: First, with power disconnected, discharge the high voltage capacitor. See the section Safe discharging of the high voltage capacitor.

Assuming the oven passes the above test for interlocks and door alignment, the triac (if used) may be defective. There could also be a wire shorting to the chassis. However, the most likely problems are in the microwave generator.

An ohmmeter can be safely used to quickly determine if the capacitor, HV diode, or magnetron are a dead short (as well as for an open magnetron filament).

Use an ohmmeter to test the diode and capacitor. While connected in circuit, the resistance in at least one direction should be several M ohms. (Try it in both directions, use the higher reading). Test the magnetron from the filament to chassis - it should be high in at least one direction. Test the filament for continuity - the resistance of a good filament is close to 0 (less than 1 ohm).

Where the capacitor and diode are combined into one unit, it should be possible to test each component individually. In some cases, it may also be possible to replace only the one that is found to be defective or make up a substitute HV cap/diode assembly from individual components if the combined unit is excessively expensive or no longer available.

These may be considered to fail/no conclusion tests - they can definitively identify parts that are bad but will not guarantee that they are good. Parts may test ok with no voltage applied but then fail once operated in-circuit. Connections may open up when they heat up. The magnetron may short out when full voltage is applied.

Don't overlook the wiring as no heat or erratic operation can result from simple bad connections!

An alternative way of determining if the problem is in the control circuits (triac, relay, wiring) or microwave generator (HV transformer, HV capacitor, HV diode, magnetron, wiring, etc.) is to connect the HV transformer primary directly to a line cord and plug. Tape the removed wire lugs to prevent shorts.

Plug the transformer cord into a switched outlet strip which includes a fuse or circuit breaker.

Put a cup of water into the oven cavity to act as a load.

- Power the oven via its line cord. Initiate a cook cycle. It should go through the normal cycle (of course no heat) without blowing the fuse or any unusual sounds. If there is a problem in this case, something in the controller or its wiring is shorted.

- Now, initiate a 1 minute cook cycle on HIGH and with the oven running, switch on the HV transformer.

    - If the transformer or other HV components are faulty, the outlet strip fuse will blow or circuit breaker will trip. Or, if a lamp is plugged into the outlet strip at the same time, it will likely dim significantly due to the heavy load before the fuse or breaker cuts out.

    - If the problem is with the triac or its drive, the oven will now heat normally. When the cook cycle is near its end, switch off the outlet strip. Check the water's temperature.

More complete information on testing and replacing the individual components is provided in the next few sections.

Testing the high voltage diode

WARNING: First, with power disconnected, discharge the high voltage capacitor. See the section [Safe discharging of the high voltage capacitor]

The HV diode can fail shorted (most likely) or open. It is not likely for there to be anything in between as so much heat would result that the diode would not remain that way for long.

- A shorted HV diode will likely result in a loud hum from the HV transformer when a cook cycle is initiated.

The main fuse will probably not blow.

- An open HV diode will result in AC instead of DC across the magnetron with a peak negative value (the only one that matters) about 1/2 of what it should be. The result will likely be little or no detectable heat but no other symptoms.

The resistance measured across the leads of the HV diode should be greater than 10 M ohm in at least one direction when disconnected from the circuit. However, the HV diode is composed of multiple silicon diodes in series to get the voltage rating. Its forward voltage drop will therefore be too great (6 V or more) for a DMM to produce a definitive answer as to whether it actually works as a rectifier.

The HV diode can be tested with a DC power supply (even a wall adapter of at least 12 or 15 V output), series resistor (to limit current), and your multimeter. This will determine proper behavior, at least at low voltages.

The following is the schematic of a simple HV diode tester:

```
              240 ohms, 1 W
   + o-----------/\/\---------+------------o +
                              |
                            __|__ HV        Good: 6 to 10 V
 15 VDC                     _\_/_ diode     Shorted: 0 to 2 V
                              |             Open or reversed: 15 V
                              |
   - o------------------------+------------o -
```

The voltage drop in the forward direction should be at least 6 V with a few mA of current but may be somewhat higher (8 V or more) with a few hundred mA. If your DMM or VOM has a resistance scale operated off a battery of at least 6 V, you may get a reading in one direction (but only one) without the need for an external power supply.

Or, assume for now that the diode is good if it is not shorted - which is likely.

Although a shorted HV diode is usually an isolated event, it is possible for failures elsewhere to have caused the diode to blow. Possible causes include a shorted HV cap, arcing between windings in the HV transformer, and possibly even a defective magnetron or damaged waveguide. These may only occur with full voltage so unless there is obvious physical damage (e.g., charring between the HV transformer windings or hole burned in the waveguide), it may be necessary to eliminate the other components one by one.

Replacing the HV diode

WARNING: First, with power disconnected, discharge the high voltage capacitor. See the section Safe discharging of the high voltage capacitor.

Most HV diodes have press fit (Fast-On) or ring lugs so replacement is very straightforward. Discharge the high voltage capacitor. Make sure you get the polarity correct if your replacement can be installed either way. Putting the diode in backwards will result in positive instead of negative high voltage and, needless to say, no heat, but no other symptoms either.

Note: the lugs on your new HV diode may just be crimped onto the wire leads and not welded or soldered. If this is the case, take care not to stress them excessively which might result in bad connections now or in the future. It may be a good idea to solder the lugs to the wires as well (though this may be overkill).

Where the diode is part of the capacitor assembly, it may be possible to just replace the diode leaving the old one unconnected (at one end) as long as the original diode isn't tied to ground inside the case. This will probably be much much cheaper than replacing the entire assembly.

HV diode ratings

Most replacement microwave oven diodes are rated 12 to 15 kV PRV at .5 A. A PRV of around 8 kV is actually required even for a small oven. Here is why: Until the magnetron heats up and starts conducting in its forward direction, what you have is a half wave rectifier/filter formed by the HV transformer secondary, the HV diode, and the HV capacitor. The reverse voltage across the HV diode will be equal to: 2 * 1.414 * (VRMS of the HV transformer). This can easily be 6 or 7 kV or more! Once the magnetron start conducting, the reverse voltage goes down somewhat.

HV diodes rated at .5 A are adequate for most domestic microwave ovens. For example, the largest of these will have a nameplate rating of around 1,800 W power line input and a HV transformer secondary of 2,500 VAC. While there are some losses in the HV transformer, and some power is used by the magnetron filament, controller, motors, and light, this still leaves, perhaps, 1,600 W into the HV generator. However, due to the design of the half wave doubler circuit, not all the power flows through the HV diode (as would be the case with a regular power supply. Thus, even though calculations using Ohms law (I = P/V = 1,600/2,500 or .64 A) would suggest that .5 A is not enough, closer to 1/2 of the total current actually flows through the HV diode.

To be doubly sure that your new HV diode is happy, run the oven on full power (high) for 10 minutes with two quarts of water as a load (or a roast). Unplug the oven (while your spouse prepares the veggies), quickly DISCHARGE THE HV CAPACITOR, and then check the HV diode for overheating. It might be warm but should not be too hot to touch. Unless you have the largest oven on earth, this test is probably not needed.

Testing the high voltage capacitor

WARNING: First, with power disconnected, discharge the high voltage capacitor. See the section Safe discharging of the high voltage capacitor.

- A shorted HV capacitor will blow the fuse instantly.

- An open HV capacitor will result in no heat but no other symptoms.

(The following assumes no internal rectifier or other circuitry except of a bleeder resistor. Adjust procedures accordingly if your oven is different.)

The resistance measured across the terminals of the high voltage capacitor should be very high - several M ohms for bleeder resistor. If it is less than 1 M ohms, the capacitor is definitely shorted. Yes, if you measure 0.00 ohms across the terminals (and they are not bussed together on the case), then the capacitor is positively, without a shadow of a doubt, bad!

A high resistance does not prove that the capacitor is actually functional, just not shorted with no voltage across it. If you have a capacitance meter, check it for proper value (should be printed on the case). Even this does not prove that it will not short when full voltage is applied. Substitution is the only sure test beyond this.

Replacing the high voltage capacitor

WARNING: First, with power disconnected, discharge the high voltage capacitor. See the section Safe discharging of the high voltage capacitor.

Make a diagram of the precise wiring as multiple connections are often made to the capacitor terminals. The capacitor is usually mounted with a clamp which is easily loosened. Sometimes, the capacitor is jammed into a location that requires moving some other components to extract it.

Replace in reverse order. Tighten the clamp securely but not so much as to distort the case.

Where the capacitor assembly also includes the HV diode, it is possible to just replace the capacitor if space permits leaving the old one unconnected (at one end). However, the cost of a generic replacement diode is small (around $3) so replacing both at the same time is usually best. However, you don't need to use the exact combined part - which may be very expensive or difficult to obtain. Just make sure the ratings of the capacitor and diode are correct (use a generic replacement microwave oven HV diode and a microwave HV capacitor with a uF rating within 10% or so of the old one and at least equal working voltage).

What if the HV diode or capacitor are leaky?

An (electrically) leaky HV diode or cap would likely fail totally in short order since it would be dissipating a lot of power. However, until this happened, the oven might continue to operate and not blow a fuse. The effect on performance in both cases would be to reduce the effective voltage across the magnetron and thus the output power.

I consider these sorts of failures somewhat unlikely as the HV diode and capacitor do not generally fail half-way!

Testing the magnetron

WARNING: First, with power disconnected, discharge the high voltage capacitor. See the section Safe discharging of the high voltage capacitor.

- A magnetron with an open filament will result in no heat but no other symptoms. The bad connection may be internal (in which case the magnetron will need to be replaced) or external at the filament terminals (which may be repairable).

- A magnetron with with a short between the filament/cathode and anode will likely result in a loud hum from the HV transformer and/or magnetron when the cook cycle is initiated but the main fuse will probably not blow.

- A magnetron with other faults may result in a variety of symptoms including erratic or low output power or intermittent operation. See the section: Comprehensive list of magnetron failure modes.

There is no totally definitive way to determine if a magnetron is good without actually powering it under operating conditions but the following tests will catch most problems:

- Magnetron filament. The resistance should be infinite from the filament connections to the case and a fraction of an ohm between the filament terminals with the wiring disconnected from the magnetron.

  While measuring resistance from filament chassis, gently tap the magnetron to determine if there is an intermittent short. However, such problems may only show up once the filament heats up and parts expand.

  It may be possible to determine if the magnetron filament is actually working by connecting just the filament connections to a low voltage high current supply on a Variac (e.g., a microwave oven transformer but just the filament connections). The ceramic insulators are translucent and should show a glow with a working filament. The one at the antenna may be visible if the magnetron is removed from the oven or with a dental mirror looking into the waveguide. WARNING: Make sure you ONLY have the filament connected!

- Evidence of arcing (visible blackening around ventilation holes in base or burnt odor) usually indicates a bad magnetron.

- Melting or other damage to the antenna cover ('bull-nose' or 'bullet') may be the result of arcing due to problems in the oven cavity or waveguide (perhaps operating with nothing in the oven) or a defective magnetron.

  (This part is only visible with the magnetron removed from the oven). If a problem elsewhere has been corrected, the damaged antenna cover can be pulled off and replaced from a magnetron that died of other causes - try your local appliance repair shop. (The shape doesn't matter as long as it fits tightly - there are several diameters, however.) Your magnetron may still be good.

  Note: Since the antenna is attached directly to one of the vanes which is part of the anode assembly, it will test as a dead short to the case on your multimeter using DC and is normal. At 2.45 GHz, this won't be the case! :)

Most common magnetron failure modes:

- Filament could be shorted to case - check with ohmmeter. Anything less than infinity means the tube is bad though it could be charring due to arcing outside the vacuum in the box with the filament connections. Tap the tube while measuring to check for intermittents.

- Filament could be shorted to itself - tough to test since it is such a low resistance to start. Compare with good magnetron. (Yeh, right. If you had one, this wouldn't be an issue!) Tap the tube while measuring to check for intermittents. This fault isn't really likely.

- Filament could be open - check with ohmmeter. Tap the tube while measuring to check for intermittents. However, loose filament connectors (Fast-Ons) are more likely than a broken filament. Therefore, check directly at the magnetron terminals with both lugs pulled off.

- Magnetron could be gassy (or up to air) and arcover internally once power is applied. The filament could expand, shift position, and short once heated. There is no easy way to test for these possibilities other than substituting a known good magnetron.

- Internal or external arcing resulting in physical damage. External arcing could be at the antenna or inside the filament box. Internal arcing will not leave any visible evidence but the damage will result in the magnetron failing totally or running with reduced output.

- Overheating might result from a broken or cracked magnet (reduced magentic field) or other internal problems. While there may be some output power, the thermal protector will shut down the oven prematurely.

Comprehensive list of magnetron failure modes

(Portions from: John Gallawa (microtech@gallawa.com).)

Here is a list of typical magnetron failure modes. The percentage of each type of failure varies. Currently, internal shorts and loose filament connectors are probably at the top of the list. An internal plate-cathode short may only manifest itself under the stress of high voltage during operation.

1. Shorts. (a) Internal plate-cathode/filament short or (b) Internal arcing.

   Symptoms: No heat, loud hum when entering cook cycle, possible blown HV fuse (but will not likely blow the main fuse).

   In ovens equipped with fuses that monitor the high voltage system, such as some commercial Sharp models and most commercial and domestic Amana models, the high voltage fuse would probably blow. But, rarely will a shorted magnetron cause the main line fuse to blow. (I suppose the transformer absorbs most of the current surge.) In fact, with reference to the other symptoms below, there are almost no failures where the magnetron causes the line fuse to blow.

2. Loose filament connectors (these may be repairable). There will often also be visual symptoms at the magnetron: Signs of overheating, such as discoloration; and evidence of carbon tracks or pits on magnetron terminals when the connectors are removed. An intermittent filament (internal) is also possible (but not repairable).

   Symptoms: No heat or erratic heat.

   The slip-on connectors can loosen, overheat, build up resistance and eventually loose contact. If the the magnetron terminal(s) have not been burned too severely, the connection(s) can usually be repaired. We prefer cleaning up the terminal, then soldering the filament wires directly to the terminal.

   Note: when discharging HV capacitor, since there is no load, it may end up being charged to a much higher voltage than is normal. Be prepared for a larger spark if you use a screwdriver to discharge it!

3. Open filament.

   Symptoms: No heat.

   See note about HV capacitor in (2) above.

4. In the older glass-dome models, the vacuum envelope can rupture.

   Symptoms: No heat, loud buzz due to arcing when entering cook cycle, possible blown HV fuse.

See comments about fuses in (1) above.

5. Filament breakdown. Usually occurs after a few minutes of normal operation, possible blown HV fuse.

   Symptoms: No heat, loud hum once it occurs.

   See comments about fuses in (1) above.

6. Low output. Occurs as cathode emission decreases from long use.

   Symptoms: Reduced cooking power.

7. Moding. Occurs when magnetron oscillates in one or more undesirable frequencies.

   Symptoms: (a) Reduced or no cooking power, (b) RF interference. However, some food products (with high water content) may cook normally, whereas the result with other foods is very unsatisfactory. RF interference is possible but usually only occurs if there is actual structural damage to either the magnetron, its RF gasket or waveguide flange, or its RF (feed-through) capacitors.

8. Off frequency. Physical characteristics can change and cause magnetron to oscillate at frequencies slightly higher or lower than 2.45 GHz.

   Same as (7a) above.

9. RF leakage. Structural failure can cause leakage from magnetron housing.

   Symptoms: Microwave leakage into electronics bay, erratic control panel behavior. It can be very frustrating because the symptoms disappear when the oven's outer cover is removed. With the cover in place, the escaping RF energy is confined, and eventually builds up around the control panel circuitry causing unusual symptoms.

10. Insulation breakdown of the internal leads or at magnetron insulators or antenna terminal.

    Symptoms: Arcing, burning smell from magnetron, loud hum, no heat.

11. Cracked magnet(s).

    Symptoms: Reduced or no cooking power, magnetron overheating, occasional 'snapping' sound.

Where to obtain replacement magnetrons

Depending on the age of your oven the magnetron may still be under warranty. Check the original paperwork that came with the oven - either the users manual or a separate warranty document. Contact the manufacturer if specific instructions on how to file claims are not provided. Full coverage on the magnetron of several years is common. If you have not sent in the warranty registration card (right, who actually does this?!), a copy of the sales receipt or other proof of date of purchase may be required.

Both original and generic replacement magnetrons are available. Going direct to the oven manufacturer will guarantee a compatible magnetron but is by far the most expensive option. For a typical oven, one without the gold-plated trim :-), such a replacement may be more than half the cost of a similar new oven. In some cases (like Sears), you may need to convince their service department that you are qualified to be poking around inside one of *their* appliances before they will consider selling one to you (too many lawyers).

In some cases, original magnetrons may also be available from parts suppliers like MCM Electronics - at somewhat less rediculous prices. They will be identified as 'original' or 'genuine' along with the manufacturer and their part number.

Generic replacement magnetrons are available for the majority of microwave ovens. These will almost certainly be much less expensive than original parts. Essentially, there is only one type 'tube' (at least for any similar power range). The differences are mostly mechanical. However, quality may vary. In some cases, the generic variety may actually be better than the original. See the section: Comments on replacement magnetron quality for some recommendations.

Comments on replacement magnetron quality

(From John Gallawa (microtech@gallawa.com).)

In my experience, mags purchased from after-market suppliers may or may not be OEM parts (there are not that many manufacturers of magnetrons in the world). Here's the interesting thing, though: In many cases, these after-market tubes are actually higher in quality than the original tube, as in the case of the OEM Sanyo magnetrons, which tend to fail prematurely. Of course, the opposite can also be true, depending on the after-market supplier. Some manufacturers, such as Toshiba and Hitachi, produce both high and low end magnetrons. They sell these under a variety of specialty names, as well as under manufacturer brand names. I have seen the low-end tubes in many brand-new microwave ovens.

When buying magnetrons from other than the manufacturer, I have found it best to go to a supplier who specializes in microwave oven parts (i.e. AMI, Global Micro-parts, QB products). These sales people are usually more knowledgeable about the magnetrons they sell, and they can help you with proper choice and application.

Replacing the magnetron

WARNING: First, with power disconnected, discharge the high voltage capacitor. See the section Safe discharging of the high voltage capacitor.

When you receive the replacement, compare it with the original. It is critical that the replacement magnetron be mechanically identical: this means that the mounting configuration (studs or holes and their location), waveguide seating surface, and the orientation of the filament connections and cooling fins are the same. The studs may be removable so that the same assembly can be used with or without them. The cooling fins are particularly important as there must be adequate airflow from the fan for removal of the substantial waste heat - up to half of the input power to the magnetron ends up as heat. The shape of the antenna terminal - cone, bull nose, or square - doesn't matter.

Magnetron replacement is generally straightforward but other assemblies like the cooling fan may need to be removed to gain access. Make careful notes of both the wiring and mechanical relationships. Usually, the magnetron is fastened to the waveguide with 4 nuts on studs. When removing it from its mounting, do not lose the RF gasket - a metal mesh ring which seals the connection against microwave leakage. Reuse it unless your replacement magnetron comes with a new one. Transfer any thermal protector to the new unit. Replace other components in reverse order and then reattach the filament and HV wires.

Although the magnetron is a vacuum tube, there is probably no glass in yours (unless it is quite old) so it isn't really very fragile. However, a sharp blow or fall (during shipping as well if not properly packed) could shatter the filament. Do keep it (the magnets) away from your diskettes unless you want them bulk erased!

As for the old one, see the section: The magnets in dead magnetrons. :-)

Testing the high voltage transformer

WARNING: First, with power disconnected, discharge the high voltage capacitor. See the section Safe discharging of the high voltage capacitor.

- A shorted winding or short between a winding and the core/chassis in the HV transformer may result in a blown fuse, loud hum, overheating, audible arcing, a burnt aroma, or simply no heat.

- An open winding will likely result in no heat but no other symptoms.

The typical schematic is shown below:

```
                            +--------------------o White wire
                          ||( Filament winding
                          ||  +--------------------o White wire
                          ||
                          ||  +--------------------o Red Wire
           AC H o---------+ ||(
                          )||(
                          )||( HV Winding
                .1 to .5 )||( 1.5 to 2.5 KV RMS
                    ohms )||( .5 A or MORE
                          )||( 25 to 150 ohms
                          )||(
           AC N o---------+ ||(
                           | +-+ HV return connected to frame
                           |   |
           AC G o------------+---+
```

Disconnect terminals as required to make the following tests:

- The resistances of the primary should be .1 to .5 ohms (.2 ohms typical).

- The resistance of the filament winding will likely be so low as not to be detectable with your multimeter. The only measurement easily made would be that there is no short to the chassis.

- Typical resistance readings for the transformer HV secondary are in the 25 to 150 ohms range (depending on the power rating of the oven) from HV connection to chassis. A typical midsize might be 65 ohms. An open would be an obvious failure. However, based on the way these are wound, a winding-to-winding short would not cause enough of a resistance change to be detected with an ohmmeter unless you could compare with an identical model transformer from the same lot number.

- Check the resistance between all windings (and to the core):

  - Filament to primary, high voltage, and core, should be infinite.

    It may be possible to repair a filament winding which is shorted to the core (the only likely place) as it is only 2 or 3 turns of heavy wire. However, it must be insulated for 5,000 V, may get quite hot with normal use, and similar fire resistant materials must be used for the repair as were present original. However, if the filament winding is adjacent to the HV winding (in the same channel), the arcing may have been taking place to the HV winding rather than the core. Therefore, you need to make sure that it hasn't been damaged as well.

  - Primary to high voltage and core should be infinite.

  - High voltage to core should be between 25 and 150 ohms as discussed above.

- If you have a clamp-on ammeter, you can measure the primary current with all secondaries disconnected. See the section: Testing the HV transformer using an AC current meter.

Testing the high voltage transformer more fully is difficult without fancy equipment. Only major short circuits can be identified in the transformer with an ohmmeter since the nominal resistance of the windings is unknown. However, open windings (not very likely) can be located and other faults can be identified by the process of elimination.

Note: in the discussion below, it is assumed that the fuse is blowing due to a possible short in the HV transformer. Alternatively, there may be a loud hum as the HV transformer struggles due to a fault in the HV transformer or a shorted HV diode, magnetron, or a short in the HV wiring. Also note that depending on the severity of the fault, the fuse may not actually blow (at least not immediately) but there will likely be a loud hum when the HV transformer is powered.

- Disconnect the primary of the HV transformer and initiate a cook cycle. If the fuse still blows, you have a problem elsewhere such as a defective interlock or shorted wire.

- Assuming the fuse does not blow, unplug the oven and reconnect the primary of the HV transformer.

- If the other components - HV diode, HV capacitor, magnetron - test out, remove the high voltage and filament connections to the transformer, power up the oven, and initiate a cook cycle. If the fuse does not blow, the transformer is likely good and there are still problems in the high voltage components. Possibly something is failing only when full voltage is applied.

- If the fuse still blows, then the problem is likely with the triac (if used), a shorted wire, or shorted transformer.

- If the fuse does not blow with the secondary isolated, reconnect only the magnetron filament (not the HV) to the transformer and power it up again. If the fuse now blows, then it is possible that the magnetron filament is shorted.

- If your oven uses a triac, remove and bypass it. Now, if the fuse still blows when the oven is plugged in (door closed to enable the interlocks), the problem is likely with the transformer.

  Unplug the oven, discharge the HV capacitor.

- Check for damaged wires that may be shorting to the chassis. Repair or replace these as necessary.

Testing the HV transformer using an AC current meter

Where the HV transformer doesn't blow a fuse but overheats or produces insufficient output, this test may be useful. If you have a clamp-on AC ammeter, the transformer can be powered up to see if the primary current it draws is reasonable with no load.

WARNING: Up to 3,000 VAC on HV terminal - AND possibly other windings if there is a short in the transformer somewhere. Use a 3 prong cord with H and N connected to the primary and G firmly screwed to the transformer core/mounting structure. Or, just remove the 3 secondary connections and power it through the existing wiring using the normal oven controls. The meter's clamp needs to go around H or N but not both. Stand well clear when you apply power!

Use of a Variac is recommended but not essential. However, here are the input current readings at various input voltages for the HV transformer from a typical mid-size microwave oven:

```
  Input VAC   Input Amps
 ------------------------
     80           .3
     90           .6
    100          1.1
    110          2.0
    115          3.0
    120         >4.0
```

Above about 100 VAC, there was also a noticeable hum (though not nearly as great as with a secondary short).

No, these readings do not indicate a problem. Microwave oven transformers are designed with as little copper as possible. And, yes, the non-linear increase in current indicates that the core is saturating with no load.

If your readings are similar to these, the transformer is likely good. Shorted turns would result in much higher current at all input voltages.

Replacing the high voltage transformer

WARNING: First, with power disconnected, discharge the high voltage capacitor. See the section Safe discharging of the high voltage capacitor.

Replacement of a HV transformer is straightforward but other assemblies may be using the transformer bolts for their mounting and/or may block your way.

Label the wires before pulling off the Fast-Ons if there is any doubt as to where they go.

If the replacement transformer is not mechanically identical, you may need to use some creativity in anchoring it and any structures that are attached to its frame. However, the transformer must be secure - don't just sit it in place.

Try not to drop either the old or new transformer on your foot!

Testing and repairing the wiring and connections

WARNING: First, with power disconnected, discharge the high voltage capacitor. See the section Safe discharging of the high voltage capacitor.

Inspect the wiring - especially between the magnetron, HV transformer, and other components of the high voltage circuits for signs of arcing and excessive heating or burning. Arcing may be the result of the wire scraping against a sharp sheet metal edge due to poor placement and or vibration. A bit of electrical tape may be all that is needed.

Since the magnetron filament in particular uses high current, any resistance at the press (Fast-On) connections will result in heating, weakening of the lug, more heating, and eventual failure or erratic operation. Try to pull off each of the lugs. They should not be loose - you should have to work at removing them. However, note that some lugs are of the locking variety and require that you push a little tab to release them.

Check for loose, burnt, or deteriorated lugs in the filament circuit (not just the magnetron). If you find evidence of this:

- Remove the lugs and clean the terminals with fine sandpaper or a file. If they are not too badly deteriorated, they will still work even if they are somewhat ugly.

- If the lugs and their wire connections appear to be in good condition but come off their terminals easily, try squeezing them a little tighter with a pair of pliers and reinstall. Otherwise, cut off the old ones and replace them.

- If any connections between the lug and the wire or HV diode are at all loose, solder it with a high wattage soldering iron or soldering gun.

- Alternatively, use a drill to make a hole in each terminal, and then fasten the (tinned) wire directly (or better yet) a new ring lug to the terminal with a machine screw, nut, and lockwasher. Soldering is also possible.

  These approaches will work as long as there is enough metal remaining for a solid connection and may permit you to salvage a magnetron or HV transformer that would otherwise need to be replaced.

Also check for bad solder connections between the terminals on the high voltage transformer and the enameled wire used for its windings. If you find anything suspect, scrape away the enamel and surface corrosion and resolder with a high wattage soldering iron or soldering gun.

Testing thermal protectors and thermal fuses

There may be two types of devices present in your oven:

- Thermal protectors are thermostats that open a set of high current contacts at a preset temperature. They should reset when they cool off. However, like a relay or switch, the contacts sometimes deteriorate.

- Thermal fuses will open at a preset temperature but do not reset. They blow and need to be replaced.

At room temperature, both types should read as a dead short with an ohmmeter (disconnect one terminal as there may be low resistance components or wiring which may confuse your readings). If the resistance is more than a small fraction of an ohm, the device is bad. Replacements are somewhat readily available. You must match both the temperature and current ratings.

If you suspect a bad thermal protector in the HV transformer primary, clip a 100 W light bulb or AC voltmeter across it and operate the oven. If the thermal protector is functioning properly, there should never be any voltage across it unless there is actual overheating. If the bulb lights up or the meter indicates approximately line voltage - and there is no sign of overheating - the thermal protector is defective and will need to be replaced.

An overheating condition would generally be obvious as the mounting surface on which the thermal protector is located would be scorching hot when it tripped - too hot to touch (but discharge the HV capacitor first - a burn from the heat will be nothing compared to the potential shock!).

Replacement of a thermal protector is very straightforward as it is almost always screwed in place with push-on lug terminals. The new thermal fuse will probably come with lugs attached.

Testing and replacing the triac

A triac may fail in a variety of ways:

- A shorted triac would result in the oven coming on as soon as the door is closed or the power being stuck on high no matter what the touchpad setting.

- An open triac or one that didn't respond to the gate would result in no heat and possibly other things like the fan and turntable not working as well.

- A triac that didn't turn off would result in the parts of the oven continuing to run even after the timer counted to zero.

- A triac where one half was shorted would result in a blown fuse due to it acting as a rectifier pumping DC through the HV transformer.

- A triac where one half doesn't properly turn off would result in the main fuse blowing when the cook cycle completed.

Nearly all triac failures will be shorts. Thus, measuring across the MT1 and MT2 terminals of the triac (the power connections) should read as a high resistance with a multimeter. A few ohms means a bad triac.

As noted above, triacs can fail in other - possibly peculiar ways - so substitution or bypassing may be necessary to rule out all possibilities.

Replacement is very straightforward - just don't get the wires mixed up.

Testing and replacing the power relay

A defective relay can result in a variety of symptoms:

- A relay with its contacts welded (stuck) closed would result in the oven coming on as soon as the door is closed or the power being stuck on high no matter what the touchpad setting.
- A relay that doesn't close (due to defective contacts or a bad coil) would result in no heat and possibly other things like the fan and turntable not working as well.

If the relay is totally inoperative, test for voltage to the coil. If the voltage is correct, the relay may have an open coil. If the voltage is low or zero, the coil may be shorted or the driving circuit may be defective. If the relay makes a normal switching sound but does not correctly control its output connections, the contacts may be corroded, dirty, worn, welded closed, binding, or there may be other mechanical problems.

Remove the relay from the circuit (if possible) and measure the coil resistance. Compare your reading with the marked or specified value and/or compare with a known working relay of the same type. An open coil is obviously defective but sometimes the break is right at the terminal connections and can be repaired easily. If you can gain access by removing the cover, a visual examination will confirm this. If the resistance is too low, some of the windings are probably shorted. This will result in overheating as well as no or erratic operation. Replacement will be required.

The resistance of closed contacts on a relay that is in good condition should be very low - probably below the measurable limits on a typical multimeter - a few milliohms. If you measure significant or erratic resistance for the closed contacts as the relay is switched or if very gentle tapping results in erratic resistance changes, the contacts are probably dirty, corroded, or worn. If you can get at the contacts, the use of contact cleaner first and a piece of paper pulled back and forth through the closed contacts may help. Superfine sandpaper may be used as a last resort but this is only a short term fix. The relay will most likely need to be replaced if as in this case the contacts are switching any substantial power.

Items of Interest

Microwave leakage meters

A routine test for radiation leakage should be done before returning an oven you have worked on especially if the door or magnetron/waveguide were disturbed during the repair process. Use it around the door seem and ventilation holes in the cabinet. An inexpensive meter is better than nothing but will not be as sensitive and will not allow you to quantify the amount of any leakage.

If you work on microwave ovens, such a meter is a *must* for personal safety reasons as well as minimizing the risk of liability after returning them to your customers.

These should be available wherever you buy quality test instruments. They are usually made by the same companies that manufacture other service equipment. Prices and capabilities vary widely. MCM Electronics sells an inexpensive unit suitable for quick checks on a go/no-go basis for $6.99 and an FDA approved unit (including calibration), for $388.

Note: you should also perform an electrical leakage test to assure that all case parts are securely connected to the Ground of the AC plug.

Comments on microwave leakage meters

(From Barry Collins (bcollins@mindspring.com).)

I found an old manual for a Narda 8100B Electromagnetic Leakage Monitor. (I used to work for a manufacturer of Microwave ovens.) While I don't personally recall ever having damaged a probe while checking for leakage, I do know that it is possible to do so and did happen on rare occasions.

The Narda manual states that their probes use an antenna/thermocouples design. Holaday (sp?) makes another line of detectors and those may use a thermistor array.

I have confirmed that by removing the styrofoam cone from the end of a Holaday uW leakage detector's probe and then bringing its tip near a heat source (40W bulb) caused the meter to have a significant deflection. Thus, the cones are not only used as spacers. They prevent radiant heat sources from affecting the meter reading, as well.

The Holaday probes that I used had 8 diodes in the tip that formed an array.

Newer designs (Holaday) claim to be more or less immune to damage resulting from placing them into high energy fields. I do know that the older Narda equipment was prone to such damage.

There is a section in the Narda manual that details how to select the proper probe to measure "unknown" leakage levels. In a nutshell, one should start with the highest power rated probe and work toward the lowest power rated probe (three listed in all). The goal is to have a meter deflection of more than 10% of it's scale while not going off scale for sake of accuracy. While it didn't specifically mention damage to the probes, there were overtones throughout the text that implied such (watch needle, listen for alarm, stop and replace probe, etc...).

The three probes were listed as (high/low range for each):

```
  Probe          Range
----------------------------------------
  8120A    0.2 mW to   2.0 mW/square cm
  8121A    2.0 mW to  20.0 mW/square cm
  8122A   20.0 mW to 200.0 mW/square cm
```

This is from memory, but I believe that the maximum leakages we were allowed by the governmental agency were:

- Less than 2.0 mw/square cm off of our assembly line
- Less than 3.0 mw/square cm leaving the warehouse
- Less than 5.0 mw/square cm in consumers home

As you no doubt know, with a hole cut in the oven (in reference to those who want to modify one - see the section: Microwave ovens for non-standard applications --- sam), the density can easily reach several times these numbers, especially on the newer 1,000 watt plus models. Damage would occur where one intentionally held the lower power rated probe in the strong field until the thermocouple (or thermistor?) overheated.

Simple microwave leak detectors

Since these do not really provide an absolute measurement, their utility is somewhat limited. All microwave ovens leak to some extent. Determining by how much is why you pay the big bucks for a real leakage meter!

WARNING: These are no substitute for a properly calibrated commercial unit!

(From: Leon Heller (leon@lfheller.demon.co.uk).)

A very simple design I saw somewhere (Electronics World, probably) consisted of a half-wave dipole with a Shottky diode detector between the two elements. I think one measured the voltage across the diode via a resistor and capacitor smoothing arrangement using a 50 uA meter. You can buy these detectors quite cheaply.

(From: Ren Tescher (ren@rap.ucar.edu).)

I saw an article about it in Modern Electronics in the early eighties. It is simply a Schottky Barrier Diode (SBD) and an LED wired together. The leads of the SBD are left intact and straight and act as a 1/4 wavelength dipole.

Here's the circuit:

```
                             SBD
      <-----------------+-|<|-+----------------->
                        |     |
                        +-|>|-+
                             LED
```

The LED is soldered close to SBD using as short of leads as possible (being careful not to ruin either part with too much heat). (Note that the diodes are connected anode to cathode, not cathode to cathode.)

I then taped/glued it 1 1/2 and perpendicular from the end of a popsicle stick (this gives it a 'standoff' distance).

Put a large container of water (>=2 cups) in the microwave and run it on HIGH for 2 minutes. While it is running, slowly sweep the tester around the door seal, hinges and door latch. You may have to dim the lights to see if the LED lights up.

Any leaking uwaves will be picked up by the dipole 'antenna', the SBD will rectify the waves, and when sufficient rectified voltage has built up, the LED will light up.

I built 10 of these at home and then compared them to the commercial tester we had at work. The commercial tester had three ranges and the most sensitive range was divided into 3 color bands, red, yellow, green. The home-built testers all 'fired' at some point in the 'yellow' range. I attribute the variances within the yellow (caution) range to individual characteristics of the diodes - they all came from the bargain bin at Radio shacks....

A solid glow would indicate excessive leakage, especially if the tester still glows if it is pulled beyond the 1-1/2 inch standoff distance to 3 inches. Typically the LED just flickers, around the hinge/latch areas. (US law allows increased leakage as the oven ages).

You may notice that no radiation leaks through the viewing window, contrary to the old wives tale of not looking through the window while it's cooking. (The screen really is a very good microwave shield --- sam).

Small leaks may be remedied by adjusting or cleaning the door and hinges and/or by distance (square law= doubling the distance quarters the power). Large leaks - trash the oven.

(From: James P. Meyer (jimbob@acpub.duke.edu).)

Get a small neon bulb. The NE-2 size is a good one. Use some resistors to make a voltage divider for 115 VAC to feed the bulb. Adjust the voltage across the bulb so that it's just barely glowing. Make the divider network resistance large enough to limit the current through the bulb to just a couple of mA. Put the bulb on the end of a line cord and plug. INSULATE everything completely.

Adding this onto a neon circuit tester is one option and will provide an insulated housing as well.

Plug the whole thing into an AC outlet. Wave the bulb around the door gaskets and if it gets brighter when the oven is turned on, then you have located a leak. The bulb detector can be very sensitive. You may even be able to use it to find wires behind drywall in your house.

How safe is a repaired microwave oven?

So you fixed up Aunt Minnie's Radarange or picked up a microwave at a yard sale or scavenged one off the curb. The only problem you could find was a blown fuse, truly horrible mess of decayed burnt-on food, or a thriving community of cockroaches inside. How safe is it to use (assuming you evicted the cockroaches)?

As long as there is no serious damage to the door (a 6 inch hole would quality as serious damage) and the door fits square, it should be properly sealed. As long as the waveguide is tightly mounted and undamaged, there should be no leakage from there. Make sure the metal cover has all its fingers engaged around the front (though with a properly installed magnetron, there should be minimal microwave leakage into the electronics bay).

An inexpensive leakage tester - around $8 - will not be as sensitive or accurate as the $500 variety by may provide some peace of mind. However, as noted below, they may indicate dangerous leakage even when your oven is within acceptable limits.

The most important considerations are the door and door seal.

(From Barry Collins (bcollins@mindspring.com).)

Those inexpensive hand held meters (from Radio Shack, etc..) can give very inaccurate readings. While they definitely serve a purpose, they have caused a more than a few people to unnecessarily fear microwave ovens over the years. Also, I just changed jobs from working for a company that made gas ranges. CO detectors caused similar panic among users of the appliances. I'd highly recommend anyone with gas heat or appliances to purchase a quality CO detector, but not one of those inexpensive type that go off whenever there is a thermal inversion of smog a city.

Efficiency of microwave ovens

The efficiency of an electric heating element is 100% - period. However, using an electric stove to heat 1 cup of tea may result in much wasted energy as the element and pot must be heated as well and there are losses due to convection and conduction to the surrounding environment. Furthermore, you won't heat just *1 cup* of tea but more likely 2 or 3 just to be sure you have enough!

A microwave oven is not likely to be more than 60% efficient - possibly as low as 50 percent or even less. While the magnetron tube itself may have an efficiency rating of 75%, there are losses in the high voltage transformer, cooling fans, and turntable motor (if used). The light bulb and controller also use small amounts of power. These all add up to a significant overhead. In addition, the waveform applied to the magnetron by the half wave doubler circuit is not ideal for maximum efficiency.

However, you are not heating the surrounding countryside as the microwaves only affects what you are cooking and not the container or oven cavity itself and you are more likely to only load the amount of food you expect to be eating. For a single cup of tea, the microwave oven may use 1/10th the energy of a typical electric cooktop element to bring it to a boil!

Therefore, it makes sense to use a microwave oven for small short tasks where the losses of an electric or gas oven or cooktop would dominate. However, gastronomic preferences aside, a conventional oven is better suited for that 20 pound turkey - even if you could distort its anatomy enough to fit the typical mid-size microwave!

Microwave oven design and cost reduction

(From Barry Collins (bcollins@mindspring.com).)

Microwave oven design is a black art. What one hopes for is to deliver all the power from the magnetron into the food and not have a high SWR reflect back into the magnetron and burn it out. Size, shape, placement of food items affect the SWR. The microwaves are designed for the most part to work optimally with an average load. Models equipped with turn-table models compensate for this by breaking up the SWR as the food revolves. My oven has a stirrer fan design and has been working for going on 18 years now without the first hint of a problem (maybe a little less power). I personally know that it had one of the lowest SWRs available at the time. Not to mention it has an older design, non-cost reduced, cooler running, more efficient magnetron (that cost $13.00 instead of $9.45). The thing that I found disturbing about microwave oven design was the trends to go with hotter an hotter insulation classes on the components used in them. The original transformers were class H while the newer ones are now class N. This was all done in the name of cost reduction to remain competitive. The windings AWG got smaller and the temperature rise went up accordingly. The magnetrons were cost reduced in a similar fashion. Size was reduced and the number of fins were reduced. Their temperature went up while their efficiency went down. But then the cost went from $300 to $149 while life went from 10 years-plus to 5 years or less and they became disposable items. That's one area, I'd almost hesitate to hope the Government would have mandated an efficiency.

Problems with running a microwave oven with metal inside or totally empty

Metal in microwave ovens may or may not be a problem depending on the specific situation. Sharp edges and points create strong field gradients which tend to spark, arc, or create other fireworks. With some food in the oven to absorb the power, this is probably not likely to damage the oven. You will note that some ovens come with metal fixtures in addition to the oven walls themselves (e.g., Sharp convection/microwave combo).

Having absolutely nothing in the oven chamber or just metal is the potentially more likely damaging situation for the magnetron as you are dumping several hundred W to over a kW of power into a reflective cavity with no load. In the worst case, you could end up with a meltdown inside the waveguide requiring replacement of various expensive components including the magnetron.

Older microwave ovens with used glass magnetrons were perhaps more susceptible to these disasters (all modern overs use magnetrons with ceramic construction but I really don't know how much this matters) but it's still a good idea to avoid running a microwave empty. They don't need preheating! :)

More on metal in the microwave

(From: Don Klipstein (don@Misty.com).)

Mainly, you need exposed water or food to absorb the microwaves. Otherwise, they just reflect around the oven and get back to the magnetron tube. This may be bad for the tube, and in an unpredictable manner.

It is even not too good to run a microwave empty. The walls of the main cooking chamber are metal.

In the event the microwave runs empty OK, adding metal objects change the microwave reflection pattern and might possibly unfavorably change things.

If you have exposed food or water, the tube should not mind some stray metal too much. If the added metal does not interfere with microwaves mainly getting from the tube to the target food or water and being absorbed, the magnetron should be OK.

Even if the tube does not mind, there is another concern. Metal objects close to other metal objects or to the walls of the cooking chamber may arc to these. Any arcing is generally not a good thing. If you add metal objects in a manner safe for the tube, try to keep these at lease a half inch (a bit over a cm.) from the walls to avoid arcing. Safe distances are uncertain and are usually less if the metal objects are small and a large amount of food or water is exposed.

If any metal object has major contact with a microwave absorbing food target and such target is still heavily exposed, you should be OK. Examples would be wrapping foil around the wingtips of a whole chicken or whole turkey, or a bottle of liquid (on its side) with a metal lid with liquid contacting much of the lid. This is usually OK. Just avoid unrelated problems due to major temperature change of anything in contact with a non-heat-rated glass container.

A plain glass bottle if ice-cold stuff might possibly break from thermal shock when heated, but any metal lid on a bottle largely full of microwave-absorbing stuff should not present a problem especially if the bottle is on its side so that stuff is contacting or very nearly contacting much of the lid.

Burnt smell from oven - after incident

> "My daughter tried to heat up one of those 'soup in a box' containers and it burned - actually charred. I wasn't home at the time, so I don't know if it was neglect or inappropriate use, but the lasting effect is that there is a strong odor, similar to that which you smell after a fire that I cannot seem to get rid of. What do you recommend. I have a Sharp Convection/Microwave, that even after the incident described still performs well."

Start by cleaning the interior of the oven thoroughly with mild detergent and water. You may have to do this several times to get all of the sticky film left behind. If this doesn't help enough, smoke may have gotten into the waveguide above the oven chamber. If possible, remove the waveguide cover and clean it and as best as possible the accessible part of the waveguide.

However, the odor may persist since the smoke can penetrate to places you cannot access for cleaning. With a combination convection and microwave oven especially, there are many passages where the air would normally circulate in convection mode which will be coated even if the oven was used in microwave mode. However, I would expect that the smell will decrease and eventually go away. Most likely, nothing in the oven has actually sustained any damage.

Some have suggested boiling a cup of lemon scented water or vinegar to help speed things along. It won't hurt - maybe even help. :)

Microwave ovens and grounded dedicated circuits

A microwave oven should be used only on a properly wired 3 wire grounded circuit. Check with a circuit tester to make sure your 3 prong outlet is correctly wired. Many are not. Install one if it is not grounded. There is a very important safety reason for this requirement: the return for the high voltage is through the chassis. While unlikely, it is theoretically possible for the entire high voltage to appear on the metal case should certain internal connections come loose. With a properly grounded outlet, this will at most blow a fuse. However, with the case floating, a shocking (or worse) situation could develop - especially considering that microwave ovens are usually situated near grounded appliances like ranges and normal ovens and wet areas like kitchen sinks.

A dedicated circuit is desirable since microwave ovens are significant users of power. Only about 50 to 60% of the electricity used by a microwave oven actually gets turned into microwaves. The rest is wasted as heat. Therefore, a 700 W oven will actually use up to 1400 W of power - nearly an entire 15 Amp circuit. Convection ovens have heating elements which are similar energy hogs. At least, do not put your refrigerator on the same circuit!

Microwave ovens and GFCIs

A Ground Fault Circuit Interrupter (GFCI) protects people from shocks should a situation develop where an accessible part of an appliance should short to a live wire. Touching this may result in a shock or worse. A GFCI detects any difference between the currents in the Hot and Neutral wires and shuts off the power should this difference exceed a few mA.

A GFCI is not needed with a properly grounded microwave oven as any such fault will blow a fuse or trip a circuit breaker. In most cases, it will not hurt to have a GFCI as well. However, with some combinations of oven design and your particular wiring, due to the highly inductive nature of the high voltage transformer, nuisance tripping of the GFCI may occur when you attempt to cook anything - or at random times. However, this usually does not indicate any problem. Plug the oven into a properly grounded circuit not on a GFCI.

Can a microwave oven be built into (or hung under) a cabinet?

Assuming it is a regular microwave and not a convection/microwave combo, the major issues are:

- Providing adequate air flow through its ventilation grill which is usually located in the rear.

(A convection/microwave can get quite hot and have ventilation in other places. In this case I would suggest contacting the manufacturer of the oven for specific requirements.)

- Providing adequate structural support so the microwave doesn't end up in the soup. :-(These are HEAVY appliances - cabinetry and/or drywall may not be up to the task. Models designed as over-the-range or combined microwave and exhaust fan units mount via a massive plate fastened securely into the wall structure (screwed directly to the studs, not just the sheetrock!). They may additionally be bolted into the cabinet above but this will not (or should not) be the sole means of support.

- Local building codes may specify when and if this approach can be used. So, before doing any demolition, check with your friendly township inspector!

There are special (likely highly overpriced) models available for this type of mounting.

To use a normal microwave, my recommendation would be to build a shelf rather than a totally sealed, enclosed, conformal cabinet. It can have sides and a top as long as you leave a couple of inches all around. This will result in a microwave oven that is much more easily serviced should the need arise and replaced in the future with a model that is not quite identical.

Just make sure it is securely supported - the microwave weighs quite a bit and must endure a fair amount of abuse from heavy casseroles and the inevitable door yanking/slamming!

Note that one of the advantages of buying a microwave oven designed for under cabinet or wall mounting is that it may provide convenient access for servicing from the front - not having to remove the entire unit to check or change a fuse! For example, some GE units have a hinged front panel - remove a couple of screws and most of the internal components can be accessed for service. This would not be possible where a countertop oven is used in a permanent installation.

(From: Roy Smith (roy@popmail.med.nyu.edu).)

I've installed a GE over-the-range microwave. It really was quite straight-forward. There is a backplate which you attach to the wall with whatever combination of lag bolts, screws, expansion bolts, etc you can get to work (i.e. wherever you can find studs, etc). It comes with a template to make this easy. The rear-bottom edge of the oven then clips onto the backplate to form a kind of hinge, and you pivot the oven up into place. There are two long bolts that run the depth of the oven near the top which you use to complete the attachment of the oven to the backplate. You then bolt it into the cabinet above it for additional security.

Taking a microwave oven oversees (or vice versa)

Microwave ovens are high power appliances. Low cost transformers or international voltage adapters will not work. You will need a heavy and expensive step down or step up transformer which will likely cost as much as a new microwave oven. Sell the oven before you leave and buy a new one at your destination.

Furthermore, for microwave ovens in particular, line frequency may make a difference. Due to the way the high voltage power supply works in a microwave oven, the HV capacitor is in series with the magnetron and thus its impedance, which depends on line frequency, affects output power.

High voltage transformer core saturation may also be a problem. Even with no load, these may run hot even at the correct line frequency of 60 Hz. So going to 50 Hz would make it worse - perhaps terminally - though this is not likely.

- Going from 50 Hz to 60 Hz at the same line voltage may slightly increase output cooking power (and heating of the magnetron). The line voltage could be reduced by a small amount to compensate.
- Going from 60 Hz to 50 Hz may slightly decrease output power and possibly increase heating of the HV transformer due to core losses. Using a slightly lower line voltage will reduce the heating but will further decrease the cooking power.

The digital clock and timer will likely run slow or fast if the line frequency changes as they usually use the power line for reference. Of course, this may partially make up for your change in output power! :-)

Microwave oven test-mode

(From Mark Paladino (paladino@frontiernet.net).)

Some microwave ovens have a self-test feature. This self-test is usually accessed by pressing a couple of keys on the touch pad. You can usually test things like keys, switches controller etc. Check the manual for any self-test info. Some microwaves have this information tucked in a pocket or hidden somewhere behind panels.

High frequency inverter type HV power supplies

While the vast majority of microwave ovens - perhaps every single one you will ever see - use minor variations on the tried and trusted half wave doubler circuit, a few models have been designed using solid state high frequency inverters - in many ways similar to the deflection/HV flyback power supply of a TV or monitor.

A typical circuit (from a Sharp microwave oven) uses full wave rectified but mostly unfiltered pulsating DC as the power to a large ferrite inverter transformer which sort of looks like a flyback on steroids. See High Voltage Inverter Power Supply from Sharp Microwave Oven. This means that the microwave output is pulsing at both 60 Hz and the frequency of the inverter!

```
        Bridge Rectifier         Inverter Transformer            Magnetron
                                       o
  H o----+---|>|------+--------+-------+    +--------------------------+
        ~|            |+      _|_ Drive )::( Filament 1T #18           |

  not shown)       +-----------+            +--+---/\/\----+---------+
                                             o  |    1.2  _|_
 (Except for filament, # turns estimated)       o H1       -   Chassis Ground
```

The chopper transistor is marked: Mitsubishi, QM50HJ-H, 01AA2. It is a LARGE NPN type on a LARGE heatsink. :-)

Note the similarity between the normal half wave doubler circuit and this output configuration! Base drive to the chopper transistor is provided by some relatively complex control circuitry using two additional sets of windings on the inverter transformer (not shown) for feedback and other functions in addition to current monitoring via the 'Sense' resistor in the transformer return.

It is not known whether power levels in this over were set by the normal long cycle pulse width modulation or by control over a much shorter time scale. However, since the filament of the magnetron is powered from the same transformer as the HV - just as in a 'normal' microwave oven, this may not be very effective.

Compared to the simplicity of the common half wave doubler, it isn't at all surprising why these never caught on (what is diagramed above includes perhaps 1/10th the actual number of components in a typical inverter module, which can be seen in the photo). Except for obvious problems like a tired fuse, component level troubleshooting and repair would be too time consuming. Furthermore, as with a switchmode power supply (which is what these really are) there could be multiple faults which would result in immediate failure or long term reliability problems if all bad parts were not located. Schematics are not likely available either. And, a replacement module would likely cost as much as a new oven!

This is simply a situation where a high tech solution was doomed from the start. The high frequency inverter approach would not seem to provide any important benefits in terms of functionality or efficiency yet created many more possibly opportunities for failure. The one major advantage - reduced weight - is irrelevant in a microwave oven. Perhaps, this was yet another situation where the Marketing department needed something new and improved!

Dangerous (or useful) parts in a dead microwave oven?

A microwave oven with its power cord cut or removed AND its high voltage capacitor safely discharged is an inanimate object. There are no particularly hazardous parts inside. Of course, heavy transformers can smash your feet and sharp sheet metal can cut flesh. And, the magnets in the magnetron may erase your diskettes or mess up the colors on your TV.

Some may feel there is nothing of interest inside a microwave oven. I would counter that anything unfamiliar can be of immense educational value to children of all ages. With appropriate supervision, an investigation of the inside of a deceased microwave oven can be very interesting.

However, before you cannibalize your old oven, consider that many of the parts are interchangeable and may be useful should your *new* oven ever need repair!

For the hobbiest, there are, in fact, some useful devices inside:

- Motors - cooling fan and turntable (if used). These usually operate on 115 VAC but some may use low voltage DC. They can easily be adapted to other uses.
- Controller and touchpad - digital timer, relay and/or triac control of the AC power. See the section: Using the control panel from defunct microwave oven as an electronic timer.
- Interlock switches - 3 or more high current microswitches.

- Heavy duty power cord, fuse holder, thermal protector, other miscellaneous parts.

- High voltage components (VERY DANGEROUS if powered) - Typical HV transformer (1,500 to 2,500 VRMS, 0.5 A), HV rectifier (12 to 15 kV PRV, 0.5 A), and HV capacitor (approximately 1 uF, up to 1,500 to 2,500 VAC (4,200 to 7,000 VDC).

- Magnetron - there are some nifty powerful magnets as part of the assembly. Take appropriate precautions to protect your credit cards, diskettes, and mechanical wristwatches. See the section: The magnets in dead magnetrons.

DOUBLE WARNING: Do not even think about powering the magnetron once you have removed any parts or altered anything mechanical in the oven. Dangerous microwave leakage is possible.

The magnets in dead magnetrons

The dead magnetron you just replaced is fairly harmless. There is no residual radiation but it does contains a pair of powerful ferrite ring magnets. These can be removed without extensive disassembly and make really nice toys but should be handled with care. Not only can they pinch flesh (yes, they are that powerful) but they will suck all the bits right off your tapes, diskettes, and credit cards. If you do want to save the magnets:

- Disassemble the magnetron assembly as follows:

    - Remove the top portion of the magnetron - it is either fastened with screws or some metal tabs which are easily bent out of the way.

    - Remove the cover over the box where the filament connections are located. This usually requires peeling off the sheet metal around the edges.

    - Cut the thick copper connections to the filament near the tube itself. (The thick copper coils are RFI chokes and prevent any microwave energy from escaping via the filament circuit.)

    - Spread the frame apart just a bit and lift out the tube with heat sink fins. CAUTION: the sheet metal fins may be sharp!

    - The magnets can now be pulled off. They may need cleaning. :-(

    - The magnetron tube itself can be disassembled by grinding off the welds around the edges of the large cylinder or cutting around it outer edge near one end with a hack saw but it takes quite a bit of curiosity to make this a worthwhile exercise. There is a slight chance that the coating on the filament is poisonous so don't take chances. You don't need to get inside to remove the magnets.

- Keep the magnets a safe distance away from any magnetic media including what might be in your back pocket, mechanical wrist watches, and color computer monitors and TVs.

- Paint the magnets with plastic enamel or coat them with the stuff used on tool handles to reduce their tendency to chip. The chips are as magnetic as the overall magnet. The ferrite is basically a ceramic and fragile. Smack them too hard and they will shatter.

- Take care not to get your skin between the magnets when you bring them together since the attractive force when nearly touching is substantial.

- Store the magnets in a box packed in the center of another box with at least 4 inches on all sides. Clearly mark: powerful magnets with appropriate warnings.

Having said that, these magnets can be used to demonstrate many fascinating principles of magnetism. Have fun but be careful.

Also see the section: Magnetron construction - modern microwave oven.

Using the control panel from defunct microwave oven as an electronic timer

It is usually possible to remove just the touchpad and controller board to use as a stand-alone timer with a switched output. Be careful when disconnecting the touchpanel as the printed flex cable is fragile. With many models, the touchpanel (membrane touchpad) needs to be peeled off of the front plastic panel or the entire assembly can be removed intact.

The output will control a 10-15 A AC load using its built in relay or triac (though these may be mounted separately in the oven). Note that power on a microwave oven is regulated by slow pulse width modulation - order of a 30 second cycle if this matters. If it uses a triac, the triac is NOT phase angle controlled - just switched on or off.

Precise control of microwave oven power

For heating a casserole, the 10 to 30 second cycle time typically used for microwave oven pulse width heat control is fine. However, for other purposes, this results in unsatisfactory results. This question was posed by someone who wanted to modify the circuitry to their microwave oven to provide continuous control and a constant heating rate.

Just cycling faster (without any other modifications is not the answer). One problem is that the filament of the magnetron is turned on and off as well. This would result in a very non-linear relationship between on-time and power as the cycle became shorter and shorter.

It should be possible to put a Variac (variable autotransformer) on the input to the high voltage transformer - between the controller and HV primary. (For safety, DON'T attach it externally, DON'T bypass or disable any door interlocks, and make sure the cooling fan is always powered from the full line voltage.) The power to the filament will still be affected but there will be a range over which continuous control will be possible. My guess is that this would be between 60 and 80 percent and full voltage from the Variac will result in 0 to 100 percent of cooking power (the magnetron is a non-linear device - there is a threshold voltage below which no output is generated). However, there will be a lag as the filament heats and cools. Also, running for an extended period of time at reduced filament temperature may eventually damage the cathode coating. I do not know if this is likely.

Where manual control is all that is needed, this approach may be the adequate.

If the filament were put on its own transformer (with appropriate insulation ratings), then instantaneous control of power should be possible using a Variac on the HV transformer primary or a phase control scheme using a triac - a high power light dimmer or motor speed control might even work. Alternatively, a triac or solid state relay can be turned on and off at the peaks of the AC (to minimize inrush) similar to the pulse width modulation that is normally used for the oven - but at a much higher frequency. This could easily be computer controlled with feedback from a temperature sensor.

In any case, you want everything else - including cooling fans - to be on the full line voltage not affected by any power control scheme or timer.

Has technology gone too far?

Don't you just hate it when your kitchen appliances have the highest IQ in the household? What more could you want? Maybe, a microwave with a robot arm to retrieve the food from your fridge or freezer! But wait, you haven't seen it all. Just the the World needs is a smart microwave. You WILL see ovens (if they don't exist already) that with the help of a barcode or Dallas ID chip on the frozen package or food container, will contact a recipe database at the Web site for the product to determine exactly how to optimally overcook it and turn it into rubber. :)

(From: Dave Marulli (marulli@rdcs.kodak.com).)

We bought a Sharp unit with the Interactive Display feature.

There is a list of common items that you might Defrost, Cook, or Reheat. You pick one of those tasks, choose a number from the list, enter the 'quantity', hit start and it picks the time and power level. There is even an 'on-line' help feature. A typical session goes like this:

```
    Button Pressed                                    Screen Output
   ----------------                                ------------------------------
      CompuCook                                     Enter Food Category
          1                                         Baked Potato, Enter Quantity
          4                                         Press Start
```

Unit turns on and starts cooking. If the little word HELP lights up, you press the HELP button and it gives you little hints like, DO NOT COVER, or CUT IN HALF, etc.

For things like CompuDefrost, you tell it what you are defrosting, how many pounds, and hit start. It will turn on for a while, then beep at you and tell you to break the pieces apart, cover the edges, etc. You do as you are told, close the door hit start and it continues until it's time for you to do some thing else.

Same idea for CompuReHeat: Tell it how many slices of pizza or bowls of pasta you want to reheat, and it sets itself up and takes off.

It even has the obligatory POPCORN button!

Another neat feature is that you can hold the start button on without setting any time and it will stay on for as long as you hold the button. This is great for melting cheese, softening butter or chocolate, etc.

But, does it run Lotus??? :-) --- sam.

(From: Steve Dropkin (sdropkin@isd.net).)

The one we bought has an LCD screen that's maybe three inches square, takes you step-by-step through anything the oven can do, and includes 600 recipes (!). While that sounds like overkill, the attraction for me was that the menu-driven interface actually seemed simpler and more inviting than the ovens with timing buttons and 24 others marked "popcorn," "baked potato," "hot dog," "frozen dinner," "beverage," "sandwich," "waffles," etc. They looked just way too busy. (Same argument I have against a lot of mainstream HiFi equipment these days. I just want to listen to the music, not reengineer the sound source ...)

(From: Andrew Webber (webbers@magma.ca).)

Our microwave has a button for popcorn. As far as I can tell, all it does is automatically set 5 minutes. The manual says to monitor the popcorn anyway since it varies based on bag size, etc. So on principal I choose 5 minutes on high and stop it at 1:45 (why not set for 3:15? because the one time I tried it the popcorn was burnt!). I can choose 5 minutes with two presses (QUICK, 5) and popcorn with two presses (POPCORN, START).

But that popcorn button sure is a good selling point! :)

Microwave ovens for non-standard applications

Occasionally, people ask questions about the use of a microwave oven to do things other than heating food. In general, these have to be taken on a case-by-case basis. Obviously, softening sticks of Dynamite is probably not to be recommended! (There actually is a reason for this - a microwave can develop hot spots - heating is not as uniform as with normal ovens. Do your dynamite softening in a normal oven).

Special kilns that will fit inside a microwave oven are apparently available to achieve really high temperatures. They consist of a ceramic (expanded alumina or something similar) insulating cylinder lined with a microwave susceptor - possibly a ferrite material. Temperatures exceeding 1000 degrees C (yellow-white heat) are possible after a few minutes on high. See for example Microwave Melting of Metals.

If any modifications are made to the oven that would compromise the integrity of the door seals or provide other places where microwave radiation could escape, then special tests MUST be done to assure the safety of the users of the equipment. The following is one such case in point:

> "My Dad and I are using a microwave oven to heat oak strips by passing them through the microwave field of a 1000W oven. We cut out squares (4"x 4") in the glass front and metal back of the oven to allow these strips to pass through the field. I am concerned about potential microwave leakage of a harmful nature."

Geez!!! You guys are out of your collective mind. Sorry, having said that I feel much better. :-(

My first recommendation (though this is too weak a term) would to not do this.

My second (and up to N where N is a very large number) recommendation would be not to do this.

However, if you insist, use a good conductive sheet metal such as copper or aluminum to reduce the size of the opening as close to the material as possible. The wood stock will tend to reduce leakage while it is in place but the opening will leak like crazy when there is nothing in the hole. The sheet metal must be in electrical contact with the mesh in the door and the metal back. The smaller the opening, the less will be the leakage. Also, make sure there is always a load in the oven (a cup of water, for example) to keep the magnetron happy.

Next, borrow an accurate microwave leakage detector. A large appliance repair shop or electronics store may rent you one if you are persistent enough. Use this to identify the safe limits front and back. Label these and don't go closer while the oven is in operation. The operators may have to remain further away or some additional shields may needed if these distances are not satisfactory. The leakage detector or microwave field strength meter should come with information on acceptable power limits. It is something like 2 mW per square cm a foot or so from the oven - check it out. However, there is no assurance that even this limit is safe.

CAUTION (In addition to the loony nature of this entire project!): Since the leakage you encounter may be orders of magnitude greater than what is typical of even a misaligned microwave oven, start with the probe at a distance of a few feet and slowly move it closer while watching the meter or readout. Don't set it next the opening as you hit START! This will prevent the possibility of damage to the expensive leakage tester (which could be costly) and exposure risk to you as well.

The only known confirmed danger from microwave radiation is from internal heating effects. The eye is particularly sensitive to this and it doesn't take much of an increase in temperature to denature the tissue of the central nervous system (i.e., scramble your brain). The human body does not have an adequate warning system since nerve endings sensitive to heat are somewhat sparse. Thus, while the dangers may be overstated, it doesn't make sense to take chances.

What is wrong with radiant heat???

(From Barry Collins (bcollins@mindspring.com).)

You did the right thing to discourage people from breaching the integrity of a microwave oven, because there are so many factors involved that one has to assume personal (or property) injury (or damage) may result from such actions.

I personally don't feel uncomfortable with what the person was doing, provided they had taken reasonable precautions (too numerous to list). Power does fall off with the square of the distance and microwaves, barring any reflective surface, are very directional by nature. Just don't stand in front of the source. (I met one of the Japanese engineers who had unintentionally placed his head in a test oven that was working. He reported warmth, but no lasting damage, aside from the resulting joke.) Field density and exposure time is a large factor. One tends to remove one's hand when one senses heat. I think the story goes that this was how the heating affect was originally discovered.

The number one precaution I've always held near and dear to me is to protect one's eyes. The Narda manual has multiple warning in it about this. The aqueous membranes of the eyes are perfect absorption material for stray microwaves. This can happen much faster than with fleshy parts of the body and don't heal anywhere near the way a flesh injury does. It is this that you might want to point out in your FAQ's.

Short course on Amana

(From: Charles Godard (cgodard@iamerica.net).)

Everything depends on "Air Flow". If the stirrer does not turn, you will always get a "Hot! spot" on the left bottom of the door. In addition the stirrer bearing will sometimes arc and may melt at the spots where it arcs.

If your blower is running up to speed, remove the cover and replace the foam gasket material. This forces air over the stirrer when the cover is replaced. If stirrer still does not turn, remove the grease shield and check the stirrer for burns that are causing it to stick. If this is ok or you correct it and stirrer still does not turn, then replace the grease shield with a later model that looks almost the same as the original, but has one small modification which you will see when you compare the two.

Never let one go out of the shop unless the stirrer is turning. It will soon be back unless all they do is heat coffee. Next time it may be a cavity or magnetron overload that has opened due to the stirrer not turning.

It's good work on a quality product. I wish I had a hundred restaurant customers using them. The older Amana's power stays near 1500 watts forever. Retail customers are junking them because of $100 - to $125 repair bills. What a waste!

Computer system near microwave oven?

> "Can placing my microwave oven in close proximity to my computer and printer do any damage to either of them? The back of the oven would be right next to the printer and about 16 inches from the computer. I have gotten conflicting answers from the guy who rebuilt my computer and the guys at Radio Shack."

Did the kids at Radio Shack even understand the question??? :)

Your request is certainly a bit unusual. My feeling is that it should be fine. The problem would more likely be the magnetic field from the large transformer in the microwave oven causing interference on your monitor (wiggling, jiggling, shimmering, etc. due to its effect on the electron beams in the CRT). There should be no significant microwave leakage from the oven, especially the rear. Keep in mind that there is a computer of sorts inside the microwave controlling it!

However, you will need separate grounded electrical circuits for the microwave and computer equipment if you intend to ever use them at the same time.

Why Microwave-Safe Containers Get Destroyed

You probably have a cabinet full of so-called microwave-safe containers that look like they have been exposed to damage from a nuclear explosion. Why? It probably comes down to unequal heating of the contents or heating continuing long past the point where boiling takes place. I would assume that putting a microwave-safe container in an oven with a cup of water in a separate container wouldn't result in any damage to the microwave-safe container. But if the contents of the microwave-safe container are being heated, then some parts will get much hotter than others resulting in local melting and other damage. I doubt it is the microwave radiation itself doing anything to the material of the container directly and complaining to the oven manufacturer isn't likely to be very satisfying. :)

- Back to Microwave Oven Repair FAQ Table of Contents.

Service Information

Advanced troubleshooting

If the solutions to your problems have not been covered in this document, you still have some options other than surrendering your microwave to the local service center or the dumpster.

Unlike most other types of consumer electronic equipment, a service manual is rarely required. A sufficiently detailed schematic is nearly always pasted to the inside of the cover and includes all power components, interlocks, fuses, protectors, and wiring. This is entirely sufficient to deal with any problems in the microwave generator. No adjustments or alignment should even be required so detailed procedures for these are not needed.

However, when tackling electronic faults in the controller, a service manual with schematics will prove essential. Whether these are available depends on the manufacturer. For legal reasons, some manufacturers are reluctant to sell service information or replacement parts for microwave ovens. They are concerned with litigation should an unqualified person be injured or killed.

Suggested Reference

I know of at least one book dealing specifically with microwave oven repair. It is very complete and includes many actual repair case histories. There is a good chance that your specific problem is covered.

1. Microwave Oven Repair, 2nd Edition
   Homer L. Davidson
   TAB Books, a division of McGraw Hill, Inc., 1991
   Blue Ridge Summit, PA 17294-0850
   ISBN 0-8306-6457-2 (hard), ISBN 0-8306-3457-6 (pbk.)

This may be available at your public library (621.83 or 683.83 if your library is numbered that way) or from a technical bookstore.

Cost of repair parts

Assuming you have located one or more bad components, the question is whether an oven that is a few years old is worth fixing. Typical parts cost for generic replacements:

- HV diode: $2-5 (except for the bolt-on variety which can range up to $50. It should be possible to replace these with the $2 variety with wire leads);

- Power fuse: $.40.

- HV Capacitor: $10-20.

- Magnetron: $30-100. Common generic replacements are $30-40.

- Overtemperature thermostat (thermal protector): $4.50.

- Interlock Switch: $2.50.

- Triac: $12.00 (unless original replacement in which case you will need to take out a mortgage - try the generic variety).

Parts suppliers like MCM Electronics can provide these components to fit the vast majority of microwave ovens.

Touchpads and controller parts like the microprocessor chip are usually only available from the manufacturer of the oven. Prices are high - a touchpad may cost $30 or more.

Sensors and other manufacturer specific parts will be expensive.

While the HV transformers are fairly standard, they are not readily available from the common replacement parts sources. However, they do not fail that often, either.

Here is one place that seems to stock some: AMI Parts, Eagle Grove, IA. Voice phone: 1-800-522-1264. However, they won't be cheap - expect to pay $50 or more!!! In addition, MCM Electronics now lists at least one Goldstar model replacement.

With the prices of microwave ovens dropping almost as fast as PCs, a few year old oven may not be worth fixing if the problem is a bad magnetron or touchpad. However, except for a slight decrease in power output as the oven is used over the years and the magnetron ages, there is little to go bad or deteriorate. Therefore, you can expect a repaired oven to behave just about like new.

Interchangeability of components

The question may arise: If I cannot obtain an exact replacement or if I have another microwave oven carcass gathering dust, can I substitute a part that is not a precise match? Sometimes, this is simply desired to confirm a diagnosis and avoid the risk of ordering an expensive replacement and/or having to wait until it arrives.

For safety related items, the answer is generally NO - an exact replacement part is needed to maintain the specifications within acceptable limits with respect to line isolation, radiation emission, and to minimize fire hazards. For microwave ovens such parts include the power fuses, interlock switches, and anything else that could potentially lead to microwave radiation leakage - like a magnetron which did not fit the waveguide properly.

Fortunately, while an exact match may be required, it doesn't have to be from the original manufacturer - most parts are interchangeable. Thus the organs from that carcass may be able to provide renewed vitality to your ailing microwave.

Here are some guidelines:

1. Fuses - exact same current rating and at least equal voltage rating. This will probably be a ceramic 1-1/4" x 1/4" 15 or 20 A 250 V fast blow type. For the repair, use an exact replacement. For testing only, a similar type may be used.

2. Thermal protectors - same temperature and maximum current rating. You must be able to mount it securely and flush against the same surface as the old one.

3. Interlock switches - must have the same terminal configuration and at least equal current rating. Of course, a secure fit is very important as well for it to perform its safety function. Many of these are interchangeable.

4. HV capacitor - similar (within 5%) and at least equal working voltage. Note that the working voltage rating of these capacitors is not consistent with the way capacitors in other electronic equipment are specified and is usually the RMS voltage of the AC input from the HV transformer. There- fore, it is not possible to substitute something from your junkbox unless it is from a microwave oven. In addition, this is one situation where

higher capacity (uF) is not better. The power output is related to capacitance. Thus, the value should be matched fairly closely or else other parts may be overloaded. However, a smaller one can be used for testing.

5. HV diode - most of these have similar electrical ratings so a substitution is possible if you can make it fit physically. This would be particularly desirable where your oven has one of those chassis mount $50 dollar varieties - it may be acceptable to use a $2.75 generic replacement.

6. Relays and triacs - substitutes will generally work as long as their specifications meet or exceed those of the original. Creative mounting may be required.

7. Magnetrons - a large number of microwave ovens use the same basic type but the mounting arrangement - holes vs. studs, orientation of the cooling fins, etc., differ. You can safely substitute a not exact match for testing purposes IF you can make it fit the waveguide securely without gaps. However, if the cooling fins end up being on the wrong side, it will heat up very quickly - 50% of the input power goes to heat - and will not be suitable as a permanent replacement.

8. HV transformer - same (within 5%) voltage and at least equal current rating. Mounting should not be a problem but don't just leave it loose - you could end up with a disaster.

9. Fans and motors - speed/power and direction must match and mounting must be possible. Speed isn't so critical for a turntable but for a magnetron cooling fan, inadequate air flow will result in overheating and shutdown or failure. Common shaded pole type motors may be interchangeable with other appliances or if a mounting arrangement can be cobbled together.

10. Mica waveguide cover - cut to match.

11. Turntable and mode mixer components - if they fit, use them.

12. Light bulb - similar ratings and base.

13. Temperature sensors, thermistors, etc. - depends on the particular model.

14. Mechanical timers - compatible switching and mounting arrangement.

15. Cordsets - must be 3 wire heavy duty grounded type. Make sure the replacement has at least as high a current rating as the original. Observe the color code!

16. Controller and touchpad - small parts like resistors, diodes, capacitors, and so forth can often be substituted. Forget about the controller ICs or display. The touchpad is likely to be custom both electrically and physically as well unless you have a similar model microwave to cannibalize.

Can I substitute a slightly different HV capacitor for a blown one?

It is not always possible or convenient to obtain an exact replacement high voltage capacitor. What will the effects be of using one that is a slightly different value?

First, the voltage rating must be at least equat to that of the original. It can be higher but never never lower or you will probably be replacing it again in the very near future.

Now for the uF rating:

Unlike a conventional power supply filter capacitor, the capacitor in a microwave is in a voltage doubler and effectively in series with the load (magnetron). Therefore, its value **does** have an impact on output power. A larger capacitor will slightly increase the output power - as well as heat dissipation in the magnetron. Too small a capacitor and the doubler will not produce full output.

As an example, the impedance of a 1 uF capacitor at 60 Hz is about 2.5 K ohms. The cap is in effect in series with the magnetron. A 1 kW magnetron running on just over 3 kV RMS is about 10 K ohms. These are really really rough calculations.

Thus the power difference is not a straight percent for percent change - I estimate that it is about a 1:4 change - increase the capacitor's uF rating by 10 percent and the power and magnetron heat dissipation will go up by 2.5% (assuming the relationship is linear right around the nominal value). I have not confirmed this, however.

Therefore, I would say that using a capacitor with up to a 10-15% difference (either way) in uF rating is probably acceptable but a closer match is better.

Obtaining replacement parts for microwave ovens

For general electronic components like resistors and capacitors, most electronics distributors will have a sufficient variety at reasonable cost. Even Radio Shack can be considered in a pinch.

However, places like Digikey, Allied, and Newark do not have the specialized parts like magnetrons, HV capacitors and diodes, interlock switches, thermal protectors, etc., needed for microwave oven repair.

Your local appliance distributor or repair parts outlet may be able to obtain an exact replacement or something that is an ecceptable substitute. However, the cost will be higher than for generic parts from the places listed below if they carry what you need.

Going direct to the manufacturer is a possibility but expect to pay more than might be charged for generic replacement parts by an independent company. Also, some places like Sears, may refuse to sell you anything microwave oven related due to safety concerns - unless they are convinced you are a certified repair technician, whatever that might mean. Their prices are inflated as well.

Another alternative is to determine who actually made your oven. This is obvious with name brands like Panasonic and Sharp. However, Sears doesn't manufacture their own appliances, but an inspection inside may reveal the actual manufacturer. Then, go direct to the horse's mouth. Many companies will be happy to sell service parts but availability may be a problem on older ovens. I had to give up on a Sharp microwave/convection oven that was 15 years old because specialized replacement parts were no longer available from Sharp.

Note: I have heard that in other parts of the world, there may be restrictions on who can actually purchase microwave oven parts other than things like light bulbs, turntables, and standard door switches. In the U.S., certain companies (like Sears) may set their own rules - you have to convince them that you have at least the intelligence of an average carrot and possibly sign a 100+ page document written by too many lawyers. :)

Sources for replacement microwave oven parts

See the document: Major Service Parts Suppliers for some companies that I have used in the past and others that have been recommended. They may include microwave oven parts in their catalog but don't specialize in them.

The following suppliers have web sites with on-line catalogs and list a very extensive selection of microwave oven parts. There is a chance that they may not want to sell to the general public. I suppose this may be due to several factors including the potential liability issues, complaints/attempts to return parts when a repair doesn't work, and the small quantities involved. However, it is definitely worth checking as the public web sites implie a desire to deal with the entire Internet community.

- Global/MPI/All Appliance Parts
  Phone: 1-800-325-8488
  Web: http://www.allapplianceparts.com/

  Their web site includes a very extensive selection of microwave oven parts. For example, nearly 50 different magnetrons are listed along with little photos of each!

- AMI (Appliance Maintenance International)
  U.S. Phone: 1-800-522-1264
  U.S. Fax: 1-800-442-3601
  Int. Phone: 1-515-448-5311
  Int. Fax: 1-515-448-3601
  Email: ami@amiparts.com
  Web: http://www.amiparts.com/

  Distributor of consumer and commercial microwave oven parts. Extensive on-line catalog of microwave oven parts with on-line parts lookup and ordering.

Here is another one:

- Electronix, Corporation
  Web: http://www.electronix.com/

  Magnetrons, interlock switches, lamps, glass trays, diodes, thermal fuses, couplers, latches, rivets, stirrers, fans, waveguides, more... Also: Techweb, $6/month.

The following company will definitely not sell you anything but should be able to provide the name of a local appliance parts distributor.

- QB Products
  Phone: 1-800-323-6856

  Master distributor, they sell only to appliance and electronics parts distributors like Marcone, Tritronics, Johnstone, etc. You can call them to find the nearest distributor.)

DISCLAIMER

Some of the contact information and summary of products may be out of date as I don't place orders that often. In general, the range of offerings increases with time so it is best to check with the company's Web site and/or request a catalog. However, I won't be responsible if you miss an opportunity to buy your favorite horizontal output transistor because the listing below didn't include HOTs as a line item! Corrections are welcome.

Introduction

Scope of This Document

Note: This document replaces the individual sections in each of major repair guides.

The following sections provide contact info and/or links to companies specializing in service parts (as opposed to general electronics distributors).

For general electronic components like resistors and capacitors, most electronics distributors will have a sufficient variety at reasonable cost. Even Radio Shack can be considered in a pinch.

However, for modern electronic equipment repairs, places like Digikey, Allied, and Newark do not have the a variety of Japanese semiconductors like ICs and transistors or any components like flyback transformers or degauss Posistors.

The companies below are good sources for consumer electronics replacement parts, especially for VCRs, TVs, and other audio and video equipment. For equipment specific parts suppliers, see the individual repair guides.

I have used those in the first section personally. In general, I have been quite satisfied with their quality and reliability. I do not have personal experience with the others but in general, they get listed here as a result of a recommendations from satisfied customers via email or on the USENET newsgroup sci.electronics.repair.

- Back to Major Service Parts Suppliers Table of Contents.

Service Parts Suppliers I (Sam) Have Used

- MCM Electronics
  U.S. Voice: 1-800-543-4330
  U.S. Fax: 1-513-434-6959
  Web: http://www.mcmelectronics.com/

  VCR parts, Japanese semiconductors, tools, test equipment, audio, consumer electronics including microwave oven parts and electric range elements, etc.

- Dalbani
  U.S. Voice: 1-800-325-2264
  Int. Voice: 1-305-716-0947
  U.S. Fax: 1-305-594-6588
  Int. Fax: 1-305-716-9719
  Web: http://www.dalbani.com/

  Excellent Japanese semiconductor source, VCR parts, other consumer electronics, car stereo, CATV).

- Premium Parts
  U.S. Voice: 1-800-558-9572
  U.S. Fax: 1-800-887-2727

Very complete VCR parts, some tools, adapter cables, other replacement parts.

- Back to Major Service Parts Suppliers Table of Contents.

Other Service Parts Suppliers

These companies have been recommended but I do not have personal experience with them. The following are good sources for consumer electronics replacement parts, especially for VCRs, TVs, and other audio and video equipment. Catalogs are a must. (The first 4 I have used and have been satisfied with service and selection. The others have been recommended by others.)

- Global Micro Parts, 1-800-325-8488, http://www.allapplianceparts.com/.

  They specialize in microwave oven parts, but also carry some other major appliance parts.

- Cititronix/Panson, U.S. Phone: 1-800-846-2484, U.S. Fax: 1-800-726-0142.

  JC Penney, JVC, Kenwood, Maganvox, Service parts for: Fisher, GE, Hitachi, Panasonic, Philco, Philips, Quasar, RCA, Sanyo, Sharp, Sony, Sylvania, Technics, Zenith.

- Electro Dynamics, Inc., 7 Oser Avenue, Hauppauge, NY 11788, Phone: 1-631-951-4922 They also have a sister company that deals with mostly computer parts, "Computer Components" (CCI - I believe) at the same address, phone: 1-631-951-4749. Catalogs are available from both.

- Electronic Parts Center, Phone: 1-800-501-9888, Fax: 1-626-285-6873, Web: http://home.earthlink.net/~epcs/.

  Includes many popular CD pickups at reasonable prices.

- Electronix, 313 W. Main St., Fairborn, OH 45324-5036. Phone: 937-878-1828, Web: http://www.electronix.com/.

- Electronic Warehouse Corp., 1-800-221-0424.

- Fox International, 1-800-321-6993.

- Good Vibes, 1807 S. Neil St., Champaign, IL, Phone: 1-217-351-0909; Rantoul, IL, Phone: 1-217-892-5622; and Bloomington, IL, Phone: 1-309-664-6909. Web: http://www.gvibes.com/partsforsale.html.

  Service parts inventory includes hard-to-find items: Teac reel-to-reel replacement heads, B/W speaker drivers, Sony custom IC chips, etc. They have a wide range of new old stock parts many of which are no longer available from the manufacturer.

- MAT Electronics: 400 Pike Road, Huntingdon Valley, PA 19006-1610, Phone: 1-800-628-1118.

- Parts Express, 340 E. First St, Dayton, OH 45429, Phone: 1-800-338-0531, Fax: 1-513-222-4644, Web: http://www.parts-express.com/.

- RNJ Electronics: 805 Albany Ave., P.O. Box 528, Lindenhurst, New York 11757, Phone: 1-800-645-5833.

- Sears Parts. Replacement parts and accessories for Sears and some other appliances, electronics, and garden and power tools.

- Tritronics: 1306 Continental Drive, Abingdon, MD 21009-2334. Phone: 1-800-638-3328.

Also see the extensive mail order lists at:

- Sam's Neat, Nifty, and Handy Bookmarks under "Electronics Service Parts Sources".
- List of Mail Order Electronics Companies though this is somewhat dated.
- AF4K's List of Parts Suppliers.

Also see the document: "Troubleshooting of Consumer Electronic Equipment" for additional parts sources as well as the equipment specific supplier lists at the end of each Repair Guide. The chapter: "Laser and Parts Sources" of "Sam's Laser FAQ" also includes extensive lists of new and surplus electronics supplies that may be useful.

Sam's Neat, Nifty, and Handy Bookmarks

Version 4.20f (05-May-04)

For contact info, please see the Sci.Electronics.Repair FAQ Email Links Page.

Introduction

This is a snapshot of the bulk of the primary bookmark file I use with Netscape Communicator 4.8. I strive to keep it up to date but regrettably, this is about as possible as keeping up to date with all the free magazines that come my way. With so many Web sites coming and going and changing it is inevitable that some URLs will result in "404 missing" errors. I am resigned to this for individuals on mom-and-pop ISPs. However, there really is no excuse when large companies change their Web site organization and don't provide an easy way to locate the replacement page for those that have disappeared. Some do but many don't seem to care if you find them or not. Even the U.S. Postal Service will forward your mail for several months. Out of courtesy, Web sites should do this with Web site addresses as well!

The bookmarks, below, are divided into major categories and sometimes further sub-divided but not too deeply. I apologize for the organization (or relative lack thereof). Maybe someday I will reformat this stuff using fancy HTML tables and add meaningful descriptions of each entry. Then again, maybe pigs will fly. :-) This version is pretty clean but I don't guarantee that for the subsequent ones - I 'processed' it mostly by hand (well, OK, I did use a computer!) with some help from GNU EMACS. What is really needed is a SED or PERL script (or something) to do that automatically. I promise get to that first thing after the pigs start flying. :)

Laser Equipment and Parts - New, surplus, mail order

All Electronics - New/surplus, occasional laser bargains
ALPEC Team, Inc. - Laser pointers, modules, sights
American Science & Surplus
Anchor Optical Surplus
Arbor Scientific - Kits and demos, parts and equipment.
Bid-Service LLC Lasers - Systems related to semiconductor processing
BMI Surplus Equipment Brokers - Includes lasers and optical equipment
BSC Optics - High quailty optics and optical equipment
Bull Electrical (UK) - Lasers page.
C and H Sales Company - Electronic surplus
Carl's Electronics - Plans for 40W CO2 laser, more.
Cascade Laser Corp. - Laser repair and components
Casix - Laser optics (China) - Optical and laser components and kits
C and H Sales Company - Electronics Surplus
CTR Surplus - Electrical, PSs, RF, Optics, more
DeHarpporte Trading Company - Laser pointers, DPSS lasers and modules
Dfreshh Laser lighting and sound: Some laser rental/surplus sales
DIY Electronics (Kitsrus) - Diode laser modules
Edmund Scientific - Optics, lasers, electronics, kits, etc.
EIO - Surplus electronics, some laser. and computer parts
Electronic Surplus Online! - Includes some laser equipment
Enlight Technologies, Inc.- DPSS lasers, modules, and pointers
Europe Laser Exchange - Lasers and laser systems (mostly large but some small)
Future Horizons - Werid stuff probably to be avoided
HB-Laserkomponenten - HeNe, Ar/Kr ion, Co2, Nd:YAG, new/used
Herbach and Rademan - Electronic surplus, HeNe lasers/PSs, more.
Hi-Tech Electronic Surplus
H.V. Component Associates (HV diodes)
Holland Laser Products - Surplus lasers, test equipment, vacuum systems, etc.
Holograms and Lasers International
Hosfelt (Specials include laser pointers, etc.)
HSC Electronic Supply (Halted Specialties) - Electronics and some lasers
Images SI, Inc. - Parts and kits for many types of projects
Information Unlimited - Sci. Proj, Kits, Lasers, HV, Plans, Books, Parts
Intelite, Inc. - Lasers and electro optics products

Kentek Corporation - Laser replacement parts, accessories, etc.
KERN laser systems, etching, and profiling
Labtrader - Laser/Optics for Sale
Laseramazers.com - Laser show equipment inc. diode, DPSS, HeNE, and Ion lasers
Laser Laser Productions - Laser equipment and parts for sale
Laser Pointers and Modules (arcos.org)
Laser Pointers (hut.fi/~mkallio/sivut)
Laser Resale, Inc. - Surplus, buy, sell, lasers and components
Lasershop - New and used lasers, optics, plans, more.
Laser Surplus Inc. - New and Used Laser Equipment
Laser Surplus Sales - Lasers, PSs, Optics, Test/Mesaurement
Laser Technical Instruments - Laser line generators
Laserworks - Laser entertainment hardware
LasPro - DPSS laser kit
Latronix (Sweden) - laser and optics
Lauritsen Laser Labs - Laser trade/swap/service club
LMDC - Optics, motion control, lasers. Sales, integration, consulting.
Main Line Optical Instruments
Marlen P. Jones - Electronics, lasers, optics, more.
MediaLas Laserproducts GmbH (Germany) - Showlaser-components
Meredith Instruments - All sorts of laser surplus
Midwest Laser Products - New and surplus lasers and components
MWK Laser Products - Laser Parts and Equipment
Musser & Associates - Optical tables, breadboards, components, more.
Neodymium Glass - Surplus rods, slabs, and other optics from LLNL
NVG, Inc. - Diode lasers, laser diodes, drivers, optics, more.
OATLEY Electronics (Australia) - HeNe and diode lasers, kits.
OE Technologies - High voltage components, optics, PM tubes, more.
OptoSigma - Optic and optical components
PEMED Surgical Lasers - Surplus CO2 and YAG laser systems
Pendex Corporation - Refurbished laser and optics equipment
Plans and Kits Unlimited - Amusing site, but very negative reviews.
RedLine 115 Laser Modems.
Resources Un-LTD
Second Hand Laser - Surplus from HB-Laserkomponenten GmbH
SICK, Inc. - Laser measurement systems
Sterling Resale Optics - Surplus optics
Surplus Shack - Optics, instruments, equipment
SVBx High Tech Labs - Plans, parts, circuits, bbs, chat, more.
SVSKITS.com - Laser show and robotics kits and parts
TECNET - Used Equipment Database of Surplus Assets

Ted's High Voltage & Other Items For Sale
University of Utah Surplus Property
Used-Lasers.com - Photos and links not clear if anything for sale
Used Line - Ads for used scientific equipment, some lasers
Wacky Willy's Surplus Stores

Laser Equipment Sales, Rentals, and Service

Anderson Lasers, Inc. - Industrial, scientific, light show lasers, more.
Cambridge Lasers Laboratories, Inc. - Ion laser repair, upgrade, rental.
Cascade Laser Corp. - Laser repair and components.
CASIX - China based supplier of laser optics, components, and kits
Control Laser Corporation - Laser Marking Systems
Creative Technology - Laser pointers, diode/DPSS modules, consulting
Directed Light, Inc. - Laser equipment for industry
DZ Laser Service - Specializing in ILT laser repair
Edmund Scientific - HeNe, diode, Argon lasers, optics, kits
EK Photonics - SS laser parts, accessories, repair
Ellison Research Labs - Electronics consulting including laser repair
Evergreen Laser Corporation - Ion laser service and refurb.
Excitek, Inc. - Ion laser sales and service, CO2 tube regassing
G.L. Services - Laser safety, display, service, refurb, more.
Grapevine Laser - Sales and service of Ar/Kr ion lasers.
HB-Laserkomponenten - HeNe, CO2, Nd:YAG laser sales and service
Holo-Spectra - Laser resale, repair & refurb, lightshows, more
HGM Medical Lasers Inc. - DPSS and other medical/surgical laser systems
H&H Research - Ion laser sales and service
H&H Research (alternate site) - Ion laser sales and service
Laser Components (USA), Inc. - Importer/distributer of laser diodes/modules, optics, detectors, more.
Laser Components (DE) GmbH- Far IR diode lasers, other electrooptics, more.
Laser Components (UK) Ltd. - Far IR diode lasers, other electrooptics, more.
LaserDealer.Com - Laser Engravers for Signage and Industry
Laser Devices, Inc - Laser gun sights, laser pointers, laser diodes and drivers
Laser Electronics Ltd. - Lasers. controllers, rentals, reprocessing
Laser Electronics (Operations) Pty Ltd (Austrialia) - Supplier
Laser Innovations - Ion laser sales, service, and support
Laser Labs, Inc. - Medical, surgical, scientific lasers, laser tubes
Laser Labs, Inc. - Light show equipment and sorfware
LaserNexus. - Scientific, Industrial & Medical Lasers Components & Optics
Laseroptronix (Sweden) - Lasers, laser and other optical equipment

Foctek Photonics, Inc. (China) - Laser and NL/EO crystals and optics
FOCUS, Inc. (Russia) - Custom optics

G-L

GEOLA (General Optics Laboratory) - Nd lasers and holography systems

Gigahertz-Optik, Inc. - Light measurement systems
GSI Lumonics - Laser Systems, Components, Instrumentation, Life Science and Metrology
Hamamatsu - PMTs, PDs, LEDs, sensors, light sources, more.
Hankwang - CO2 and YAG lasers (Koria)
Heraeus Noblelight, Inc. - Flashlamps, arc lamps, and other specialty lamps
Hewlett Packard - Laser Interferometer Positioning Systems
High Brightness Solutions - Laser diodes, modules, DPSSLs, photodiodes.
High End Systems On Line - Lighting control including Laser Chorus
II-VI Incorporated - Laser optics, components, detectors, more.
ILX Lightwave - Fiber optics and diode laser instrumentation
Industrial Microphotonics Company - Diode Array and Diode Bar Manufacturer
Infineon Technologies - High power CW and pulsed laser diodes and other semis.
Institute of Inorganic Chemistry (Russia) - Laser and optoelectronic crystals
International Light - Light Measurement Systems, Instruments, Detectors, etc.
ISP Optics - IR and UV optical materials and components
ITI Electrooptics - Laserr and non-linear crystals
Janos Technology, Inc. - Precision optics from exotic materials
JDS Uniphase Corporation - Lasers and subsystems, more
JMAR Technologies, Inc. - Picosecond lasers. more.
Jodon, Inc. - HeNe lasers and tubes, non-contact gauging, more.
JSL (Joachim Sacher Lasertechnik) - Laser diodes, external cavity diode lasers, accessories
Kaiser Systems, Inc. - HV power suppiles, cap chargers, more.
Keon Optics - Optical polishing and thin films coating
Kigre, Inc: - Solid state laser components and systems
Koito Manufacturing Company, Ltd. - HeCd whitelight laser
Lambda Physik - Excimer and dye lasers and dyes
LASAG Industrial Lasers - Nd:YAG pulsed lasers for welding, cutting, drilling
Laser 2000 International - Lasers, optics and fibre optic equipment.
Laser Analytics - Lead-salt tunable diode lasers
Laser Beam Products - CO2 and other high power laser optics
Laser Crystal Ltd.: Non-linear optical elements, LBO, BBO, KTP. more
Laser Diode, Inc. - FO TX/RX, GaAs lasers
Laser Diode Array, Inc. - Large multi-bar laser diode arrays
Laser Drive, Inc. - PSs for HeNe, Ar+, CO2, lasers, tungsten & discharge lamps

Laser Drivers - iC-Haus laser diode drivers
Laser Kinetics Inc. - CO2 laser systems
LaserMax - Diode laser modules
Laser Physics - Air Cooled Argon Ion Lasers
Laser Power Corp. - CO2 laser optics, IR coatings and DPSS ulasers
Laser Quantum Ltd - Diode Pumped Solid State Lasers and accessoris
Laser Research Optics - CO2 laser optics
Laser Science, Inc. - N2, CO2, and N2 pumped dye lasers, more.
Laserscope - Turn-key medical/surgical laser systems
Laser SOS USA. Inc. - laser parts, consumables, oem light sources, more
Lasermate Corp. - LD modules, drivers, pointers, optics, DPSSLs
Lasever, Inc. (China) - DPSS lasers - IR, green, blue
Lasiris, Inc. - Lasers and accessories for structured lighting
LASOS Laser-Fertigung GmbH
LASTEK - Photonics products for research
Latronix AB - Laser and optics systems and components
Leadlight technology, Inc. - Green laser pointers and DPSs modules, more.
Lee Laser- High power Ng:YAG lasers
LiCONiX Lasers - HeCd lasers (now part of Melles Griot)
Light Solutions Corporation - DPSS lasers.
Lightwave Electronics - DPSS lasers
LIMO - Micro-Optics & Laser Systems
Litton Airtron - Synthetic solid state laser rods and slabs
Logic Systems, Inc. - Includes PSU for large frame ion lasers
Lumex - Vsible and IR laser diodes, LEDs, LCDs, more.
LUMITEK International, Inc. - Sensors, viewers, detectors, safety gear.
LumrnX Technologies, Inc. -- Coaxial flashlamp pumped dye lasers
Lumonics, Inc. - See GSI Lumonics
Lynton Lasers - Medical, surgical, conservation, cleaning.

M-P

Macken Instruments, Inc. - Laser beam power and measrement.
Maier Photonics - Thin film optical filters
Meadowlark Optics, Inc. - Polarization control devices

Polaroid Laser Diodes
Polytec PI - Piezo stages, SS, excimer, dye lasers.
Positive Light, Inc. - UV, DPSS Nd:YLF, Ti:Sapph, more.
Power Technology Inc. - Laser Diodes/Modules/HeNe PSs/more
Precision Projection Systems - Components for Light Effects/Shows
Pulslight Company (Bulgaria) - Copper bromide lasers for industry and medicine

Q-Z

QED (Quality Electro-optical Devices) - DPSS lasers
Q-Peak Applied Photonic Systems, Inc. - DPSS lasers, contract R&D
Quantronix Corporation - High power solid state lasers.
Quantum Technology, Inc. -- NL optics, EO, HV drivers, etc.
Radiant Dyes - Dye lasers, accessories, more.
Quarton, Inc. - Laser pointers, laser sights, laser tools. more.
Raicol -- Nonlinear and electrooptic crystals and elements
Rainbow Photonics AG (Switzerland) - DPSS lasers, more.
Rocky Mountain Instrument - Electro-optics system design, dev., mfg.
Rofin-Sinar Technologies - High power CO2, Nd:YAG, diode lasers, markers
Reaserch Electro-Optics (REO) - Optical coatings, tunable HeNe lasers, more.
Roithner-Lasertechnik (Austria) - Diode lasers, LEDs, laser components, more
Rolyn Optics California - Optics for Industry
Ross Optical Industries - Optics of all kinds
Semiconductor Lasers International Corporation - Laser diodes.
SDL, Inc. -- High power laser diodes, subsystems, and accessories.
SensorPhysics - Laser beam diagnostics instruments
Science and Technology Center FIRN (Russia) - LSB DPSS microchip lasers, modules, systems.
Sensors Unlimited, Inc.
Shanghai Uniwave Technology (China) - DPSS Lasers, optics, crystals
Sharp Microelectronics of the Americas - Optoelectronic Components
Sony Laser Diodes
SOPRA, Inc. - High energy excimer lasers and optical instruments

Spectragen, Inc. - Laser crystals, IR and UV optics, more.
Spectracom Inc. 980nm Laser Products
Spectra-Physics Lasers - Lasers and laser systems, optics, etc.
Spectronika Ltd. - CV lasers and systems
Spectron Laser Systems - Nd:YAG and sealed tube CO2 lasers
SPECTRAL laser - High power HeNe, sealed CO2 lasers, power supplies
StockerYale Inc. (formerly Lasiris, Inc.) - Lasers for structured lighting, more.
Sunlit Systems Co. (Taiwan) - Green laser modules & pointers, laser projectors
Superconix, Inc. - Laser crystals, non-linear crystals, more
Synrad - CO2 Laser Manufacturer
Litton/Airtron/Synoptix - Laser and non-linear crystals
Thorlabs, Inc. - Optics, laser diodes and drivers, LD database
Thomson-CSF Laser - Lasers for science and industry
Thomson-CSF Laser Diodes
TOPTICA Photonics AG - Tunable laser systems, laser diodes, optical disk testers, more.
Toshiba Optoelectronics -- Visible Laser Diodes
Transverse Industries Co., Ltd. - Green DPSS laser modules, other laser products
TuiOptics GmbH (Germany) - Tunable and other diode lasers
U-Oplaz Technolgies, Inc. - Non-linear crystals, optics. Distributor for CASIX
Unique-m.o.d.e. - Customized high power diode laser systems
Universal Laser Systems, Inc. - Sealed RF excited air-cooled CO2 lasers
Uniwave Technology - DPSS, non-linear optics, CASIX dist.
ValpeyFisher - Ultrasonics and Optics
Vector Technology Limited (UK) - Diode laser modules, sensors, comm. systems.
VLOC - Laser and non-linear crystals and optics
VLOC - Laser crystals, doublers, polarizers, and other optics
Wavelength Electronics - Laser diode drivers, TE coolers, heaters
World Laser Optics - High power DOEs, laser pwr meter, software, more.

DISCLAIMER

We will not be responsible for damage to equipment, your ego, blown parts, county wide power outages, spontaneously generated mini (or larger) black holes, planetary disruptions, or personal injury that may result from the use of this material.

- Back to Simple High Voltage Generator Table of Contents.

Introduction

Simple High Voltage Generator

The basic circuit described in this document is capable of generating up to 30 kilovolts or more from a low voltage DC source using the flyback (LOPT) transformer salvaged from a B/W or color TV or computer monitor. Typical output with a 12 VDC 2 A power supply or battery will be 12,000 V. Maximum output current at full voltage is typically around 1 to 2 mA. Higher currents are available but the output voltage will drop. At 2 kV, more than 10 mA may be possible depending on your particular flyback transformer input voltage and current.

Safety Considerations

Before thinking about experimenting with anything using or producing high voltages, see the document: Safety Guidelines for High Voltage and/or Line Powered Equipment. While the circuit described below isn't likely to be lethal using the suggested input voltage and components, who knows how you might 'enhance' it! :-)

- Back to Simple High Voltage Generator Table of Contents.

High Voltage Inverter

HV Inverter Circuit Diagram

As you can see from the schematic below, it doesn't get much simpler than this!

A slightly modified version of this basic circuit which I use as an RF source to excite a glow discharge in helium-neon laser and other gas discharge tubes is shown in: Flyback Based RF Source. This one uses a flyback transformer without a high voltage rectifier (or with the rectifier removed). The inductor, L1, is an addition that should reduce the stress on the transistors and power supply by limiting current at the time each of the transistors go into saturation just before the base drive switches to the opposite side. I have not specifically tested this circuit with the inductor but have used it with similar inverters.

These designs are similar to circuits found in: "Build your own working Fiberoptic, Infrared, and Laser Space-Age Projects", Robert E. Iannini, TAB books, 1987, ISBN 0-8306-2724-3 and many other places.

For larger (e.g., color TV or monitor) flybacks, or use with more than 12 VDC in, transistors with higher power ratings may be needed for sustained operation in addition to a good heat sink. An alternative is to parallel more than one power transistor along with small (e.g., .05 ohm, 2 W) current balancing resistors in series with their emitters.

HV Inverter Assembly

Read the following in its entirety! This assumes the basic circuit using a small flyback and input voltage of 12 VDC or less. Some modifications may be needed when using larger flybacks and higher input voltages.

1. Obtain flyback transformer with known good HV secondary winding. primary may be left intact if it is known to be in good condition - non shorted. A flyback removed due to failure may be used if it was the primary that failed and the primary turns can be removed without damaging the HV secondary or losing the secondary return connection! Flybacks fail in both ways (primary and secondary).

2. Locate the return for the high voltage winding. This may be a different color wire than the low voltage winding or may exit from the potted part of the flyback in a different place. It is not possible to use an ohmmeter to locate the return for the high voltage winding if your flyback has a built-in HV rectifier or multiplier as the forward voltage drop of the rectifier diodes is much greater than the battery voltage used in your multimeter. However, a winding connection that has infinite resistance to every other terminal is likely to be the HV return. On flybacks with no HV rectifier or multiplier, the return is easily located by measuring resistance between the HV output and all other terminals. The HV winding will have a resistance of 100s-1000s of ohms compared to single digit readings or less for all the other windings.

3. Wind 10 turn center tapped drive winding and 4 turn centertapped feedback winding using #16 to 20 gauge insulated wire. Make sure both halves of each coil are wound in same direction. Connect centertap in each case at the winding - do not bring out a loop. Insulate well with electrical tape.

4. Vcc should typically be in the range 12 to 24 volts at a couple of amps. Circuit should start oscillating at around a Vcc of 5 V or so. If you do not get any HV out, interchange the connections to the transistor bases. Heat sinks are advised for the transistors. Be aware of the capability of your flyback (B/W monitors up to 15 kV, color up to 30 kV). You risk destroying the secondary windings and/or HV rectifier if you get carried away. Running this on 24 volts will probably cause an internal arc-over in a small flyback, at which point you start over with more caution and a new flyback.

5. Actual output will depend on turns ratio of the flyback you have.

   - For a typical small B/W TV, monochrome computer monitor, or video display terminal, you should be able to get around 12,000 volts with 12 VDC input.

     I built one from a dead Mac-Plus flyback from which I removed the (dead) primary windings.

   - With a large color TV or color monitor flyback, 30,000 V or more will be possible using a 24 VDC power supply.

6. The frequency of operation will be in the kHz to 10s of kHz range depending on Vcc, load, and specific flyback characteristics.

7. You can experiment with the number of turns, resistor values, etc. to optimize operation and power output for you needs.

8. CAUTION: contact with output will be painful, though probably not particularly dangerous due to low (a few mA) current availability.

   HOWEVER, if you add a high voltage capacitor to store the charge, don't even think about going near the

HV!

HV Inverter Parts List

None of the component values are critical. It is quite likely that everything needed is already patiently waiting in your junkbox. If not, except for the flyback, most if not all of the parts should be available from Radio Shack. See the section: "Low voltage power supply" for a simple design to use with this inverter.

Some experimenting with different value resistors and even the number of turns on each winding may improve performance for your particular flyback.

- Q1, Q2 - 2N3055 or similar NPN power transistors (reverse polarity of Vcc if using PNP transistors.) Maximum stress on transistors are about 2 to 3 times VCC. Heat sinks will be needed for continuous operation.

- R1 - 110 ohms, 2 W resistor (5 W for Vcc of 24 V). This provides base current to get circuit started.

- R2 - 27 ohms, 5W resistor. This provides return path for base feedback during operation.

- T1 - Flyback transformer from/for B/W TV, video display terminal, color TV, computer monitor, etc., modified according to text above.

  Most modern flybacks include built-in HV rectifier diode(s) and/or voltage multiplier (tripler) so output without additional components will be high voltage positive or somewhat smoothed HV DC.

  Note: this kind of flyback transformer drives the CRT directly and uses its glass envelope as the main high voltage filter capacitor. (A foot square piece of 1/8 inch Plexiglas with Aluminum foil plates makes an filter capacitor.)

- Wire - a couple of feet of #16-#20 hookup wire, magnet wire, or any other insulated wire for home made primaries. Use electrical tape to fix windings to core. Wind feedback winding on top of drive winding.

Suggested Enhancements

Here are some minor changes that should improve the efficiency of this circuit.

(From: Robert (rrtcj@hotmail.com).)

- Use a more modern transistor like the 2N3773 instead of the 2N3055. It has higher current (30 A) and higher voltage (140 V) ratings as well as higher Hfe thus requiring less base current.

- Use a single feedback winding (2 turns) with each end connected to the base of one transistor and over a 150 ohm resistor connected to Vcc. (I'm not quite sure exactly what this means but my guess is to connect a 150 ohm resistor from one of the bases to Vcc to provide the startup base drive. --- Sam.)

- Add an inductor (about 0.4 mH, can be more but not less) in series to the flyback circuit. Since both transistor are switched on for a little moment (when there is no voltage in the feedback), so there will be high currents (causing losses resulting in excessive power disspation in the transistors) The coil prevents the current spike without wasting power like a resistor.

Measurements: With an input voltage of 16 VDC, the output voltage is about 12 kV. Without the filter choke, the input current with no load is 5 A; with the filter choke it is only 3.2 A. With the output shorted (arcing), the current is about 9 A in both cases.

In fact I don't need big heatsinks. With the 2N3773, I can drive this circuit continuously with one medium-size heatsink and the transistors get only warm!!!

Low Voltage Power Supply

LV Power Supply Description

The power supply (12 to 24 V) doesn't need to be anything fancy. Regulation is not needed so a simple power transformer-bridge rectifier-filter capacitor design will be fine. The circuit described below will provide about 15 VDC at up to 3 A. Unless you are going for maximum output, this should be adequate.

During initial testing at least, a Variac on the input (or variable voltage power supply) is highly desirable to avoid blowing anything should your wiring or parts not be quite right and to gain a feel for the capabilities of your circuit before it is too late! In neither of these is available, use a 10 ohm 25 W power resistor or 100 W light bulb in series with the load (inverter) to limit current to a safe value - one that won't fry too many things too quickly.

A typical circuit is shown below:

```
                  _         T1
  H o-----o/ o---- _------+                5 A diodes

                           )||          ~         D4     -        _|_
  N o---------------------+                                        -
```

LV Power Supply Parts List

All of these parts should be readily available:

- T1 - 12 V, 3 A power transformer.
- S1 - SPST toggle switch.
- F1 - Fuse, 1 A.
- D1-4 - Silicon rectifier diodes, 5 A minimum. Or, 5 A bridge rectifier.
- C1 - Electrolytic filter capacitor, 20,000 uF or more, 25 V minimum.

Typical Flyback Schematic

This diagram shows a typical flyback that might be found in a direct view color television or computer monitor. Resistances are included for illustrative purposes only and may be quite different on your flyback!

The high voltage section on the right may actually be constructed as a voltage multiplier rather than a single winding with multiple HV diodes. The rectifiers or multiplier, and/or focus/screen divider may be external to the flyback transformer in some models.

Flyback transformers used in black-and-white TVs and monochrome computer monitors do not have a focus and screen divider network.

The ferrite core of a flyback transformer is constructed with a precision gap usually formed by some plastic spacers or pieces of tape. Don't lose them if you need to disassemble the core. The ferrite core is also relatively fragile, so take care.

The focus and screen divider network uses potentiometers and resistors (not shown) with values in the 10s to 100s of M ohms so they may not register at all on your multimeter. The high voltage rectifiers (CR1 to CR3 on this diagram) are composed of many silicon diodes in series and will read open on a typical VOM or DMM.

Note that there is no standardization to the color code. However, the fat wire to the CRT is most often red but could also be black. Of course, you cannot miss it with the suction cup-like insulator at the CRT anode end.

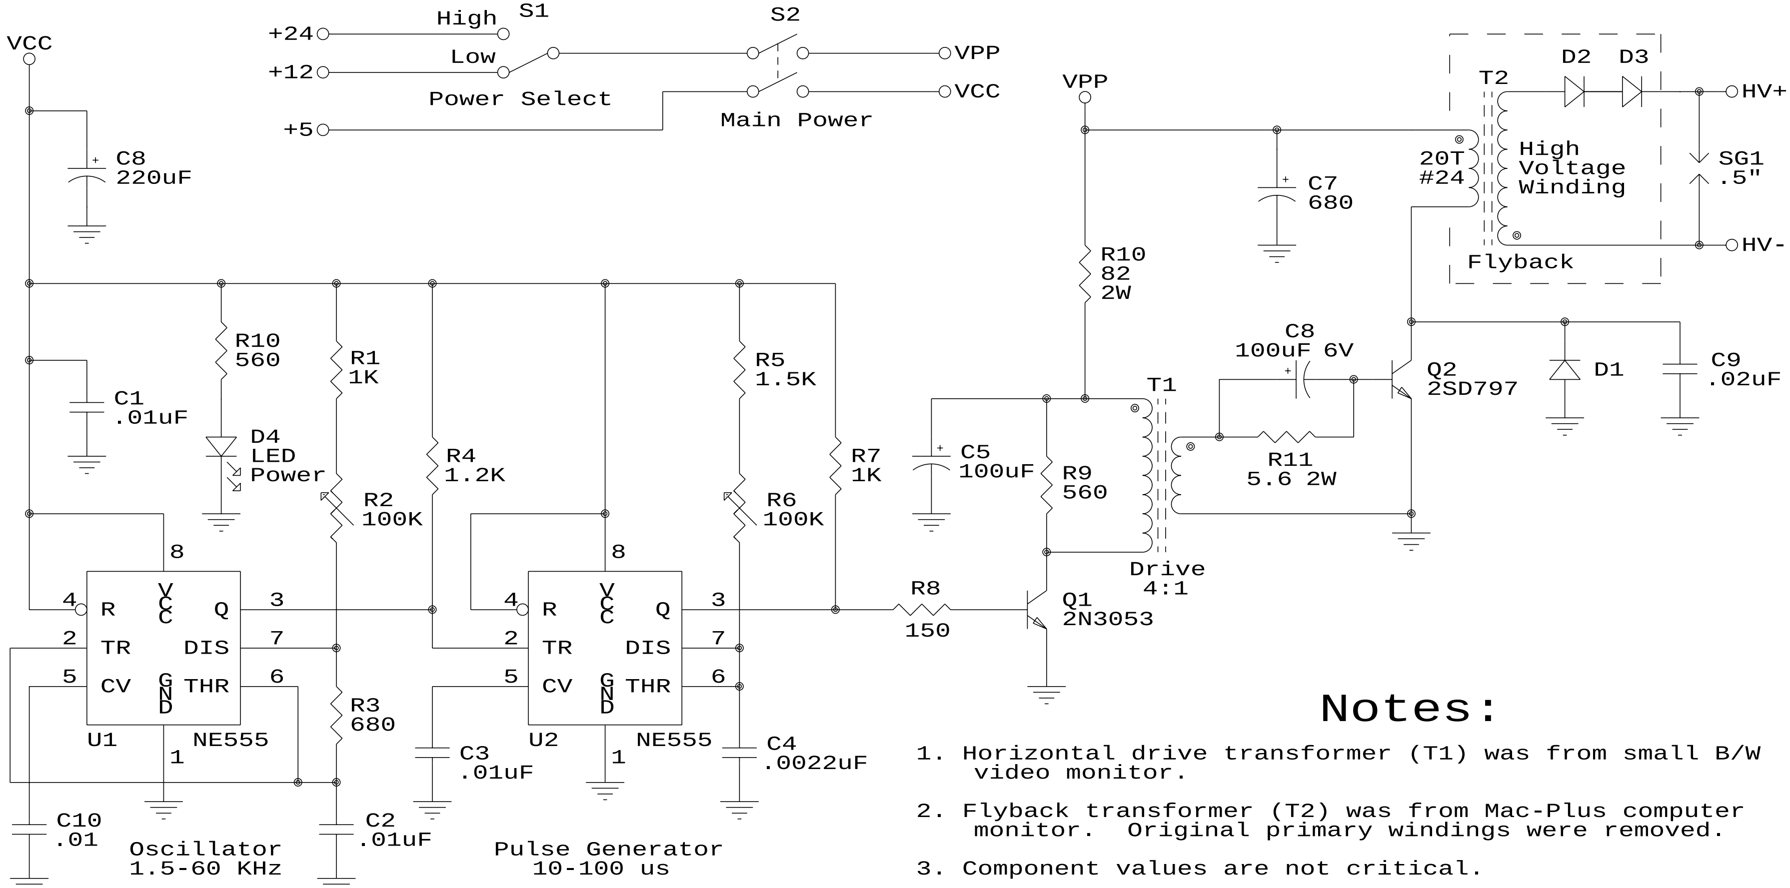
-- end V1.25a --



Notes:

1. Horizontal drive transformer (T1) was from small B/W video monitor.
2. Flyback transformer (T2) was from Mac-Plus computer monitor. Original primary windings were removed.
3. Component values are not critical.
4. Output may exceed 25,000 V at certain combinations of frequency and pulse width with 24 V power - could destroy The sparkgap provides some protection.
5. Input power was current limited to about 5 A.
6. Good heatsink important on Q2 for continuous operation.

DISCLAIMER

Jacob's Ladders - especially large ones using line powered transformers - can be both deadly, destructive, or both.

We will not be responsible for damage to equipment, your ego, blown parts, county wide power outages, spontaneously generated mini (or larger) black holes, planetary disruptions, or personal injury that may result from the use of this material.

- Back to Jacob's Ladder Table of Contents.

Introduction

What is a Jacob's Ladder?

A Jacob's Ladder is the type of high voltage "climbing arc" display seen in many old (and usually bad) Sci-Fi movies. Jacob's Ladder come in all shapes, styles, and sizes. Here is info on a common type that is easy to construct with readily available parts. However, read the section: Jacob's Ladder SAFETY before attempting to power any high voltage project of this type.

How Does a Jacob's Ladder Work?

The simple explanation is that an arc starts at the bottom and due to the fact that hot air rises, tends to move up the diverging rods until they are too far apart for the voltage provided by the power source. A more complete explanation is given below:

(From: Kenny Greenberg (kenny@neonshop.com).)

While it is true that warm air pushes the arc up the ladder, there is also the typical 'high leakage' or reactance curve of the transformer contributing to the effect. The transformer will happily arc across the bottom as long as Paschen's Law will allow. Once this arc is struck the current in the arc will actually increase to the transformer's preset limit. The heat is also creating higher resistance.

Normally the transformer would try choke the voltage down as current increased. But just above the arc exists a path that the transformer can easily maintain and which in fact will lower its current. Voila.

At the top of course we are not only at the upper limit of the transformer but it is also where the current is very low and so all the fun breaks apart only to reignite down below.

A very interesting variant existed in the 1930's which used separate horizontal electrodes at various points along one side instead of a continuous vertical line. Each electrode is attached to a separate neon unit. They are tied together and return to the HV transformer. The convection current was optimized by placing this in a housing with vents at the bottom and top. The result is an animator with no moving parts.

The downside is the nitric acid that gets produced so keep it away from things that may be corrode.

Jacob's Ladder SAFETY

WARNING: See Safety Guidelines for High Voltage and/or Line Powered Equipment before firing up any Jacob's Ladder or other high voltage or line powered project!

Make sure that no one can come in contact with this - particularly curious onlookers. Separating the potential victims from any possible contact with the high voltage is really the only foolproof way of protecting against fools or the unaware - and you from a lawsuit. People not familiar with high voltage phenomena (or aware only through grade-C sci-fi movies) can be incredibly naive.

A GFCI (Ground Fault Circuit Interrupter) is of no use in protecting against HV contact since the secondary of a neon sign transformer is isolated from the line but its centertap is usually connected to the case - which should be grounded. However, a GFCI would be a good idea in any case when you are working with line connected equipment.

12,000 volts will jump approximately anywhere from 3/8 to 3/4 inch in dry air, with sharp points and edges generally but maybe not quite always favoring longer distances. This distance occaisionally varies unpredictably with humidity. Don't forget that 12,000 VAC is approximately 17,000 V peak. Neon sign transformers have current limited outputs - 30 mA is typical - but that is still highly dangerous - lethal under the wrong conditions.

You can build a small Jacob's Ladder using a high voltage transformer of lower capacity or a DC-AC inverter using a TV flyback transformer. While these would be less dangerous, there is little room for carelessness when working with any type of high voltage device. Even if there is no resistive path, the stray capacitance can permit enough AC current to flow to give you a painful experience!

Electrical discharges in air are also a producer of ozone which may be a health hazard. See the section: About Ozone Production. They also can produce significant Radio Frequency Interference (RFI) so the FCC may come calling if you run the thing for an extended period of time.

- Back to Jacob's Ladder Table of Contents.

Building a Jacob's Ladder

Basic Components

There are only two major parts to a basic Jacob's Ladder: a high voltage power source and a pair of rods arranged in a narrow V configuration on an insulated and fireproof support.

You will need 12 to 15 kVAC at 20 to 30 mA. However, the exact values are not at all critical. A neon sign (luminous tube) transformer is the usual source for this power though an oil burner ignition transformer will work in a pinch (some say better and cheaper) or you could build an inverter type power supply.

- Luminous tube transformers can be obtained used from sign shops or demolition companies. The cost will be anywhere from free to $50 or more depending on size and condition and whether the seller has a use or other buyers for this sort of equipment.

  Typical ratings: 12,000 to 15,000 VRMS current limited to 20 to 30 mA. Larger ones are available - up to 60 mA or even 120 mA - but this is not required. More information on neon sign transformers can be found in the chapter: The Home-Built Laser Assembly and Power Supply of Sam's Laser FAQ.

- Oil burner ignition transformers can be removed from discarded oil burners. These will probably be free for the asking at your local HVAC company. However, you will likely have to disassemble the disgustingly icky burner assembly and properly dispose of the unwanted parts as part of the deal.

  Typical ratings: 8,000 to 10,000 VRMS current limited to 10 to 25 mA.

- Both neon signs and oil burner ignitions may be powered by solid state inverters in some cases. These are likely suitable as well - and higher tech!.

  Inverter voltage and current ratings will be similar to their transformer counterparts, above. However, since the frequency of operation is in the 10s of kHz range instead of 50/60 Hz, behavior for the Jacob's Ladder will differ somewhat. For example, if they run on filtered DC (internally), there will be none of that 50/60 Hz buzz associated with those classic sci-fi movies! Perhaps, more of a starship engine sound. :)

- A small Jacob's Ladder can be powered from the types of high voltage inverters described in Various Schematics and Diagrams. However, since these only produce a couple of mA, the result will not be quite as spectacular.

- I DO NOT recommend the following: microwave oven transformers, utility pole transformers, and 100 kVA substation transformers :-). See the section: Why NOT to use Microwave Oven Transformers for additional comments if you are not yet convinced.

  - Microwave oven transformers produce only about 1,500 to 2,500 VAC which is too low. Several in series would be required but this is an extremely dangerous and unwieldy arrangement. They can supply AMPS of current which is an instantly lethal situation, are not current limited to anything that would conceivably let a human survive (0.5 AMPs or more), and do not have the required insulation for such operation.

  - Utility pole and substation transformers. Aside from requiring a fork lift or 10 ton crane to move, I don't think the power company would be happy if one of these were to disappear one night :-). It goes without saying that these would even be overkill (no pun...) for the State electric chair.

Having said that, see the section: Notes on Really BIG Jacob's Ladders for some more information.

Construction

Take a pair of thin metal rods - the steel wire from old metal coat hangers works quite well. Straighten them out and mount them on an insulated non-flammable support with a gap of about 1/4 inch at the bottom and 1 to 3 inches at the top forming a narrow tall 'V'. Mounting locations should not be in the path of the rising arc. Connect the high tension output of the transformer to the two rods using high voltage insulated wire unless the routing is such that there is no chance of arcing where you don't want it. DO NOT use automotive ignition cable for this unless it is the non-resistive type. Some adjustment of the spacing at the bottom (to get the arc started) and at the top (to determine when the arc is extinguished and how fast it rises) may be required (but do so only with the power off!). Depending on the voltage and power rating of your high voltage source, these dimensions may vary considerably. Spirals and other more creative configurations are also possible.

```

IMPORTANT SAFETY NOTE: Essential line fuse, power switch, and power indicator lamp not shown. Centertap (case) MUST be connected to Safety (earth) Ground!!

A Jacob's Ladder works on the principle that the ionized air in the arc is a lower resistance than the air around it and heated air rises. The arc strikes at the point of lowest breakdown voltage - the small gap at the bottom. The heated plasma rises and even when it is an inch or more in width is an easier path for the current to follow. Eventually, the gap becomes too wide, the arc extinguishes and is reestablished at the bottom. For best results, shield the whole thing from drafts but don't use anything that can catch fire!

Clive's Gabriel Electrode to Help the Arc to Strike

(From: Clive Mitchell (clive@emanator.demon.co.uk).)

You know how critical the gap between the electrodes at the bottom of a Jacob's ladder can be. Too wide and the arc won't strike, and too narrow and it won't make it all the way to the top.

Because I live in the UK I'm more or less saddled with a 10 kV limit on the maximum neon transformer available. Since the lower voltage makes the gap even more critical, I designed a slight enhancement that works really well.

It's simply a third electrode placed between the strike gap at the bottom of the vee. It is connected to either one of the main electrodes via two 1M ohm high voltage resistors.

When an arc should occur, the following happens...

1. The voltage on the middle electrode floats to the potential of the electrode it's connected to via the resistors.

2. It's easy for an arc to jump the short distance from the other electrode to the middle one.

3. When an arc has struck and current is flowing, the voltage on the middle electrode flies up due to the high resistance value.

4. The combination of high voltage at the middle electrode and the ionized path makes the arc strike all the way across.

It's simple, but works perfectly.

I've never seen anyone use this on a Jacob's ladder before so what do I call it? How about the Gabriel electrode (in keeping with the biblical theme).

Why NOT to use Microwave Oven Transformers

Using multiple high voltage transformers from microwave ovens to construct a Jacob's Ladder is a very bad idea for several reasons:

- Microwave oven transformers are absolutely positively lethal if you or anyone else gets too close, AMPS available - especially if you are going to put them in series as would be needed to obtain adequate voltage. You might as well tap directly off of your utility's substation power bus.
- Unlike luminous tube (neon sign) or oil burner ignition transformers, they are NOT current limited to anything that will allow running on a 15 or 20 amp branch circuit so some other means of preventing your breakers (or your utility's substation breakers) from popping like cherry bombs will be needed.
- The most you will get out of a microwave oven transformer is about 2 to 2.5 kVAC. This is way to little for a decent Jacob's Ladder and putting them in parallel will not help. Therefore, 4 or 5 in series would be needed to obtain adequate voltage.
- Their insulation is not rated for series operation so one or more of the windings will see excessive voltage. There will likely be fireworks - and not where you want them.

I bet you are also going to try to run them on 220 VAC to double the output voltage as well, huh??

Similar comments apply to the use of utility pole or substation transformers.

A word to the wise: at some point, bigger is just stupid. Sorry.

- Back to Jacob's Ladder Table of Contents.

Additional Information

Notes on Really BIG Jacob's Ladders

(From: Steve Roberts (osteven@en.com).)

Microwave oven transformers make excellent Jacob's Ladders and Tesla Coil drivers with a properly chosen series cap in the primary for power factor correction. One of the major problems with the hollow "E" core current limited neon sign and furnace ignition transformers is that they do not source enough current to maintain a plasma on larger Jacob's Ladders, and the current limiting makes them lousy as pulsed laser drivers as well.

However, the high current from a microwave oven transformer will source a 10" inch arc in nitrogen/oxygen mixtures once it has been started at about 1/2". There are several European web sites that show back to back microwave oven transformer powered ladders. A key problem is that you have to mount the transformers on Lucite or Lexan because the center tap is grounded on the secondary side. For a advanced safety conscious experimenter it is not a problem to use these, provided you use either 1" diameter rods of copper or carbon rods for the ladder rails. While I would not approve of just anybody playing with these either, it can be done and produces spectacular results, if you don't mind the electric meter spinning at Mach 1!

They also make nice stable cores for high current low voltage transformers when rewound, I use them to power 25 amp 3.2 volt laser tube filaments all the time with out blowing breakers.

Snock's High Voltage Page has a number of articles and links relating to large Jacob's Ladders and other high voltage projects.

And Now for the Audio Feed

(From: Norman E. Litsche (nlitsche@worldnet.att.net).)

One of those old(bad) movies had a huge Jacob's Ladder inside a large transparent (glass, I assume - Plexiglass wasn't around then) hollow column resonant at 60 Hz. Unbelievable sound! Always wanted to build one like this but never had the time, the big resonant column or the really huge neon sign transformer that would have been needed.

(Assuming 1,100 feet per second for the speed of sound in air, a column closed at one end would be a 1/4 wavelength resonator resulting in an actual height of about 4.6 feet for a 60 Hz fundamental. --- sam)

About Ozone Production

If the Jacob's Ladder is large, significant ozone is an inherent byproduct unless you run it in an inert gas which might be an interesting experiment though I don't know how performance will be affected.

(From: Pamela Hughes (phughes@omnilinx.net).)

The arc is a plasma of hot ionized gas. Molecules like O_2 are broken down to the atomic level and ionized. when these ions collide with the surrounding air, they cause chemical reactions... the O can combine with nitrogen and form small amounts of nitrogen oxides, and with O_2 to form ozone (O_3). However, the high temps in an arc also tend to destroy these molecules too so you'd probably only produce trace amounts if it weren't for the UV given off by the arc. Ultraviolet seems to be the main mechanism for producing O_3 as it can ionize in the air far enough from the arc that it will be cool enough for ozone to exist (a spark gives off UV and ionizes the air around it) A glow discharge is better at generating ozone than an arc though, since it maximizes the UV and the pressures and temps are much lower (i.e., put a conductive coating on the outside of a glass tube and a wire down the center of it, then apply enough voltage to produce a glow discharge inside the tube as you pump oxygen at low pressure through the tube. Shortwave UV lamps will produce it too (they use these as sterilizers in dairy barns).

Jacob's Ladders and the FCC

Operating Jacob's Ladders (as well as Tesla coils) are broad-band RF sources and can interfere with radio, TV, maybe cell phone, cordless phone, and other communications equipment. There have been reports of the FCC tracking down and fining people for this interference - I don't know if these stories are true but it is definitely something to think about before running your creation for an extended period of time, at least. The FCC would probably confiscate your setup as well - which would likely be more traumatic than the fine (as hefty as it might be!) Perhaps, consider a Faraday cage in addition to the Plexiglass ozone shield :-).

Introduction

Scope of This Document

The first part of this note describes procedures for testing of diodes (signal, rectifier, and zener); bipolar (NPN or PNP, small signal and power) transistors; SCRs, and MOSFETs for catastrophic failures like shorts and opens.

In most cases, this will identify bad silicon transistors. Gain, frequency response, etc. are not addressed here. While the tests can be applied to germanium devices, these are more likely to change characteristics, it would seem, without totally failing.

It is also possible to determine the lead arrangements of identified diodes and bipolar transistors as well as breakdown voltage ratings.

Curve tracers are pieces of electronic test equipment similar to an oscilloscope. They can not only test transistors and other devices but evaluate the functional specifications as well. The chapter: "Curve Tracer Design" includes information on their basic principles of operation and provides details on some very additions to conventional scopes to add some basic curve tracer capability.

This document evolved from a posting on the USENET newsgroup: sci.electronics (no longer active - closest replacement in the sci.electronics hierarchy is probably sci.electronics.components) from Randy Fromm (Randy@randyfromm.com) who maintains a Technical Department with an extensive collection of repair related information.

Safety Considerations

None of the tests described in this document require probing live circuits. However, should you need to do so, see the document: Safety Guidelines for High Voltage and/or Line Powered Equipment first.

Before touching, probing, or unsoldering any component, make sure the equipment is unplugged and any large capacitors have been safely discharged. See the document: Capacitor Testing, Safe Discharging, and Other Related Information or the specific document dealing with your equipment for details. Not only can coming in contact with a live circuit or charged capacitor ruin your entire day, your test equipment could be damaged or destroyed as well.

Testing Semiconductor Devices with a VOM or DMM

VOMs and DMMs

Analog and Digital meters behave quite differently when testing nonlinear devices like diodes and transistors. It is recommended that you read through this document in its entirety.

Caution: An analog VOM on the lowest resistance range may put out too much current for smaller devices possibly damaging them. Ironically, this is more likely with better meters like the Simpson 260 which can test to lower ohms (X1 scale). Use the next higher resistance range in this case or a DMM as these never drive the device under test with significant current. However, this can result in false readings as the current may be too low to adequately bias the junctions of some power devices or devices with built in resistors.

Testing Diode Junctions with a Multimeter

On an (analog) VOM, use the low ohms scale. A regular signal diode or rectifier should read a low resistance (typically 2/3 scale or a couple hundred ohms) in the forward direction and infinite (nearly) resistance in the reverse direction. It should not read near 0 ohms (shorted) or open in both directions. A germanium diode will result in a higher scale reading (lower resistance) due to its lower voltage drop.

For the VOM, you are measuring the resistance at a particular (low current) operating point - this is not the actual resistance that you will see in a power rectifier circuit, for example.

On a (digital) DMM, there will usually be a diode test mode. Using this, a silicon diode should read between .5 to .8 V in the forward direction and open in reverse. For a germanium diode, it will be lower, perhaps .2 to .4 V or so in the forward direction. Using the normal resistance ranges - any of them - will usually show open for any semiconductor junction since the meter does not apply enough voltage to reach the value of the forward drop. Note, however, that a defective diode may indeed indicate a resistance lower than infinity especially on the highest ohms range. So, any reading of this sort would be an indication of a bad device but the opposite is not guaranteed.

Note: For a VOM, the polarity of the probes is often reversed from what you would expect from the color coding - the red lead is negative with respect to the black one. DMMs usually have the polarity as you would expect it. Confirm this using a known diode as a reference. Also, 'calibrate' your meter with both silicon and germanium semiconductors so you will know what to expect with an unknown device.

Transistor Testing Methodology

As with diode junctions, most digital meters show infinite resistance for all 6 combinations of junction measurements since their effective resistance test voltage is less than a junction diode drop (if you accidentally get your skin involved it will show something between 200K and 2M Ohms). The best way to test transistors with a DMM is to make use of the "diode test" function which will be described after the analog test. For both methods, if you read a short circuit (0 Ohms or voltage drop of 0) or the transistor fails any of the readings, it is bad and must be replaced. This discussion is for OUT OF CIRCUIT transistors *ONLY*.

One exception to this occurs with some power transistors which have built in diodes (damper diodes reversed connected across C-E) and resistors (B-E, around 50 ohms) which will confuse these readings. If you are testing a transistor of this type - horizontal output transistors are the most common example - you will need to compare with a known good transistor or check the specifications to be sure. There are some other cases as well. So, if you get readings that do not make sense, try to confirm with a known good transistors of the same type or with a spec sheet.

Before testing an unknown device, it is best to confirm and label lead polarity (of voltage provided in resistance or diode test mode) of your meter whether it be an analog VOM or digital DMM using a known good diode (e.g., 1N4007 rectifier or 1N4148 signal diode) as discussed below. This will also show you what to expect for a reading of a forward biased junction. If you expect any Germanium devices, you should do this with a Ge diode as well (e.g., 1N34).

The assumption made here is that a transistor can be tested for shorts, opens, or leakage, as though it is just a pair of connected diodes.

```
          C                                     C
          o                                     o
          |           +--|>|---o C              |           +--|<|---o C
        |/            |                       |/            |
   B o---|     =  B o---+                  B o---|     =  B o---+
        |>            |                       |<            |
          |           +--|>|---o E              |           +--|<|---o E
          o                                     o
          E                                     E

        NPN Transistor                        PNP Transistor
```

Obviously, simple diodes can be tested as well using the this technique. However, LEDs (forward drop too high more most meters) and Zeners (reverse breakdown - zener voltage - too large for most meters) cannot be fully tested in this manner (see the specific sections on these devices).

Testing with a (Analog) VOM

For NPN transistors, lead "A" is black and lead "B" is red; for PNP transistors, lead "A" is red and lead "B" is black (NOTE: this is the standard polarity for resistance but many multi-meters have the colors reversed since this makes the internal circuitry easier to design; if the readings don't jive this way, switch the leads and try it again). Start with lead "A" of your multi-meter on the base and lead "B" on the emitter. You should get a reasonable low resistance reading. Depending on scale, this could be anywhere from 100 ohms to several K. The actual value is not critical as long as it is similar to the reading you got with your 'known good diode test', above. All Silicon devices will produce somewhat similar readings and all Germanium devices will result in similar but lower resistance readings.

Now move lead "B" to the collector. You should get nearly the same reading. Now try the other 4 combinations and you should get a reading of infinite Ohms (open circuit). If any of these resistances is wrong, replace the transistor. Only 2 of the 6 possible combinations should show a low resistance; none of the resistances should be near 0 Ohms (shorted).

As noted above, some types of devices include built in diodes or resistors which can confuse these measurements.

Testing with a (Digital) DMM

Set your meter to the diode test. Connect the red meter lead to the base of the transistor. Connect the black meter lead to the emitter. A good NPN transistor will read a JUNCTION DROP voltage of between .45v and .9v. A good PNP transistor will read OPEN. Leave the red meter lead on the base and move the black lead to the collector. The reading should be the same as the previous test. Reverse the meter leads in your hands and repeat the test. This time, connect the black meter lead to the base of the transistor. Connect the red meter lead to the emitter. A good PNP transistor will read a JUNCTION DROP voltage of between .45v and .9v. A good NPN transistor will read OPEN. Leave the black meter lead on the base and move the red lead to the collector. The reading should be the same as the previous test. Place one meter lead on the collector, the other on the emitter. The meter should read OPEN. Reverse your meter leads. The meter should read OPEN. This is the same for both NPN and PNP transistors.

As noted, some transistors will have built in diodes or resistors which can confuse these readings.

Testing Power Transistors

Power transistors without internal damper diodes test just about like small signal transistors using the dual diode model, high in one direction B-E or B-C. If there is a built in damper diode, it is across C-E back biased under normal operating conditions. Therefore, a reading between C-E will also test low in one direction and B-C will show a double diode drop in the reverse direction. Also, there is often a low value resistor - about 50 ohms - between B-E when there is a built in damper. This will show up as a nearly zero volt junction drop on the diode test scale of a DMM but such a reading does not indicate a bad part. Use the resistance scale to confirm.

Testing Darlington Transistors

A Darlington is a special type of configuration usually consisting of 2 transistors fabricated on the same chip or at least mounted in the same package. Discrete implementations as well as Darlingtons with more than 2 transistors are also possible.

In many ways, a Darlington configuration behaves like a single transistor where:

- the current gains (Hfe) of the individual transistors it is composed of are multiplied together and,
- the B-E voltage drops of the individual transistors it is composed of are added together.

Darlingtons are used where drive is limited and the high gain - typically over 1,000 - is needed. Frequency response is not usually that great, however.

```
                                   C
```

```
                    o
                    |
            +-------+
            |       |
        B1 |/ C1    |
    B o-----|       |
           |\ E1    |
            |  B2 |/ C2
            +-----|
                  |\ E2
                    |
                    o
                    E
```

Testing with a VOM or DMM is basically similar to that of normal bipolar transistors except that in the forward direction, B-E will measure higher than a normal transistor on a VOM (but not open and 1.2 to 1.4 V on a DMM's diode test range due to the pair of junctions in series. Note, 1.2 V may be too high for some DMMs and thus a good Darlington may test open - confirm that the open circuit reading on your DMM is higher than 1.4 V or check with a known good Darlington.

Testing Digital or Bias Resistor Transistors

Occasionally you may find a transistor that includes an internal bias resistor network attached to the base and emitter so that it can be driven directly from a digital (e.g., TTL) source. These may be used in consumer electronic equipment where space is critical or for no good reason other than to make it difficult to locate a suitable replacement device!

```
                     C
                     o
                     |
          R1        |/
    B o---/\/\---+----|      Typical R1, R1: 47K.
                 |    |\
                 /     |
              R2 \     |
                 /     |
                 |     |
                 +------+
                       |
                       o
                       E
```

The addition of R1 makes testing with a multimeter other than for shorts more difficult. With a VOM, you should see a difference in the B-E and B-C junctions in the forward and reverse directions. However, a DMM will probably read open across all pairs of terminals.

Testing Unijunction and Programmable Unijunction Transistors

Unijunction Transistors (UJTs) and Programmable Unijunction Transistors (PUTs) are used in similar sorts of circuits though the UJT is all but extinct. They both exhibit a negative resistance characteristic and can be used easily in low to medium frequency free running relaxation oscillators and other trigger type circuits.

- The UJT goes into heavy conduction from E to B1 when E becomes more positive than a critical trigger voltage, Vt = n * Vbb + .6. (n, the 'intrinsic standoff voltage' is typically about .6). It continues to conduct until the emitter current drops below some minimum 'valley current' value. Sounds sort of like a thyristor, right? :)

- The PUT is even more like a thyristor: The PUT in that the triggering takes place when the G becomes more positive than the A (probably plus a diode drop, .6 V) so that the threshold voltage can now be set with a voltage divider feeding the anode. Then, current flows from the G to the K terminal. Note that its leads are even labeled like an SCR but it behaves sort of backwards!

For an initial test, check between B1 and B2 (UJT) or A and K (PUT) with an ohmmeter. The resistance should be the same in both directions and typically a few K ohms or more. A short or wildly different readings would indicate a bad device.

This doesn't prove that the device is good - only that it isn't blown up. A more complete test requires a simple circuit and some means of detecting an audio output signal.

For the UJT:

```
 +5 VDC o--------+---------+
                 |         |
                 /         |
              R1 \         |
            100K /         |
                 \         |
                 |         |B2
                 +-----. |-+
                 |      \|   Q1 UJT
                 |      E|-+--------o
                 |         |B1
             C1 _|_        /      To scope or
          .01uF ---     R3 \      audio amp
                 |      1K /      ~1K Hz
                 |         \
                 |         |
   Gnd o---------+---------+--------o
```

For the PUT (Programmable Unijunction Transistor), an additional voltage divider (R3 and R4) is needed to set the threshold:

```
+10 VDC o--------+---------+
                 |         |
                 /         /
              R1 \      R3 \
            100K /      1K /
```

```
              \         \
              |         |
              |         +-------+
              |         |       |
              +-----.   |A      |
              |     G\__|__ Q1  |
              |       _\_/_ PUT |
              |         |K      |
              |         +-------|------o
              |         |       |
          C1 _|_        /       /   To scope or
       .01uF ---     R2 \    R4 \   audio amp
              |      1K /    1K /   ~1K Hz
              |         \       \
              |         |       |
Gnd o---------+---------+-------+------o
```

(From: Spehro Pefhany (speff@interlog.com).)

A PUT is essentially an SCR with a large reverse gate breakdown voltage (G can be more positive than A by maybe 40 V) and a sensitive gate. When the voltage at A exceeds the voltage at G by a diode drop, and assuming enough voltage from A to K, the SCR turns on (conducts from A to K) and stays that way until the current drops below the holding current (typically around 100 uA, but it drops with increasing resistance in series with the gate).

Symbol and example:

```
                       _
                     /   \
  A   G              -----
  | /               |     |
-----               |     |
 \ /    PUT          -----  2N6028
-----                | | |
  | K                A G K
```

If you connect your meter from A to K, it should measure open both ways. If you connect the positive lead (which may be red or black, depending on the meter design) to A and the negative lead to K, and then momentarily short G to K it should change to a relatively low resistance reading (meter dependent). It will most likely stay latched when the G lead is returned to being open, because the meter measuring current will exceed the "holding current" of the PUT (called "valley current" in PUT specs).

If your meter has a "diode" range (in the ohms group), using that would assure there is enough open-circuit voltage to make this work, but it works this way in the half-dozen or so meters I have checked, using reasonable ohms ranges.

Measurements between A and G, with K open, should be similar to a silicon diode (fairly low in one direction, open in the other). Between G and K, with A open, should be open in both directions.

PUTs are pretty sensitive (less than 1 uA trigger current) so be sure to keep fingers away from the G lead.

* Back to Semiconductor Testing Table of Contents.

Thyristors - SCRs and Triacs

What are Thyristors

Thyristors are used to control power in numerous applications including light dimmers and motor speed controls, solid state relays, some microwave ovens, photocopiers, traction motors for electric locomotives and electric cars, power inverters for transmission of electric power over long distances, frequency converters, other DC-DC or DC-AC or AC-AC inverters, AC-DC regulated power supplies, and many other applications where efficient power control is required.

A Silicon Controlled Rectifier is one type of thyristor used where the power to be controlled is unidirectional. The Triac is a thyristor used where AC power is to be controlled. (There are exceptions in both cases but for this simple discussion these can be ignored).

Both types are normally off but may be triggered on by a low current pulse to an input called the Gate. Once triggered on, they remain on until the current flowing through the main terminals of the device drops below a hold value which is very close to zero. It is usually not possible (at least not easy) to turn thyristors off while current is flowing. However, there are special types called Gate Turnoff Thyristors which enable this type of control as well.

Both SCRs and Triacs are 4 layer PNPN structures.

How Does a Thyristor Work?

The usual way an SCR is described is with an analogy to a pair of cross connected transistors - one is NPN and the other is PNP. The base of the NPN is connected to the collector of the PNP and the base of the PNP is connected to the collector of the NPN.

If we connect the positive terminal of a supply to say, a light bulb, and then to the emitter of the PNP transistor and its return to the emitter of the NPN transistor, no current will flow as long as the breakdown voltage ratings of the transistor are not exceeded because there is no base current to either transistor. However, if we provide some current to the base of the NPN (IG(+).)ransistor, it will turn on and provide current to the base of the PNP transistor which will turn on providing more current to the NPN transistor. The entire structure is now in the solid on state and will stay that way even when the input to the NPN's base is removed - until the power supply goes to zero and the load current goes below the hold value.

The same scenario is true if we reverse the power supply and use the IG(-) input for the trigger.

```
               +------+
+ >------------+ LOAD +----------------+
               +------+                |
                                       |
                                     E \|
                                 PNP    |---+-------< IG(-)
```

```
                                      C /|   |
                                       |     |
                                       |   |/ C
                     Gate IG(+)  >-----+---|    NPN
                                           |\ E
                                             |
                                             |
- >------------------------------------------+
```

A Triac works in a basically similar manner except that the polarity of the Gate can be either + or - during either half cycle of an AC cycle.

For a light dimmer or motor speed control, for example, the exact time when the thyristor is triggered relative to the zero crossings of the AC power is used to determine the power level. Trigger the thyristor early in the cycle and the load is driver an high power. Trigger the thyristor late in the cycle and there is only a small amount of power delivered to the load. The thermal or mechanical inertia is generally counted to smooth out the power and results in smooth continuous operation (i.e., a light bulb controlled by a dimmer does not flicker.)

The advantage of thyristors over simple variable resistors is that they (ideally) dissipate very little power as they are either fully on or fully off.

There are a wide variety of other types of thyristor and thyristor-like devices. In particular, are diacs and sidacs which have no gate input but simply turn on when a specified threshold voltage is exceeded across their main terminals. See the section: Testing Diacs and Sidacs. These are often used to trigger other thyristors in phase control applications.

For more information on thyristors, see Horowitz and Hill or any thyristor databook.

Testing SCRs and Triacs

- For SCRs, the gate to cathode should test like a diode (which it is) on a multimeter. The anode to cathode and gate to anode junctions should read open in both directions.

- For triacs, the gate to main terminal 1 (MT1) should test like a diode junction in both directions. MT1 to MT2 and gate to MT2 junctions should read open in both directions. (CAUTION: I'm not sure the MT1 and MT2 designations are universal - check the datasheet to be sure!)

- For diacs and sidacs, there is no gate terminal - resistance should be infinite in both directions. For more complete testing, see the section: Testing Diacs and Sidacs.

Note: Some thyristors will have a low G-K/MT1 resistance but it should not read as a short.

The real test is quite simple but will require a low voltage DC power supply and two resistors. For triacs, a negative output from the supply is desireable as well to test the triggering when the gate is negative).

R1 will be used to limit current through the device and R2 will be used to limit current to the gate. A 12 VDC supply of at least 200 mA capacity with a 100 ohm 2 W resistor for R1 and 1 K 1/4 W resistor for R2 should work for most small to medium power SCRs. Check the 'minimum gate current' and 'holding current' specs to be sure. For larger devices, R1 and/or R2 may need to be smaller.

```
                 R1
  + o----+-----/\/\---------+-----o Test+
         |   100, 2W      __|__
         |                _\/\_ Device Under Test - DUT
12 VDC   |    R2          / |   (SCR or triac).
         +---/\/\---o <--'  |
             1K     o       |
                    |       |
  - o---------------+------+-----o Test-
```

1. Connect the supply as shown.

2. Trigger the gate from the positive of the supply through the current limiting resistor (R2) and see that the DUT turns on stays on when the gate is disconnected.

3. Open the circuit to the anode (with the gate connected to the cathode) and again reconnect the anode resistor. The DUT should now be off again.

- For triacs, repeat steps (2) and (3) with R2 supplied from a negative voltage.
- For diacs, testing must be at full rated voltage. See the section: Testing Diacs and Sidacs.

If the device passes these tests, it is behaving properly and is probably functional. However, without applying full voltage or current, there is no way of knowing if it will meet all specifications.

You can replace the DC supply with a low voltage power transformer (say, 12 VAC). Use a scope to monitor the voltage across the DUT or R1. Then, when the gate is connected to R2, you should see the voltage across the DUT drop to nearly zero when it switches on part way through the positive cycle. This phase will be determined by the voltage and value of R2. It should remain off for the entire negative cycle (SCRs only) with the gate connected and remain off all the time with the gate connected to the cathode.

(From: T. O. Prellwitz (timilen@halcyon.com).)

If you have a semiconductor curve tracer you can configure a small audio transformer circuit to drive the gate. I did this with my B&K and it works well. The secondary should provide enough voltage to drive the gate of the SCR and the negative swing of the AC will cycle the scr off while the positive phase turns it on. I drive the transformer with an audio generator. Hope this offers some ideas.

Testing Diacs and Sidacs

Diacs and Sidacs are thyristors without any gate terminal. They depend on the leakage current to switch them on once the voltage across the device exceeds their specified ratings. With an ohmmeter, they can be tested only for shorts. Resistance should be infinite in both directions.

However, you can test a diac or sidac with a resistor, variable power supply (you will need at least the rating of the device), and a DMM. Hook them in series and monitor across the device. With care, your variable supply can be a Variac, 1N4007, and 1 uF, 200 V capacitor. Use a 47 K resistor to limit the current:

```
            D1            R1
   ~ o----|>|----+-----/\/\---------+------o Test+
        1N4007   |      47K         |
                _|_ C1            __|__
Variable AC     --- 1 uF          _\/\_ Device Under Test - DUT
0 to 140 VRMS    |                  |
                 |                  |
   ~ o-----------+------------------+------o Test-
```

CAUTION: this is not isolated from the power line. Use an isolation transformer for safety. If the DUT is rated more than about 180 V, you will need to use a doubler and higher voltage capacitor but testing is otherwise similar.

As you increase the input, the voltage on the DUT will track it until the rated voltage at which point it will drop abruptly to zero and stay there until the voltage is reduced below its holding current. Repeat with the opposite polarity.

With a scope it is even easier as you can use an AC supply directly (remove D1 and C1) and observe that the DUT will turn on at the proper voltage on both polarities of the AC waveform and stay on until the voltage crosses 0.

Use an isolation transformer for safey.

Thyristors Driving Inductive Loads

> "I am trying to turn on a triac which is driving an inductive load (solenoid) using a digital signal without using an opto triac. I get limited success."

(From: Jeroen Stessen (Jeroen.Stessen@philips.com).)

It is soooo easy: just use a DC current to drive the gate of the triac. Even the polarity of the current doesn't matter, although most triacs are more sensitive for a negative input current (flowing out of the gate to a negative supply). A large triac may require some 50 mA.

There will be some applications where there is no 50 mA supply available. That's where you would want to drive with short pulses. But these pulses would have to occur around the expected instant of the zero-crossing of the load current, which is a bit tricky with an inductive load.

As an alternative you could look for a more sensitive triac, for not too large load currents there are types down to 5 mA or so. If you have 50 mA of DC to spare, go for it, it will work.

By the way, never switch an inductive load like a power transformer ON at the zero crossing of the mains voltage. That's guaranteed to drive the transformer into saturation and create the worst possible current transient. Try and switch on at maximum mains voltage, at +/- 90 degrees delay. Do not use a voltage differentiator to generate +90 degrees phase shift, as it will be too sensitive to mains disturbances. Instead, use a double integrator to give 2 * -45 degrees and a low-pass filter. Using only 1 integrator to approach -90 degrees gives too much attenuation of the voltage, hence 2 are recommended.

Burning Up of Thyristors

(From: Neill Means (means@expert.cc.purdue.edu).)

Any thyristor will have a maximum change in current vs change in time dI/dt. If this is exceeded, then current flowing through the thyristor will find the path of least resistance through the silicon. Unfortunately, for us, this can be thought of as a molecular sized lightning bolt streaking through the doped layers of silicon - finding the path of least resistance from individual molecule to individual molecule. This soon results in an 'avalanche' of electrons streaming through a very small path and this process feeds on itself until the thyristor dies. This whole process probably takes only microseconds to happen.

I don't know if fast blow fuses will help this situation if the current changes too rapidly. A fuse is a very analog device with mass and it seems like it would be a slow, lumbering giant compared to almost instantaneous current change.

The solution for this problem? I am guessing putting an appropriately sized inductor in series with the light bulb, but just be sure to add the correct over voltage snubbing network. The inductor will keep the current from changing too rapidly.

Additional Semiconductor Tests

Identifying Unknown Bipolar Transistors

The type (NPN or PNP) and lead arrangement of unmarked transistors can be determined using a multimeter based on similar considerations. This, again, assumes the back-to-back diode model. The collector and emitter can then be identified based on the fact that the doping for the B-E junction is always much higher than for the B-C junction. Therefore, the forward voltage drop will be very slightly higher - this will show up as a couple of mV (sometimes more) difference on a DMM's diode-test scale or a slightly higher resistance on an analog VOM.

To determine the lead arrangement, label the pins on the unknown device 1, 2, and 3. Put the positive probe (as determined above) of you multimeter on pin 1. Now, measure the resistance (VOM) or diode drop (DMM) to the other two pins. If the positive probe is on the base of a good NPN transistor, you should get low resistance readings or a low diode drop to the other two leads. The B-C resistance or diode drop will be just slightly lower than the B-E reading.

If one or both measurements to the other two pins is high, put the positive probe on pin 2 and try again. If still no cigar, try pin 3.

If this still doesn't work, you may have a PNP transistor - repeat with the negative probe as the common pin.

If none of the six combinations yields a pair of low readings - or if more than one combination results in a pair of low readings, your transistor is likely bad - or it is not a bipolar transistor!

As noted, some power transistors have built in base resistors or damper diodes and will confuse these measurements. However, the lead arrangement of these types of transistors is usually self evident (standard TO3, TOP3, or TO220 cases). There are also some transistors with series base resistors which may prove confusing. There are relatively rare, however.

Voltage ratings are more difficult and require a low current variable DC power supply with a maximum voltage output greater than the expected (or desired) breakdown rating of the transistors being tested. A fixed DC supply with a suitable potentiometer is also satisfactory. For tests up to 100 V, a 100K ohm pot would be satisfactory. Put a current limiting resistor of about 100 K ohms in series with the output. For higher voltage transistors, use an appropriate power supply and increase the value of the potentiometer (if used) and current limiting resistor. It should be possible to determine approximate values for Breakdown Voltages such as:

BVcbo - collector to base, emitter open. BVceo - collector to emitter, base open. BVces - collector to emitter, base shorted to emitter. BVebo - emitter to base, collector open.

Apply your variable voltage across the appropriate leads and monitor at the transistor with your VOM or DMM. The breakover point should be easily detectable. The current limiting resistor should prevent damage to the part from power dissipated in the reverse biased junction.

This approach also works for signal, rectifier, zener diodes, and other similar devices.

Luke's Comments on Junction Voltage Drops and Doping

(From: Luke Enriquez VK3DLE (ecsclfe@lux.latrobe.edu.au).)

The B-C junction voltage drop is always very slightly lower than the E-B junction drop. The drop is given by the equation:

$$Vdrop = Vt * \ln (Na*Nd/ni^2)$$

where:

```
Vt = kT/q = 26 mV at 300 degrees K

ni = intrinsic carrier concentration in a pure sample of silicon
     (ni = 1.5 * 10^10 cm-3 at 300 deg K for silicon)

Nd = doping density atoms/cm^3 in the n-type material

Na = doping density atoms/cm^3 in the p-type material
```

This equation means that if the doping density at the Base-Emitter junction is higher than the Base-Collector junction, the Vdrop of the Base-Emitter junction will be higher than that of the Base-Collector junction.

This has been confirmed below on a selection of common transistors using an El-cheapo DMM:

Transistor	B-C Voltage	B-E Voltage
TIP3055	0.640	0.642
TIP2955	0.668	0.668
BD140	0.697	0.699
2N2369A	0.682	0.710
PN3563	0.752	0.753
BC108	0.715	0.716

CAUTION: Do not hold the transistor under test in your hand. For every degree the transistor increases in tempreture, the Base-Emitter Diode Drop (commonly called Vbe) decreases by 2 mV. This is a significant amount when determining the B-E and B-C junctions.

Lance's Method for Determining C and E on an Unmarked Bipolar Transistor

(Slightly edited for readability --- sam)

(From: Lance (cast@iafrica.com).)

Using an analog (VOM - a DMM will not work), on its highest resistance range I test across the collector and the emitter one way and then change the leads around. The reading that is lower reading is the one to note (the one with the most leakage on a uA meter). Sometimes the needle only just barely moves. For a PNP the positive lead is on the emitter and for a NPN the positive lead is on the collector. Now you know the base collector and emitter, this has helped me work out how a circuit works by finding the legs of the working transistors and then repairing it. I found this in a very old mag more than fifteen years ago. If I can't remember which way is what I use a known transistor. I then find out the hard way. (Note: for a VOM, the polarities of the leads are often opposite of the color code as noted above --- sam).

Testing MOSFETs

(From: Paul Mathews (optoeng@whidbey.com).)

1. Verify gate has infinite resistance to both drain and source. Exception: FETs with protection circuitry may act like there is a zener shunting GS, i.e., diode drop for gate reverse bias, ~20V breakdown in fwd bias.

2. Connect gate to source. Drain to source should act like a diode.

3. Forward bias GS with ~5 V. DS in forward bias should measure very low ohms. In reverse bias, it will still act like a diode.

The usual failure mode: GS short AND DS short. In other words, everything connected together.

(From: Richard Torrens (4qd@argonet.co.uk).)

A lot of common multimeters have a diode range: you can use this to measure a MOSFET out of circuit and get a good idea of whether it is OK. Meter negative on the source, you should get no reading (open circuit) on the drain. Not on the gate but if you measure the drain AFTER measuring the gate you will find it conducts. A finger between source and gate will bleed away the charge and the MOSFET stops conducting.

You really need a 'scope to check the drive circuit. What it does will depend on the circuit configuration, whether there is current limiting etc.

(From: E. Wolsner (interser@algonet.se).)

My way of testing a power MOSFET is indeed simple and normally sufficient:

One ohmmeter is connected to the drain and the source, measuring the resistance between drain and source, which should be very high. Another ohmmeter is connected between gate and source. This ohm-meter should have a high resistance capability (maybe 20 M ohms) and thus have a relatively high test voltage (more than 5 volts). Now this voltage, when connected with the proper polarity, will turn the mosfet on, which will be indicated by the first ohm-meter. It will show zero resistance. To turn the transistor off, you reverse the gate-source voltage, and the drain-source ohm-meter will again indicate high resistance.

(Portions from: Egon Wolsner (interser@algonet.se).)

The multimeter must be able to provide at least 5 volts output on the resistance measuring range (this usually means that a DMM will not work). If it does, here is the procedure:

First you measure the resistance between the drain and source terminals, it should be infinity. Then connect the plus to the gate and the minus to the source pin. That should turn the MOSFET on. Then you measure the resistance between the drain and source pins, which should verify that the resistance is indeed near zero. (The gate capacitance will hold the device in the on-state long enough for this test.) Turn the mosfet off by shorting the gate and source pins (for a n-channel MOSFET)

(From: Bruce (reglarnavy@aol.com).)

You can get a pretty good idea about the condition of a MOSFET with some quick & simple bench tests. The first thing you can do with a meter is measure the parasitic substrate diode that connects the drain to the source. In an NMOS part, this diode's cathode will be at the drain, and the anode at the source. It will meter out similar to any conventional diode in both fwd / reverse directions. You can see this diode in the schematic representation of the FET in some databooks and a few schematics. The FET should show infinite resistance, gate - source and gate - drain. If it does not, then the gate oxide may be blown.

A second simple test can be done with a meter and a 9 V battery. First, short the gate to the source to discharge any stored charge there. Then put your meter on ohms and connect it across the drain - source. It should measure as an open. Briefly connect the 9 V across the gate (+) to source (-) , again, NMOS polarities, and the meter resistance should fall to a very low resistance, on the order of an ohm or less. Removing the battery will not change the reading, because in a good FET, Ciss will remain charged for a long time and keep the FET on. Most FETs come on at Vgs=2 volts or so.

If these two tests work, then the FET is off to a good start. Substituting a power supply and a proper load resistor for the meter, and a variable voltage (a pot across the 9v will work) for the Vgs supply, in the aforementioned test, will obviously be a more realistic test, and will also let you measure Vds, Id, etc.

BEWARE ESD WITH FETS! Wear a wrist strap, keep the parts away from insulators like plastics, and make sure your soldering iron tips are grounded. If you do not have any of the black ESD foam to keep your parts in, then look around for an anti-static bag that once may have contained a computer board, SIMMs, etc.

Testing IGBT

Basic testing IGBTs (Insulated Gate Bipolar Transistors) should be similar to an enhancement mode N-channel MOSFET except that the threshold voltage may be larger than a typical MOSFET (e.g., 8 V instead of 4 V).

1. Check for shorts with an ohmmeter.
2. Put a current limited supply across C-E with an ammeter in series.

3. Apply at least 10 V G-E. The transistor should turn on.
4. Ground the gate. The transistor should turn off.

A curve tracer should be able to be configured for IGBT testing to determine more complete behavior.

Testing LEDs

Electrically, LEDs (and IR emitting diodes, strictly speaking called IREDs) behave like ordinary diodes except that their forward voltage drop is higher.

Typical values are:

IR: 1.2 V, Red: 1.85 V, Yellow: 2 V, Green: 2.15 V. The new blue LEDs will be somewhat higher (perhaps 3 V). These voltages are at reasonable forward current. Depending on the actual technology (i.e., compounds like GaAsP, GaP, GaAsP/GaP, GaAlAs, etc.), actual voltages can vary quite a bit. For example, the forward voltage drop of red LEDs may range at least from 1.50 V to 2.10 V. Therefore, LED voltage drop is not a reliable test of color though multiple samples of similar LEDs should be very close. Obviously, if the device is good, it will also be emitting light when driven in this way if the current is high enough.

So, test for short and open with a multimeter (but it must be able to supply more than the forward voltage drop to show a non-open condition).

An LED can be weak and still pass the electrical tests so checking for output is still necessary.

Therefore, if these tests don't find a problem, drive the LED from a DC supply and appropriate current limiting resistor. For the IR types, you will need a suitable IR detector. See the document: "Notes on the Troubleshooting and Repair of Hand Held Remote Controls" for a variety of options.

Testing Opto-Isolators and Photo-Interrupters

Both these classes of components are basically similar: a light source (usually an IR LED) and photodetector together in a single package.

- The opto-isolator will be totally sealed with adequate separation between the two parts to provide the specified isolation voltage rating.

- The photo-interrupter (and similar devices) will provide a beam path that can be blocked or otherwise modified by external means.

For both types, the photodetector can be a photodiode, phototransistor, photothyristor, or other more complex device or circuit.

Refer to an optoelectronics databook or the catalog of a large electronics distributor for specific pinouts and specifications.

Assuming a photodiode or phototransistor type (most common), these can be tested for basic functionality pretty easily:

Wire up a test circuit as follows:

```
 +5 o-----+------------------+
          |                  |
          /                  /
          \ 500              \ 5K
          /                  /
          \                  \
          |  _|_ S1          |
          +--- ----+         +-------------o Out
               - - | - - - - | -
              :  __|__      _|_ :
          LED :  _\_/_ ---> /_\ : Phododiode
              :    |         |  :
               - - | - - - - | -
Gnd o--------------+---------+-------------o Gnd
```

Depressing S1 should result in the Output dropping from +5 V to close to 0 V. For monitoring on a scope, drive the LED with a pulse generator and current limiting resistor instead of S1. With a photo-interrupter type, blocking or adding a reflector to the optical path (as appropriate) should result in similar behavior.

Testing Thermistors

There are two types of thermistors:

- Positive Temperature Coefficient (PTC) types have a resistance that increases with increasing temperature.
- Negative Temperature Coefficient (NTC) types have a resistance that decreases with increasing temperature.

For a small thermistor, put an ohmmeter on it and the heat it up with a blow dryer, heat gun, or the tip of a soldering iron - the resistance should change smoothly (up or down depending on whether it is PTC or NTC type). If the resistance changes erratically, or goes to infinity or zero, the device is bad. However, you will need specifications, temperature measuring sensors, etc. to really determine if it is operating correctly.

Testing Thermo-Electric (Peltier) Devices

While these are often called Thermo-Electric Coolers (TECs), they are equally good (or poor) at heating. The typical TEC uses a series connected string of thermocouple-like junctions sandwiched between a pair of ceramic plates. They are generally specified in terms of maximum temperature difference (typically between 60 to 70 °C); maximum current, voltage, and power dissipation; and physical dimensions.

Most problems will be obvious - like the entire thing was smashed by your pet elephant or melted down due to applying too much power. :) However, a hairline crack in one of the interior junctions could be undetectable without testing.

The best way to test a TEC is to apply a controlled current and monitor the voltage across the device as a function of current and measure the temperature difference between the hot and cold surfaces. Then, compare the readings with the device's specifications. If these aren't known, it may be possible to match up your device with one of similar dimensions. One major supplier is Melcore.

Testing for continuity can be done with an ohmmeter but really only if the temperature of the two sides is exactly equal - otherwise there will be a voltage offset (the junctions also generates voltage when a temperature difference is present - and this can also serve as a test of sorts).

The I-V characteristics should be fairly linear over a relatively wide range of current within the device's specified operating range. However, the voltage for a given current does vary slightly with the temperature difference between the hot and cold surfaces.

- Back to Semiconductor Testing Table of Contents.

Miscellaneous Information

Differences Between Ordinary, Fast Recovery, and Schottky Diodes

When the polarity reverses on a diode, it takes finite time for the charge carriers to be cleared from the area of the junction. During this time, reverse current flows. For high frequency applications - i.e., switching power supplies, horizontal deflection circuits, etc. - a normal diode would act more like a short circuit and result in poor performance or even burn out.

There are a variety of alternatives: fast, super-fast, ultra-fast (and so forth) recovery diodes, schottky diodes, and others that must be used in high frequency signal, switching, and power supply circuits:

Thus, if you find a bad diode in a piece of electronic equipment, don't assume it is just an ordinary diode because the case looks the same. Replacing a fast recovery diode with a 1N4007 will very likely just result in more confusion. A proper device must be used even for testing. In most cases, a faster part can be substituted without problems. However, there are occasional situations where the specific characteristics of a slow part (a reverse pulse due to its long recovery time or high capacitance) are depended upon for the circuit to operation properly!

(From: John Popelish (jpopelish@rica.net).)

Fast recovery diodes have a little gold added to the silicon (and perhaps other process changes) that make the minority carriers (holes in n type and electrons in p type sides of the junction) have shorter lifetimes, so that in addition to sweeping them out by applied voltage, the carriers spontaneously disappear. This makes the diodes turn off faster. Other tricks help the diodes to turn off with less of a snap, to reduce high frequency noise generation. These changes usually compromise other properties of the diode, like reverse leakage, forward drop or breakdown voltage, so there are lots of different combinations of trade-offs.

Schottky diodes are really just half diodes. A metal intimately bonded to a p type semiconductor. Holes have a zero lifetime in metal, so the minority lifetime is just about zero for schottky diodes. They also have about half a diode drop in the forward direction, and so are twice as efficient even for low frequency rectification. The trade off here is that they can only be made to handle low reverse voltages and even there, they have more reverse leakage than junction diodes.

Motorola published a diode handbook that goes into a lot more detail on these things and I recommend it.

Horizontal Output Transistor Pinouts

You will nearly always find one of two types of horizontal output transistors in TVs and monitors:

- Metal can - TO3 package:

```
                  _
                / O \          View from bottom (pin side).
              / o   o \
             (  B   E  )       B = Base, E = Emitter, C = Collector.
              \       /
                \ O / C        The metal case is the Collector.
```

- Plastic tab - Mostly these will be the TO3Pn (n = several suffixes) package but some B/W TVs and mono monitors or video display terminals may use HOTs in the smaller TO220 package:

```
                     TO3Pn
       TO220         _____
       _____        /     \
      |  o  |      |   O   |      View from front (label side).
      |-----|      |-------|
      |Label|      |       |      B = Base, E = Emitter, C = Collector.
      |_____|      | Label |
       | | |       |_______|      If there is an exposed metal tab, that is
       | | |         | | |         the Collector as well.
       B C E         | | |
                     B C E
```

Some other transistor types use the same pinout (TO66 for metal can, TO218 and TO220 for plastic tab) but not all. However, for horizontal output transistors, these pinouts should be valid.

Note that those with a built in damper diode may read around 50 ohms between B and E (near 0 on the diode test range) - this is normal as long as the resistance is not really low like under 10 ohms.

Difference Between Normal and 'R' Marked Parts

> "Does anyone know the difference between transistor BDY58R and BDY58 (if any at all)?"

(From: Paul Grohe (grohe@galaxy.nsc.com).)

Yep! We "hit our head" on this one while diagnosing a sick scope.

Electrically, the parts are exactly the same. The "R" stands for 'reverse'. The 'R' pinout is a mirror image of the normal one.

```
                 C                                   C
            ____|_|____                         ____|_|____
```

```
      |           |                      |           |
      |___________|                      |___________|
       | |     | |                        | |     | |
        B       E                          E       B

Top view of 'normal' SOT              Top view of 'R' SOT
```

This makes layout of high-frequency pairs easier because traces do not have to cross over one another, and the layout is 'cleaner' but bites you if you are unaware!

Testing Zener Diodes

The following applies to both testing of zeners for failure and determining the ratings of an unknown device. Zeners most often fail short or open with short probably more likely. However, it is also possible, though a lot less common, for the zener voltage to change (almost always to a lower voltage) and/or for the shape of the I-V curve to change dramatically (e.g., become less sharp cornered).

With a VOM, a good zener diode should read like a normal diode in the forward direction and open in the reverse direction unless the VOM applies more than the zener voltage for the device. A DMM on its diode test range may read the actual zener voltage if it is very low (e.g., a couple V) but will read open otherwise. The most common failure would be for the device to short - read 0.0 ohms in both directions. Then, it is definitely dead. :)

Some zeners are marked with a JEDEC (1N) part number, others with a couple of colored bands (e.g., for 18 V, brown/gray), or a house number or house color code.

You can easily test a zener and identify its voltage rating with a DC power supply, resistor, and multimeter. You will need a power supply (a DC wall adapter or AC wall adapter with a rectifier and filter capacitor is fine) greater than the highest zener voltage you want to test. Select a resistor that will limit current to a few mA. For example, for zeners up to about 20 V, you can use:

```
                 R=2K
24VDC o----------/\/\----------+----------o
                              _|_.        +
                             '/_\ ZD   VOM/DMM
                               |          -
  Gnd o------------------------+----------o
```

This same approach applies to other devices that exhibit a similar behavior such as the B-E junction of a bipolar transistor.

Testing MOVs

MOVs are used mostly for surge suppression in power strips and the front-ends of the power supplies of TVs, VCRs, and other consumer electronic equipment. They are those brightly colored things that look like Epoxy dipped capacitors. At least, that's what they look like when new. A common failure mode is for the MOV to be totally obliterated by a surge or from old age. Then testing is not needed! :)

They are supposed to be located beyond the line fuse (though possibly not always). In this case, where the line fuse blows but there is no visible damage to the MOV(s), the simplest test may be to just temporarily remove the MOV(s) and see if your problem goes away.

A multimeter can be used to test for leakage (there should be none) but the best option is to remove the device. Since the proper functioning of the equipment doesn't depend on any MOVs (in 99.9999 percent of the cases - the exception being where the MOV is used as a high voltage triggering device or something like that rather than a surge suppressor), remove the MOV(s), test the equipment, and just replace the MOV(s) if in doubt.

(From: Brad Thompson (Brad_Thompson@pop.valley.net).)

Usually, the manufacturers specify a maximum leakage current (usually one milliampere) at a AC specified voltage. You'd need a Variac adjustable AC source, an isolation transformer (for safety), an AC voltmeter and an AC milliammeter to make the measurement.

An MOV works as follows: It's essentially a batch of metallic-oxide grains separated by insulating layers. Repeated voltage surges break down the insulating layers, lowering the overall resistance and eventually causing the device to draw too much current and trip whatever overcurrent protection is inherent in the system.

I've seen MOVs exuding tiny metallic "teardrops" through their epoxy coatings, which remained bright and shiny. These devices needed replacement!

(From: Kevin Carney (carneyke@us.ibm.com).)

This is not a valid test for breakdown voltage but these devices read a few megohms when damaged. The new replacements read open on my meter that has a 20 Megohm range of a DMM.

More Gory Details on Zeners and Similar Diodes

(From: Gord Neish (gord.neish@sk.sympatico.ca).)

To those how enjoy the theory!!

When is a Zener not a Zener??

If is voltage is over 6 volts, technically it's an avalanche diode. Here's an engineering text quote that explains rather well:

> "The zener effect refers to removing bound electrons from outer shells by means of an electric field. In other words, as a reverse voltage is applied to a diode, an electric field appears at the junction. When this field is intense enough, outer-shell electrons are dislodged, resulting in a significant increase in reverse current.
>
> The avalanche effect is different. In this case, when the diode is reverse biased, minority carriers are flowing. For higher reverse voltages these minority carriers can attain sufficient velocity to knock bound electrons out of there outer shells. These released electrons then attain sufficient velocity to dislodge more bound electrons, etc. The process is well named, since it is suggestive of an avalanche."

As noted, the voltage where the zener effect leaves off and the avalanche effect takes over is approximately 6 volts.

More accurately, the zener effect dominates below 4 volts and the avalanche effect dominates above 6 volts and a combination of the two between 4 and 6 volts.

Now, which one is in effect significantly affects the temperature characteristics of the device.

- A zener diode (4 volts or less) has a negative temp. coefficient (as temp increases voltage drops).
- An avalanche diode (6 volts or more) has a positive temp. coefficient (as temp increases voltage increases).
- A zener/avalanche diode (4-6 volts) the effects tend to cancel each other resulting a very temp stable diode.

Introduction to Curve Tracers

Curve Tracer Design

A curve tracer is a piece of test equipment or an add-on to an oscilloscope which provides a graphical display of the V-I (or other parameters) of an electronic component. The design of a curve tracer is simple in principle (description here for bipolar transistors):

For the horizontal (collector supply) you need a variable ramp generator. If your scope has a sweep output, then you can derive it from this - if you are not interested in frequency response, an audio amplifier may be adequate with a volume control to adjust the amplitude.

For the base drive you need a programmable current source capable of putting out a series of constant currents for the base drive. Here, a counter driving a D/A set up for a current output mode. Use the trigger output or sweep output of the scope to increment the counter so that it sequences through a set of say, 10 current settings.

Then, you need some way of sensing collector current to drive the vertical channel - a small series resistor in the emitter circuit, for example.

For simple diode tests, you can just use a variable AC voltage source like a variable isolation transformer (with a current limiting resistor) across the diode. The X (horizontal) input of the scope goes across the device under test. The Y (vertical) input of the scope goes across the current limiting resistor or a separate series current sense resistor. See the section: Quick and Dirty Curve Tracer.

Then, you can jazz it up with microprocessor controlled on-screen display.

Curve tracers can be big expensive things (e.g., multi-$K) or little add-ons to regular scopes. Here one company selling a curve tracer kit or assembled. I have no idea how good it is but check out Gootee Systems for more info.

Popular Electronics, May 1999, has complete plans for a "Semiconductor Tester" which can handle NPN and PNP bipolar transistors, JFETs and MOSFETs, all sorts of diodes including zeners, and a variety of other devices. This is basically a curve tracer adapter for an oscilloscope. With a little ingenuity, it can be enhanced to test virtually all the semiconductors discussed in this document.

Therefore, if you want a sophisticated piece of test equipment, one of these would be suitable. Or, get yourself a used Tektronix 575 curve tracer. This will do just about everything you could possibly want (including the testing of vacuum tubes with the addition of a bit of external circuitry.)

However, to just test 2 terminal devices - or to just get a feel for device characteristics, there are much simpler, cheaper, alternatives.

Quick and Dirty Curve Tracer

I threw the following circuit together in about 10 minutes. With minor modifications, it is capable of displaying V-I curves for diodes, zeners, transistors, thyristors, resistors, capacitors, inductors, etc.

I used a 12 VAC transformer just because it was handy. You can use anything you like as long as you understand the safety implications of higher voltages and make sure the components you use can withstand the power that might be dissipated in them if the Device Under Test (DUT) is a dead short. In addition, it is bad form to blow out the DUT while testing it! A signal generator driving a small audio transformer could also be used if it is desired to test components at frequencies other than 60 (or 50) Hz.

```
          o-------+     X       R1
                  )|| +------/\/\/\------+----o Horizontal Scope Input
                  )||(                   |         (Voltage Display)
                  )||(                   o
    Adjustable AC )||(                   +
     from Variac  )||(                  DUT
                  )||(                   -
                  )||(                   o
                  )||( Y       R2        |
                  )|| +--+---/\/\/\------+----o Scope Ground
          o-------+      |
                   T1    +--------------------o Vertical Scope Input Inverted)
                                                  (Current Display)
```

CAUTION: turn down the intensity of the scope so the spot is just barely visible so that when there is no input, you don't end up drilling a hole in the face of the CRT!

- R1: Current limiting and phase shift control. I used 500 ohms which works well for small signal semiconductors and capacitors around 1 uF.
- R2: Current sense. I used 10 ohms and put the scope on the one of the .1, .2, or .5 V/cm ranges.
- T1: Small power transformer. I used the 12 VAC wall wart from an obsolete modem. This will supply a voltage of up to about 17 V peak to your DUT.

  For higher power or higher voltage devices, substitute a suitable larger transformer.

Modify these (selector switches might be nice) for your needs. A Variac provides a convenient method of adjusting the voltage applied to the DUT.

- Zener diodes - the result will be exactly like the picture in your textbook. Try this with a 5 or 6 V zener to confirm that your rig is working.
- Resistors - the display should be a straight diagonal line. You should be able to compute their value from the ratio of V to I.
- Capacitors - you should see the phase shift between voltage and current resulting in an ellipse (though you will probably have to adjust the scale factors to obtain a usable display with typical capacitor values).
- Bipolar transistors - a source of (DC) base current is needed. You can be fancy or simple. For a simple source, I used a variable 0 to 15 V power supply and a current limiting resistor. Since we know that the voltage drop across the B-E junction is fairly constant at around .7 V (for silicon), the output of the supply can be calibrated in terms of base current.
- SCRs - connect a suitable resistor in series with a diode or two (or a diac) between the gate and DUT+ (so that gate current in included in the V-I curve). When the threshold current is exceeded, the device should turn on and remain on until the zero crossing. With the reverse polarity, the device should remain off. For triacs, use diodes in parallel in both directions or a diac. A triac should trigger on both polarities of the AC waveform.

In-Circuit Tester

The following is along the same lines as the "Quick and Dirty Curve Tracer" but is suitable for in-circuit testing as the current and voltage are limited to safe values for most devices (less than 1 VAC and than 1 mAAC respectively).

The very complicated circuit is shown in: curve.gif and below in ASCII.

CAUTION: Use at your own risk. I cannot absolutely guarantee that there won't be certain devices in use today that didn't exist in 1975 that might be unhappy with this approach.

(From: Wern Thiel (wern@zoo.toronto.edu).)

                      |         |
     o----------------+---------+-------------o Horizontal Scope Input
```

In the August 1975 issue of Popular Electronics author Lou Garner wrote in a story called "A simple On-Board Tester" about this fairly simple piece of test equipment.

The device can be used with any type of oscilloscope and consists of a 6 volt filament transformer, three 1/4 watt resistors and two test probes. Half of the filament voltage is applied to a voltage divider consisting of 220 ohm and 100 ohm resistors, yielding 1 volt ac on top of the 1 K ohm resistor. This voltage can be applied to any component or combination of components across which the test leads are placed. The current is limited to one milliampere by the 1 K ohm resistor.

The voltage across the probes is connected to the horizontal input of a scope while the voltage across the 1 K ohm resistor as a result of the current through it is connected to the vertical input.

What we see on the scope is a voltage across a component under test versus the current through the component:

```
Resistors:      Open   Horizontal line.
                10 K   10 degree.
                 1 K   45 degree.
                   0   Vertical line.

Capacitor:       .1 uF  Shallow ellipse.
                2.6 uF  Circle.
               50.  uF  Narrow vertical.

Transformer:            Ellipse depending on impedance.

Diodes (Germanium):     Right angle display.

Diodes (Silicon):       Right angle one side longer
                        (any leakage showing less sharp angle).

Transistors:            Test as two diodes (B to E and B to C).

Integrated Circuits:    Input for gates and counters show a certain signature
                          display.

                        Outputs display a different signature.

                        A short will show a vertical line.

                        An open will show a horizontal line
```

In circuit testing is done with *no* power applied to the equipment under test.

With some experience one is able to test components in and out of circuit and troubleshoot without danger of a damage to components.

Testing Vacuum Tubes (or FETs) on a Bipolar Curve Tracer

A transistor curve tracer can be easily adapted to test vacuum tubes (OK, valves for those of you on the other side of the lake) if it has an adequate voltage range for the collector (now plate) drive and independent control of base and collector polarity. All that is needed is to add a separate transformer to power the tube's filament(s) and a resistor to convert base current to voltage.

For FETs, just leave off the transformer.

(From: Michael Covington (mcovingt@ai.uga.edu).)

Get an old Tektronix 575 (mine cost $25 at a hamfest). That is a transistor curve tracer that goes back to the 1950s and goes up to 200 volts.

It doesn't have FET settings, but you can control the 'base' and 'collector' polarity independently. So what you do is put a 1 K resistor from 'base' to ground, so that you can read milliamps as volts. Then put a positive-going voltage on the 'collector' and a negative-going current into the 'base'.

For tubes, emitter, collector, and base are cathode, plate, and grid, respectively. Naturally you also need a filament supply; I use a lab-type DC supply because it's handy and can't introduce hum.

I also test FETs that way (without the filament supply, of course). Then, emitter, collector, and base become source, drain, and gate respectively.

DISCLAIMER

Although working on small appliances is generally less risky than dealing with equipment like microwave ovens, TVs, and computer monitors, those that plug into the wall can still produce a very lethal electric shock as well cause a fire from incorrect or careless repairs both during servicing or later on. It is essential that you read, understand, and follow all safety guidelines contained in this document and in the document: Safety Guidelines for High Voltage and/or Line Powered Equipment.

Improper repair of battery operated devices can also result in bad consequences for you, the device, and any equipment attached to it.

We will not be responsible for damage to equipment, your ego, county wide power outages, spontaneously generated mini (or larger) black holes, planetary disruptions, or personal injury or worse that may result from the use of this material.

- Back to Small Appliances and Power Tools Repair FAQ Table of Contents.

Introduction

Note: The chapters: "AC Adapters" and "Batteries" have been relocated to the document: Notes on the Troubleshooting and Repair of AC Adapters, Power Supplies, and Battery Packs.

Where do you keep your dead appliances?

If you have ever tried to get a small household appliance or portable power tool repaired, you understand why all that stuff is likely to be gathering dust in your attic or basement closet or junk box. It does not pay! This may be partially by design. However, to be fair, it may take just as much time to diagnose and repair a problem with a $20 toaster as a $300 VCR and time is money for a repair shop. It is often not even economical to repair the more expensive equipment let alone a $40 electric heater. The cost of the estimate alone would probably buy at least one new unit and possibly many more.

However, if you can do the repair yourself, the equation changes dramatically as your parts costs will be 1/2 to 1/4 of what a professional will charge and of course your time is free. The educational aspects may also be appealing. You will learn a lot in the process. Many problems can be solved quickly and inexpensively. Fixing an old vacuum cleaner to keep in the rec room may just make sense after all.

This document provides maintenance and repair information for a large number of small household appliances and portable power tools. The repair of consumer electronic equipment is dealt with by other documents in the "Notes on the Troubleshooting and Repair of..." series. Suggestions for additions (and, of course, correction) are always welcome.

You will be able to diagnose problems and in most cases, correct them as well. Most problems with household appliances are either mechanical (e.g., dirt, lack of or gummed up lubrication, deteriorated rubber parts, broken doohickies) or obvious electrical (e.g., broken or corroded connections, short circuits, faulty heating elements) in nature. With minor exceptions, specific manufacturers and models will not be covered as there are so many variations that such a treatment would require a huge and very detailed text. Rather, the most common problems will be addressed and enough basic principles of operation will be provided to enable you to narrow the problem down and likely determine a course of action for repair. In many cases, you will be able to do what is required for a fraction of the cost that would be charged by a repair center - or - be able to revive something that would otherwise have gone into the dumpster - or remained in that closet until you moved out of your house (or longer)!

Since so many appliances are variations on a theme - heating, blowing, sucking, rotating, etc. - it is likely that even if your exact device does not have a section here, a very similar one does. Furthermore, with your understanding of the basic principles of operation, you should be able to identify what is common and utilize info in other sections to complete a repair.

Should you still not be able to find a solution, you will have learned a great deal and be able to ask appropriate questions and supply relevant information if you decide to post to sci.electronics.repair (recommended), alt.home.repair, or misc.consumers.house. It will also be easier to do further research using a repair textbook. In any case, you will have the satisfaction of knowing you did as much as you could before finally giving up or (if it is worthwhile cost-wise) taking it in for professional repair. With your newly gathered knowledge, you will have the upper hand and will not easily be snowed by a dishonest or incompetent technician.

Some Tidbits

You may not realize the following:

- Virtually any table lamp can be restored to a like-new condition electrically for less than $5 in parts.

- The cause of a vacuum cleaner that starts blowing instead of sucking is likely a dirt clog somewhere. It is virtually impossible for the motor to spin in the wrong direction and even if it did, the vacuum would still have some suction due to the type of blower that is commonly used.

- Many diagnoses of burned out motors are incorrect. Very often motor problems are actually something else - and minor. A truly burned out motor will often have died spectacularly and under adverse conditions. It will likely be smelly, charred, or may have created lots of sparks, tripped a circuit breaker or blew a fuse. A motor that just stopped working may be due to worn or gummed up (carbon) brushes, dirt, or a fault elsewhere in the appliance like a bad connection or switch or circuit - or the AC outlet might be bad. The most likely cause of a vacuum cleaner or other similar appliance that just stopped working is a break in a wire of the power cord - probably at the plug - due to continual stress from being dragged around by its tail!

- Fluorescent lamps use only 1/3 to 1/2 of the power of an incandescent lamp of similar light output. With all the lighting used in an average household, this can add up particularly for high power ceiling fixtures. However, fluorescent light color and quality may not be as aesthetically pleasing and fixtures or lamps may produce Radio Frequency Interference (RFI) causing problems with TV or radio reception. Dimmers can usually not be used unless they are specifically designed for fluorescent fixtures. Compact fluorescent lamps do indeed save energy but they can break just like any other light bulb!

- The initial inrush current to an incandescent bulb may be 10 times the operating current. This is hard on switches and dimmers and is part of the reason behind why bulbs tend to burn out when switched on and not while just sitting there providing illumination. Furthermore, an erratic switch or loose connection can shorten the life of an incandescent bulb due to repeated thermal shock. And, these are not due to short circuits but bad intermittent connections. True short circuits are less common and should result in a blown fuse or tripped circuit breaker.

- Bulb Savers and other devices claiming to extend the life of incandescent light bulbs may work but do so mostly by reducing power to the bulb at the expense of some decrease in light output and reduced efficiency. It is estimated that soft start alone (without the usual associated reduction in power) does not prolong the life of a typical bulb by more than a few hours.

  Thus, in the end, these device increase costs if you need to use more or larger bulbs to make up for the reduced light output. The major life cycle expense for incandescent lighting is not the cost of the bulbs but the cost of the electricity - by a factor of 25 to 50! For example, it costs about $10 in electricity to run a 100 W bulb costing 25 cents over the course of its 1000 hour life. However, these devices (or the use of 130 V bulbs) may make sense for use in hard-to-reach locations. Better yet, consider compact or normal fluorescent bulbs or fixtures which last much longer and are much more efficient than incandescents (including halogen).

- Smart bulbs are legitimate technology with built in automatic off, dimmers, blink capability, and other 'wizzy' features but they burn out and break just like ordinary bulbs. Thus, it hardly makes sense to spend $5 to $10 for something that will last 1000 to 1500 hours. Install a proper dimmer, automatic switch, or external blinker instead.

- A Ground Fault Circuit Interrupter (GFCI) protects people against shock but does not necessarily protect appliances from damage due to electrical faults. This is the function of fuses, circuit breakers, and thermal protectors. A GFCI *can* generally be installed in place of a 2-wire ungrounded outlet to protect it and any outlets downstream. Check your local electrical Code to be sure if this is permitted.

- Don't waste your money on products like the 'Green Plug', magnetic water softeners, whole house TV antennas that plug into the wall socket, and other items of the ''it sounds too good to be true' variety. These are very effective only at transferring money out of your wallet but rarely work as advertised.

    - The Green Plug will not achieve anywhere near the claimed savings and may actually damage or destroy certain types of appliances like, guess what?: refrigerators and other induction motor loads. Ever seen the demo?

      The Green Plug is supposed to reduce reactive power (V and I out of phase due to inductive or capacitive loads) but residential users don't pay for reactive power anyway, only the real power they use. In addition, this is a minor concern for modern appliances.

      The demo you see in the store that shows a utility meter slowing down substantially when the Green Plug is put in the circuit is bogus for two reasons: (1) The motor being powered is totally unloaded resulting in a high ratio of reactive to real power. Under normal use with a motor driving a load, the reduction in electricity use would be negligible. (2) The meter is wired to include reactive power in its measurement which, as noted above, is not the case with residential customers.

    - Magnetic and radio frequency water softeners are almost certainly 100% scams. They cloak absolutely useless technology in so much 'technobabble' that even Ph.D. scientists and engineers have trouble sorting it all out. The latest wrinkle adds advanced microprocessor control optimized for each potential mineral deposit. Yeh, sure.

      Mention the word 'magnetism' and somehow, people will pay $300 for $2 worth of magnets that do nothing - and then be utterly convinced of their effectiveness. They forget that perhaps the instruction manual suggested changes in their water use habits - which was the true reason for any improvement. Perhaps the magnets can be used to stick papers on the refrigerator once you discover they don't do anything for the water.

      BTW, the same goes for magnetic wine flavor enhancers. :-)

    - Whole house TV antennas are great for picking up signals with ghosts, noise, and other distorting effects. The premise that 'more is better' is fundamentally flawed when it comes to TV reception. In rare cases they may produce a marginally viewable picture in an otherwise unfavorable location but these are the exceptions. A pair of set-top rabbit ears will generally be superior.

I will be happy to revise these comments if someone can provide the results of evaluations of any of these devices conducted by a recognized independent testing laboratory. However, I won't hold my breath waiting.

---

* Back to Small Appliances and Power Tools Repair FAQ Table of Contents.

Basic Appliance Theory

What is inside an appliance?

There isn't much rocket science in the typical small appliance (though that is changing to some extent with the use of microcomputer and fuzzy logic control). Everything represents variations on a relatively small number of basic themes:

* Heating - a resistance element similar to what you can see inside a toaster provides heat to air, liquids, or solids by convections, conduction, or direct radiant (IR) heat.

* Rotation, blowing, sucking - a motor provides power to move air as in a fan or vacuum cleaner, water as in a sump pump, or provide drive as in an electric pencil sharpener, food mixer, or floor polisher.

* Control - switches and selectors, thermostats and speed regulators, and microcomputers determine what happens, when, how much, and assure safe operation.

Basic electrical principles

Relax! This is not going to be a tutorial on computer design. Appliances are simple devices. It is possible to repair many appliance faults without any knowledge beyond 'a broken wire is probably a problem' or 'this part is probably bad because it is charred and broken in half'. However, a very basic understanding of electrical principles will enable you to more fully understand what you are doing. Don't worry, there will be no heavy math. The most complicated equations will be variations on Ohm's law: V=I*R and P=V*V/R.

Voltage, current, and resistance

If you have any sort of background in electricity or electronics, then you can probably skip the following introductory description - or have some laughs at my expense.

The easiest way to explain basic electrical theory without serious math is with a hydraulic analogy. This is of the plumbing system in your house:

Water is supplied by a pipe in the street from the municipal water company or by a ground water pump. The water has a certain pressure trying to push it through your pipes. With electric circuits, voltage is the analog to pressure. Current is analogous to flow rate. Resistance is analogous the difficulty in overcoming narrow or obstructed pipes or partially open valves.

Intuitively, then, the higher the voltage (pressure), the higher the current (flow rate). Increase the resistance (partially close a valve or use a narrower pipe) and for a fixed voltage (constant pressure), the current (flow rate) will decrease.

With electricity, this relationship is what is known as linear: double the voltage and all other factors remaining unchanged, the current will double as well. Increase it by a factor of 3 and the current will triple. Halve the resistance and for a constant voltage source, the current will double. (For you who are hydraulic engineers, this is not quite true with plumbing as turbulent flow sets in, but this is just an analogy, so bear with me.)

Note: for the following 4 items whether the source is Direct Current (DC) such as a battery or Alternating Current (AC) from a wall outlet does not matter. The differences between DC and AC will be explained later.

The simplest electrical circuit will consist of several electrical components in series - the current must flow through all of them to flow through any of them. Think of a string of Christmas lights - if one burns out, they all go out because the electricity cannot pass through the broken filament in the burned out bulb.

Note the term 'circuit'. A circuit is a complete loop. In order for electricity to flow, a complete circuit is needed.

```
                    Switch (3)
         _____________/ ______________
        |                             |
        | (1)                         | (4)
+-------+--------+                +---+----+
|  Power Source  |                |  Load  |
+-------+--------+                +---+----+
        |           Wiring (2)        |
        |_____________________________|
```

1. Power source - a battery, generator, or wall outlet. The hydraulic equivalent is a pump or dam (which is like a storage battery). The water supply pipe in the street is actually only 'wiring' (analogous to the electric company's distribution system) from the water company's reservoir and pumps.

2. Conductors - the wiring. Similar to pipes and aqueducts. Electricity flows easily in good conductors like copper and aluminum. These are like the insides of pipes. To prevent electricity from escaping, an insulator like plastic or rubber is used to cover the wires. Air is a pretty good insulator and is used with high power wiring such as the power company's high voltage lines but plastic and rubber are much more convenient as they allow wires to be bundled closely together.

3. Switch - turns current on or off. These are similar to valves which do not have intermediate positions, just on and off. A switch is not actually required in a basic circuit but will almost always be present.

4. Load - a light bulb, resistance heater, motor, solenoid, etc. In true hydraulic systems such as used to control the flight surfaces of an aircraft, there are hydraulic motors and actuators, for example.

   With household water we usually don't think of the load. However, things like lawn sprinklers, dishwasher rotating arms, pool sweepers, and the like do convert water flow to mechanical work in the home (some homes, at least!). Hydraulic motors are used to aircraft and spacecraft, large industrial robots, and all sorts of other applications.

Here are 3 of the simplest appliances:

- Flashlight: battery (1), case and wiring (2), switch (3), light bulb (4).

- Table lamp: wall outlet (1), line cord and internal wiring (2), power switch (3), light bulb (4).

- Electric fan, vacuum cleaner, garbage disposer: wall outlet (1), line cord and internal wiring (2), power switch (3), motor (4).

Now we can add one type of simple control device:

5. Thermostat - a switch that is sensitive to temperature. This is like an automatic water valve which shuts off if a set temperature is exceeded. Most thermostats are designed to open the circuit when a fixed or variable temperature is

exceeded. However, air conditioners, refrigerators, and freezers do the opposite - the thermostat switches on when the temperature goes too high. Some are there only to protect against a failure elsewhere due to a bad part or improper use that would allow the temperature to go too high and start a fire. Others are adjustable by the user and provide the ability to control the temperature of the appliance.

With the addition of a thermostat, many more appliances can be constructed including (this is a small subset):

- Electric space heater (radiant), broiler, waffle iron: wall outlet (1), line cord and internal wiring (2), power switch (3) and/or thermostat (5), load (heavy duty heating element).

- Electric heater (convection), hair dryer: wall outlet (1), line cord and internal wiring (2), power switch (3) and/or thermostat (5), loads (4) (heating element and motor).

Electric heaters and cooking appliances usually have adjustable thermostats.

Hair dryers may simply have several settings which adjust heater power and fan speed (we will get into how later). The thermostat may be fixed and to protect against excessive temperatures only.

That's it! You now understand the basic operating principle of nearly all small appliances. Most are simply variations (though some may be quite complex) on these basic themes. Everything else is just details.

For example, a blender with 38 speeds just has a set of buttons (switches) to select various combinations of motor windings and other parts to give you complete control (as if you need 38 speeds!). Toasters have a timer or thermostat activate a solenoid (electromagnet) to pop your bread at (hopefully) the right time.

6. Resistances - both unavoidable and functional. Except for superconductors, all materials have resistance. Metals like copper, aluminum, silver, and gold have low resistance - they are good conductors. Many other metals like iron or steel are fair but not quite as good as these four. One, NiChrome - an alloy of nickel and chromium - is used for heating elements because it does not deteriorate (oxidize) in air even at relatively high temperatures.

   A significant amount of the power the electric company produces is lost to heating of the transmission lines due to resistance and heating.

   However, in an electric heater, this is put to good use. In a flashlight or table lamp, the resistance inside the light bulb gets so hot that it provides a useful amount of light.

   A bad connection or overloaded extension cord, on the other hand, may become excessively hot and start a fire.

The following is more advanced - save for later if you like.

7. Capacitors - energy storage devices. These are like water storage tanks (and similar is some ways to rechargeable batteries). Or, a system consisting of a a rubber diaphragm separating the water from a volume of trapped air. As water is pumped in, energy is stored as the air is compressed as in the captive air or expansion tanks found in home heating systems or well water storage tanks.

   Capacitors are not that common in small appliances but may be used with some types of motors and in RFI - Radio Frequency Interference - filters as capacitors can buffer - bypass - interference to ground. The energy to power an electronic flash unit is stored in a capacitor, for example. Because they act like reservoirs - buffers - capacitors are found in the power supplies of most electronic equipment to smooth out the various DC voltages required for each device.

8. Inductors - their actual behavior is like the mass of water as it flows. Turn off a water faucet suddenly and you are

likely to hear the pipes banging or vibrating. This is due to the inertia of the water - it tends to want to keep moving. Electricity doesn't have inertia but when wires are wound into tight coils, the magnetic field generated by electric current is concentrated and tends to result in a similar effect. Current tends to want to continue to flow where inductance is present. (For the more technical reader, the air chamber used to prevent/minimize the water hammer effect is the equivalent of an RC snubber!)

The windings of motors and transformers have significant inductance but the use of additional inductance devices is rare in home appliances except for RFI - since inductance tends to prevent current from changing, it can also be used to prevent interference from getting in or out.

9. Controls - rheostats and potentiometers allow variable control of current or voltage. A water faucet is like a variable resistor which can be varied from near 0 ohms (when on fully) to infinite ohms (when off).

Ohm's Law

The relationships that govern the flow of current in basic circuits (without capacitance or inductance - which is the case with many appliances) are contained in a very simple set of equations known an Ohm's Law.

The simplest of these are:

```
V = I * R (1)
I = V / R (2)
R = V / I (3)
```

Where:

- V is Voltage in Volts (or millivolts - mV or kilovolts - kV).
- I is current in amperes (A) or milliamps (mA)
- R is resistance in Ohms (ohms), kilo-Ohms (K Ohms), or mega-Ohms (M Ohms).

Power in watts (W) is equal to voltage times current in a resistive circuit (no capacitance or inductance). Therefore, rearranging the equations above, we also obtain:

```
P = V * I      (4)
P = V * V / R  (5)
P = I * I * R  (6)
```

For example:

- For a flashlight with a pair of Alkaline batteries (3 V) and a light bulb with a resistance of 10 ohms, we can use (2) to find that the current is I = (3 V) / (10 ohms) = .3 A. The from (4) we find that the power is: P = (3 V * .3 A) = .9 W.

- For a blow-dryer rated at 1000 W, the current drawn from a 120 V line would be: I = P / V (by rearranging (4) = 1000 W / 120 V = 8.33 A.

As noted above:

- Increase voltage -> higher current. (If the water company increases the pressure, your shower used more water in a given time.)

- Decrease resistance -> higher current. (You have a new wider pipe installed between the street and your house. Or, you open the shower valve wider.)

(Note that the common use of the term 'water pressure' is actually not correct. The most likely cause of what is normally described as low water pressure is actually high resistance in the piping between your residence and the street. There is a pressure drop in this piping just as there would be a voltage drop across a high value resistor.)

DC and AC

While electricity can vary in any way imaginable, the most common forms for providing power are direct current and alternating current:

A direct current source is at a constant voltage. Displaying the voltage versus time plot for such a source would show a flat line at a constant level. Some examples:

- Alkaline AA battery - 1.5 V (when new).
- Automotive battery - 12 V (fully charged).
- Camcorder battery - 7.2 V (charged).
- Discman AC adapter - 9 VDC (fully loaded).
- Electric knife AC adapter - 3.6 VDC.

An Alternating Current (AC) source provides a voltage that is varying periodically usually at 60 Hz (U.S.) or 50 Hz (many other countries). Note that 1 Hz = 1 cycle per second. Therefore, a 60 Hz AC voltage goes through 60 complete cycles in each second. For power, the shape of the voltage is a sinusoid which is the smoothest way that anything can vary periodically between two levels.

The nominal voltage from an AC outlet in the U.S. is around 115 VAC. This is the RMS (Root Mean Square) value, not the peak (0 to maximum). In simple terms, the RMS value of an AC voltage and the same value of a DC voltage will result in identical heating (power) to a resistive load. For example, 115 VAC RMS will result in the same heat output of a broiler as 115 VDC.

Direct current is used for many small motor driven appliances particularly when battery power is an option since changing DC into AC requires some additional circuitry. All electronic equipment require various DC voltages for their operation. Even when plugged into an AC outlet, the first thing that is done internally (or in the AC adapter in many cases) is to convert the AC to various DC voltages.

The beauty of AC is that a very simple device - a transformer - can convert one voltage into another. This is essential to long distance power distribution where a high voltage and low current is desirable to minimize power loss (since it depends on the current). You can see transformers atop the power poles in your neighborhood reducing the 2,000 VAC or so from a local distribution transformer to your 115 VAC (actually, 115-0-115 were the total will be used by large appliances like electric ranges and clothes dryers). That 2,000 VAC was stepped down by a larger transformer from around 12,000 VAC provided by the local substation. This, in turn, was stepped down from the 230,000 VAC or more used for long distance electricity transmission. Some long distance lines are over 1,000,000 volts (MV).

When converting between one voltage and another with a transformer, the amount of current (amps) changes in the inverse ratio. So, using 230 kV for long distance power transmission results in far fewer heating losses as the current flow is reduced by a factor of 2,000 over what it would be if the voltage was only 115 V, for example. Recall that power loss from P=I*I*R is proportional to the square of the current and thus in this example is reduced by a factor of 4,000,000!

Many small appliances include power transformers to reduce the 115 VAC to various lower voltages used by motors or or electrical components. Common AC adapters - often simply called transformers or wall warts - include a small transformer as well. Where their output is AC, this is the only internal component other than a fuse or thermal fuse for protection.

Where their output is DC, additional components convert the low voltage AC from the transformer to DC and a capacitor smoothes it out.

Series and parallel circuits

Up until now, we have been dealing with the series circuit - all parts are in a single line from power source, wiring, switches, load, and anything else. In a series circuit, the current must be the same through all components. The light bulb and switch in a flashlight pass exactly the same value of amperes. If there were two light bulbs instead of one and they were connected in series - as in a Christmas tree light set - then the current must be equal in all the bulbs but the voltages across each one would be reduced.

The loads, say resistance heating elements, are now drawn with the schematic symbol (as best as can be done using ASCII) for a resistor.

```
                     Switch
            _____________/ __________________
           |                I -->             |
           |                      ^    ^      |
           |                      |    |     / R1
           |                      |   V1     \ Load 1
   +-------+--------+             |    |     /
   |  Power Source  |                  v__   |
   +-------+--------+            V(S)  ^      |
           |                           |     / R2
           |                      |   V2     \ Load 2
           |                      |    |     /
           |                      v    v      |
           |__________________________________|
```

The total resistance, R(T), of the resistors in this series circuit is:

```
                    R(T) = R1 + R2                (7)
```

The voltage across each of the resistors would be given by:

```
                    V1 = V(S) * R1 / (R1 + R2)    (8)
                    V2 = V(S) * R2 / (R1 + R2)    (9)
```

The current is given by:

```
                    I = V(S)  / (R1 + R2)        (10)
```

However, another basic configuration, is also possible. With a parallel circuit, components are connected not one after the other but next to one another as shown below:

```
                     Switch
            _____________/ ___________________________
           |                     I -->  |            |
           |                 ^          |            |
```

```
   +-------+--------+          |           / R1         / R2
   |  Power Source  |        V(S)          \ Load 1     \ Load 2
   +-------+--------+          |           /            /
           |                   v           |v I(1)      |v I(2)
           |_____________________________|____________|
```

Now, the voltages across each of the loads is necessarily equal but the individual currents divide according to the relative resistances of each load.

The total resistance, R(T), of the parallel resistors in this circuit is:

```
                    R(T) = (R1 * R2) / (R1 + R2)  (11)
```

The currents through each of the loads would be given by:

```
                    I1 = V(S)/R1                  (12)
                    I2 = V(S)/R2                  (13)
```

The total current is given by:

```
                    I = I1 + I2                   (14)
```

Many variations on these basic arrangements are possible but nearly all can be reduced systematically to a combination of series or parallel circuits.

On-line educational resources

> The How Stuff Works Web site has some really nice introductory material (with graphics) on a variety of topics relating to technology in the modern world. Of relevance to this document are articles on motors, power adapters, relays, batteries, etc.

Check out Sam's Neat, Nifty, and Handy Bookmarks in the "Education and Tutorials" area for links to introductory material on electronics and other related fields.

Appliance Troubleshooting

SAFETY

Appliances run on either AC line power or batteries. In the latter case, there is little danger to you except possibly from burns due to short circuits and heating effect or irritation from the caustic chemicals from old leaky batteries.

However, AC line power can be lethal. Proper safety procedures must be followed whenever working on live equipment (as well as devices which may have high energy storage capacitors like TVs, monitors, and microwave ovens). AC line power due to its potentially very high current is actually considerably more dangerous than the 30 kV found in a large screen color TV!

These guidelines are to protect you from potentially deadly electrical shock hazards as well as the equipment from accidental damage.

Note that the danger to you is not only in your body providing a conducting path, particularly through your heart. Any involuntary muscle contractions caused by a shock, while perhaps harmless in themselves, may cause collateral damage - there are many sharp edges inside this type of equipment as well as other electrically live parts you may contact accidentally.

Safety myths

For nearly all the appliances we will be covering, there is absolutely no danger of electrical shock once the unit is unplugged from the wall socket (not, however, just turned off - the plug should be removed from the wall socket).

You may have heard warnings about dangers from unplugged appliances. Perhaps, these were passed down from your great great grandparents or from local bar room conversation.

Except for devices with large high voltage capacitors connected to the line or elsewhere, there is nothing inside an appliance to store a painful or dangerous charge. Even these situations are only present in microwave ovens, fluorescent lamps and fixtures with electronic ballasts, universal power packs for camcorders or portable computers, or appliances with large motors. Other than these, once an appliance is unplugged all parts are safe to touch - electrically that is. There may still be elements or metal brackets that are burning hot as metal will tend to retain heat for quite a while in appliances like toasters or waffle irons. Just give them time to cool. There are often many sharp edges on sheetmetal as well. Take your time and look before you leap or grab anything.

Safety guidelines

The purpose of this set of guidelines is not to frighten you but rather to make you aware of the appropriate precautions. Appliance repair can be both rewarding and economical. Just be sure that it is also safe!

- Don't work alone - in the event of an emergency another person's presence may be essential.
- Always keep one hand in your pocket when anywhere around a powered line-connected or high voltage system.
- Wear rubber bottom shoes or sneakers.
- Wear eye protection - large plastic lensed eyeglasses or safety goggles.
- Don't wear any jewelry or other articles that could accidentally contact circuitry and conduct current, or get caught in moving parts.
- Set up your work area away from possible grounds that you may accidentally contact.
- Know your equipment: small appliances with 2 prong plugs do not use any part of the outside case for carrying current. Any metal parts of the case will either be totally isolated or possibly connected to one side of the line through a very high value resistor and/or very low value capacitor. However, there may be exceptions. And, failures may occur. Appliances with 3 prong plugs will have the case and any exposed metal parts connected to the safety ground.
- If circuit boards or other subassemblies need to be removed from their mountings, put insulating material between them and anything they may short to. Hold them in place with string or electrical tape. Prop them up with insulation

sticks - plastic or wood.

- Parts of heating appliances can get very hot very quickly. Always carefully test before grabbing hold of something you will be sorry about later.

- If you need to probe, solder, or otherwise touch circuits with power off, discharge (across) large power supply filter capacitors with a 2 W or greater resistor of 100-500 ohms/V approximate value (e.g., for a 200 V capacitor use a 50 K ohm resistor). The only places you are likely to find large capacitors in small appliance repair are in induction motor starting or running circuitry or the electronic ballasts of fluorescent fixtures.

- Connect/disconnect any test leads with the equipment unpowered and unplugged. Use clip leads or solder temporary wires to reach cramped locations or difficult to access locations.

- Perform as many tests as possible with the device unplugged. Even with the power switch supposedly off, if the unit is plugged into a live outlet, line voltage may be present in unexpected places or probing may activate a motor due to accidentally pressing a microswitch. Most parts in household appliances and power tools can be can be tested using only an ohmmeter or continuity checker.

- If you must probe live, put electrical tape over all but the last 1/16" of the test probes to avoid the possibility of an accidental short which could cause damage to various components. Clip the reference end of the meter or scope to the appropriate ground return so that you need to only probe with one hand.

- Use an isolation transformer if there is any chance of contacting line connected circuits. A Variac(tm) is not an isolation transformer!

  The use of a GFCI (Ground Fault Circuit Interrupter) protected outlet is a good idea but will not protect you from shock from many points in a line connected TV or monitor, or the high voltage side of a microwave oven, for example. (Note however, that, a GFCI may nuisance trip at power-on or at other random times due to leakage paths (like your scope probe ground) or the highly capacitive or inductive input characteristics of line powered equipment.) A fuse or circuit breaker is too slow and insensitive to provide any protection for you or in many cases, your equipment. However, these devices may save your scope probe ground wire should you accidentally connect it to a live chassis.

- Don't attempt repair work when you are tired. Not only will you be more careless, but your primary diagnostic tool - deductive reasoning - will not be operating at full capacity.

- Finally, never assume anything without checking it out for yourself! Don't take shortcuts!

Should I unplug appliances when not in use?

There is no hard and fast rule. Personally, I do unplug heating appliances when I am done with them. The quality of internal construction is not always that great and this is a minor annoyance to avoid a possible fire hazard should something fail or should such an appliance accidentally be left on.

BTW, electronic equipment should always be unplugged during lightning storms since it may be very susceptible to power surge and lightning damage. Don't forget the telephones and computer modems as well. This is not as much of a problem with small appliances that do not include electronic controllers as except for direct lightning strikes, the power switch will provide protection.

Troubleshooting tips

Many problems have simple solutions. Don't immediately assume that your problem is some combination of esoteric complex convoluted failures. For a dead appliance, the most likely cause might just be a bad line cord or plug! Try to remember that the problems with the most catastrophic impact on operation (an appliance that blows fuses) usually have the simplest causes (a wire shorting due to frayed insulation).

If you get stuck, sleep on it. Sometimes, just letting the problem bounce around in your head will lead to a different more successful approach or solution. Don't work when you are really tired - it is both dangerous and mostly non-productive (or possibly destructive - especially with AC line powered appliances).

Whenever working on precision equipment, make copious notes and diagrams. Yes, I know, a toaster may not exactly be precision equipment, but trust me. You will be eternally grateful when the time comes to reassemble the unit. Most connectors are keyed against incorrect insertion or interchange of cables, but not always. Apparently identical screws may be of differing lengths or have slightly different thread types. Little parts may fit in more than one place or orientation. Etc. Etc.

Pill bottles, film canisters, and plastic ice cube trays come in handy for sorting and storing screws and other small parts after disassembly.

Select a work area which is well lighted and where dropped parts can be located - not on a deep pile shag rug. Something like a large plastic tray with a slight lip may come in handy as it prevents small parts from rolling off of the work table. The best location will also be relatively dust free and allow you to suspend your troubleshooting to eat or sleep or think without having to pile everything into a cardboard box to eat dinner.

Basic hand tools

A basic set of precision hand tools will be all you need to work on most appliances. These do not need to be really expensive but poor quality tools are worse than useless and can cause damage. Stanley and Craftsman tools are fine. Needed tools include a selection of Philips and straight blade screwdrivers, socket drivers, open end or adjustable wrenches of various sizes, needlenose pliers, wire cutters, tweezers, and dental picks.

An electric drill or drill press with a set of small (1/16" to 1/4") high quality high speed drill bits is handy for some types of restoration where new holes need to be provided. A set of machine screw taps is also useful at times.

A medium power soldering iron and rosin core solder (never never use acid core solder or the stuff for sweating copper pipes on electrical or electronic repairs!) will be required if you need to make or replace any soldered connections. A soldering gun is desirable for any really beefy soldering. See the section: Soldering techniques.

A crimping tool and an assortment of solderless connectors often called 'lugs' will be needed to replace damaged or melted terminals in small appliances. See the section: Solderless connectors.

Old dead appliances can often be valuable sources of hardware and sometimes even components like switches and heating elements. While not advocating being a pack rat, this does have its advantages at times.

Soldering techniques

Soldering is a skill that is handy to know for many types of construction and repair. For modern small appliances, it is less important than it once was as solderless connectors have virtually replaced solder for internal wiring. However, there are times where soldering is more convenient - for example, when performing repairs at 1 AM and a replacement crimp lug is not available.

Use of the proper technique is critical to reliability and safety. A good solder connection is not just a bunch of wires and terminals with solder dribbled over them. When done correctly, the solder actually bonds to the surface of the metal (usually copper) parts.

CAUTION: You can easily turn a simple repair (e.g., bad solder connections) into an expensive mess if you use inappropriate soldering equipment and/or lack the soldering skills to go along with it. If in doubt, find someone else to do the soldering or at least practice, practice, practice, soldering and desoldering on a junk unit first!

Effective soldering is by no means difficult but some practice may be needed to perfect your technique.

The following guidelines will assure reliable solder joints:

- Only use rosin core solder (e.g., 60/40 tin/lead) for electronics work. A 1 pound spool will last a long time and costs about $10. Suggested diameter is .030 to .060 inches for appliances. The smaller size is preferred as it will be useful for other types of precision electronics repairs or construction as well. The rosin is used as a flux to clean the metal surface to assure a secure bond. NEVER use acid core solder or the stuff used to sweat copper pipes! The flux is corrosive and it is not possible to adequately clean up the connections afterward to remove all residue.

- Keep the tip of the soldering iron or gun clean and tinned. Buy tips that are permanently tinned - they are coated and will outlast countless normal copper tips. A quick wipe on a wet sponge when hot and a bit of solder and they will be as good as new for a long time. (These should never be filed or sanded).

- Make sure every part to be soldered - terminal, wire, component leads - is free of any surface film, insulation, or oxidation. Fine sandpaper or an Xacto knife may be used, for example, to clean the surfaces. The secret to a good solder joint is to make sure everything is perfectly clean and shiny and not depend on the flux alone to accomplish this. Just make sure the scrapings are cleared away so they don't cause short circuits.

- Start with a strong mechanical joint. Don't depend on the solder to hold the connection together. If possible, loop each wire or component lead through the hole in the terminal. If there is no hole, wrap them once around the terminal. Gently anchor them with a pair of needlenose pliers.

- Use a properly sized soldering iron or gun: 20-25 W iron for fine circuit board work; 25-50 W iron for general soldering of terminals and wires and power circuit boards; 100-200 W soldering gun for chassis and large area circuit planes. With a properly sized iron or gun, the task will be fast - 1 to 2 seconds for a typical connection - and will result in little or no damage to the circuit board, plastic switch housings, insulation, etc. Large soldering jobs will take longer but no more than 5 to 10 seconds for a large expanse of copper. If it is taking too long, your iron is undersized for the task, is dirty, or has not reached operating temperature. For appliance work there is no need for a fancy soldering station - a less than $10 soldering iron or $25 soldering gun as appropriate will be all that is required.

- Heat the parts to be soldered, not the solder. Touch the end of the solder to the parts, not the soldering iron or gun. Once the terminal, wires, or component leads are hot, the solder will flow via capillary action, fill all voids, and make a secure mechanical and electrical bond. Sometimes, applying a little from each side will more effectively reach all nooks and crannies.

- Don't overdo it. Only enough solder is needed to fill all voids. The resulting surface should be concave between the wires and terminal, not bulging with excess solder.

- Keep everything absolutely still for the few seconds it takes the solder to solidify. Otherwise, you will end up with a bad connection - what is called a 'cold solder joint'.

- A good solder connection will be quite shiny - not dull gray or granular. If your result is less than perfect reheat it and add a bit of new solder with flux to help it reflow.

Practice on some scrap wire and electronic parts. It should take you about 3 minutes to master the technique!

Desoldering techniques

Occasionally, it will be necessary to remove solder - either excess or to replace wires or components. A variety of tools are available for this purpose. The one I recommend is a vacuum solder pump called 'SoldaPullet' (about $20). Cock the pump, heat the joint to be cleared, and press the trigger. Molten solder is sucked up into the barrel of the device leaving the terminal nearly free of solder. Then use a pair of needlenose pliers and a dental pick to gently free the wires or component. Other approaches that may be used in place of or in addition to this: Solder Wick which is a copper braid that absorbs solder via capillary action; rubber bulb type solder pumps, and motor driven vacuum solder rework stations (pricey).

See the document: Troubleshooting and Repair of Consumer Electronic Equipment for additional info on desoldering of electronic components.

Soldering pins in plastic connectors

The thermoplastic used to mold many common cheap connectors softens or melts at relatively low temperatures. This can result in the pins popping out or shifting position (even shorting) as you attempt to solder to them to replace a bad connection, for example.

One approach that works in some cases is to use the mating socket to stabilize the pins so they remain in position as you solder. The plastic will still melt - not as much if you use an adequately sized iron since the socket will act as a heat sink - but will not move.

An important consideration is using the proper soldering iron. In some cases, a larger iron is better - you get in and out more quickly without heating up everything in the neighborhood.

Solderless connectors

Most internal connections in small appliances are made using solderless connectors. These include twist on WireNuts(tm) and crimped terminal lugs of various sizes and configurations.

WireNuts allow multiple wires to be joined by stripping the ends and then 'screwing' an insulated thimble shaped plastic nut onto the grouped ends of the wires. A coiled spring (usually) inside tightly grips the bare wires and results in a mechanically and electrically secure joint. For appliance repair, the required WireNuts will almost always already be present since they can usually be reused. If you need to purchase any, they come in various sizes depending on the number and size of the wires that can be handled. It is best to twist the individual conductor strands of each wire together and then twist the wires together slightly before applying the WireNut.

Crimped connectors, called lugs, are very common in small appliances. One reason is that it is easier, faster, and more reliable, to make connections using these lugs with the proper crimping equipment than with solder.

A lug consists of a metal sleeve which gets crimped over one or more wires, an insulating sleeve (usually, not all lugs have these), and a terminal connection: ring, spade, or push-on are typical.

Lugs connect one or more wires to the fixed terminals found on switches, motors, thermostats, and so forth.

There are several varieties:

- Ring lugs - the end looks like an 'O' and must be installed on a threaded terminal of similar size to the opening in the ring. The screw or nut must be removed to replace a ring lug.

- Spade lugs - the end looks like a 'U' and must be installed on a threaded terminal of similar size to the opening in the spade. These can be slipped on and off without entirely removing the screw or nut.

- Push-on lugs - called 'FastOns' by one manufacturer. The push-on terminal makes a tight fit with a (usually) fixed 'flag'. There may also be a latch involved but usually just a pressure fit keeps the connection secure. However, excessive heat over time may weaken these types of connections, resulting in increased resistance, additional heating, and a bad connection or melt-down.

The push-on variety are most common in small appliances.

In the factory, the lugs are installed on the wires with fancy expensive equipment. For replacements, an inexpensive crimping tool and an assortment of lugs will suffice. The crimping tool looks like a pair of long pliers and usually combines a wire stripper and bolt cutter with the crimping function. It should cost about $6-10.

The crimping tool 'squashes' the metal sleeve around the stripped ends of the wires to be joined. A proper crimp will not come apart if an attempt is made to pull the wires free - the wires will break somewhere else first. It is gas-tight - corrosion (within reason) will not affect the connection.

Crimping guidelines:

- Use the proper sized lug. Both the end that accepts the wire(s) and the end that screws or pushes on must be sized correctly. Easiest is to use a replacement that is identical to the original. Where this is not possible, match up the wire size and terminal end as closely as possible. There will be a minimum and maximum total wire cross sectional area that is acceptable for each size. Avoid the temptation to trim individual conductor strands from wires that will not fit - use a larger size lug. Although not really recommended, the bare wires can be doubled over to thicken them for use with a lug that is slightly oversize.

- For heating appliances, use only high temperature lugs. This will assure that the connections do not degrade with repeated temperature cycles.

- Strip the wire(s) so that they fit into the lug with just a bit showing out the other (screw or push-on) end. Too long and your risk interference with the terminals and/or shorting to other terminals. Too short and it is possible that one or more wires will not be properly positioned, will not be properly crimped, and may pull out or make a poor connection. The insulation of the wires should be within the insulating sleeve - there should be no bare wire showing behind the lug.

- Crimp securely but don't use so much force that the insulating sleeve or metal sleeve is severed. Usually 1 or 2 crimps for the actual wire connection and 1 crimp to compress the insulating sleeve will be needed.

- Test the crimp when complete - there should be no detectable movement of the wires. If there is, you didn't crimp hard enough or the lug is too large for your wires.

Wire stripping

In order to make most connections, the plastic or other insulating covering must be removed to expose the bare copper conductors inside. The best way to do this is with a proper wire stripper which is either adjustable or has dedicated positions for each wire size. It is extremely important that the internal conductor (single wire or multiple strands) are undamaged. Nicks or loss of some strands reduces the mechanical and electrical integrity of the connection. In particular, a seriously nicked wire may break off at a later time - requiring an additional repair or resulting in a safety hazard or additional damage. The use of a proper wire stripper will greatly minimize such potential problems.

A pen knife or Xacto knife can be used in a pinch but a wire stripper is really much much easier.

Attaching wires to screw terminals

Screw terminals are often seen in appliances. In most cases, lugs are used to attach one or more wires to each terminal and when properly done, this usually is the best solution. However, in most cases, you can attach the wire(s) directly if a lug is not available:

1. The best mechanical arrangement is to put the wire under a machine screw or nut, lock washer, and flat washer. However, you will often see just the screw or nut (as in a lamp switch or wall socket). For most applications, this is satisfactory.

2. Avoid the temptation to put multiple wires around a single terminal unless you separate each one with a flat washer.

3. Strip enough of the wire to allow the bare wire to be wrapped once around the terminal. To much and some will poke out and might short to something; too little and a firm mechanical joint and electrical connection may be impossible.

4. For multistranded wire, tightly twist the strands of stripped wire together in a clockwise direction as viewed from the wire end.

5. Wrap the stripped end of the wire **clockwise** around the terminal post (screw or stud) so that it will be fully covered by the screw head, nut, or flat washer. This will insure that the wire is grabbed as the screw or nut is tightened. A pair of small needlenose pliers may help.

6. Hold onto the wire to keep it from being sucked in as the screw or nut is tightened. Don't overdo it - you don't need to sheer off the head of the screw to make a secure reliable connection.

7. Inspect the terminal connection: the bare wire should be fully covered by the head of the screw, nut, or flat washer. Gently tug on the wire to confirm that it is securely fastened.

Test equipment

Very little test equipment is needed for most household appliance repair.

First, start with some analytical thinking. Many problems associated with household appliances do not require a schematic. Since the internal wiring of many appliances is so simple, you will be able to create your own by tracing the circuits in any case. However, for more complex appliances, a schematic may be useful as wires may run behind and under other parts and the operation of some custom switches may not obvious. The causes for the majority of problems will be self evident once you gain access to the interior - loose connections or broken wires, bad switches, open heating element, worn motor brushes, dry bearings. All you will need are some basic hand tools, a circuit and continuity tester, light oil and grease, and your powers of observation (and a little experience). Your built in senses and that stuff between your ears represents the most important test equipment you have.

The following will be highly desirable for all but the most obvious problems:

1. Circuit tester (neon light) - This is used to test for AC power or confirm that it is off. For safety, nothing can beat the simplicity of a neon tester. Its use is foolproof as there are no mode settings or range selections to contend with. Touch its two probes to a circuit and if it lights, there is power. (This can also take the place of an Outlet tester but it is not as convenient (see below). Cost: $2-$3.

2. Outlet tester (grounds and miswiring) - This will confirm that a 3 prong outlet is correctly wired with respect to Hot, Neutral, and Ground. While not 100% assured of correct wiring if the test passes, the screwup would need to be quite spectacular. This simple device instantly finds missing Grounds and interchanged Hot and Neutral - the most common wiring mistakes. Just plug it into an outlet and if the proper two neon light are lit at full brightness, the outlet is most likely wired correctly. Cost: about $6.

   These are just a set of 3 neon bulbs+resistors across each pair of wires. If the correct bulbs light at full brightness - H-N, H-G - then the circuit is likely wired correctly. If the H-G light is dim or out or if both the H-G and G-N are dim, then you have no ground. If the N-G light is on and the H-G light is off, you have reversed H and N, etc.

   What it won't catch: Reversed N and G (unlikely unless someone really screwed up) and marginal connections since the neon bulbs doesn't use much current. For this (particularly important for the G since it won't do any good if its resistance back to the service panel is too high) you need a real load like a 100 W light bulb. Or, build a tester consisting of 100 W light bulbs (instead of neon lamps) wired between each of the prongs.

   It also won't distinguish between 110 VAC and 220 VAC circuits except that the neon bulbs will glow much brighter on 220 VAC but without a direct comparison, this could be missed.

   For something that appears to test for everything but next week's weather:

   (From: Bill Harnell (bharne@adss.on.ca).)

   Get an ECOS 7105 tester! (ECOS Electronics Corporation, Oak Park, Illinois, 708-383-2505). Not cheap, however. It sold for $59.95 in 1985 when I purchased somewhere around 600 of them for use by our Customer Engineers for safety purposes!

   It tests for:

   Correct wiring, reversed polarity, open Ground, open Neutral, open Hot, Hot & Ground reversed, Hot on neutral, Hot unwired, other errors, over voltage (130 VAC+), under voltage (105 VAC-), Neutral to Ground short, Neutral to Ground reversal, Ground impedance test (2 Ohms or less ground impedance - in the equipment ground conductor).

   Their less expensive 7106 tester performs almost all of the above tests.

   FWIW, I have no interest in the ECOS Corporation of any kind. Am just a very happy customer.

3. Continuity tester (buzzer or light) - Since most problems with appliances boil down to broken connections, open heating elements, defective switches, shorted wires, and bad motor windings, a continuity tester is all that is needed for most troubleshooting. A simple battery operated buzzer or light bulb quickly identifies problems. If a connection is complete, the buzzer will sound or the light will come on. Note that a dedicated continuity tester is preferred over a similar mode on a multimeter because it will operate only at very low resistance. The buzzer on a multimeter sounds whenever the resistance is less than about 200 ohms - a virtual open circuit for much appliance wiring.

   A continuity tester can be constructed very easily from an Alkaline battery, light bulb or buzzer, some wire, and a set of test leads with probes. All of these parts are available at Radio Shack.

```
                   AA, C, or D cell    1.5 V flashlight bulb or buzzer
                            +|  -             +------------------+
  Test probe 1  o-----------| |--------------|  Bulb or buzzer  |-------+
                             |                +------------------+       |
                                                                         |
```

```
    Test probe 2  o-------------------------------------------------+
```

CAUTION: Do not use this simple continuity tester on electronic equipment as there is a slight possibility that the current provided by the battery will be too high and cause damage. It is fine for most appliances.

4. GFCI tester - outlets installed in potentially wet or outdoor areas should be protected by a Ground Fault Circuit Interrupter (GFCI). A GFCI is now required by the NEC (Code) in most such areas. This tester will confirm that any outlets protected by a GFCI actually will trip the device if there is a fault. It is useful for checking the GFCI (though the test button should do an adequate job of this on its own) as well as identifying or testing any outlets downstream of the GFCI for protection.

   Wire a 3 prong plug with a 15 K ohm 1 W resistor between H and G. Insulate and label it! This should trip a GFCI protected outlet as soon as it is plugged in since it will produce a fault current of about 7 mA.

   Note that this device will only work if there is an actual Safety Ground connection to the outlet being tested. A GFCI retrofitted into a 2 wire installation without a Ground cannot be tested in this way since a GFCI does not create a Ground. However, jumpering this rig between the H and and a suitable earth ground (e.g., a cold water in an all copper plumbing system) should trip the GFCI. Therefore, first use an Outlet Tester (above) to confirm that there is a Safety Ground present.

   The test button works because it passes an additional current through the sense coil between Hot and Neutral tapped off the wiring at the line side of the GFCI and therefore doesn't depend on having a Ground.

   If you want to be fancier, you can build a combination outlet and GFCI tester. Wire up a neon indicator with current limiting resistor) across each pair of wires. Add a 15K ohm 1 W resistor in series with a pushbutton switch between H and G. If the H-G neon is lit (indicating a proper Ground connection), pressing the button should trip the GFCI.

5. Multimeter (VOM or DMM) - This is necessary for actually measuring voltages and resistances. Almost any type will do - even the $14.95 special from Sears. Accuracy is not critical for household appliance repair but reliability is important - for your safety if no other reason. It doesn't really matter whether it is a Digital MultiMeter (DMM) or analog Volt Ohm Meter (VOM). A DMM may be a little more robust should you accidentally put it on an incorrect scale. However, they both serve the same purpose. A cheap DMM is also not necessarily more accurate than a VOM just because it has digits instead of a meter needle. A good quality well insulated set of test leads and probes is essential. What comes with inexpensive multimeters may be too thin or flimsy. Replacements are available. Cost: $15-$50 for a multimeter that is perfectly adequate for home appliance repair.

   Note: For testing of household electrical wiring, a VOM or DMM can indicate voltage between wires which is actually of no consequence. This is due to the very high input resistance/impedance of the instrument. The voltage would read zero with any sort of load. See the section: Phantom voltage measurements of electrical wiring.

Once you get into electronic troubleshooting, an oscilloscope, signal generator, and other advanced (and expensive) test equipment will be useful. For basic appliance repair, such equipment would just gather dust.

Getting inside consumer electronic equipment

Yes, you will void the warranty, but you knew this already.

Appliance manufacturers seem to take great pride in being very mysterious as to how to open their equipment. Not always, but this is too common to just be a coincidence.

A variety of techniques are used to secure the covers on consumer electronic equipment:

1. **Screws:** Yes, many still use this somewhat antiquated technique. Sometimes, there are even embossed arrows on the case indicating which screws need to be removed to get at the guts. In addition to obvious screw holes, there may be some that are only accessible when a battery compartment is opened or a trim panel is popped off.

   These are almost always of the Philips variety though more and more appliances are using Torx or security Torx type screws. Many of these are hybrid types - a slotted screwdriver may also work but the Philips or Torx is a whole lot more convenient.

   A precision jeweler's screwdriver set including miniature Philips head drivers is a must for repair of miniature portable devices.

2. **Hidden screws:** These will require prying up a plug or peeling off a decorative decal. It will be obvious that you were tinkering - it is virtually impossible to put a decal back in an undetectable way. Sometimes the rubber feet can be pryed out revealing screw holes. For a stick-on label, rubbing your finger over it may permit you to locate a hidden screw hole. Just puncture the label to access the screw as this may be less messy then attempting to peel it off.

3. **Snaps:** Look around the seam between the two halves. You may (if you are lucky) see points at which gently (or forcibly) pressing with a screwdriver will unlock the covers. Sometimes, just going around the seam with a butter knife will pop the cover at one location which will then reveal the locations of the other snaps.

4. **Glue:** Or more likely, the plastic is fused together. This is particularly common with AC adapters (wall warts). In this case, I usually carefully go around the seam with a hacksaw blade taking extreme care not to go through and damage internal components. Reassemble with plastic electrical tape.

5. It isn't designed for repair. Don't laugh. I feel we will see more and more of this in our disposable society. Some devices are totally potted in Epoxy and are 'throwaways'. With others, the only way to open them non-destructively is from the inside.

Don't force anything unless you are sure there is no alternative - most of the time, once you determine the method of fastening, covers will come apart easily. If they get hung up, there may be an undetected screw or snap still in place. However, sometimes it is just impossible (by design) to disassemble an appliance without doing some damage. That's life (and aids the manufacturer's bottom line!).

When reinstalling the screws, first turn them in a counter-clockwise direction with very slight pressure. You will feel them "click" as they fall into the already formed threads. Gently turn clockwise and see if they turn easily. If they do not, you haven't hit the previously formed threads - try again. Then just run them in as you normally would. You can always tell when you have them into the formed threads because they turn very easily for nearly the entire depth. Otherwise, you will create new threads which will quickly chew up the soft plastic. Note: these are often high pitch screws - one turn is more than one thread - and the threads are not all equal.

The most annoying (to be polite) situation is when after removing the 18 screws holding the case together (losing 3 of them entirely and mangling the heads on 2 others), removing three subassemblies, and two other circuit boards, you find that the adjustment you wanted was accessible through a hole in the case just by partially peeling back a rubber hand grip! (It has happened to me).

When reassembling the equipment make sure to route cables and other wiring such that they will not get pinched or snagged and possibly broken or have their insulation nicked or pierced and that they will not get caught in moving parts. This is particularly critical for AC line operated appliances and those with motors to minimize fire and shock hazard and future damage to the device itself. Replace any cable ties that were cut or removed during disassembly and add additional ones of your own if needed. Some electrical tape may sometimes come in handy to provide insulation insurance as well. As long as it does not get in the way, additional layers of tape will not hurt and can provide some added insurance against future problems. I often put a layer of electrical tape around connections joined with WireNuts(tm) as well just to be sure that they will not come off or that any exposed wire will not short to anything.

Getting built up dust and dirt out of a equipment

This should be the first step in any inspection and cleaning procedure.

Appliances containing fans or blowers seem to be dust magnets - an incredible amount of disgusting fluffy stuff can build up in a short time - even with built-in filters.

Use a soft brush (like a new cheap paint brush) to remove as much dirt, dust, and crud, as possible without disturbing anything excessively. Some gentle blowing (but no high pressure air) may be helpful in dislodged hard to get at dirt - but wear a dust mask.

Don't use compressed air on intricate mechanisms, however, as it might dislodge dirt and dust which may then settle on lubricated parts and contaminating them. High pressure air could move oil or grease from where it is to where it should not be. If you are talking about a shop air line, the pressure may be much much too high and there may be contaminants as well.

A Q-tip (cotton swab) moistened with politically correct alcohol can be used to remove dust and dirt from various hard to get at surfaces.

Lubrication of appliances and electronic equipment

The short recommendation is: Don't add any oil or grease unless you are positively sure it is needed. Most parts are lubricated at the factory and do not need any further lubrication over their lifetime. Too much lubrication is worse then too little. It is easy to add a drop of oil but difficult and time consuming to restore a tape deck that has taken a swim.

NEVER, ever, use WD40! WD40 is not a good lubricant despite the claims on the label. Legend has it that the WD stands for Water Displacer - which is one of the functions of WD40 when used to coat tools for rust prevention. WD40 is much too thin to do any good as a general lubricant and will quickly collect dirt and dry up. It is also quite flammable and a pretty good solvent - there is no telling what will be affected by this.

A light machine oil like electric motor or sewing machine oil should be used for gear or wheel shafts. A plastic safe grease like silicone grease or Molylube is suitable for gears, cams, or mechanical (piano key) type mode selectors. Never use oil or grease on electrical contacts.

One should also NOT use a detergent oil. This includes most automotive engine oils which also have multiple additives which are not needed and are undesirable for non-internal combustion engine applications.

3-In-One(tm) isn't too bad if that is all you have on hand and the future of the universe depends on your fan running smoothly. However, for things that don't get a lot of use, it may gum up over time. I don't know whether it actually decomposes or just the lighter fractions (of the 3) evaporate.

Unless the unit was not properly lubricated at the factory (which is quite possible), don't add any unless your inspection reveals the specific need. Sometimes you will find a dry bearing, motor, lever, or gear shaft. If possible, disassemble and clean out the old lubricant before adding fresh oil or grease.

Note that in most cases, oil is for plain bearings (not ball or roller) and pivots while grease is used on sliding parts and gear teeth.

In general, do not lubricate anything unless you know there is a need. Never 'shotgun' a problem by lubricating everything in sight! You might as well literally use a shotgun on the equipment!

Common appliance problems

Despite the wide variety of appliances and uses to which they are put, the vast majority of problems are going to be covered in the following short list:

1. Broken wiring inside cordset - internal breaks in the conductors of cordsets or other connecting cords caused by flexing, pulling, or other long term abuse. This is one of the most common problem with vacuum cleaners which tend to be dragged around by their tails.

   Testing: If the problem is intermittent, (or even if it is not), plug the appliance in and turn it on. Then try bending or pushing the wire toward the plug or appliance connector end to see if you can make the internal conductors touch at least momentarily. Ii the cordset is removable, test between ends with a continuity checker or multimeter on the low ohms scale. If it is not detachable, open the appliance to perform this test.

2. Bad internal connections - broken wires, corroded or loosened terminals. Wires may break from vibration, corrosion, poor manufacturing, as well as thermal fatigue. The break may be in a heating element or other subassembly. In many cases, failure will be total as in when one of the AC line connections falls off. At other times, operation will be intermittent or erratic - or parts of the appliance will not function. For example, with a blow dryer, the heating element could open up but the fan may continue to run properly.

   Testing: In many cases, a visual inspection with some careful flexing and prodding will reveal the location of the bad connection. If it is an intermittent, this may need to be done with a well insulated stick while the appliance is on and running (or attempting to run). When all else fails, the use of a continuity checker or multimeter on the low ohms scale can identify broken connections which are not obviously wires visibly broken in two. For testing heating elements, use the multimeter as a continuity checker may not be sensitive enough since the element normally has some resistance.

3. Short circuits. While much less frequent than broken or intermittent connections, two wires touching or contacting the metal case of an appliance happens all too often. Partially, this is due to the shoddy manufacturing quality of many small appliances like toaster ovens. These also have metal (mostly) cabinets and many metal interior parts with sharp edges which can readily eat through wire insulation due to repeated vibrations, heating and cooling cycles, and the like. Many appliances are apparently designed by engineers (this is being generous) who do not have any idea of how to build or repair them. Thus, final assembly, for example, must sometimes be done blind - the wires get stuffed in and covers fastened - which may end up nicking or pinching wires between sharp metal parts. The appliance passes the final inspection and tests but fails down the road.

   A short circuit may develop with no operational problems - but the case of the appliance will be electrically 'hot'. This is a dangerous situation. Large appliances with 3 wire plugs - plugged into a properly grounded 3 wire circuit - would then blow a fuse or trip a circuit breaker. However, small appliances like toaster, broilers, irons, etc., have two wire plugs and will just set there with a live cabinet.

   Testing: Visually inspect for bare wires or wires with frayed or worn insulation touching metal parts, terminals they should not be connected to, or other wires. Use a multimeter on the high ohms scale to check between both prongs of the AC plug and any exposed metal parts. Try all positions of any power or selector switches. Any resistance measurement less than 100K ohms or so is cause for concern - and further checking. Also test between internal terminals and wires that should not be connected together.

   Too many people like to blame everything from blown light bulbs to strange noises on short circuits. A 'slight', slow, or marginal short circuit is extremely rare. Most short circuits in electrical wiring between live and neutral or ground (as opposed to inside appliances where other paths are possible) will blow a fuse or trip a breaker. Bad connections (grounds, neutral, live), on the other hand, are much much more common.

4. Worn, dirty, or broken switches or thermostat contacts. These will result in erratic or no action when the switch is flipped or thermostat knob is turned. In many cases, the part will feel bad - it won't have that 'click' it had when new or may be hard to turn or flip. Often, however, operation will just be erratic - jiggling the switch or knob will make the motor or light go on or off, for example.

   Testing: Where there is a changed feel to the switch or thermostat with an associated operational problem, there is little doubt that the part is bad and must be replaced. Where this is not the case, label the connections to the switch or thermostat and then remove the wires. Use the continuity checker or ohmmeter across each set of contacts. They should be 0 ohms or open depending on the position of the switch or knob and nothing in between. In most cases, you should be able to obtain both readings. The exception is with respect to thermostats where room temperature is off one end of their range. Inability to make the contacts open or close (except as noted above) or erratic intermediate resistances which are affected by tapping or jiggling are a sure sign of a bad set of contacts.

5. Gummed up lubrication, or worn or dry bearings. Most modern appliances with motors are supposedly lubricated for life. Don't believe it! Often, due to environmental conditions (dust, dirt, humidity) or just poor quality control during manufacture (they forgot the oil), a motor or fan bearing will gum up or become dry resulting in sluggish and/or noisy operation and overheating. In extreme cases, the bearing may seize resulting in a totally stopped motor. If not detected, this may result in a blown fuse (at the least) and possibly a burnt out motor from the overheating.

   Testing: If the appliance does not run but there is a hum (AC line operated appliances) or runs sluggishly or with less power than you recall when new, lubrication problems are likely. With the appliance unplugged, check for free rotation of the motor(s). In general, the shaft sticking out of the motor itself should turn freely with very little resistance. If it is difficult to turn, the motor bearings themselves may need attention or the mechanism attached to the motor may be filled with crud. In most cases, a thorough cleaning to remove all the old dried up and contaminated oil or grease followed by relubing with similar oil or grease as appropriate will return the appliance to good health. Don't skimp on the disassembly - total cleaning will be best. Even the motor should be carefully removed and broken down to its component parts - end plates, rotor, stator, brushes (if any) in order to properly clean and lubricate its bearings. See the appropriate section of the chapter: Motors 101 for the motor type in your appliance.

6. Broken or worn drive belts or gears - rotating parts do not rotate or turn slowly or with little power even through the motor is revving its little head off. When the brush drive belt in an upright vacuum cleaner breaks, the results are obvious and the broken belt often falls to the ground (to be eaten by the dog or mistaken for a mouse tail - Eeek!) However, there are often other belts inside appliances which will result in less obvious consequences when they loosen with age or fail completely.

   Testing: Except for the case of a vacuum cleaner where the belt is readily accessible, open the appliance (unplugged!). A good rubber belt will be perfectly elastic and will return to its relaxed length instantly when stretched by 25 percent and let go. It will not be cracked, shiny, hard, or brittle. A V-type belt should be dry (no oil coating), undamaged (not cracked, brittle, or frayed), and tight (it should deflect 1/4" to 1/2" when pressed firmly halfway between the pulleys).

   Sometimes all that is needed is a thorough cleaning with soap and water to remove accumulated oil or grease. However, replacement will be required for most of these symptoms. Belts are readily available and an exact match is rarely essential.

7. Broken parts - plastic or metal castings, linkages, washers, and other 'doodads' are often not constructed quite the way they used to be. When any of these fail, they can bring a complicated appliance to its knees. Failure may be caused by normal wear and tear, improper use (you tried to vacuum nuts and bolts just like on TV), accidents (why

was your 3 year old using the toaster oven as a step stool?), or shoddy manufacturing.

Testing: In many cases, the problem will be obvious. Where it is not, some careful detective work - putting the various mechanisms through their paces - should reveal what is not functioning. Although replacement parts may be available, you can be sure that their cost will be excessive and improvisation may ultimately be the best approach to repair. See the section: Fil's tips on improvised parts repair.

8. Insect damage. Many appliance make inviting homes for all sort of multi- legged creatures. Evidence of their visits or extended stays will be obvious including frayed insulation, short circuits caused by bodily fluids or entire bodies, remains of food and droppings. Even the smallest ventilation hole can be a front door.

   The result may be any of the items listed in (1) to (7) above. Once the actual contamination has been removed and the area cleaned thoroughly, inspect for damage and repair as needed. If the appliance failed while powered, you may also have damage to wiring or electronic components due to any short circuits that were created by the intruders' activities.

- Back to Small Appliances and Power Tools Repair FAQ Table of Contents.

Types of Parts Found in Small Appliances

So many, so few

While there are an almost unlimited variety of small appliances and power tools, they are nearly all constructed from under two dozen basic types of parts. And, even with these, there is a lot of overlap.

The following types of parts are found in line powered appliances:

- Cordsets - wire and plug.
- Internal wiring - cables and connectors.
- Switches - power, mode, or speed selection.
- Relays - electrically activated switches for power or control.
- Electrical overload protection devices - fuses and circuit breakers.
- Thermal protection devices - thermal fuses and thermal switches.
- Controls 1 - adjustable thermostats and humidistats.
- Controls 2 - rheostats and potentiometers.
- Interlocks - prevent operation with case or door open.
- Light bulbs - incandescent and fluorescent.
- Indicators - incandescent or neon light bulbs or LEDs.
- Heating elements - NiChrome coils or ribbon, Calrod, Quartz.
- Solenoids - small and large.
- Small electronic components - resistors, capacitors, diodes.
- Transformers - low voltage, high voltage.
- Motors - universal, induction, DC, timing.
- Fans and Blowers - bladed or centrifugal.
- Bearings and bushings.
- Mechanical controllers - timing motors and cam switches.
- Electronic controllers - simple delay or microprocessor based.

Battery and AC adapter powered appliance use most of the same types of parts but they tend to be smaller and lower power than their line powered counterparts. For example, motors in line powered devices tend to be larger, more powerful, and of different design (universal or induction compared to permanent magnet DC type). So, we add the following:

- Batteries - Alkaline, Lithium, Nickel-Cadmium, Lead-acid.
- AC adapters and chargers - wall 'warts' with AC or DC outputs.

The only major category of devices that these parts do not cover are gas discharge lamps and lighting fixtures (fluorescent, neon, mercury, and sodium), which we will discuss in a separate chapters.

Cordsets - wire and plug

A 'cordset' is a combination of the cord consisting of 2 or 3 insulated wires and a plug with 2 or 3 prongs. Cord length varies from 12 inches (or less) for some appliances like toasters to 25 feet or more for vacuum cleaners. Most common length is 6-8 feet. The size of the wire and type of insulation also are important in matching a replacement cordset to an appliance.

CAUTION: Some cordsets are more than what meets the eye. See the section: When a cordset is more than a cord and plug.

Most plug-in appliances in the U.S. will have one of 3 types of line cord/plug combinations:

1. **Non-polarized 2 prong:** The 2 prongs are of equal width so the plug may be inserted in either direction. These are almost universal on older appliances but may be found on modern appliances as well which are double insulated or where polarity does not matter. (Note: it **must** not matter for user safety in any case. The only time it can matter otherwise is with respect to (1) possible RFI (Radio Frequency Interference) generation or (2) service safety (this would put the center contact of a light bulb socket or internal switch and fuse on the Hot wire).

2. **Polarized 2 prong:** The prong that is supposed to be plugged into the Neutral slot of the outlet is wider. All outlets since sometime around the 1950s (???) have been constructed to accept polarized plugs only one way. While no appliance should ever be designed where the way it is plugged in can result in a user safety hazard, a lamp socket where the shell - the screw thread part - is plugged into Neutral is less hazardous when changing a light bulb. In addition, when servicing a small appliance with the cover removed, the Hot wire with a polarized plug should go to the switch and fuse and thus most of the circuitry will be disconnected with the switch off or fuse pulled.

   Thus, if you are replacing a plug and don't know (or didn't label) how the old one was hooked up, the narrow prong should go to the fuse, switch, thermostat or other control, center of the socket, etc. Since you may have trouble finding non-polarized plugs these days, this applies to older appliances as well and there is really no problem in replacing a non-polarized plug with a polarized one on an appliance.

3. **Grounded 3 prong:** In addition to Hot and Neutral, a third grounding prong is provided to connect the case of the equipment to safety Ground. This provides added protection should internal wiring accidentally short to a user accessible metal cabinet or control. In this situation, the short circuit will (or is supposed to) blow a fuse or trip a circuit breaker or GFCI rather than present a shock hazard. DO NOT just cut off the third prong if your outlet does not have a hole for it. Have the outlet replaced with a properly grounded one (which may require pulling a new wire from the service panel). As a short term solution, the use of a '3 to 2' prong adapter is acceptable IF AND ONLY IF the outlet box is securely connected to safety Ground already (BX or Romex cable with ground). Grounding also is essential for surge suppressors to operate properly (to the extent that they ever do) and may reduce RFI susceptibility and emissions if line filters are included (as with computer equipment and consumer electronics). Power conditioners require the Ground connection for line filtering as well.

Each of these may be light duty (less than 5 Amps or 600 Watts), medium duty (8 A or 1000 W) or heavy duty (up to 15 A or 1800 W). The rating is usually required to be stamped on the cord itself or on a label attached to the cord. Thickness of the cord is not a reliable indication of its power rating! (Note: U.S. 115 VAC 15 amp circuits are assumed throughout this document unless otherwise noted.)

Light duty cordsets are acceptable for most appliances without high power heating elements or heavy duty electric motors. These include table lamps, TVs, VCRs, stereo components, computers, dot matrix and inkjet printers, thermal fax machines, monitors, fans, can openers, etc. Electric blankets, heating pads, electric brooms, and food mixers are also low power and light duty cordsets are acceptable. The internal wires used is #18 AWG which is the minimum acceptable wire size (highest AWG number) for any AC line powered device.

Medium or heavy duty cordsets are REQUIRED for heating appliances like electric heaters (both radiant and convection), toasters, broilers, steam and dry irons, coffee makers and electric kettles, microwave and convection ovens, laser printers, photocopiers, Xerographic based fax machines, canister and upright vacuum cleaners and shop vacs, floor polishers, many portable and most stationary power tools. The internal wires used will be #16 AWG (medium duty) or #14 AWG (heavy duty).

For replacement, always check the nameplate amps or wattage rating and use a cordset which has a capacity at least equal to this. The use of an inadequate cordset represents a serious fire hazard.

Three prong grounded cordsets are required for most computer equipment, heavy appliances, and anything which is not double insulated and has metal parts that may be touched in normal operation (i.e., without disassembly).

The individual wires in all cordsets except for unpolarized types (e.g., older lamp cord) will be identified in some way. For sheathed cables, color coding is used. Generally, in keeping with the NEC (Code), black will be Hot, white will be Neutral, and green will be Safety Ground. You may also find brown for Hot, blue for Neutral, and green with a yellow stripe for Safety Ground. This is used internationally and is quite common for the cordsets of appliances and electronic equipment.

For zip cord with a polarized plug, one of the wires will be tagged with with a colored thread or a ridge on the outer insulation to indicate that it is the Neutral wire. For unpolarized types, no identification is needed (though there still may be some) as the wires and prongs of the plug are identical. However, fewer and fewer devices use non-polarized cords/plugs now so you are more likely to see this with older ones.

In general, when replacement is needed, use the same configuration and length and a heavy duty type if the original was heavy duty.

- Substituting a heavy duty cordset for a light duty one is acceptable as long as the additional stiffness is acceptable in terms of convenience.

- A shorter cord can usually be used if desired. In most cases, a longer cord (within reason) can be substituted as well. However, performance of heavy duty high current high wattage appliances may suffer if a really long cord (or extension cord) is used voltage drop from the wire resistance. For a modest increase in length, use the next larger wire size (heavy duty instead of medium duty, #14 instead of #16, for example).

- Where the old one was non-polarized, a polarized replacement is fine and usually preferred, for example, if:

    - It is an incandescent fixture. Connect the Neutral (wide prong/ridged wire) to the shells of the light bulb sockets.

    - It has an on/off switch or fuse in-line with the power. Connect the Hot wire to that side of the input.

    - There is a high value resistor and/or capacitor network between one side of the line and the case (for RFI suppression). Connect this to the Neutral.

  If the input is completely symmetric (e.g., it goes into a power transformer and no where else), then the polarity doesn't matter.

Before disconnecting the old cord, label connections or make a diagram and then match the color code or other wire identifying information. In all cases, it is best to confirm your final wiring with a continuity tester or multimeter on the low ohms scale. Mistakes on your part or the manufacturer of the new cord are not unheard of!

Common problems: internal wiring conductors broken at flex points (appliance or plug). With yard tools, cutting the entire cord is common. The connections at the plug may corrode as well resulting in heating or a broken connection.

Testing: Appliance cordsets can always be tested with a continuity checker or multimeter on a the low ohms scale.

Squeeze, press, spindle, fold, mutilate the cord particularly at both ends as while testing to locate intermittent problems.

If you are too lazy to open the appliance (or this requires the removal of 29 screws), an induction type of tester such as used to locate breaks in Christmas tree light strings can be used to confirm continuity by plugging the cord in both ways and checked along its length to see if a point of discontinuity can be located. A permanent bench setup with a pair of outlets (one wired with reverse polarity and clearly marked: FOR TESTING ONLY) can be provided to facilitate connecting to either of the wires of the cordset when using an induction type tester.

Note: broken wires inside the cordset at either the plug or appliance end are among the most common causes of a dead vacuum cleaner due to abuse it gets - being tugged from the outlet, vacuum being dragged around by the cord, etc. Many other types of appliances suffer the same fate. Therefore, checking the cord and plug should be the first step in troubleshooting any dead appliance.

If the cord is broken at the plug end, the easiest thing to do is to replace just the plug. A wide variety of replacement plugs are available of three basic types: clamp-on/insulation piercing, screw terminals, and wire compression.

- Clamp-on/insulation piercing plugs are installed as follows: First, the cord is cleanly cut but not stripped and inserted into the body of the plug. A lid or clamping bar is then closed which internally pierces the insulation and makes contact with the prongs. When used with the proper size wire, these are fairly reliable for light duty use - table lamps and other low power appliances. However, they can lead to problems of intermittent or bad connections if the wire insulation thickness does not precisely match what the plug expects.

- Plugs with screw terminals make a much more secure robust connections but require a bit more time and care in assembly to assure a proper connection and avoid stray wire strands causing short circuits or sticking out and representing a shock hazard. Tightly twist the strands of the stripped wire together before wrapping around the screw in a clockwise direction before tightening. Don't forget to install the fiber insulator that is usually supplied with the plug.

- The best plugs have wire clamp terminals. The stripped end of the wire is inserted into a hole and a screw is tightened to clamp the wire in place. Usually, a molded plastic cover is then screwed over this assembly and includes a strain relief as well. These are nearly foolproof and consequently are used in the most demanding industrial and medical applications. They are, not surprisingly, also typically the most expensive.

Where damage is present at the appliance end of the cord, it may be possible to just cut off the bad portion and reinstall what remains inside of the appliance. As long as this is long enough and a means can be provided for adequate strain relief, this is an acceptable alternative to replacement of the entire cordset.

When a cordset is more than a cord and plug

While most appliances use normal cordsets, some, especially an increasing number of newer ones include various circuitry in the plug itself:

- Sometimes, the plugs themselves include built-in fuses which if blown, might result in an incorrect diagnosis of a bad cordset. And, replacing the cordset with a normal one would result in the loss of the prtection provided by the fuses.

- A variety of electronic equipment as well as rechargeable (and other) appliances now use switching power supply type wall adapters rather than the usual bulky, heavy wall transformer. These weigh almost nothing and are only slighly larger than a normal wall plug. However, they are an essential part of the unit since the AC line voltage is converted into a lower DC voltage inside the oversize plug! These are functionally equivalent to the more common type (probably better in fact in terms of regulation and efficiency) and both provide the essential line isolation required for safety. Neither the entire cordset nor the plug can be cut off and replaced. An exact replacement for that particular model must be installed.

- Some appliances include either a Ground Fault Circuit Interrupter (GFCI) or what I call a GFCK (Ground Fault Circuit Killer) in an oversize plug. These provide protection from shock for items like hair dryers that might contact or be dropped into water. A GFCI can be reset once the fault condition is removed (it is unplugged and dried out). A GFCK is a one time circuit breaker type device. If it is activated, the appliance will need to be repaired to reset it (which may not be worth the cost since it will require replacement of the special GFCK cordset). While the appliance will still work if the special plug or the entire cordset is replaced with a normal one, the protection will be lost and it should then ONLY be used in a GFCI protected outlet. See the sections: "What is a GFCI?" and "The Ground Fault Circuit Killer (GFCK)".

Appliance cord gets hot

This applies to all high current appliances, not just space heaters though these are most likely to be afflicted since they are likely to be run for extended periods of time.

Of course, if the problem is with an *extension* cord, then either it is overloaded or defective. In either case, the solution should be obvious.

Some cords will run warm just by design (or cheapness in design using undersized conductors).

However, if it is gets hot during use, this is a potential fire hazard.

If it is hot mainly at the plug end - get a heavy duty replacement plug - one designed for high current appliances using screw terminals - at a hardware store, home center, or electrical supply house. Cut the cord back a couple of inches.

If the entire cord gets warm, this is not unusual with a heater. If it gets really hot, the entire cord should be replaced. Sometimes with really old appliance, the copper wires in the cord oxidize even through the rubber insulation reducing their cross section and increasing resistance. This leads to excessive power dissipation in the cord. Replacement *heavy duty* cordsets are readily available.

Note that just because the cord itself gets warm does NOT mean that the wiring in the walls is heating significantly. The smallest allowable wiring size inside the walls is #14 which has a resistance of about 2.5 ohms per thousand feet. An appliance drawing 10 A through 50 feet of cable (100 total feet of wire going both ways) would result in a 2.5 V drop and 25 W dissipation. But since this is distributed over 50 feet of cable, heating in any location is minimal.

Extension cords

We treat extension cords too casually - abusing them and using underrated extension cords with heavy duty appliances. Both of these are serious fire and shock hazards. In addition, the use of a long inadequate extension will result in reduced voltage due to resistive losses at the far end. The appliance may not work at full capacity and in some cases may even be damaged by this reduced voltage.

Extension cord rules of use:

- The capacity must be at least equal to the SUM of the wattages or amperages of all the appliances plugged in at the far end. Larger is fine as well and is desirable for long extensions. Check the rating marked on the cord or a label attached to the cord. Thickness of the outside of the cord is not a reliable indication of power rating.

- Use a type which is the most restrictive of any appliances that will be plugged in (e.g., 3 prong if any are of this type, 2 prong polarized otherwise unless your outlets are non-polarized (old dwellings).

- Use only outdoor type extension cords (usually colored yellow or orange) outdoors if there is ANY chance of dampness or moisture contacting them. These are water proof (well, at least, water resistent). One should, of course, avoid working with electricity under wet conditions in any case!

- Use only as long an extension as required. For very long runs, use a higher capacity extension even if the power requirements are modest.

- NEVER run extensions under carpeting as damage is likely and this will go undetected. Never run extensions inside walls. Add new outlets where needed with properly installed building wire (Romex). This must be done in such a way that it meets the National Electric Code (NEC) in your area. It may need to be inspected if for no other reason than to guarantee that your homeowner's insurance won't give you a hard time should any 'problems' arise. Surface mount outlets and conduit are available to extend the reach of existing outlets with minimal construction if adding new ones is difficult or too costly.

- Don't use heavy duty extensions as a long term solution if possible. Similarly, don't use extensions with 'octopus' connections - install an outlet strip.

Extension cords of any type, capacity, and length can be easily constructed from components and wire sold at most hardware stores and home centers. This is rarely economical for light duty polarized types as these are readily available and very inexpensive. However, for heavy duty 3 prong extensions, a custom constructed one is likely to save money especially if an unusual length is required. Making up a heavy duty extension with a 'quad' electrical box with a pair of 15 amp duplex outlets is a very rugged convenient alternative to a simple 3 prong socket.

Common problems: internal wiring conductors broken at flex points (socket or plug). With yard tools, cutting the entire cord is common. The connections at the plug may corrode as well resulting in heating or a bad or intermittent connection.

Testing: Extension cords can always be tested with a continuity checker or multimeter on a the low ohms scale.

Extension cord repair

- For a $1 light duty extension cord, repair is generally not worth the effort. However, if you insist, a new plug or socket can be installed at the cut end.

- Where a heavy duty extension has been cut near one end (e.g., by an electric hedge clipper or lawn mower - usually the socket end), purchase a proper plug or socket designed for outdoor use (if appropriate) and attach it to the cut end. If both sections are long enough, you can make up two shorter extensions. There, now you have two extension cords where there was only one before. :-)

- I do NOT recommend splicing damaged or broken wires except possibly as a temporary measure. In that case, the wires should be reattached by soldering or with the use of solderless or crimp connectors and then thoroughly insulated and reinforced with multiple layers of plastic electrical tape to assure both the electrical and physical integrity.

Determining the location of a break in an extension cord

This isn't worth the time it would take to describe for a $.99 6 foot K-Mart special but it might make sense for a 100 foot heavy duty outdoor type. If the problem is near one end, a couple of feet can be cut off and a new plug or socket installed. If more towards the middle, the wires can be cut and spliced or two smaller cords could be made from the pieces.

But, how do you locate the break?

- Use a Time Domain Reflectometer (TDR). Oops, don't have one? And, you probably don't even know what this means! (Basically, a TDR sends a pulse down a wire and measures how long it takes for a reflected pulse to return from any discontinuities. The delay is a measure of distance.) Don't worry, there are alternatives that cost less than $20,000. :-)

- If there is no obvious damage - you didn't attempt to mow the cord by accident - the most likely location is at the end where the plug of socket strain relief joins the wire. Squeezing, squishing, pushing, etc., with the cord plugged into a live outlet and lamp or radio plugged into the other end may reveal the location by a momentary flash or blast of sound.

- Try a binary search with a probe attached to a straight pin. This works best with a cord where the wires are easily located - not the round double insulated type. Attach one probe of your multimeter to the prong of the plug attached to the broken wire. Start at the middle with your pin probe. If there is continuity move half the distance to the far end. If it is open, move half the distance toward near end. Then 1/4, 1/8, and so forth. It won't take long to located the break this way. Of course, there will be pin holes in the insulation so this is not recommeded for outdoor extension cords unless the holes are sealed.

- You may be able to use one of those gadgets for testing Christmas Tree light sets - these inexpensive devices sense the AC field in proximity to its probe. Plug the cord in so that the Hot of your AC line is connected to one of the wires you know is broken (from testing with an ohmmeter) and run the device along the cord until the light changes intensity.

  This also works for appliance cords where you are too lazy to go inside to check continuity. You may need to try both wires in the cord to locate the broken one.

- If you have a capacitance meter (or a DMM with a capacitance range), measure the capacitance between the bad wire and the other two wires at both ends. The ratio of capacitances will correspond to the ratio of distances of good wire and so will tell you approximately where the break is located.

- If you have some real test equipment (but not a TDR!) attach the output of a frequency generator to the prong of the plug for the wire you know is broken. Use an oscilloscope as a sensor - run the probe along the cord until the detected signal abruptly drops in intensity. You may need to ground the good wires to prevent them from picking up the signal and propagating it past the break.

  An AM or multiband radio may also be suitable as a detector.

Internal wiring - cables and connectors

Wiring isn't super glamorous but represents the essential network of roads that interconnect all of the appliance's internal parts and links it to the outside world.

Inside the appliance, individual wires (often multicolored to help identify function) or cables (groups of wires combined together in a single sheath or bundle) route power and control signals to the various components. Most are insulated with plastic or rubber coverings but occasionally you will find bare, tinned (solder coated), or plated copper wires. In high temperature appliances like space heaters and toasters, the insulation (if present) will be asbestos (older) or fiberglass. (Rigid uninsulated wires are also commonly found in such applications.) Particles flaking off from either of these materials are a health hazard if you come in contact, inhale, or ingest them. They are also quite fragile and susceptible to damage which may compromise their insulating properties so take care to avoid excessive flexing or repositioning of wires with this type of insulation. Fiberglass insulation is generally loose fitting and looks like woven fabric. Asbestos is light colored, soft, and powdery.

Color coding will often be used to make keeping track of the wires easier and to indicate function. However, there is no standard except for the input AC line. Generally, black will be used for Hot, white will be used for Neutral, and green or uninsulated wire will be used for Safety Ground. While this is part of the NEC (Code) for electrical wiring (in the U.S.), it is not always followed inside appliances. You may also find brown for Hot, blue for Neutral, and green with a yellow stripe for Safety Ground. This is used internationally and is quite common for the cordsets of appliances and electronic equipment.

Where a non-polarized plug (cordset) is used, either AC wire can be Hot and both wires will typically (but not always) be the same color.

Other colors may be used for switched Hot (e.g., red), thermostat control, motor start, solenoid 1, etc. Various combinations of colored stripes may be used as well. Unfortunately, in some cases, you will find that all the wiring is the same color and tracing the circuit becomes a pain in the you-know-what.

Where multiple wires need to go from point A to point B along the same path, they will often be combined into a single cable which is bundled using nylon or cloth tie-wraps or run inside a single large flexible plastic sheath. For electronic interconnects and low voltage control and signal wiring, molded flat cables are common (like those for the cables to the diskette and hard drives of your PC). These are quite reliable and can be manufactured at low cost by fully automatic machines.

The thickness of the insulation of a wire or cable is not a reliable indication of its capacity or voltage rating. A fat wire may actually have a very skinny central conductor and vice-versa. In some cases, the wire conductor size and voltage rating will be printed on the insulation but this not that common. If replacement is needed, this information will be essential. However, the ampacity (maximum current) can be determined from the size of the metal conductor and for any of the line powered appliances discussed in this document, wire with a 600 V rating should be more than adequate.

The type of insulation is critical in appliances that generate heat - including table lamps and other lighting fixtures. There is special high temperature insulated wire (fixture wire) which should be used when replacement is needed. For heating appliances like toasters, hair dryers, and deep friers, fiberglass or high temperature silicone based rubber insulated wire or insulating sleeves must be used should the original wiring need replacement. An appliance repair motor rebuilding shop would be the most likely source - common electronics distributors may not carry this stuff (especially if you only need a couple feet)!

Connections between individual wires and between individual wires and other components are most often made by crimp or screw terminals, welding, or press-in contacts. For cables, actual multipin and socket connectors may be used.

Common problems: internal wiring conductors broken, corroded, or deteriorated due to heat or moisture. Dirty, corroded, weakened, or damaged connector contacts are common requiring cleaning and reseating or replacement. Damage to insulation from vibration, heat, movement, or even improper manufacture or design is also possible. Careless reassembly during a previous repair could result in pinched broken wires or insulation as well as short circuits between wires, or wiring and sharp sheet metal parts.

Testing: Inspect for obvious breaks or wires that have pulled out of their terminations. Integrity of wiring can be determined with a continuity checker or multimeter on a the low ohms scale. Flexing and wiggling wires especially at connections while observing the meter will identify intermittents.

Switches - power, mode, or speed selection

Most appliances have at least one switch to turn the appliance on and off. In some cases, this may be combined with a thermostat or other control. However, switches serve a variety of functions as well.

- Power - Nearly all appliances that run on AC directly (no wall transformer) provide some means of completely disconnecting at least one side of the AC line when not in use. This may be a rocker, slide, push-push, trigger, toggle, rotary, or other separate switch. It may also be combined with another function like a speed control or thermostat.

- Selector, mode, function - these switches may be used to determine speed in a mixer or blender, or the heat or air-only setting on a blow-dryer, for example.

- Internal (not user accessible) - these perform functions like detecting the position of a mechanism (e.g., limit switch), cam operated timing, and other similar operations that are not directly performed by the user.

In all cases, the function of a switch is the same - to physically make (on) or break (off) the circuit or connect one signal to another.

- The most common type of switches have a set of metallic contacts (special materials to resist arcing and corrosion) which are brought together as a result of mechanical motion of a rocker, lever, etc. to complete the circuit There is usually some sort of snap action to assure rapid make and break of the circuit to minimize deterioration due to arcing.

- Mercury switches - found in thermostats, silent wall switches, and a variety of other places, use a small quantity of mercury (a metal which is a liquid at room temperature) to complete the circuit. Depending on the orientation of a glass or metal/insulator capsule, the mercury either contacts a set of terminals (on) or is separate from them (off). Since any arcing occurs in the liquid mercury, there is virtually no deterioration of internal parts of a mercury switch. Life is nearly infinite when used within its ratings. See the section: About mercury wall switches.

Common problems with switches include: dirt, worn, or melted contacts, broken plastic or fiber parts, bad connections to terminals.

Testing: Switches can always be tested with a continuity checker or a multimeter on a low ohms scale.

WARNING: Mercury is a heavy metal and is poisonous. I know it is fun to play with beads and globs of the stuff (and I have done it) but do not recommend it, at least not on a daily basis. Dispose of any from broken mercury switches or thermometers safely. If you insist on keeping it, use a piece of paper as a scoop and put the mercury in a bottle with a tightly sealed cap. See the section: Comments on mercury poisoning.

About mercury wall switches

The types of mercury switches used for wall switches are quite clever and provide in effect a snap action (called hysteresis) due to their construction and the surface tension of the liquid mercury itself. This despite the fact that the motion of the toggle lever is totally smooth and silent. It is not possible to put the lever in such a position that there could be marginal contact and random on-off cycles. The mercury capsule inside such a switch consists of a metallic shell with an insulating (glass or ceramic) spacer in between the two halves. Connection to the switch's wiring is made via sliding contacts to the metal portion of the capsule. There is a small hole toward one side in the spacer. Rotating the capsule results in the mercury flowing through the hole to make contact:

- In the off position, the hole is above the level of the liquid mercury.
- In the on position, the hole is below the level of the liquid mercury.
- When turning the switch on, the hole is rotated below the surface and as soon as the mercury touches, surface tension quickly pulls it together. There is no 'contact bounce'.
- When turning the switch off, the mercury pulls apart as the capsule is rotated to raise the hole. Eventually, surface tension is not sufficient to hold the two globs of mercury together and they part suddenly.

Problems are rare with these mercury switches. In fact, GE mercury switches used to carry a *50* year warranty! I don't know if they still do.

In principle, these are also the safest type of switch since any sparking or arcing takes place inside the sealed mercury capsule. However, the contact between the screw terminals and the capsule are via sliding contacts (the capsule is press fit between the metal strips to which the screws are attached) and with time, these can become dirty, worn, or loose. For this reason, some electricians do not like mercury switches, particularly for high current loads.

Comments on mercury poisoning

While I recognize the dangers of mercury poisoning, I was one of those who used to play with mercury quite extensively from broken thermometers, mercury switches, and any other sources I could find. In high school, I used to go through the back storage rooms in search of mercury. This was before the era of regulations protecting everyone from everything. I still have a couple pounds of the stuff, safely stored.

The danger isn't so much from occasional contact with metallic mercury as from mercury vapor which may build up in an enclosed spaces and from soluble mercury compounds. You get significant contact with metallic mercury from amalgam ("silver") tooth fillings and while there is controversy about their safety and some people have had their old fillings ripped out at great expense (and disconfort!), there is as far as I know, no conclusive scientific evidence linking mercury poisoning to amalgam fillings.

Having said that, I agree that it's probably a bad idea to be playing with mercury on a daily basis but pushing a few drops of it around or losing one drop to the floorboards isn't going to make everyone sick. If this were the case, half the houses in the World would be HAZMAT zones from broken fluorescent lamps - which have significant metallic mercury in them.

If anyone has evidence to the contrary, please cite refereed scientific publications and I will read them, not hyped popular press reports.

Relays - electrically activated switches for power or control

Relays are switches that are activated by an electrical signal rather than a button or toggle. They are used to switch power (as in an central air conditioning system) or control signals (as in a telephone or modem).

- The most common relays are electromechanical - an electromagnet is used to move a set of contacts like those in a regular switch.

- Solid state relays have no moving parts. They use components like thyristors or MOSFETs to do the switching.

For more information on relays, see the document: Notes on the Troubleshooting and Repair of Audio Equipment and other Miscellaneous Stuff.

Contact configurations

The arrangement of contacts on a switch is often abbreviated mPnT where:

- 'm' identifies the number of separate sets of contacts.
- 'P' stands for Poles or separate sets of contacts.
- 'n' identifies the number of contact positions.
- 'T' stands for Throw which means the number of contact positions.

In addition, you may see:

- NC (Normally Closed and NO (Normally Open) may be used to designate terminals when the switch is in the off or deactivated state. This applies to power switches where OFF would be down or released and ON would be up or pushed in. It also applies to momentary pushbutton switches and relays.
- MBB (Make Before Break) and BBM (Break Before Make) designate how the connections behave as the switch is thrown. Most switches found in small appliances will be of the BBM variety.

This also applies to relays except that the contact switching is activated by an electrical signal rather than a finger.

The most common types are:

- SPST - Single Pole Single Throw. Terminal (A) is connected to terminal (B) when the switch is on:

```
          A ______/ _______ B
```

  This is the normal light or power switch. For electrical (house) wiring, it may be called a '2-way' switch.

- DPST - Double Pole Single Throw. Terminal (A) is connected to terminal (B) and terminal (C) is connected to terminal (D) when the switch is on:

```
          A ______/ _______ B
                  :
          C ______/ _______ D
```

  This is often used as a power switch where both wires of the AC line are switched instead of just the Hot wire.

- SPDT - Single Pole Double Throw. A common terminal (C) is connected to either of two other terminals:

```
                   _______ NC
         C ______/
                   _______ NO
```

This is the same configuration as what is known as a '3-way' switch for electrical (house) wiring. Two of these are used to control a fixture from separate locations.

- DPDT - Double Pole Double Throw. Essentially 2 SPDT switches operated by a single button, rocker, toggle, or lever:

```
                   _______ NC1
      C1 ______/
               : _______ NO1
               :
               : _______ NC2
      C2 ______/
                 _______ NO2
```

- SP3T, SP4T, etc. - Single Pole selector switch. A common terminal (C) is connected to one of n contacts depending on position. An SP5T switch is shown below:

```
               _________ 1
                 _______ 2
       C ______/  ______ 3
                 _______ 4
               _________ 5
```

Electrical overload protection devices - fuses and circuit breakers

The purpose of fuses and circuit breakers is to protect both the wiring from heating and possible fire due to a short circuit or severe overload and to prevent damage to the equipment due to excess current resulting from a failed component or improper use (using a normal carpet vacuum to clear a flooded basement).

Fuses use a fine wire or strip (called the element) made from a metal which has enough resistance (more than for copper usually) to be heated by current flow and which melts at a relatively low well defined temperature. When the rated current is exceeded, this element heats up enough to melt (or vaporize). How quickly this happens depends on the extent of the overload and the type of fuse.

Fuses found in consumer electronic equipment are usually cartridge type - 1-1/4" mm x 1/4" or 20 mm x 5 mm, pico(tm) fuses that look like green 1/4 W resistors, or other miniature varieties. Typical circuit board markings are F or PR.

More than you could ever want to know about fuses can be found at the Littlefuse Web site. Go to Resouces->Reference Materials->Fusology to start.

Circuit breakers may be thermal, magnetic, or a combination of the two. Small (push button) circuit breakers for appliances are nearly always thermal - metal heats up due to current flow and breaks the circuit when its temperature exceeds a set value. The mechanism is often the bending action of a bimetal strip or disc - similar to the operation of a thermostat. Flip type circuit breakers are normally magnetic. An electromagnet pulls on a lever held from tripping by a calibrated spring. These are not usually common in consumer equipment (but are used at the electrical service panel).

At just over the rated current, it may take minutes to break the circuit. At 10 times rated current, the fuse may blow or circuit breaker may open in milliseconds.

The response time of a 'normal' or 'rapid action' fuse or circuit breaker depends on the instantaneous value of the overcurrent.

A 'slow blow' or 'delayed action' fuse or circuit breaker allows instantaneous overload (such as normal motor starting) but will interrupt the circuit quickly for significant extended overloads or short circuits. A large thermal mass delays the temperature rise so that momentary overloads are ignored. The magnetic type breaker adds a viscous damping fluid to slow down the movement of the tripping mechanism.

Common problems: fuses and circuit breakers occasionally fail for no reason or simply blow or trip due to a temporary condition such as a power surge. However, most of the time, there is some other fault with the appliance which will require attention like a bad motor or shorted wire. Dirty, corroded, or weak contacts (holding the fuse or circuit breaker) may get hot and contribute to nuisance tripping. Circuit breakers can also go bad just due to age (this particularly applies to those in the electrical service panel - one that buzzes and/or trips occasionally for no apparent reason may need replacement).

Testing: Fuses and circuit breakers can be tested for failure with a continuity checker or multimeter on the low ohms scale. A fuse that tests open is blown and must be replaced (generally, once the circuit problem is found and repaired.) Of course, if the fuse element is visible, a blown fuse is usually easy to identify without any test equipment. A circuit breaker that tests open or erratic after the reset button is pressed, will need replacement as well.

Note that in general, circuit breakers should **NOT** be used for repeated switching nor should they be reset on a circuit with any substantial load (or overload or short circuit). Their contacts are not designed for this type of operation. Here are some additional comments:

(From: Tom Hardy (th7675@istate.net).)

Many people use circuit breakers as switches (including my father-in-law!). The problem is that the contacts become burned, creating resistance and thus abnormal heating causing the breaker to be unable to carry its rated load. The other thing this does (especially with Square-D QO style breakers) through heating is causes the buss bar contact to loose it's spring tension (in reference to circuit breakers installed in an electrical service panel). This will (as happened to my father-in-law) burn up part of the buss bar and ruin the electric panel. Most people will just reset a breaker if it trips, without first removing the load. This also causes burned contacts as mentioned above. I have found many defective breakers before they go bad, usually feeding higher current appliances. Just turn on the appliance for 15 to 20 minutes and then feel the front of the breaker with your hand. If its warm or hot, there is usually reason to suspect future trouble if it's not replaced.

Fuse postmortem

Quite a bit can be inferred from the appearance of a blown fuse if the inside is visible as is the case with a glass cartridge type. One advantage to the use of fuses is that this diagnostic information is often available!

- A fuse which has an element that looks intact but tests open may have just become tired with age. Even if the fuse does not blow, continuous cycling at currents approaching its rating or instantaneous overloads results in repeated heating and cooling of the fuse element. It is quite common for the fuse to eventually fail when no actual fault is present.

- A fuse where the element is broken in a single or multiple locations blew due to an overload. The current was probably more than twice the fuse's rating but not a dead short.

- A fuse with a blackened or silvered discoloration on the glass where the entire element is likely vaporized blew due to a short circuit.

This information can be of use in directly further troubleshooting.

Fuse or circuit breaker replacement

As noted, sometimes a fuse will blow for no good reason. Replace fuse, end of story. In this situation, or after the problem is found, what are the rules of safe fuse replacement? It is inconvenient, to say the least, to have to wait a week until the proper fuse arrives or to tromp out to Radio Shack in the middle of the night.

Even with circuit breakers, a short circuit may so damage the contacts or totally melt the device that replacement will be needed.

Five major parameters characterizes a fuse or circuit breaker:

1. **Current rating:** This should not be exceeded (you have heard about not putting pennies in fuse boxes, right?) (The one exception to this rule is if all other testing fails to reveal which component caused the fuse to blow in the first place. Then, and only then, putting a larger fuse in or jumpering across the fuse **just for testing** will allow the faulty component to identify itself by smoking or blowing its top!) A smaller current rating can safely be used but depending on how close the original rating was to the actual current (or how much surge current there is on power-on), an underrated fuse may blow immediately.

   Some equipment may use fuses with strange current ratings like 1.65 A instead of 1.5 A. In such cases, it won't hurt to try a common lower current value like 1.5 A. The worst that will happen is that it will blow, probably not immediately but some time in the future even if there is no problem. Using the next higher common value like 1.75 A isn't recommended except for testing. The irony is that these strange values are often used in the primaries of switchmode power supplies where their function is to blow due to catastrophic failure, not a slight overload, and it really doesn't matter if they are slightly larger (but only slightly larger!). However, for reasons of liability, this is still not recommended. Don't do it!

2. **Voltage rating:** This is the maximum safe working voltage of the circuit (including any inductive spikes) which the device will safety interrupt. Thus, you may see fuses where the elements look like [|------|] versus [|==--==|]. Aside from the shape and size, the type of material used for the fuse element as well as what's surrounding it (e.g., air or sand) will affect voltage rating. It is safe to use a replacement with an equal or high voltage rating.

   And, it's quite likely that there will be no difference between 125 V and 250 V fuses except the labeling. It really doesn't cost more to make higher voltage fuses in the same package size of the type found in consumer electronic equipment so any labeling like this would be more of a regulatory issue.

   For high voltage, current limited equipment (up to 500 V or more, up to 10 times the fuse current rating), it may still be acceptable to use a 250 V fuse.

3. **AC versus DC:** Fuses rated for AC and DC may not be the same. For a given voltage, a shorter gap can be used to reliably interrupt an AC circuit since the voltage passes through zero 120 (100) times a second. For example, a fuse rated 32 VDC may look similar to one rated for 125 VAC.

4. **Type:** Normal, fast blow, slow blow, etc. It is safe to substitute a fuse or circuit breaker with a faster response characteristic but there may be consistent or occasional failure mostly during power-on. The opposite should be avoided as it risks damage to the equipment as semiconductors tend to die quite quickly.

5. **Mounting:** It is usually quite easy to obtain an identical replacement. However, as long as the other specifications are met, soldering a normal 1-1/4" (3AG) fuse across a 20 mm fuse is perfectly fine, for example. Sometimes, fuses are soldered directly into an appliance.

   However, any soldering of wires directly to a fuse should be done with care and it may weaken the fuse element or its connection if the fuse doesn't just fall apart. Thus, where soldered-in fuses are used, obtain replacements with wire leads that preattached or solder in a fuse holder.

Thermal protection devices - thermal fuses and thermal switches

These devices protect against excessive temperature due to either a fault in the appliance (locked motor overheating) or improper use (blow dryer air blocked). They are at least as important as normal fuses or circuit breakers for prevention of fire and damage due to overheating. Also see the document: Notes on the Troubleshooting and Repair of AC Adapters, Power Supplies, and Battery Packs.

There are three typical types:

1. **Thermal fuses:** This is similar to an electrical fuse but is designed to break the circuit at a specific temperature. These are often found in heating appliances like slow cookers or coffee percolators or buried under the outer covering of motor windings or transformers. Some also have an electrical fuse rating as well. Like electrical fuses, these are one-time only parts. A replacement that meets both the thermal and electrical rating (if any) is required.

   CAUTION: When replacing a thermal fuse, DO NOT SOLDER it if at all possible. If the device gets too hot, it may fail immediately or be weakened. Crimp or screw connections are preferred. It is normally possible to obtain "crimp rings" when you order - they may be included. Then, just cut off the old fuse but leave some wire, slip the old and new wires into a crimp ring (twist them for added mechanical stability) and compress the ring tightly with a pair of pliers. Note the direction: If the appliance uses a polarized plug, it is recommended that the isolated lead of the thermal fuse be attached to the Hot AC wiring and the bare metal body of the thermal fuse which is connected to one lead be attached to the wiring of the appliance. This is a minor point but it doesn't cost anything!

```
                       *                     *
      To AC Hot -------||--     ______     --||-------- To appliance wiring
                     --||------<______|------||--
                           New Thermal Fuse

  * Twisted and crimped connection for maximum mechanical strength.
```

   If you must solder, use a good heat sink (e.g., wet paper towels, little C-clamps) on the leads between the thermal fuse and the soldering iron, and work quickly!

2. **Thermal switches or thermal protectors (strip type):** These use a strip of bimetal similar to that used in a thermostat. Changes in temperature cause the strip to bend and control a set of contacts - usually to to break a circuit if the set temperature is exceeded. Commonly found in blow dryers and other heating appliances with a fixed selection of heat settings. They may also be found as backup protection in addition to adjustable thermostats.

3. **Thermal switches or thermal protectors (disk type):** These use a disk of bimetal rather than a strip as in most thermostats. The disk is formed slightly concave and pops to the opposite shape when a set temperature is exceeded. This activates a set of contacts to break (usually) a circuit if the rated temperature is exceeded. They may also be found as backup protection in addition to adjustable thermostats. A typical thermal switch is a small cylindrical device (i.e., 3/4" diameter) with a pair of terminals and a flange that is screwed to the surface whose temperature is to be monitored.

In some applications, device types (2) and (3) may be used as the primary temperature regulating controls where adjustment is not needed.

Comments on importance of thermal fuses and protectors

Like a normal fuse or circuit breaker, a thermal fuse or thermal protector provides a critical safety function. Therefore, it is extremely ill advised to just short it out if it fails. Some designs even make this option extra tempting by providing an easy way to bypass even one buried inside a power transformer - using an additional, normally unused terminal.

For testing, it is perfectly acceptable to temporarily short out the device to see if the equipment then operates normally without overheating. However, while these fuses do sometimes just fail on their own, most likely, there was another cause. If you know what it was - you were trying to charge a shorted battery pack, using your window fan to mix cement, or something was shorted externally, then the fuse served its protective function and the equipment is fine. IT SHOULD BE REPLACED WITH THE SAME TYPE or the entire transformer, motor, or whatever it was in should be replaced! This is especially critical for unattended devices. Otherwise, especially with unattended devices, you have a situation where if the overload occurred again or something else failed, the equipment could overheat to the point of causing a fire - and your insurance company may refuse to cover the claim if they find that a change was made to the circuit. And even for portable devices like blow dryers and portable power tools, aside from personal safety should the device malfunction, the thermal protector is there to prevent damage to the equipment itself - don't leave it out!

More on thermal fuses

(From: Paul Grohe (grohe@galaxy.nsc.com).)

The following is From Microtemps' literature (`95 EEM Vol.B p1388):

> "The active trigger mechanism of the thermal cutoff (TCO) is an electrically non-conductive pellet. Under normal operating temperatures, the solid pellet holds spring loaded contacts closed. When a pre-determined temperature is reached, the pellet melts, allowing the barrel spring to relax. The trip spring then slides the contact away from the lead and the circuit is opened. Once TCO opens a circuit, the circuit will remain open until the TCO is replaced....."

Be very careful in soldering these. If the leads are allowed to get too hot, it may "weaken" the TCO, causing it to fail prematurely. Use a pair of needle-nose pliers as heat sinks as you solder it.

I have replaced a few of these in halogen desk lamp transformers. The transformers showed no signs of overheat or overload. But once I got it apart, the TCO's leads had large solder blobs on them, which indicated that the ladies that assembled the transformers must have overheated the cutouts leads when they soldered them.

The NTE replacement package also comes with little crimp-rings, for high-temp environments where solder could melt or weaken (or to avoid the possibility of soldering causing damage as described above --- sam).

Controls 1 - adjustable thermostats and humidistats

Thermostats are use to regulate the temperature in heating or cooling type appliances. Common uses include heaters, air conditioners, refrigerators, freezers, hair dryers and blow dryers, toaster ovens and broilers, waffle irons, etc. These are distinguished from the thermal switches discussed above in that they usually allow a variable temperature setting.

Four types are typically found in appliances. The first three of these are totally mechanically controlled:

1. **Bimetal strip:** When two metals with different coefficients of thermal expansion are sandwiched together (possibly by explosive welding), the strip will tend to bend as the temperature changes. For example, if the temperature rises, it will curve towards the side with the metal of lower coefficient of expansion.

   In a thermostat, the bimetal strip operates a set of contacts which make or break a circuit depending on temperature. In some cases the strip's shape or an additional mechanism adds 'hysteresis' to the thermostat's characteristics (see the section: What is hysteresis?).

2. **Bimetal disk:** This is similar to (1) but the bimetal element is in the shape of a concave disk. These are not common in adjustable thermostats but are the usual element in an overtemperature switch (see the section: Thermal protection devices - thermal fuses and thermal switches).

3. **Fluid operated bellows:** These are not that common in small appliances but often found in refrigerators, air conditioners, baseboard heaters, and so forth. An expanding fluid (alcohol is common) operates a bellows which is coupled to a set of movable contacts. As with (1) and (2) above, hysteresis may be provided by a spring mechanism.

Other variations on these basic themes are possible but (1)-(3) cover the vast majority of common designs.

Testing of mechanical thermostats: Examine for visible damage to the contacts. Use a continuity checker or ohmmeter to confirm reliable operation as the knob or slider is moved from end to end if it will switch at room temperature. Gently press on the mechanism to get the contacts to switch if this is not possible. Use an oven on low or a refrigerator or freezer if needed to confirm proper switching based on temperature.

4. **Electronic thermostats:** These typically use a temperature variable resistance (thermistor) driving some kind of amplifier or logic circuit which then controls a conventional or solid state relay or thyristor.

Testing of electronic thermostats: This would require a schematic to understand exactly what they are intended to do. If a relay is used, then the output contacts could perhaps be identified and tested. However, substitution is probably the best approach is one of these is suspected of being defective.

Humidistats, as their name implies, are used to sense relative humidity in humidifiers and dehumidifiers. Their sensing material is something that looks kind of like cellophane or the stuff that is used for sausage casings. It contracts and expands based on the moisture content of the air around it. These are somewhat fragile so if rotating the control knob on a humidifier or dehumidifier does not result in the normal 'click', this material may have been damaged or broken.

Testing of mechanical humidistats: examine for visible damage to the contacts. Use a continuity checker or ohmmeter to confirm reliable operation as the knob or slider is moved from end to end. Gently press on the mechanism to get the contacts to switch if this is not possible. Gently exhale across the sensing strip to confirm that the switching point changes.

What is hysteresis?

An intuitive explanation of hysteresis is that it is a property of a system where the system wants to remain in the state that it is in - it has memory.

Examples of systems with hysteresis:

- Thermostats - without hysteresis your heater would be constantly switching on and off as the temperature changed. A working thermostat has a few degrees of hysteresis. As the temperature gradually increases, at some point the thermostat switches off. However, the temperature then needs to drop a few degrees for it to switch on again.

- Toggle switches - the click of a toggle switch provides hysteresis to assure that small vibrations, for example, will not accidentally flip the switch.

Examples of systems which ideally have little or no hysteresis:

- Audio amplifiers - input vs. output.

- Pendulums on frictionless bearings - force vs. position.

Hysteresis is usually added thermostats by the use of a spring mechanism which causes the mechanism to want to be in either the open or closed position but not in between. Depending on the appliance, there may be anywhere from 0 hysteresis (waffle iron) to 5-10 degrees F (space heater). Sometimes, the thermal mass of the heated device or room provides the hysteresis since any change to the temperature will not take place instantaneously since the heating element is separated from the thermostat by a mass of metal. Therefore, some overshoot - which in effect performs the same function as a hysteresis mechanism - will take place.

Controls 2 - rheostats and potentiometers

These controls are usually operated by a knob or a slide adjustment and consist of a stationary resistance element and a wiper that can be moved to determine where on the fixed element it contacts. In some cases, they are not actually user controls but are for internal adjustments. In other cases, they are operated by the mechanism automatically and provide a means of sensing position or controlling some aspect of the operation.

- Rheostats provide a resistance that can be varied. Usually, the range is from 0 ohms to some maximum value like 250 ohms. They are used to control things like speed and brightness just by varying the current directly, or via an electronic controller (see the section: Electronic controllers - simple delay or microprocessor based").

```
B o-------------+
                |
                V
A o--------/\/\/\/\/\-----
        250 ohm rheostat
```

  In the diagram above, the resistance changes smoothly from 0 to 250 ohms as the wiper moves from left to right.

  Very often, you will see the following wiring arrangement:

```
B o-------------+------+
                |      |
                V      |
A o--------/\/\/\/\/\--+
       250 ohm rheostat
```

  Electrically, this is identical. However, should the most common failure occur with the wiper breaking or becoming disconnected, the result will be maximum resistance rather than an open circuit. Depending on the circuit, this may be preferred - or essential for safety reasons.

  Testing: Disconnect at least one of the terminals from the rest of the circuit and then measure with an ohmmeter on the appropriate scale. The resistance should change smoothly and consistently with no dead spots or dips.

- Potentiometers are either operated by a knob or a slide adjustment and implement a variable resistance between two end terminals as shown below. This can be used to form a variable voltage divider. A potentiometer (or 'pot' for short) can be used like a rheostat by simply not connecting one end terminal. These are most often used with electronic controllers.

```
B o-------------+
                |
                V
A o--------/\/\/\/\/\--------o C
      1K ohm potentiometer
```

In the diagram above, the resistance between A and B varies smoothly from 0 to 1K ohms as the wiper moves from left to right. At the same time, the resistance between B and C varies smoothly from 1K to 0 ohms. For some applications, the change is non-linear - audio devices in particular so that the perceived effect is more uniform across the entire range.

Testing: Disconnect at least two of the terminals from the rest of the circuit and then measure with an ohmmeter on the appropriate scale. The resistance should change smoothly and consistently with no dead spots or dips. Try between each end and the wiper. Check the resistance across the end terminals as well - it should be close to the stamped rating (if known).

Rheostats and potentiometers come in all sizes from miniature circuit board mounted 'trimpots' to huge devices capable of handling high power loads. The resistance element may be made of fine wire ('wirewound') or a carbon composition material which is silkscreened or painted on.

Interlocks - prevent operation with case or door open

Most of these are simple switches mechanically activated by the case or door. Sometimes, optical or magnetic interlocks are used (rare on small appliances but common on things like printers). Line cords that are firmly attached to the case and disconnect automatically when the case is removed are another example of an interlock. Interlocks may be designed to prevent injury during normal operation (e.g.. food processor blades will not start when cover is removed) or during servicing (remove AC power to internal circuits with case removed).

1. **Interlock switches:** Various kinds of small switches may be positioned in such a way that they disconnect power when a door is opened or cover is removed. These may fail due to electrical problems like worn or dirty contacts or mechanical problems like a broken part used to activate the interlock.

   Testing: Use an ohmmeter or continuity checker on the switches. The reading should either be 0 ohms or infinite ohms. Anything in between or erratic behavior is indication of a bad switch or cord.

2. **Attached cordset:** Should the case be opened, the cord goes with the case and therefore no power is present inside the appliance. To get around this for servicing, a 'cheater cord' is needed or in many cases the original can be easily unfastened and used directly.

   Testing: Use an ohmmeter or continuity check to confirm that both wires of the cord are connected to both AC plug and appliance connector. Wiggle the cord where it connects to the appliance and at the plug end as well to see if there might be broken wires inside.

Light bulbs - incandescent and fluorescent

Small incandescent light bulbs are often used in appliances for interior lighting or spot illumination. The common 'appliance bulb' is simply a 'ruggedized' 40 W incandescent light bulb in a clear glass envelope. Other types are found in vacuum cleaners, microwave overs, makeup mirrors, and so forth.

Testing: visual inspection will often reveal a burnt out incandescent light bulb simply because the filament will be broken. If this is not obvious, use an ohmmeter - an infinite resistance means that the bulb is bad.

See the chapter: Incandescent Light Bulbs, Lamps, and Lighting Fixtures for more info.

Small fluorescent lamps are often found in makeup mirrors, plant lights, and battery powered lanterns.

Testing: The best test for a bad fluorescent lamp (tube) is to substitute a known good one. Unfortunately, there is no easy go-no go test for a these as with an incandescent lamp. Other parts of the fixture (like the ballast or starter) could also be bad. Testing with a multimeter between the pair of pins at each end should show low resistance if the lamp is good. However, depending on the type of ballast, a lamp with an open filament may still work just fine even though strictly speaking, it is defective. Again, try a replacement to be sure. **CAUTION:** A defective ballast or starter can cause a fluorescent lamp to go bad in short order - if it still doesn't work, don't just let it continue to try to start!

See the document: Fluorescent Lamps, Ballasts, and Fixtures for additional information.

Indicators - incandescent or neon light bulbs or LEDs

Whereas lighting fixtures using incandescent or fluorescent bulbs are designed to illuminate a room or small area, an indicator is simply there to let you know that an appliance is on or in a specific mode.

There are three common types of electrical indicator lights:

1. **Incandescent bulbs:** Just like their larger cousins, an incandescent indicator or pilot light has a filament that glows yellow or white hot when activated by a usually modest (1.5-28 V) source. Flashlight bulbs are very similar but usually have some mechanical method of keeping the filament positioned reasonably accurately so that the light can be focussed by a reflector or lens. Since the light spectrum of incandescent indicators is quite broad, filters can be used to obtain virtually any colored light. Incandescent indicator lamps do burn out just like 100 W bulbs if run near their rated voltage. However, driving these bulbs at reduced voltage can prolong their life almost indefinitely.

   Incandescent indicator lamps are often removable using a miniature screw, bayonet, or sliding type base. Some are soldered in via wire leads. Others look like cartridge fuses.

   Testing: Visual inspection will often reveal a burnt out incandescent light bulb simply because the filament will be broken. If this is not obvious, use an ohmmeter - an infinite resistance is means that the bulb is bad.

2. **Neon lamps:** These are very common as AC line power indicators because they are easy to operate directly from a high voltage requiring only a high value series resistor.

   They are nearly all the characteristic orange neon color although other colors are possible and there is a nice bright green variety with an internal phosphor coating that can actually provide some illumination as well. While neon bulbs do not often burn out in the same sense as incandescent lamps, they do darken with age and may eventually cease to light reliably so flickering of old Neon bulbs is quite common. This is almost always just due to the natural aging process of the indicator and does **not** mean the outlet or appliance itself is bad.

   Some Neon bulbs come in a miniature bayonet base. Most are soldered directly into the circuit via wire leads.

   Testing: Inspect for a blackened glass envelope. Connect to AC line (careful - dangerous voltage) through a series 100K resistor. If glow is weak or absent, Neon bulb is bad.

3. **Light Emitting Diodes (LEDs):** LEDs come in a variety of colors - red, yellow, and green are very common; blue is now available as are virtually all other colors including white. These run on low voltage (1.7-3 V) and relatively low currents (1-20 mA). Thus, they run cool and are easily controlled by low voltage logic circuits. LEDs have displaced incandescent lamps in virtually all electronic equipment indicators and many appliances. Their lifetime easily exceeds that of any appliance so replacement is rarely needed.

   LEDs are almost always soldered directly into the circuit board since they rarely need replacement.

   As an item of interest which has nothing to do with appliance repair, many automotive tail lights are now red LEDs, particularly the middle brake light. In fact, the red (stop) lights in many traffic signals are now LED clusters that screw directly into a normal 115 VAC socket. This is done because one of these will outlast 50 normal incandescent lamps and the cost of replacement far exceeds the cost of the lamp itself. How can you tell which type is used? Easy, move your eyes (or head) from side-to-side while looking at the red light; since the LED actually pulses 120 times per second (for 60 Hz power), you will see a series of spots - an incandescent lamp will appear continuous. Yellow and green will probably follow shortly but all I've seen so far are the red ones using LEDs.

Testing: Use a multimeter on the diode test scale. An LED will have a forward voltage drop of between 1.7 and 3 V. If 0 or open, the LED is bad. However, note: some DMMs may not produce enough voltage on the diode test scale so the following is recommended: Alternative: Use a 6 to 9 V DC supply in series with a 470 ohm resistor. LED should light if the supply's positive output is on the LED's anode. If in doubt, try both ways, If the LED does not light in either direction, it is bad.

4. **Electroluminescent (EL) panels (sometimes used in night lights):** These produce a cool soft light (usually bluish-greenish) consuming very little power (well they don't produce all that much light, either!). A thin layer of non-conducting light emitting material is sandwiched between a pair of electrodes, one of which is transparent or translucent. They can be virtually any size though a typical night light might be 2 x 2-1/2 inches or so. The device is basically a capacitor that emits light when an AC voltage (typically 115 VAC) is applied to its plates. There may be some additional components like a current limiting resistor in series and an MOV or other surge suppressor across the actual EL device (particularly on units designed to operate on 220/240 VAC.

   Testing: Check for bad connections and bad components with a multimeter. An open series resistor, shorted EL device, or faulty (partially shorted) MOV is possible. However, sometimes these failures won't show up except when normal voltage is applied. Measure on the AC volts range across the EL device - there should be a high AC reading, probably over 100 VAC.

Heating elements - NiChrome coils or ribbon, Calrod, Quartz

All heating elements perform the same function: convert electricity into heat. In this they have one other characteristic in common: they are all nearly 100% efficient. The only electrical energy which does not result in heat is the slight amount of light (usually red-orange) that is produced by a hot element.

There are 3 basic types of heating elements. Nearly every appliance on the face of the planet will use one of these:

1. **NiChrome coil or ribbon:** NiChrome is an alloy of Nickel and Chromium which has several nice properties for use in heating appliances - First, it has a modest resistance and is thus perfect for use in resistance heating elements. It is easily worked, is ductile, and is easily formed into coils of any shape and size. NiChrome has a relatively high melting point and will pretty much retain its original shape and most importantly, it does not oxidize or deteriorate in air at temperatures up through the orange-yellow heat range.

   NiChrome coils are used in many appliances including toasters, convection heaters, blow-dryers, waffle irons and clothes dryers.

   The main disadvantage for our purposes is that it is usually not possible to solder this material due to the heating nature of its application. Therefore, mechanical - crimp or screw must be used to join NiChrome wire or ribbon to another wire or terminal. The technique used in the original construction is may be spot welding which is quick and reliable but generally beyond our capabilities.

   Testing: Visual inspection should reveal any broken coil or ribbon. If inspection is difficult, use a multimeter on the low ohms scale. Check for both shorts to the metal chassis as well as an open element (infinite ohms).

2. **Calrod(tm) sealed element:** This encloses a fine coiled NiChrome wires in a ceramic filler-binder inside a tough

metal overcoat in the form of a shaped rod with thick wire leads or screw or plug-in terminals.

These are found in toaster oven/broilers, hot plates, coffee makers, crock pots and slow cookers, electric range surface elements, conventional and convection ovens and broilers.

Testing: When these fail, it is often spectacular as there is a good chance that the internal NiChrome element will short to the outer casing, short out, and melt. If there is no visible damage but the element does not work, a quick check with an ohmmeter should reveal an open element or one that is shorted to the outer casing.

3. **Quarts incandescent tube:** These are essentially tubular high power incandescent lamps, usually made with a quartz envelope and thus their name.

   These are found in various kinds of radiant heaters. By running a less than maximum power - more orange heat - the peak radiation is in the infra-red rather than visible range.

   Testing: Look for a broken filament. Test with an ohmmeter just like an incandescent light bulb.

Repair of broken heating elements

In appliances like waffle irons and toaster ovens, these are usually welded. This is necessary to withstand the high temperatures and it is cheap and reliable as well. Welding is not normally an option for the doit yourselfer. However, if you are somewhat suicidal, see the section: Improving sensitivity of garage door openers receivers for a more drastic approach.

I have used nuts and bolts, say 6-32, bolt, wire, washer, wire, washer, lockwasher, nut. Depending on how close to the actual really hot element it is, this may work. If you are connecting to the coiled element, leave a straight section near the joint - it won't get as hot.

The use of high temperature solder or brazing might also work.

The best approach is probably to use high temperature crimp connectors:

(The following from: sad@garcia.efn.org (Stephen Dunbar))

You can connect heating element wires with high-temperature solderless connectors that are crimped onto the wires. Be sure to get the special high-temp connectors; the ordinary kind will rapidly oxidize and fall apart at high temperatures. If you want to join two wires to each other, you'll need either a butt splice connector (joins the wires end-to-end) or a parallel splice connector (the wires go into the connector side-by-side). To fasten a wire to a screw terminal you can use a ring or spade connector (though as noted above, a screw, nut, and washer(s) should work fine --- sam). If your waffle iron has quick disconnect terminals you'll need the opposite gender disconnect (AkA Faston). These come in both .187" and .250" widths.

Your best bet for getting these connectors in small quantity is probably a local appliance parts outlet that caters to do-it-yourselfers. If you can't find what you need there, try Newark Electronics (branches all over the place). I have an old copy of their catalog which lists SPC Technology Voltrex Brand High Temperature Barrel Terminals in several styles: ring, spade, disconnect, and butt splice. The prices were around $10 to $12 per 100 (this catalog is a couple of years old) for wires in the 22-18 or 16-14AWG size ranges, almost twice that for the heftier wire gauges. (Be sure to determine the wire gauge of your heating elements so you can get the right size terminal.)

You can spend a *lot* of money on crimp tools, but for occasional light use you can probably get by with one of those $10 gadgets that crimp, strip & cut wires, and cut bolts--the sort of thing you'd find in your local home center or Radio Shack.

(From: Nigel Cook (diverse@tcp.co.uk).)

The thin stainless steel strip found spot welded to multicell NiCd batteries make good crimps for joining breaks in heater resistance wire. Form a small length of this strip around a needle or something similar to make a tight spiral with enough clearance to go over doubled-up heater wire. Abraid or file the cut ends of the broken wire. Crimp into place with a double lever action crimper. If there is an area of brittle heating element around the break then cut out and splice in a replacement section with two such crimps. Such a repair to my hot-air paint stripper (indispensable tool in my electronics tool-kit) has survived at least 50 hours.

(From: Dan Sternberg (steberg@erols.com).)

Another old trick for nichrome repair is to make a paste of Borax, twist the two broken end together, and energize the circuit. A form of bond welding takes place. I've have used this on electric clothes dryer heater elements with good luck.

Solenoids - small and large

Solenoids are actuators operated by electromagnets that are used to operate valves, slide or engage various parts, eject or prevent opening of a door, and other functions. While shapes and sizes may vary, all electrically operated solenoids use an electromagnet - AC or DC - to pull on a movable piece called an armature which generally moves back and forth but rotary motion is also possible.

Solenoids are usually two position devices - they are not used to provide intermediate amounts of force or travel like motors.

Sizes ranges from small 1/2" long units providing a fraction of an ounce of force and 1/8" travel to large 3" long units providing many pounds of force with travels of 2" or more.

Testing: Inspect for free movement. Use an ohmmeter to confirm that the coil is intact. There could be other problems like shorted turns in the coil but these would be less common than lack of lubrication or an open coil. Check voltage on operating solenoid to determine whether drive power is present.

Small electronic components - resistors, capacitors, diodes

A variety of small electronic components may be found in appliances though unlike true electronic equipment, these do not usually run the show.

- **Resistors** may be used in various ways to adjust the current flowing in part of a circuit. Many different types of resistors are possible - tiny carbon or metal film types looking like small cylindrical objects often with colored bands which indicate the value.

- **Power resistors** are larger cylindrical or rectangular shaped devices which are often ceramic coated. These may get quite hot during operation. Their resistance value and power rating are usually printed on the resistor.

- **Capacitors** come in a variety of shapes and sizes. Some may look like disks, jelly beans, cylinders, boxes, etc. Their value is often marked in uF, nF, or pF.

- **Diodes or rectifiers** are solid state devices that permit electric current to only flow in one direction (positive current in the direction of the arrow when marked this way). These are most often used in appliances to change AC to DC or to cut the power to a motor or heater (by allowing only half of the AC current to pass).

For more information on these types of components, see any good introductory electronics text.

Transformers - low voltage, high voltage

A transformer consists of a laminated iron or ferrite core and 2 or more insulated windings that are most often not connected to each other directly. If one set of windings is used as the input for AC power or an audio signal (the 'primary' winding), the voltage appearing on each of the other windings (the 'secondary' winding(s)) will be related by the ratio of the number of turns on each of the windings. However, you don't get something for nothing: The current is related by the inverse of this ratio so the power doesn't change (except due to unavoidable losses).

Transformers are used in nearly every type of electronic equipment both for power and signals, and throughout the electrical distribution network to optimize the voltage/current used on each leg of the journey from the power plant to the user.

The types we are interested in with respect to household appliances and power tools are most often use to convert the AC line voltage to some other value, lower or higher:

1. **Low voltage power transformers** are found in AC wall adapters and electronic equipment as part of their power supplies to generate 1 or more DC voltages to run the device, recharge its batteries, etc. Their outputs are typically between 2 and 48 VAC but almost any other value is possible.

2. **High voltage power transformers** are found in microwave ovens, old TVs and audio equipment based on vacuum tubes, oil burner ignitions, and some neon signs. Their output can go as high as 15,000 V or more.

3. **Flyback (or LOPT), inverter, and other more specialized transformers** are driven by a high frequency oscillator or chopper in various equipment like TVs and monitors (HV, LV, and other power supplies), PCs and some of their peripherals, electronic flash units. Note that these will NOT operate from the AC line directly and are therefore useless unless driven by a proper electronic circuit.

There are also a couple of other common types of AC line operated transformers used in servicing:

4. **Isolation transformers** are wound 1:1 so that the output voltage is the same as the input voltage. However, with no direct connection between windings, equipment can be tested with less risk of shock.

5. **Variable transformers (or "Variacs", which is one brand name)** allow the output voltage to be adjusted between 0 and full (or slightly above) line voltage which is useful for testing purposes where the behavior of a piece of equipment is being determined. Some very old light dimmers may use this technology as well (newer ones use solid state phase control. See the sections starting with: Dimmer switches and light dimmers.)

See the document: Troubleshooting and Repair of Consumer Electronic Equipment for more information on these types of transformers.

Motors - universal, induction, DC, timing

A large part of the functionality of modern appliances is based on the use of motors of one form or another. We devote an entire chapter to motors. The following is just an introduction.

Motors come in all shapes and sizes but most found in small appliances can be classified into 5 groups:

1. Universal motors.
2. Single-phase induction motors.
3. Shaded pole induction motors.

4. Small permanent magnet DC motors. Synchronous timing motors.

See the chapter: Motors 101 for more detailed information on the common types of motors found in small appliances.

Fans and Blowers - bladed or centrifugal

The entire purpose of a particular appliance may be to move air or this may simply be needed for cooling. Obviously, portable and window fans are an example of the former. However, many appliances have built in fans you may not even be aware of as part of the motor(s) or other rotating components.

There are two primary types of configurations:

1. **Bladed fans:** We are all familiar with the common desk or window fan. This uses a set of rotating blades - typically 3-5 to gather and direct air. In the specific case of an oscillating desk fan, a gear drive linked to the motor also permits the general direction of air movement to be controlled in a back-and-forth motion. I recently saw one where in addition to moving back and forth, the front grille can be set to rotate at an adjustable rate providing more variation in air flow.

   The direction of the air movement with respect to blade rotation is determined by the pitch - the tilt - of the blades. Although reversing air direction is possible by reversing the motor, one direction is usually more effective than the other due to the curve of the blades.

2. **Centrifugal blowers:** These use a structure that looks similar to a squirrel cage to suck air from the center and direct it out a plenum formed around the blower. While these may be found in all sizes, the most common household application is in the vacuum cleaner. Large versions of these blowers are used in central heating and airconditioning systems, window air conditioners, and oil burners.

   Direction of rotation of the blower motor does not change the direction of airflow. However, one direction will be more effective than the other (where the blower is rotating in the same direction as the way exit port on the air plenum points. Because of this, it is not possible for a vacuum cleaner to blow out the suction hose due to a reversed motor (which in itself is for all intents and purposes, impossible as well). This is usually caused by back flow due to a blockage.

Bearings and bushings

The shafts of rotating parts normally are mounted in such a way that friction is minimized - to the extent needed for the application. A bearing is any such joint with more specific terms used to describe the typical types found in small appliances - or lawnmower, automobile engines, or 100 MW turbines.

- **Plain bearings** consist of an outer sleeve called a bushing in which a polished shaft rotates. The bushing may be made of a metal like brass or bronze or a plastic material like Teflon(tm). The shaft is usually made of steel though other materials may be found depending on the particular needs. Where a metal bushing is used, there must be means provided for lubrication. This may take the form of oiling grooves or holes and an oil reservoir (usually a saturated wad of felt) or the bushing itself may be sintered. Metal particles are compressed at high temperature and pressure resulting in a very porous but strong material which retains the lubricating oil.

  Under normal conditions, a plain bearing wears only during start and stop cycles. While the shaft is rotating at any reasonable speed, there is no metal to metal contact and thus no wear. With a properly designed and maintained bearing of this type, a very thin oil film entirely supports the shaft - thus the importance of clean oil. Your automobile engine's crankshaft is entirely supported by these types of bearings.

Eventually, even 'lubricated for life' bearings of this type may need to be disassembled, cleaned, and lubricated. The plain bearings in small appliances must be lubricated using a proper light oil like electric motor or machine oil - not automotive engine oil and NEVER NEVER WD40.

NEVER, ever, use WD40 as a lubricant (unless specifically recommended by the manufacturer of the equipment, that is)! WD40 is not a good lubricant despite the claims on the label. Legend has it that the WD actually is an abbreviation for Water Displacer - which is one of the functions of WD40 when used to coat tools. WD40 is much too thin to do any good as a general lubricant and will quickly collect dirt and dry up. It is also quite flammable and a pretty good solvent - there is no telling what will be affected by this.

WD40 has its uses but lubrication unless specifically recommended by the manufacturer (of the equipment, that is) is not one of them. Results initially may be good with that instant gratification that comes from something returning to life. However, the lighter fractions of WD40 evaporate in a few days

For very small metal-in-plastic types, the following might be useful:

(From: Frank MacLachlan (fpm@bach.n2.net).)

> "I've had good luck with a spray lubricant called SuperLube. It contains a solvent which evaporates and leaves a Teflon film which doesn't migrate or retain dust. I spray some into a spray paint cap and then apply the solution with a toothpick, allowing the lubricant to wick into the bearing areas. Worked great for some balky Logitech mice I purchased at a local swap meet."

- **Frictionless bearings** are usually of the ball or roller variety. An inner ring called a race rotates supported by a series of balls or rollers inside an outer race. There is virtually no friction even at stand-still with these bearings. However, rolling metal to metal contact is maintained at all speeds so they are not quite as wear free as a properly maintained and constantly rotating plain bearing. However, for all practical purposes in small appliances, these will last a long time and are rarely a problem.

  Sometimes, reworking an appliance to use a ball bearing instead of a plain bearing is a worthwhile effort - I have done this with electric drills and shop vacs. They run smoother and quieter with ball bearings. Not surprisingly, higher-end models of these devices (which use ball bearings) share parts with the cheaper versions and finding standard ball bearings that would fit was not difficult.

Mechanical controllers - timing motors and cam switches

While these are not that common on small appliances, they may be present in washing machines, dryers, dishwashers. and refrigerator defrost timers. They in themselves may be considered small appliances - and often can be repaired or replaced easily.

Most of these are just small timing motors (synchronous motors running off of the AC line) which rotate one or more cams (disks with bumps) which activated one or more switches at appropriate times during the rotation cycle. Typical cycle times range from a minute or less to several hours (refrigerator defrost timer). Most like washing machine timers are in the 1 hour range. Sometimes, the motor is stopped during certain portions of the cycle awaiting completion of some other operation (i.e., fill).

These controllers therefore consist of several parts:

- **Timing motor:** A very small synchronous AC line operated motor with an integral gear train is most common. Sometimes, the rotor and geartrain are in a sealed, easily replaceable unit - a little metal case that clamps within the pole pieces of the AC field magnet. In other cases, it is a separate motor assembly or an integral part of the overall timer mechanism.

- **Escapement (not present on all types):** This is a device which converts the continuous rotation of the timing motor to a rapid movement for each incremental cam position. A common type is a movement every 45 seconds to the next position. This assures that the make or break action of the switches is rapid minimizing arcing.

- **Cam(s):** One or more cams made of fiber composite, plastic, or metal, are rotated on a common shaft. There will be one set of switch contacts for each circuit that needs to be controlled.

- **Switches:** These will either be exposed sets of contacts or enclosed 'microswitches' which are operated by the cams.

Testing: If the controller is not working at all, check for power to the motor. Listen for the sound of the motor parts rotating. Check for gummed up lubrication or broken parts.

If some of the circuits do not work, check the switches for dirty or worn contacts or broken parts.

Electronic controllers - simple delay or microprocessor based

These can range from a simple R-C (resistance-capacitance) circuit to provide the time delay in a toaster to sophisticated microprocessor based systems for programming of a coffee maker or microwave oven.

While generally quite reliable, bad solder connections are always a possibility as well as failed parts due to operation in an environment prone to temperature extremes.

Testing: Check for bad solder connections and connectors that need to be cleaned and reseated. Inspect for obviously broken or burned parts. Test components for proper value.

For digital clock/programmers or microprocessor based controllers, not much else can be done without a schematic - which not likely to be easily available.

Batteries - Alkaline, Lithium, Nickel-Cadmium, Lead-Acid

More and more small appliances and power tools are cutting their cords and going to battery power. Although there are a large number of battery types, the most common for power applications (as opposed to hearing aids, for example) are:

- **Alkaline:** Primary (non-rechargeable, for the most part), long shelf life, high energy density.

- **Lithium:** Primary and secondary (rechargeable) available though most appliance applications (which are just beginning to develop) are not rechargeable. Long shelf life, very high energy density. Still quite expensive.

- **Nickel Cadmium:** Most common rechargeable technology in cordless appliances and power tools. However, relatively fast self discharge and on about half the capacity of a similar sized Alkaline. Now being replaced for higher performance applications with Nickel-Metal-Hydride (NiMH). **CAUTION** NiMH batteries generally require a different type charger or else they will rapidly fail. Thus, you can't just pop a set of NiMH cells into your old Dustbuster!

- **Lead-Acid:** Secondary type similar to the battery in your automobile but packaged in a totally sealed container which is virtually indestructible and leakproof. Medium self discharge rate but will deteriorate if left discharged for an extended period of time.

See the document: Notes on the Troubleshooting and Repair of AC Adapters, Power Supplies, and Battery Packs, and Other Related Information for more details.

AC adapters and chargers - wall 'warts' with AC or DC outputs

These wall adapters are used to power many small electronic devices and appliances directly and/or to recharge their batteries. They usually plug directly into the wall socket and convert the 115 VAC (U.S.) to a lower voltage - 3 V to 24 V AC or DC typical. More sophisticated units may actually be a switching power supply with smart electronic control of battery charging and power management. The following are typical types:

- **AC output:** 3 to 24 VAC (or more) at 50 mA to 3 A. The only internal component is a power transformer which may include a thermal or ordinary fuse for protection.

- **DC output:** 3 to 24 VDC (or more, under load) at 50 mA to 1.5 A. In addition to the power transformer, there is a rectifier, filter capacitor, and possibly a three terminal IC regulator (not that common). Some type of protection will probably be built in as well.

- **Universal/switching power supply:** Typically 6 to 18 VDC at .5 to 3 A. These will usually operate off of any voltage input from 90 to 240 VAC (or DC) and provide a well regulator output. There will generally be an internal fuse as well as overvoltage and overcurrent protection.

In some cases, a single adapter will put out multiple voltages. See the document: Notes on the Troubleshooting and Repair of AC Adapters, Power Supplies, and Battery Packs, and Other Related Information for more details.

AC Line and Battery Powered Household Appliances

Table lamps

This is the most popular type of lighting for reading or general illumination. The type described in this section takes normal 115 VAC light bulbs.

The common table lamp is just a light duty cordset, switch, and sockets for one or more incandescent light bulbs. In many cases, the switch and socket are combined into one assembly. In other designs, particularly where more than one bulb can be lit independently (for example, a large bulb up top and a night light in the base), a separate switch (rotary or push-push) selects the light bulb(s) to be turned on.

For the most common combined switch and socket, there are several varieties and these are all generally interchangeable. Therefore, if you want to take advantage of the added convenience of a 3-way bulb allowing low, medium, and high illumination, it is a simple matter to replace the simple on-off switch in your lamp with a 3-way switch (not to be confused with the 3-way switches used in house wiring to control a single light fixture from 2 places).

- Wire color coding: Brass screw is AC line Hot, Silver is Neutral.

Virtually the same switch/socket combo is used where there is a bulb in the top and the base. But instead of switching the extra contact inside a 3-way socket, that terminal goes to the bottom lamp holder.

- Wire color coding: Brass screw is AC line Hot, Silver is Neutral and is also connected to the outer shell of the bottom lampholder, Black goes to the centter of the bottom lampholder.

Push-push, pull chain, and rotary switches are common for simple on-off control. The 3-way switches are usually of the rotary variety with off-low-medium-high selected as the knob is rotated. The 3-way bulb has two filaments which can be switched on individually or in combination to provide the 3 levels of illumination.

Dimmer sockets can often be substituted for the normal kind as long as conventional incandescent bulbs (and not compact fluorescents) are to be used.

Touch and even sound activated switch-sockets are also available though my personal recommendation is to stay away from them.

Most common problems: burned out bulb, worn switch, bad plug or cord. Where the light flickers, particularly if jiggling or tapping on the switch has an effect, a bad switch is almost always the problem. Switch failure is more common when using high wattage bulbs but can occur just due to normal wear and tear.

Replacements for most common switches and sockets are readily available at large hardware stores, home centers, and electrical supply houses. It is best to take along the old switch so that an exact match (if desired) can be obtained. While the thread sizes for the screw on socket shells are quite standard, some older lamps may have an unusual size. For more complicated switches with multiple sockets, label or otherwise record the wiring. If color coded, cut the wires so that the colors are retained at both the lamp and switch ends.

Rebuilding a basic table lamp

As noted in the Introduction, virtually any table lamp can be restored to like-new electrical condition for a few dollars at most. The following is the detailed procedure for the majority of common table lamps found in the U.S.

This is assumed to be the type of lamp which has a combination socket and switch with a metal (brass-colored usually) outer shell. It is your decision as to whether a simple on-off switch or a 3-way type is to be used - they are usually interchangeable and a normal light bulb can be put into a 3-way socket (two clicks of the knob will be needed to switch a normal light bulb on or off, however). You can also put a 3-way bulb into a normal socket but you will, of course, only get one level of illumination (medium). For lamps with lighted bases, also see the section: Lamps with night-light bulbs in their base.

You will need: (1) a new socket/switch of the appropriate type and (2) a new cordset (if you want to replace this as well). A polarized type plug is desirable to minimize the possibility of shock when changing bulbs. A medium size straight blade screwdriver and wire strippers are the only required tools.

- First, unplug the lamp!!!

- Rremove and set aside any shade, frosted chimney, and other cosmetic attachments.

- Examining the metal shell, you will note that it is in two pieces. If you look carefully, there will probably be indications of where firmly pressing the top portion will allow it to be separated from the bottom part mounted on the lamp. These are usually near where the knob, button, or chain, enters the switch. Sometimes, a fine screwdriver blade will be useful to gently pry the two halves apart.

- With the top part removed, unscrew and disconnect two wires and remove the switch. If desired, loosen the set screw (if any) and unscrew the bottom portion of the shell. If you are simply replacing the switch, at this point you would just attach the new one and reassemble in reverse order. Screw on the bottom of the new switch enough so that it is either tight or until the threads are fully engaged but not pressing on or protruding above the cardboard insulating disk in the bottom half of the shell. If the entire assembly is still loose, it should be possible to tighten hardware on the bottom of the lamp to secure it against rotation. Note: it is important to do this to avoid eventual damage to the wires should the switch move around significantly during normal use.

- To replace the cordset, you may need to partially remove any felt pad that may be glued to the base of the lamp. Sometimes, it is possible to cut off the old plug, attach the new cord to the end of these wires, and pull it through. However, in most cases, there will be a knot or other strain relief in the original cord which will make this impossible (and you will want to replicate this in the replacement as well). Therefore, if needed, carefully peel back the felt pad only enough to gain access to the interior. In some cases, just cutting a small X in the center will allow sufficient access and this can be easily patched with a piece of cloth tape.

- Install the new cord in exactly the same way as the original with a knot for a strain relief if needed. If there was no strain relief to begin with, adding a knot is a good idea if there is space for one in the base. Snake the cord through to the top of the lamp.

- Strip the ends of the wires to a length of about 1/2 inch and twist the strands tightly together in a clockwise direction. If you are using a cordset with a polarized plug, identify the wire attached to the wide prong (with a continuity checker or ohmmeter if it is not clearly marked by a stripe on the insulation) and connect it to the silver colored screw. Connect the wire attached to the narrow prong to the brass colored screw. Always wrap in a clockwise direction. See the section: Attaching wires to screw terminals.

- Confirm that there are no loose wire strands and that the insulation is nearly flush with the screw to avoid possible shorts. Pop the shell top with its insulating cardboard sleeve over the switch and press firmly onto the base. There should be a very distinct click as it locks in place.

- If needed, adjust the strain relief at the base of the lamp so that pulling on the cord does not apply any tension to the wires attached to the switch. Tighten the nut in the base of the lamp holding the entire assembly in place if the socket is still loose and rotates easily. Don't overdo it - the supporting structure is often just a glass jar or something similar. Put a drop of Loctite, nail polish, Duco cement, or something similar - or a second nut - on the threads to prevent the nut from loosening. Use some household cement to reattach the felt pad you peeled back earlier.

Lamps with night-light bulbs in their base

These are the types of lamps where either the normal bulb on top or a smaller one in the base (or both) can be turned on using a turn-key or pull-chain.

This is a standard, if somewhat unusual socket. It is basically the same as a 3-way type but with the extra connection going to the bulb in the base of the lamp. In the old days when sockets were assembled with screws instead of rivets, it might have been possible to modify a new 3-way socket to provide the extra connection.

An electrical supply parts distributor or lamp store should have what you need or be able to order it for you.

Take note of the connections as you remove the old socket to avoid mistakes. When routing the wires to the bulb in the base, avoid allowing the hot bulb from contacting the insulation - the plastic stuff might melt (for a 7 W or less wattage bulb and high temperature insulation is probably not an issue, however).

What causes a lamp to flicker?

Many things can cause the light bulb in a table lamp to flicker:

- Loose bulb(s). :-)

- Squashed center contact in socket. With the plug pulled or power off, use a small flat blade screwdriver of similar tool to gently bend the center metal piece so it is raised from the base (at about a 20 or 30 degree angle).

Then, DON'T tighten the bulbs down all the way - just so they are a snug fit in the socket.

- Bad switch. These do wear out particularly if multiple high wattage bulbs are being used. If gently jiggling the switch results in flickering this is the most likely cause.

- Bad connections. These could be anywhere but the most likely locations (where only a single lamp is involved) would be either at the screw terminals on the switch or from a plug that isn't making secure contact in the outlet - check it.

- Voltage fluctuations. Occasional flickering when high wattage appliances kick in is not unusual especially if they are on the same branch circuit but could also be a symptom of other electrical problems like a loose Neutral connection - see the section: Bad Neutral connections and flickering lights or worse.

  If a dimmer control is present, keep in mind that these are somewhat more sensitive to slight voltage fluctuations especially when set at low levels. You may simply not have noticed any flickering with a normal on/off switch.

High intensity lamps

These include several types but they all use a transformer to reduce the 115 VAC to something lower like 12-24 V.

Tensor(tm) (and their clones) high intensity lamps have been around for over 30 years and are essentially unchanged today. They use a low voltage transformer producing 12-24 VAC along with a special high output light bulb that looks similar to an automotive tail light. However, it uses substantially more current for the same voltage and puts out a much more intense, whiter light. These are not halogen lamps though their spectral characteristics are similar since the filaments run hotter than normal incandescents - and have shorter lives.

Some will have multiple levels of illumination based on selecting taps on the transformer. Normal dimmers may not work (and should not be used) with these due to their transformer design - damage to the dimmer or lamp may result and this may be a fire hazard.

Problems with Tensor lamps tend to center around the socket and switch. These may fail due to overheating as a result of the high temperature and high current operation. Replacements are available but they may take some effort to locate. A replacement lamp may be cheaper. (I often find complete Tensor lamps in perfect operating condition at garage sales for around $2.

Halogen lamps and fixtures

Halogen lamps share many of the design characteristics of high intensity lamps in that they are designed for local high intensity lighting and use a transformer usually (though some may use solid state voltage conversion instead). While some halogen lamps come with dimmers, some of the advantages of the halogen cycle are lost if the bulbs are not run at full power. The worst case is where they are operated just below full power - too cool for the halogen cycle to take place but hot enough for substantial filament evaporation to occur.

Should the dimmer portion of such a fixture fail or become unreliable, it may a blessing in disguise since the lamp will either run at full intensity or can be easily rewired to do so by bypassing the electronics and just using the on/off switch!

WARNING: halogen bulbs run extremely hot and are a serious fire hazard and burn hazard if not properly enclosed. When changing a halogen bulb, wait ample time for the old one to cool or use an insulated non-flammable glove or pad to remove it. When installing the new bulb, make sure power is off, and do not touch it with your fingers - use a clean cloth or fresh paper towel. If you do accidentally touch it, clean with alcohol. Otherwise, finger oils may etch the quartz and result in early - possibly explosive failure - due to weakening of the quartz envelope.

Safety guidelines for use of halogen lamps

These guidelines were prompted by a number of fires including some fatalities that have been linked to improper use of halogen lamps - in particular the high power torchiere variety of floor lamps. However, the guidelines apply to many other types of halogen lamps including work-lights, desk lamps, slide and overhead projectors, and other lamps or fixtures where the bulb is not entirely enclosed and thermally insulated from the exterior.

(Source: The Associate Press except as noted).

Safety groups recommend the following precautions for owners of halogen torchere lamps with tubular bulbs:

- Place the lamps where they cannot be tipped over by children, pets, or strong drafts (away from open windows, for example).
- Never use halogen lamps in children's bedrooms or playrooms where combustible objects like stuffed toys may be accidentally placed on top of or next to them.
- Never use a replacement bulb of a higher wattage or of a different type than specified by the manufacturer. Avoid bulbs larger than 300 W.
- Never attempt to replace or discard a bulb that is too hot to touch.

  Do not touch the new bulb with your fingers as the oils and acids may make them more prone to exploding. Clean the bulb thoroughly with isopropyl alcohol after any accidental contact (--- sam).
- Never drape cloth over the lamp.
- Operate the lamps at less than maximum wattage on a dimmer whenever possible.

  Note that this may not result in maximum life but will be safer due to the lower temperature of the bulb (--- sam).
- Keep lamps away from elevated beds like bunk beds where the bedding may get too close to the bulb.
- Never use unprotected halogen lamps in locations like bathrooms where water may splash resulting in the bulb exploding (--- sam).
- Never operate lamps with their thermal or UV shields removed (--- sam).

Bad connections in halogen lamps

(From: Norbert Koot (norbert@ican.net).)

- Dimmable 120V household halogen lamps that make popping noises as they are turned on, and have light output that is not smooth. This appears to be common with the less expensive "torchiere" type floor lamps with straight tube bulbs as a result of poor or deteriorating contacts at the bulb ends.
- Replacement bulbs for the same lamps have recessed contacts, that may be recessed too far for the original contact to reach.

I have used the same technique to fix both these problems: with a medium power soldering iron, simply tin the contact. Then before it cools, hold a center punch in the molten solder to make a cup shape of sorts. This keeps the bulb secure in the spring-loaded lamp contacts.

Touch lamp problems

Personally, I think touch lamps are one of the dumber uses of technology to appear on this planet but that is just my opinion. :-)

These are susceptible to damage from voltage surges or just plain old random failures. In addition, the current surge that often results at the instant an incandescent bulb burns out (the bright flash) may blow the thyristor in the electronics module.

If the lamp is stuck on, the thyristor is probably shorted. The specific part can be replaced but to be sure it is bad, some testing will be needed and it is probably soldered in place. However, if you have repaired an ordinary lamp, you will be able to replace the entire module fairly easily.

If the lamp is stuck off, there could be a bad connection or bad bulb, or the electronics module is defective. Again, replacement is straightforward.

Erratic problems could be due to bad connections, dried up electrolytic capacitors (especially if the electronics module is near the hot bulb), or even external E/M interference (e.g., a dimmer or vacuum cleaner on the same circuit).

Some problems are of the following type:

> "I have 2 touch lamps in the bed room and they are both plugged in to the same receptacle. Every once in a while the lamps come on by themselves for no apparent reason. Even more strange is that every so often just one lamp turns on by itself."

(From: Tim Moore (tmoore@interserf.net).)

These use a MOSFET type circuit to switch the lamps on and off. The circuit is attached to the metal in the lamp base. When you touch it the impedance changes ever so minutely but enough to change the MOSFET from off to on and visa versa. My wife could never get our lamps to switch, she often had to blow on her hand first to get it moist so it would make better contact. Here is part of the problem. It takes a certain amount of signal from the lamp base to switch the circuit. Electronic parts all have acceptable ranges of operation and when put into identical circuits they sometimes perform differently. One circuit might need a good hard touch while the other might need only a slight touch. Power surges would often switch one of my lamps, although it didn't happen often. A strong radio signal could do it too. The bottom line is that these lamps are not rocket science and can't be counted on as 100% reliable. Sorry, that's the truth. You give up a little to get the convenience of just having to touch them. I ended up removing mine - an electrical storm wiped one out and wiped the other out a few years later.

Touch lamps and RF interference

While many people swear by touch lamps, nearly as many swear at them since in addition to frequent failures (bulb burn-outs killing the triac, for example), they can also be tempermental, cycling through their brightness settings and/or turning on or off due to static electricity, power line transients causing RFI, and stray pickup from the local ham rig.

(Portions from: John Evans - N0HJ (jaevans@codenet.net).)

Here is a fix my buddy, Ed, a fellow ham radio operator, has come up with to solve this problem.

As usual it took 8 months and 10 minutes to fix.

Two parts: 1/4 watt, 1k Ohm resistor and 2.5 mH 1/2 watt size molded coil. Connect in-line with the touch wire.

I send 2 or more watts from my rig. My son works the CB.

You'll find it on when you get home.

So the darn thing is an oscillator which changes frequency when you touch it. The circuit does the rest. By adding the resistor/inductor pair, its sensitivity is reduced and the problem disappears.

One more thing: (Most important!), you won't hear interference FROM the oscillator in the lamp anymore on your radio.

And don't open up the module inside the lamp base, you are wasting your time there, and adding more work to glue the module back together.

Just Choke off the sense wire with the resistor and 2.5 mH choke. You'll be fine.

Incandescent fixtures

A fixture is normally permanently mounted to a wall or ceiling. However, aside from not usually having a plug - being directly wired - they are similar to table lamps in what is inside.

There will be one or more sockets for light bulbs - often all wired in parallel so that all the bulbs come on at the same time. For wall fixtures, there may be a switch on the fixture though most often the switch is mounted on the wall elsewhere.

Unlike table lamps where most of the heat rises from the bulb away from the socket, mounting the sockets horizontally or inverted (base up) can result in substantial heating and eventual deterioration of the socket and wiring. Common problems relate to this type of problem - bad connections or brittle wire insulation. Replacement parts are generally available at home centers and electrical supply houses. Just make sure to kill power before working on any fixture wired into your house's electrical system!

Removing the base of a broken light bulb

Turn off power and double check! Wear safety goggles to protect against flying bits of glass.

Then use a pair of needlenose pliers or any other tool that will grip what is left of the base to twist it free. A piece of a raw potato may even work!

Locating burnt out bulbs in series circuits

Christmas and other decorative lights are constructed as series strings of low voltage light bulbs as shown below:

```
                          Bulbs
    Male o------O----O----O----O----O----O----O----O---+
    Plug                                               |
         o---------------------------------------------+
```

Or the following which permits several strings to be connected end-to-end:

```
          +----------------------------------------------+
          |             Bulbs                            |
    Male o--+---O----O----O----O----O----O----O----O---+  +--o Female
    Plug                                               |       Socket
         o---------------------------------------------+-----o
```

Many variations on these are possible including multiple interleaved series strings. One of the bulbs in each circuit may be a flasher. All newer light sets must include a fuse as well.

In a series connected circuit, if one bulb burns out, all lights go out. The newer types include a device in each bulb which is supposed to mechanically short out that bulb if it burns out. However, these don't always work or you may have a set that doesn't have this feature.

The following assumes a single series circuit - large light sets (e.g., perhaps 50 or more) will have multiple series strings so you will have to identify the particular circuit that is bad. If more than one bulb is burnt out, this may further complicate matters.

To locate a burnt out bulb in a series string, you can use the binary search approach: pull a bulb in the middle of the string. Test the bulb and between the power cord end and the middle for low resistance. If these are ok, you know the bad bulb is in the other half. Then divide the 'bad' portion in half and test one half of it and so forth. For example, using this technique, you will need to make at most 6 sets of measurements to locate a bad bulb in a 50 light set.

Sears, K-Mart, Radio Shack, among others sell inexpensive testers (e.g., Lite-Tester Plus, about $4). These detect the electric field generated by the (now floating) wire on the Hot side of the gap of the burnt out filament. These will also locate open wires and blown fuses in the same manner.

I have also heard of bulb sets in which the individual bulbs are gas filled in such a way that if the filament breaks, current flows across the gap through the gas resulting in a faint glow in the burnt out bulb. I don't know if these things still exist.

WARNING: Do not be tempted to bypass a bad bulb with a wire. This will reduce the total resistance and increase the current to the remaining lamps shortening their life. Replace a few bulbs and the entire string will pop. This is a serious safety hazard especially on older light sets that may not have internal fuses. Also, some fuses look like lamps - replace only with an identical fuse - not with a lamp!

Comments on Christmas tree bulb/string repair

Original type of problem: No light but fuses are good and no obvious damage.

(From: Ken Bouchard (bouchard@ime.net).)

My advice, is trash them and go out and buy new ones. After all, you can get them typically around 5-10 bucks a set.

Then you have the old set to raid bulbs from, for the ones that blow out.

Quality control is not an issue when they build xmas lights. One slight tug of a wire, can break it, and the entire set goes dead.

First I assume you wiggled all the bulbs, often just a loose bulb causes this. In the smaller type bulb sets the string is wired in sections, so one bulb goes out, and every 4th or 5th one is dead.

The little bulbs were also designed, that if the filament breaks in the bulb a piece of foil inside it shorts out that bulb so that the remaining lights keep on working. This works up to a point, until more than 4-5 bulbs blow out at once, then the remaining ones get too much voltage and blow out too.

Often the cheesy sockets get water in them and corrode, and/or the wires on the bulb get twisted or broken.

They also use a cheap method of crimping the wiring together in these lights. Most times you can find the broken wire, by inspecting, seeing where it goes into the socket it pulls out easily.

Well avoid doing this when the set is live (heh...) unless you like the idea of getting zapped.

Shortening a Christmas light string

For strings using large 115 V bulbs, this is easy as all the bulbs are in parallel like the outlets in your house. Cut off the unwanted bulbs and insulate the wire ends.

However, for the common type of tiny bulbs that are in series, you cannot really do this easily. Removing and bypassing 1 or 2 bulbs in a 50 light string won't have much effect on the remaining bulbs but cutting it in half will double the voltage on each bulb - you will get a very bright string of lights for a very short time.

The only way to shorten a string by more than a few percent of lights and have it survive is for the current to be limited by a bulb or resistor or to run it off of reduced voltage. A light dimmer might work except for the fact that they typically require a minimum load of 60 to 100 W - your light string is a small fraction of this.

However, for the special case of 1/2 (give or take) the original number of bulbs, there is a simple solution: A rectifier diode (1A, 200 V PRV min.) in series with the string will cut the effective voltage approximately in half. Typical part numbers are 1N4003 though 1N4007. Even Radio Shack will carry them.

Whatever you do, make sure your connections are secure (with wire nuts or properly soldered) and well insulated. For fire safety, the built-in fuse (usually at the plug-end) must be retained.

Controlling a fixture or outlet from multiple locations

Although the specific case of controlling a fixture or outlet from exactly two locations is a special case of switches at more than 2 locations, each is described separately since the former is much more common.

Should you care, these implement the multiple input XOR (exclusive OR) logic function for controlling electrical devices.

Note: See the section: Dimmer switches and light dimmers if you would like to have control of brightness of a lamp or fixture from multiple locations.

The descriptions below are for using traditional mechanical switches at more than one location. There are also electronic solutions, some even are wireless, where a control module is placed between the load (e.g., lamp or fixture) and the power line and the 'switches' or user controls are mounted remotely. The X10 system is a more general way of doing this providing fully programmable timed (automatic) switching and dimming (where appropriate) from one or more locations.

- For exactly two locations (say at the bottom and top of basement stairs), you will need a pair of what are known as 3-way switches.

  These are actually SPDT (Single Pole Double Throw) switches which look like ordinary wall switches but have 3 screws instead of 2. Two of these screws will be the same color (usually brass) while the third will be different (darker copper or brown). They may be marked as well.

Note that a socket for a 3-way bulb for a lamp is not related to this - only the name is similar.

Typical wiring for controlling a fixture or outlet from exactly two locations is as follows:

```
            Location 1         Location 2
             3-way SW     A     3-way SW          +---------+
                /o----------------o\              | Fixture |
    Hot o-----/                     \o-----------|   or    |--------o Neutral
                 o----------------o        Center | Outlet  | Shell
                          B               (brass) +---------+ (silver)

                                             /o---o                    o---o
  A 3-way switch connects either up  o---/         or down  o---o\          .
                                              o---o                  \o---o
```

As usual, the brass screw on the fixture or outlet should be connected to the Hot side of the wiring and the silver screw to the Neutral side.

Another common variation is shown below:

```
                                          Location 1          Location 2
                                           3-way SW    Rd :     3-way SW
                                    : Bk      /o-------------------o\
        Hot o--------------------------------/          Wh :          \o---+
                                    :          o-------------------o      |
                    +---------+     :                     :               |
                    | Fixture |     : Wh   Splice      Bk :               |
    Neutral o-------|   or    |---------------X---------------------------+
                    | Outlet  |     :     (Wirenut)       :
                    +---------+   14-2                  14-3
```

Details may differ for your particular installation (like to which sides the Hot and Neutral are connected and/or particular wire colors used).

You may also see something along the lines of the following which works but may not be allowed by NEC Code for obvious safety reasons (the load can be electrically live even if off and someone wiring it this way may be tempted to pull the Hots and Neutrals from separate circuits) but has that ever stopped anyone from doing something stupid?):

```
                                 +---------+
         Hot o------------o\     | Fixture |     /o------------o Hot
                             \---|   or    |---/
     Neutral o------------o      | Outlet  |      o------------o Neutral
                                 +---------+
```

(And, if you accidentally get the Hots from opposite phases - watch out!)

- For more than two locations (say at 3 doors to your dining room), you will need a combination of 3-way switches and 4-way switches. Two of the 3-way type will be needed at the ends of the circuit (below) with 1 or more 4-way type in between. Thus for 'n' switch locations, n-2 of the 4-way switches will be needed.

4-way switches have 4 terminals arranged as two pairs. In one position pair 1 is connected to pair 2 straight through. In the other position, the connections are interchanged.

Typical wiring for controlling a fixture or outlet from 3 or more locations is as follows:

```
        Location 1     Location 2     Location 3
         3-way SW   A   4-way SW   A   3-way SW        +---------+
            /o------------o\ /o-----------o\           | Fixture |
  Hot o---/                 /               \o---------|   or    |---o Neutral
             o------------o/ \o-----------o    Center  | Outlet  | Shell
                    B              B           (brass) +---------+ (silver)

                                              o---o                o\ /o
  A 4-way switch connects either straight           or exchange    /    .
                                              o---o                o/ \o
```

This can be extended to an arbitrary number of positions.

As usual, the brass screw on the fixture or outlet should be connected to the Hot side of the wiring and the silver screw to the Neutral side.

Note that a 4-way switch can be constructed from a DPDT (Double Pole Double Throw) type (e.g., toggle switch) as follows:

```
                    +--------------+
                    |              |
      A(in) o---------------+      |
                    |       |      |
                    +----o  o/ o-------+------o A(out)
                             :     |   |
                    +----o  o/ o---+----------o B(out)
                    |       |  DPDT    |
      B(in) o---------------+  toggle  |
                    |          switch  |
                    +------------------+
```

For low voltage (non-house wiring) or panel mount applications, this may be easier than using actual 4-way switches (which are probably not available in small sizes).

The 3-way switches (at least the basic white, ivory, or brown toggle type) can be found nearly anyplace that sells common electrical devices including hardware stores and home centers. You may have to look a little harder for 4-way switches as well as styles or colors to match your decor as these are not as widely available. However, a decent electrical supply house should have all of these.

The wires marked A and B (sometimes called 'travelers') may be in a single (Romex) cable and should be on the screws that are both the same color.

If you do use Romex with a black and white wire, put black tape on the insulation at the ends of the white wire (or paint the ends black) to indicate that this is a Hot wire and not a Neutral. This is required by Code but allows the use of this type of wire.

These diagrams represent one wiring arrangement. Sometimes, there are other slight variations. For example, you might find the switches in the Neutral instead of Hot portion of the wiring - however, this is not recommended.

UK translation for 3-way and 4-way wiring

For 2 locations, you would think that a pair of 2-way switches rather than 3-way switches would be needed! Makes sense, huh? Actually, the number of screw terminals on the switch correlates with the 3-way or 4-way designation. (I don't know anyone who refers to 2-way switches in the US.)

Perhaps they got it right in the UK :-).

(From: Dion L Heap (Dion@homesix.globalnet.co.uk).)

I had to translate the American into the English. If anyone UK is reading this then for what we (UK) call 2 way lighting is the normal stairs light with 2 switches controlling it, (one up & one down). Both these switches are "2 way switches", to add another switch you would be creating 3 way lighting, for this you use both the existing 2 way switches and in-between the L1 & L2 you use an "intermediate switch" I asked at my supplier for a 4 way switch & they thought I was talking Japanese. A phone call to MK technical support revealed that the UK equivalent is the aforementioned intermediate switch. this has 4 points, the L1 & L2s from the 2 existing 2 way switches are taken through the intermediate.

Identifying unmarked wiring or improperly functioning 3-way switch

(Also see the section: Controlling a fixture or outlet from multiple locations.)

So you forgot to label the wires before you removed the old switch, huh? :-).

Or, you moved the wires from the old switches to the new switches but guess what? The new switches may not have the corresponding screws in the same locations and your symptoms are that one switch has to be up for the other switch to do anything - and that is if you are lucky!

You have several options:

- Hire an electrician (depending on his/her competence, this may or may not actually be helpful!).
- If you can go back to the old hookup and/or examine the switches you removed to identify the original connections, do so! Then, transfer the wires to the proper color screws without regard to actual location on the switch.
- It may be obvious from the way the box is wired as to which are the A/B pair.
- Use a tester to figure out which wire is which (see below).
- Interchange the different colored screw wire with one of the others. If this doesn't fix it, swap the different colored screw wire with the other one. As long as you have only touched the wires on the old switch, you cannot damage anything by doing this.
    - For a single switch, this will require at most 2 swaps.
    - If you messed with both switches, this will require at most 6 swaps (2 in box 1, 3 possibilities for each of

these in box 2).

I won't even consider the case of more than 2 switches!

Of course, kill power before touching or changing anything!

Or a slight variation on the theme:

(From: Greg Fretwell (JRFC31A@prodigy.com).)

"Pull out one of the switches (the first one you "fixed" to create this problem) mark all 3 wires. Rotate them all one terminal to the right. Try it. If no luck shift one more time. One of those should work."

Here is one way to identify the proper wires more quickly than trial and error but requires testing the live wiring:

1. Identify the Hot wire. With all 3 wires in each box disconnected and their ends exposed, use a tester between each one and the a earth ground (the box if metal and properly grounded). With power on, only one of the 6 wires will be live.

Now, turn off the power and confirm that it is off by retesting the hot wire you identified above.

2. Connect the lone screw (the different or darker colored one) on one switch to this Hot wire. Connect the same-color screws on the switch to the other two wires. This should take care of one box.

3. With any luck, you should be able to connect the wires in the other box exactly the same way color wise.

(From: CodeElectric@Worldnet.att.net).

Check both boxes. There will be a single Hot - that goes on the common of the 3-way switch. Put the other two wires on the other two screws.

Now, at the other switch, you will find one hot. Put that on a screw, not the common. Switch the other switch, and you'll find another hot. That is the other traveler. You've got one wire left,,, that's the other common.

In more detail:

- First, shut off the power to the circuit. Then remove the wires from the switches. Ignore the colors of the wires... there's too many combinations to use so the colors won't mean anything.

- Look closely at the switches. You will find one screw different from the other two. It may be black, while the other 2 are gold, or may have the word 'common' printed near it. This is, (duh!) the 'common' terminal. The other two are 'traveler' terminals. Having identified the commons and travelers, make sure your family knows you're working with live wires, and let them know not to touch!!!!

- Turn the power back on, and out of the six wires that came off of the two switches, ONE of them will have power. Once you find that one, turn the power back off, and hook that one wire to the common terminal of a switch. Hook the other two wires in that box to the traveler terminals. It doesn't matter which one goes where. Put the switch into the box, and place the cover back on. You're done with than switch.

- Now turn the power back on, and check the remaining three wires. One will be hot. Flip the first switch, and another will be hot. These are your traveler wires. Turn the power back off, and hook those two wires to the two traveler terminals on the second switch. Again, it makes no difference which goes where. The final wire goes to the common terminal. Button everything up, and you should be done.

- Turn the power back on, and you should be up and running.

Dimmer switches and light dimmers

In the old days, a dimmer was a large high wattage rheostat put in series with the light bulb. (Some were probably also Variacs but these would have been more expensive.) Rheostats were both inefficient and producers of a lot of heat. Modern dimmers use a device called a triac (a type of thyristor) which is a solid state switch to control illumination by turning the light bulb on for only a part of each AC half-cycle (100 or 120 times a second depending on where you live) as determined by the adjustment knob or slider. This is called solid state phase control. Once switched on, it remains on for the remainder of the half-cycle:

- For low intensity, the current is switched on late in the half-cycle.

- For medium intensity, the current is switched on around the middle of the half-cycle.

- For high intensity, the current is switched on early in the half-cycle.

- For full intensity, the triac may be bypassed entirely. There will probably be a detectable click position with the control set to full brightness if this is present.

There is also a nice simple description of the principle of operation (with a little diagram) of a modern dimmer at How A Dimmer Switch Works.

Dimmers are available to replace standard wall switches and even for use in place of the light bulb socket/switch in most table lamps. However, nearly all of these are designed only for normal incandescent light bulbs - not fluorescents, compact fluorescents, or high intensity or halogen lamps (or any other type of lamp with a transformer).

(There are special dimmers for use with fluorescent lamps but these must be specifically matched to the lamp type and wattage and their dimming range is usually not very wide. See: the fluorescent lamp information at http://www.misty.com/~don/light.html for a discussion of dimming techniques and details on several relatively simple approaches that may work for your needs.)

Installation is generally very straightforward as there are only two wires and polarity does not matter. They simply replace the existing switch.

To assure long life, it is best to select a dimmer with a higher power rating than your maximum load. For example, if you are using four 100 W bulbs, a 600 W dimmer should be the minimum choice and one rated at 1000 W would be better. This is particularly true if halogen bulbs are used since these may be harder on dimmers than normal types. Further derating should be applied where multiple dimmers are installed in the same outlet box resulting in greater combined heating. Higher wattage dimmer switches will have better heat sinking as well which should result in the active components - the thyristors - running cooler. Dimmers are under the most stress and generate the most heat when operating at about 50% output.

Dimmers may fail due to power surges, excess load, momentary fault (short) at the instant of light bulb failure, or just plain old age. A failed dimmer will generally be stuck at full brightness since the thyristor will have shorted out. The mechanical on-off switch which is part of the dimmer will probably still work.

- A power surge may result in a failed dimmer just like any other solid state device.

- Make sure you are nor overloading the circuit controlled by the dimmer. Most common types are rated for 600 W maximum with heavy duty types up to 1,200 W or more. My advice is to not load them to more than 60 to 75% of their rating.

- When light bulbs burn out, there can be an instantaneous spike of high current due to the failure mechanism. This may blow a fuse or trip a circuit breaker - but it may also blow out a dimmer control.

- Dimmers are not always of the highest quality design or construction and parts may run hot - ever touch the wall plate of a dimmer running at 50% power? Long term reliability may not be that great.

You can't test a dimmer switch with a multimeter except to determine if it is totally shorted: With the control set mid-range, the resistance between the two terminals or wires should be high or infinite regardless of the switch position (if separate from the setting of the control). If it is under 10 ohms, the triac is shorted and at best you have a fancy on/off switch.

To more fully test it, you can make up a simple circuit with a wall plug and cord, and the dimmer in series with a 60-100 W light bulb (less wattage may not be enough to provide enough load and the dimming range may be restricted). Make sure everything is well insulatded!

For a 3-way type dimmer, test/connect between the common (different color wire ors crew) and each of the travelers (same color wires or screws) for all switch positions.

It is not generally worth worrying about repair of a dimmer as they are so inexpensive. However, before replacement confirm that there is no actual problem with the wiring (like a short circuit in the fixture) and that you are not overloading the dimmer.

Typical dimmer schematics

These are the type of common light dimmers (e.g., replacements for standard wall switches) widely available at hardware stores and home centers.

While designed for incandescent or heating loads only, these will generally work to some extent with universal motors as well as fluorescent lamps down to about 30 to 50 percent brightness. Long term reliability is unknown for these non-supported applications.

CAUTION: Note that a dimmer should not be wired to control an outlet since it would be possible to plug a device into the outlet which might be incompatible with the dimmer resulting in a safety or fire hazard.

Simplest dimmer schematic

The first schematic is of a normal (2-way) inexpensive dimmer - in fact this contains just about the minimal number of components to work at all!

S1 is part of the control assembly which includes R1.

The rheostat, R1, varies the amount of resistance in the RC trigger circuit. The enables the firing angle of the triac to be adjusted throughout nearly the entire length of each half cycle of the power line AC waveform. When fired early in the cycle, the light is bright; when fired late in the cycle, the light is dimmed. Due to some unavoidable (at least for these cheap dimmers) interaction between the load and the line, there is some hysteresis with respect to the dimmest setting: It will be necessary to turn up the control a little beyond the point where it turns fully off to get the light to come back on again.

The parts that fail most often are the triac, TH1, or the combination switch/control (S1/R1).

3-way dimmer schematics

There are at least two varieties of inexpensive 3-way style dimmer switches which differ mainly in the switch configuration, not the dimmer circuitry. You will probably have no reliable way of telling them apart without testing or disassembly.

None of the simple 3-way dimmer controls permit totally independent dimming from multiple locations. With some, a dimmer can be installed at only one switch location. Fully electronic approaches (e.g., 'X10') using master programmers and addressable slave modules can be used to control the intensity of light fixtures or switch appliances on or off from anywhere in the house. See the section: True (electronic) 3-way (or more) dimmers.

However, for one simple, if inelegant, approach to independent dimming, see the section: Independent dimming from two locations - kludge #3251.

Simple 3-way dimmer schematic 1

The schematic below is of one that is essentially a normal 3-way switch with the dimmer in series with the common wire. Only one of these should be installed in a 3-way circuit. The other switch should be a normal 3-way type. Otherwise, the setting of the dimmer at one location will always affect the behavior of the other one (only when the remote dimmer is at its highest setting - full on - will the local dimmer have a full range and vice-versa).

Note that the primary difference between this 3-way dimmer schematic and the normal dimmer schematic shown above is the addition of an SPDT switch - which is exactly what is in a regular 3-way wall switch. However, this dimmer also includes a choke (L1) and capacitor (C2) to suppress Radio Frequency Interference (RFI). Operation is otherwise identical to that of the simpler circuit.

This type of 3-way dimmer can be used at only one end of a multiple switch circuit. All the other switches should be conventional 3-way or 4-way types. Thus, control of brightness is possible only from one location. See the section: True (electronic) 3-way (or more) dimmers for reasons for this restriction and for more flexible approaches.

```

The parts that fail most often are the triac, TH1, or the combination switch/control (S1/R1).

Simple 3-way dimmer schematic 2

The schematic below is of a 3-way dimmer with a slightly more complex switching arrangement such that when the local dimmer is set to full on or full off, it is bypassed. (If you ignore the intermediate dimming range of the control, it behaves just like a normal 3-way switch.) With this scheme, it is possible to have dimmers at both locations without the dimmer circuitry ever being in series and resulting in peculiar behavior.

Whether this is really useful or not is another story. The wiring would be as follows:

```
              Location 1             Location 2
             3-way Dimmer      A    3-way Dimmer     +---------+
                  /o----------------------o\         |  Lamp   |
    Hot o------o/    Silver 1     Silver 2   \o------|   or    |-----o Neutral
           Brass   o----------------------o   Brass  | Fixture |
                     Silver 2  B  Silver 1           +---------+
```

(If dimming interacts, interchange the A and B wires to the silver screws at one dimmer).

This one uses a toggle style potentiometer where the up and down positions operate the switches. Therefore, it has 3 states: Brass to Silver 1 (fully up), dim between Brass and Silver 1 (intermediate positions), and Brass to Silver 2 (fully down).

```
                        Br  /o---o            Br   o---o          Br/\/o---o
  3-way dimmer is up o---o/   S1   or down o---o\  S1    or Dim o---o  S1
                             o---o                \o---o               o---o
                              S2                   S2                  S2
```

However, it is still not possible to have totally independent control - local behavior differs based on the setting of the remote dimmer (details left as an exercise for the reader).

Like the previous circuit, this dimmer also includes a choke (L1) and capacitor (C3) to suppress Radio Frequency Interference (RFI). It is just a coincidence (or a matter of cost) that the 3-way dimmers have RFI filters and the 2-way type shown above does not.

  Silver 2 o-----------+
```

The parts that fail most often are the triac, TH1, or the combination switch/control (S1/S2/R1).

True (electronic) 3-way (or more) dimmers

The objective is to be able to control a single fixture from multiple locations with the capability of dimming as well as just power on/off.

The simple type of 3-way dimmers are just a normal dimmer with a 3-way instead of normal switch. This allows dimming control from only one location. The other switches in the circuit must be conventional 3-way or 4-way type.

Connecting conventional dimmers in series - which is what such a hookup would require - will not really work properly. Only if one of the dimmers is set for full brightness, will the other provide full range control. Anywhere in between will result in strange behavior. The other dimmer may have a very limited range or it may even result in oscillations - periodic or chaotic variations in brightness. The safety and reliability of such an arrangement is also questionable.

True 3 way dimmers do exist but use a more sophisticated implementation than just a normal dimmer and 3-way switch since this will not work with electronic control of lamp brightness. One approach is to have encoder knobs (similar to those in a PC mouse) or up/down buttons at each location which send pulses and direction info back to a central controller. All actions are then relative to the current brightness. A low cost microcontroller or custom IC could easily interface to a number, say up to 8 (a nice round number) - of control positions. The manufacturing costs of such a system are quite low but due to its specialty nature, expect that your cost will be substantially higher than for an equivalent non-dimmable installation.

If control of intensity at only one of the locations is acceptable, a regular dimmer can be put in series with the common of one of the normal 3-way switches. However, your brightness will be set by that dimmer alone. See the section: Typical dimmer schematics.

An alternative is to use X-10 technology to implement this sort of capability. This would likely be more expensive than a dedicated multi-way switch control but is more flexible as well. X-10 transmits control information over the AC lines to select and adjust multiple addressable devices like lamps and appliances.

However, for the adventurous, see the section: Independent dimming from two locations - kludge #3251.

Independent dimming from two locations - kludge #3251

Here is a scheme which will permit dimming with independent control from two locations. Each location will have a normal switch and a dimmer knob. The toggle essentially selects local or remote but like normal 3-way switches, the actual position depends on the corresponding setting of the other switch:

```
                 Location 1       Location 2
           +--------+  4-way SW    3-way SW
Hot o--+---| Dimmer |----o\ /o--------o\            +---------+
       |   +--------+      /            \o----------| Fixture |------o Neutral
       |              +--o/ \o--------o      Center +---------+ Shell
       |              |                      (brass)           (silver)
       |              |            +--------+
       |              +------------| Dimmer |--+
       |                           +--------+  |
       +---------------------------------------+
```

As usual, the brass screw on the fixture or outlet should be connected to the Hot side of the wiring and the silver screw to the Neutral side.

The dimmers can be any normal knob or slide type with an off position.

Note that as drawn, you need 4 wires between switch/dimmer locations. 4-way switches are basically interchange devices - the connections are either an X as shown or straight across. While not as common as 3-way switches, they are available in your favorite decorator colors.

If using Romex type cable in between the two locations, make sure to tape or paint the ends of the white wires black to indicate that they may be Hot as required by Code.

And, yes, such a scheme will meet Code if constructed using proper wiring techniques.

No, I will not extend this to more than 2 locations!

Also see the section: Controlling a fixture or outlet from multiple locations.

CAUTION: However, note that a dimmer should not be wired to control an outlet since it would be possible to plug a device into the outlet which might be incompatible with the dimmer resulting in a safety or fire hazard.

Humming or buzzing lamps or fixtures on dimmers

Unlike the normal AC power, the output of a cheap dimmer is a chopped waveform with sharp edges every 120th of a second for 60 Hz power (or every 100th of a second for 50 Hz power). This can result in annoying audible vibration of the filaments of the light bulbs.

The severity of the problem is due to a variety of causes with the two most likely being related to the bulb's filament construction/supports and what, if any filtering, is provided by the dimmer itself - some are just worse than others and cost may not be a reliable indication of which-is-which.

There is nothing really wrong with your installation - incorrect wiring would result in it not working at all, blowing a fuse or tripping a breaker, or or not working in certain positions of switches in a 3-way or 4-way (multiple switch locations) setup. If it bothers you try a different brand of bulbs or a different brand of dimmer.

How do touch dimmers work?

(From: Neil).

Touch dimmers work in a couple of different ways, depending on the IC used. Simple ones, such as those in the cheap 'touch lamps' that you find for sale on market stalls, etc. normally have three or four preset brightness levels and an OFF setting, which are operated sequentially: touch once for full brightness, again to dim slightly, again to dim a bit more, etc, until the OFF setting is reached. The next touch will then bring the lamp to full brightness.

The better (and more expensive) units, such as the touch dimmer switches that are sold as direct replacements for conventional light switches, are similar, but have many more steps. A single touch will usually bring the lamp to full brightness, while keeping your finger in contact with the touch plate will slowly dim the lamp. You just remove your finger when the lamp is at the required brightness level.

Both kinds of touch dimmer have three basic parts;

1. A touch sensor - this normally works by picking up mains hum from the touch plate, and rectifying it in a high-gain amplifier.
2. A ramp generator - normally in the form of a digital counter with DAC output.
3. A mains power control element - Generally a thyristor or triac. In some designs, this is encapsulated within the IC, while in others it is a discrete component.

Most touch dimmers can be operated by standard push-button switches as well as a touch plate, and many can be adapted for remote control.

There are a number of specially designed IC's available for touch dimmers, notably the HT7704B ,a four-step device for touch lamps as described above, and the SLB0586A, which is the other kind, with facilities for remote control.

(From: Jack Schidt (jack@wintel.net).)

Body detection usually follows one of three forms:

- 60 Hz (50 Hz) detection from the touch. High impedance timer or op-amp receives 60 Hz emitted from power lines. Body is antenna, contacting button. rectification / pulse shaping drives relay.
- Resistive (DC sensing) detection from the touch. Simple enough, two closely placed touch points, simple op amp or transistor circuit pulses relay.
- AC removal (capacitance) detection from the touch. An insulated contact is AC driven through a high impedance. If a finger (or a body) comes close, that signal is attenuated, and detection is 'missing pulse' type, generating an output to toggle relay.

Light dimmers and interference with radio or TV

Due to the sharp edges on the power supplied by a cheap light dimmer, Radio Frequency Interference (RFI) may be conducted back down the wiring directly to other appliances and/or radiated through space as well. Effects will include noise bars in the picture on some TV channels and/or a buzz in the audio across portions of the AM radio band.

(Zero crossing switching, a technique used with electrical heaters and heating appliances to minimize RFI cannot be used for lighting as it would result in way too much flicker or a very limited number of brightness levels.)

Better light dimmers will include a bypass capacitor (e.g., .01 uF, 1kV) and a series inductor to suppress RFI but these components were often left off in basic models. The FCC has tightened up on their regulations around 1992 so replacing older dimmer switches with newer ones may be the easiest solution.

I can't really recommend a particular model that it better in this regard. However, the package may list 'low RFI' as a feature so checking out Home Depot or wherever won't hurt.

Installing in-line power line filters may work but other options like replacing all your house wiring with metal conduit, or only listening to FM radio are probably not realistic!

BTW, I have used dimmers and AM radios to trace wiring inside the wall! :)

Dimmer wall plate hot to touch

This is probably normal if the dimmer is controlling a load which is close to (or beyond) its maximum rating. For most inexpensive dimmers, this is 600 W. Others are commonly rated up to 1,200 W. Keep in mind that the switching device (the triac) is dissipating a wattage proportional to the load. With a full 600 W load, it may be as much as 6 to 10 W (depending on the setting of the control knob), which is not a trivial amount of power - and the face plate is used as a heat sink. The larger ones have to dissipate even more power.

My recommendation would be to get a dimmer rated for 30 to 50 percent more power than you are using. It will still get warm but will have a better (probably finned) heat sink and will be running way below it maximum rating and should be more reliable. In general, any device should be derated to boost longevity!

Can I use a dimmer to control transformer operated low voltage lighting?

(Portions from: Charles Sullivan (chrs@dartmouth.edu).)

It is very tempting to try using a common light dimmer to control devices using power transformers. Will this work?

It will usually work fine, but it can lead to a fire hazard and is not recommended. Most major dimmer manufacturers have special dimmers designed for this application, that prevent the hazard inherent in using a standard dimmer. It is worth your while to use one of those.

The problem results from the inductive nature of the impedance the transformer presents to the dimmer. The load is most inductive when the transformer is lightly loaded. Even if you set up your system with a fully loaded transformer, it can become lightly loaded when bulbs burn out. If there is any small asymmetry in the firing angle of the triac on the two half cycles, there will a be small DC voltage across the transformer winding. This is no big deal - you'll get a bit of DC current, and the core will run with some DC flux, and may saturate a bit, but neither will cause significant heating or a real hazard. However, the point at which the triac turns *off* will also then be different on the two half cycles. Because ordinary dimmer circuits time the triac turn on from the turn off point, not from the line voltage zero crossing, the asymmetry in turn-off times leads to a even greater turn-on time asymmetry. If the load is sufficiently inductive, this process can "run away" until the dimmer is acting as a diode, applying nearly full line voltage across the transformer winding. Ordinarily, this would result in enough current to trip a circuit breaker or a fuse, but smaller transformers can have enough DC resistance to keep the current low enough that the breaker does not trip. When I've experimented with this, the transformer winding soon started to smoke. I didn't continue the experiments to see what would happen next, but there have been reports of fires starting this way. A suitably rated small fuse installed in series with the transformer would probably work but I wouldn't want to depend on it.

Dimmers designed for this application can use several methods to get around the problem. Some use a DC detection circuit and shut off if DC is detected. Others use a three-wire connection scheme, such that the line- neutral voltage is available to the dimmer, and can be used for the timing reference, so that the triac is always fired at the same time relative to the line-voltage zero crossing, not relative to when the triac turns off. Thus, although there may still be a small amount of DC present due to asymmetry in the firing circuit, the system can never run away to the point of applying a much high DC voltage. (In good dimmers designed for this application, the asymmetry will also be small to begin with.)

Flashlights and lanterns

Battery operated flashlights (torches for those on the other side of the Lake) and lanterns are among the simplest of appliances. We probably all have a box or drawer full of dead flashlights.

The most common problem after dead batteries is very often damage due to leaky batteries. Even supposedly leak-proof batteries can leak. Batteries also tend to be prone to leaking if they are weak or dead. Therefore, it is always a good idea to remove batteries from any device if it is not to be used for a while. How to assure the batteries will be with the flashlight? Put them in separate plastic bags closed and fastened with a twist tie.

Test the batteries with a multimeter - fresh Alkalines should measure 1.5 V. Any cell that measures less than about 1.2 V or so should be replaced as they will let you down in the end. On a battery tester, they should read well into the green region.

Check the bulb with a multimeter on the ohms scale - a bad bulb will test open. Bulbs may fail from use just like any other incandescent lamp or from a mechanical shock - particularly when lit and hot. Replacement bulbs must be exactly matched to the number and type of batteries (cells). A type number is usually stamped on the bulb itself. There are special halogen flashlight bulbs as well - I do not really know how much benefit they provide.

The switches on cheap flashlights are, well, cheaply made and prone to unreliable operation or total failure. Sometimes, bending the moving metal strip a bit so it makes better contact will help.

Clean the various contacts with fine sandpaper or a nail file.

If a flashlight has been damaged as a result of battery leakage, repair may be virtually impossible.

High quality flashlights are another matter. Maglights(tm) and similar units with machined casings and proper switches should last a long time but the same comments apply to batteries - store them separately to avoid the possibility of damage from leakage. Keep a spare bulb with each of these - the specialty bulbs may be harder to find than those for common garbage - sorry - flashlights.

Rechargeable flashlights include a NiCd or lead-acid battery (one or more cells in series) and the recharging circuitry either as part of the unit itself or as a plug-in wall adapter or charging stand. See the sections: "Battery chargers" and "Typical rechargeable flashlight schematics" for more information.

Typical rechargeable flashlight schematics

Here are circuit diagrams from several inexpensive rechargeable flashlights. These all use very 'low-tech' chargers so battery life may not be as long as possible and energy is used at all times when plugged into an AC outlet.

First Alert Series 50 rechargeable flashlight schematic

This one is typical of combined all-in-one units using a lead-acid battery that extends a pair of prongs to directly plug into the wall socket for charging.

It is a really simple, basic charger. However, after first tracing out the circuit, I figured only the engineers at First Alert knew what all the diodes were for - or maybe not :-). But after some reflection and rearrangement of diodes, it all makes much more sense: C1 limits the current from the AC line to the bridge rectifier formed by D1 to D4. The diode string, D5 to D8 (in conjunction with D9) form a poor-man's zener to limit voltage across BT1 to just over 2 V.

The Series 50 uses a sealed lead-acid battery that looks like a multi-cell pack but probably is just a funny shaped single cell since its terminal voltage is only 2 V.

Another model from First Alert, the Series 15 uses a very similar charging circuit with a Gates Cyclon sealed lead-acid single cell battery, 2 V, 2.5 A-h, about the size of a normal Alkaline D-cell.

WARNING: Like many of these inexpensive rechargeable devices with built-in charging circuitry, there is NO line isolation. Therefore, all current carrying parts of the circuit must be insulated from the user - don't go opening up the case while it is plugged in!

```

I could not open the transformer without dynamite but I made measurements of open circuit voltage and short circuit current to determine the value of R1. I assume that R1 is actually at least in part the effective series resistance of the transformer itself.

Similar circuits are found in all sorts of inexpensive rechargeable devices. These have no brains so they trickle charge continuously. Aside from wasting energy, this may not be good for the longevity of some types of batteries (but that is another can of worms).

Brand Unknown (Made in China) rechargeable flashlight schematic

This is another flashlight that uses NiCd batteries. The charger is very simple - a series capacitor to limit current followed by a bridge rectifier.

There is an added wrinkle which provides a blinking light option in addition to the usual steady beam. This will also activate automatically should there be a power failure while the unit is charging if the switch is in the 'blink' position.

With S1 in the blink position, a simple transistor oscillator pulses the light with the blink rate of about 1 Hz determined by C2 and R5. Current through R6 keeps the light off if the unit is plugged into a live outlet. (Q1 and Q2 are equivalent to ECG159 and ECG123AP respectively.)

Solar Powered Walk Light

This was found in a Malibu(tm) LZ1 Solar light set made by Intermatic. It uses a solar cell, approximately 4 square inches in area, to charge a pair of AA NiCd cells during the day which powers a superbright yellow LED at night. I estimate the actual light output to be 2 or 3 mW at around 595 nanometers wavelength (something like stoplight yellow). Actually, it is kind of cool in more ways than one! :) If only the cheap plastic enclosure was actually waterproof....

When there is enough voltage from the solar cell, Q1 is turned on and Q2 (the LED driver) is turned off. As far as I can tell, there is nothing to actually limit current to the LED except for the combination of battery, transistors, LED, and wiring resistance. Both transistors could probably be replaced with 2N3904s. So, if you were duplicating this thing, I'd recommend adding something to control the current to the LED or at least checking it first!

Actual failure of this complex device would most likely be due to worn out NiCd cells or corrosion to due exposure to the weather.

Operational problems like weak output or inadequate lighting time could be due to insufficient Sunlight (the thing is installed under a bush!) or extended cloudy conditions. Of course, these don't produce a huge amount of light in any case!

Makeup mirrors

There are a simple movable mirror with incandescent or fluorescent lighting built in.

Replacing incandescent light bulbs can usually be done without disassembly. The bulbs may be of the specialty variety and expensive, however.

When a unit using fluorescent bulbs will no longer come on, the most likely cause is a bad bulb. However, replacement may involve disassembly to fain access. Where two bulbs are used, either one or both might be bad. Sometimes it will be obvious which is bad - one or both ends might be blackened. If this is not the case, replacement or substitution is the only sure test. These **will** be expensive $7-10 is not uncommon for an 8 inch fluorescent bulb!

Other possible problems: plug, cord, switch, light bulb sockets.

Chandeliers

A chandelier is simply an incandescent light fixture with multiple sockets. No matter how fancy and expensive, the wiring is usually very simple - all the sockets are connected in parallel to a cord which passes through the chain to a ceiling mounted electrical box.

If none of the lights come on, check for a blown fuse or circuit breaker, bad wall switch or dimmer, a bad connection in the ceiling box or elsewhere in the house wiring, or a bad connection where the cord is joined to the individual socket wires.

Where only one bulb does not light - and it is not a burned out bulb - a bad socket, loose wire connection at the socket, or bad connection at the point where the wires are joined (Wire Nuts(tm) or crimps) is likely.

Overhead (and other basic slide) projectors

(The type discussed here are overhead transparency projectors, opaque projectors, and the basic power and lighting circuits of slide projectors. Problems with the slide advance mechanism of those with automatic slide changers (e.g., Kodak Carousel) are usually mechanical in nature assuming the main motor is running. See the document: Audio Equipment and Other Miscellaneous Stufffor more information on these.)

A basic projector consists of a really bright lamp - usually halogen but some fancy ones use a High Intensity Discharge (HID) lamp (see the document: Gas Discharge Lamps, Ballasts, and Fixtures), a cooling fan, electrical and thermal protection devices, and possibly an interlock switch to prevent operation with the cover removed. The main switch may include reduced brightness settings which adds some resistance or a diode in series with the lamp.

(Repair of those with HID lamps unless it is a simple bad connection or failure in the protection devices is well beyond the scope of this document unless replacing the lamp is all that is needed. WARNING: The types of power supplies used for these may have capacitors that can retain a dangerous charge for a long time even after the plug is pulled.)

A reflector and condensing lens concentrates the light more or less uniformly onto the material to be projected {transparency or whatever) and a projection lens relays and enlarges that to the screen. Note that the large Fresnel lens (which should also be cleaned) that usually serves as the transparency platform of an overhead projector is not the primary condenser but serves a similar function directing most of the light which passes through the transparency to the projection lens. There may also be one or more pieces of heat absorbing glass between the lamp and condenser. While you're in there, a careful cleaning of the optics could be useful! After making sure the unit is unplugged, use a cloth moistened with isopropyl alcohol to clean all accessible optical surfaces. Rubbing (70%) or medicinal (91%) alcohol is fine as long as it doesn't contain any additives. Be gentle - optical glass is not that hard! WARNING: Avoid contact with the glass envelope of the lamp itself. If you do touch it by accident, use a fresh cloth or paper towel and alcohol to remove all traces of skin oils since this contamination can lead to failure at the elevated temperatures at which these run.

Like all incandescent lamps, those in projectors burn out - and since they are run at higher than normal wattage to get the most and whitest light, they usually are only rated for a small number of hours (e.g., 100). When burnout occurs, other components may be blown as well.

Since everything runs hot, deteriorated connections, contacts, sockets, etc., are quite common. Any major damage will require repair or replacement of the offending components. The fan may be on a thermostat which can also fail. If the fan doesn't start (usually immediately or after a minute or so at most), overheating WILL occur. Check the thermostat (bypass it to test) and the fan for dry bearings, bad connections, or a bad motor.

If replacing the bulb doesn't help, check the fuses and thermal protectors for opens. Check the outlet as the burnout may have blown the fuse or tripped the circuit breaker for that branch circuit.

If the new bulb runs excessively bright, TURN IT OFF IMMEDIATELY! Some of these projectors use 82 V bulbs (it will say on the bulb and/or its package), and a series diode (or diodes) may be used to reduce power to the bulb to run it at an effective voltage of 82 VRMS. (The RMS value of half wave rectified 115 VAC is close to 82 V). When the old bulb blew (or even if it didn't), these diodes can fail - often shorted. The new bulb won't last long on the full line voltage. The replacement diodes need to have a PIV rating of at least 200 V (for 115 VAC power) and a current rating adequate to handle the operating current and the initial surge (which can be 10X of that). Depending on the bulb's wattage, a 25 A or higher diode may be needed. An proper replacement will be available from the projector manufacturer but will be more expensive than one purchased from an electronics distributor.

Portable fans and blowers

These consist of a cordset, switch, and AC motor. Oscillating fans add a gearbox to automatically swivel the fan to direct air in more than one direction. Most are of the bladed variety though some small types might use a squirrel cage type centrifugal blower.

There are two kinds of problems: totally dead or stuck/sluggish.

A totally dead fan can be the result of several possible causes:

- Bad cord or plug - these get abused. Test or substitute.
- Bad power switch - bypass it and see if the fan starts working or test with a continuity checker or multimeter. Sometimes, just jiggling it will confirm this by causing the fan to go on and off.
- Open thermal fuse in motor - overheating due to tight bearings or a motor problem may have blown this. Inspect around motor windings for buried thermal fuse and test with continuity checker or multimeter. Replacement are available. For testing, this can be bypassed with care to see if the motor comes alive.
- Burned out motor - test across motor with a multimeter on the low ohms scale. The resistance should be a few

Ohms. If over 1K, there is a break in the motor winding or an open thermal fuse. If there is no fuse or the fuse is good, then the motor may be bad. Carefully inspect for fine broken wires near the terminals as these can be repaired. Otherwise, a new motor will be needed. If the motor smells bad, no further investigation may be necessary!

- Bad wiring - check for broken wires and bad connections.

As always, your continuity checker or multimeter on the low ohms scale is your best friend and can be used to trace the wiring from the wall plug through all components of the appliance.

Sluggish operation can be due to gummed up lubrication in the motor or any gears associated with an automatic oscillating mechanism. Disassemble, thoroughly clean, and then lubricate the motor bearings with electric motor oil. Use light grease for the gearbox but this is rarely a problem.

A noisy fan may be due to dry motor or other bearings or loose hardware or sheetmetal. Disassemble, clean, and lubricate the motor or gearbox as above. Inspect for loose covers or other vibrating parts - tighten screws and/or wedge bits of wood or plastic into strategic locations to quiet them down.

Damaged fan blades will result in excessive vibration and noise. These may be easily replaceable. They will be attached to the motor shaft with either a large plastic 'nut' or a setscrew. However, locating a suitable set of blades may be difficult as many cheap fans are not made by well known companies.

Computer power supply (and other) fans

Virtually all of these use brushless DC motors with stationary coils and a rotating multipole magnet which is part of the blade assembly. Most common problems are gummed up lubrication or worn bearings - especially for the cheap sleeve bearing variety found in most PCs. Occasionally, an electronic failure will result in a dead spot or other problem.

Ball bearing fans rarely fail for mechanical reasons but if the bearings become hard to turn or seize up, replacement will usually be needed. (Yes, I have disassembled ball bearings to clean and relube THEM but this used only as a last resort.)

WARNING: For power supply fans, be aware that high voltages exist inside the power supply case for some time (perhaps hours) after the unit is unplugged. Take care around the BIG capacitors. If in doubt about your abilities, leave it to a professional or replace the entire power supply!

The only type of repair that makes sense is cleaning and lubrication. Else, just replace the fan or power supply. It isn't worth troubleshooting electronic problems in a fan!

If you want to try to clean and lubricate the bearings, the blade assembly needs to be removed from the shaft. There should be a little clip or split washer holding it on. This is located under a sticker or plastic plug on the center of the rotating blade hub. Once this fastener has been removed, the blades will slide off (don't lose the various tiny spacers and washers!)

Thoroughly clean the shaft and inside the bushings and then add just a couple drops of light oil. Also, add a few drops of oil to any felt washers that may be present as an oil reservoir.

Reassemble in reverse order making sure the tiny washers and spacer go back in the proper positions.

How long this lasts is a crap shoot. It could be minutes or years.

Replacement fans are readily available - even Radio Shack may have one that is suitable. Nearly all run on 12 VDC but some small CPU fans may use 5 VDC. While current ratings may vary, this is rarely an issue as the power supply has excess capacity. Air flow rates may also vary depending on model but are usually adequate for use in PCs.

Piezo fans

These may be used for localized cooling of electronic components or some other very low air flow application. I cannot imagine a use around the house. They use a pair of piezo electric bars that vibrate thin vanes to move a few dozen air molecules per second. Drive is from the power line via a transformer or dropping resistor.

Advantages include virtually infinite life, very low power consumption, to nearly total silence when operating. However, they aren't going to cool very much :-).

(If you care, something that is said to be piezo electric changes shape (e.g., bends or compresses/expands) when a voltage is applied (and vice-versa). Many materials exhibit the piezo electric effect include crystals like quartz, various ceramics and plastics, and even some organic compounds. The most common example of a piezo electric device in modern technology is the beeper in a common digital watch, pocket alarm clock, or pager - in which case an electrical signal at a most annoying frequency causes the change in thickness of a ceramic disk and results in the audible tone.)

The piezo fan I have is just a pair of thin plastic flaps or vanes, each about 1/2" x 3", separated by perhaps 1" and slightly diverging. A pair of piezo elements at one end vibrate the vanes when driven through a dropping resistor from the 60 Hz AC line. Interestingly, the resonance is actually at 50 Hz but I do not think this unit was designed for European power. A plastic housing helps to guide the air flow - what of it there is. The result is a just detectable breeze so I wouldn't recommend using one of these to cool your Pentium II!

Except for mechanical damage, there isn't much to go wrong as long as the piezo elements themselves are getting power. However, a buildup of dirt on the vanes could change the resonant frequency to the point of greatly reducing effectiveness (to the extent that there is any to begin with!).

Don't worry, you may never see one of these things in several lifetimes :-).

Speed control of DC fans

The small fans used in computers and peripherals usually run on 5, 12 (most common) or 24 VDC. Most of the time, their speed and air flow are fine for the application. However, is it possible to vary it should the need arise?

Usually, the answer is a qualified 'yes'. Except for some that are internally regulated or thermostatically controlled, the speed is affected by input voltage. It is likely that the fan will run on anywhere from .5 to 1.25 times the nominal input voltage though starting when it is near the low end of this range may need some assistance.

A universal DC wall adapter, adjustable voltage regulator, or (variable) series power resistor can provide this control. For example:

```
                  25, 2 W        + +--------+ -
 +12 VDC o-----+---/\/\---+--------| DC FAN |----o Gnd
               |   +      |        +--------+
               +----|(----+      12 VDC, .25 A
                 10,000 uF
                   25 V
```

The 25 ohms power resistor should reduce the speed of this fan by about 25 to 30 percent. The capacitor provides full voltage for a fraction of a second to assure reliable starting.

Speed control of small AC fans

The following comments should also apply to many other types of appliances using small AC motors.

These small shaded pole fans will work just fine on a Variac. Any speed you want, no overheating, etc. I had done this with all sorts of little computer cooling fans as well as larger ones (remember those old DEC PDP-11 rack fans?).

A true rheostat (variable power resistor) will also work. However, significant power will be dissipated in the rheostat which must be sized so that the maximum power density of any portion of its element does not exceed its power handling capability - this can end up resulting in a massive device even for a small fan. For example, to vary a 120 VAC fan rated at 24 VA from between 1/2 to full power would require a 600 ohm, 25W rheostat; down to 1/4 power would require an 1,800 ohm 75 W rheostat!

Small triac based speed controls like those used for ceiling fans may also work. Even light dimmers will *probably* work for medium size fans or banks of fans though I cannot guarantee the reliability or safety of these. The problem is that small induction motors represent a highly inductive loads for the light dimmer circuitry which is designed for a resistive load. I have achieved a full range of speeds but over only about 1/4 to 1/2 of the rotation of the control knob. There is some buzz or hum due to the chopped waveform.

However, from my experiments, light dimmers may have problems driving a single small fan. If the load is too small, the result may be a peak in speed (but still way less than normal) at an intermediate position and the speed actually much lower when on full, or reduced speed even on full. In this case, adding a resistive load in parallel with the motor - a light bulb for example - may improve its range. It adds a sort of quaint look as well! :-)

If you do opt for a solid state speed control, make sure you include a fuse in the circuit. A partial failure of the triac can put DC through the motor which would result in a melt-down, lots of smoke, or worse. (This isn't a problem with a light bulb load since its resistance is the same for AC and DC; a motor's DC resistance is quite low.)

The reason these simple approaches will work for these AC motors is that they are high slip to begin with and will therefore have a high range of speed vs. input voltage. The only concern is overheating at some range of lower speeds due to reduced air flow. However, since these fans are normally protected even against stall conditions, I wouldn't expect overheating to be a problem - but confirm this before putting such fans into continuous service.

If all you need to do is provide a fixed, reduced speed for a bank of similar AC fans, try rewiring them as two sets of parallel connected fans in series. The result will be 1/2 the normal line voltage on each fan motor which may provide exactly the speed you want! The extension to more than 2 sets of fans is left as an exercise for the student :-).

Ceiling fans

While the original slow rotating ceiling mounted fan predates the widespread use of airconditioning, there is a lot to be said for the efficiency, effectiveness, and silence of this technology - not to mention the ambiance.

A ceiling fan is just an induction motor driving a set of blades. Multiple taps on the motor windings in conjuac dansnction with a selector switch provides speed control for most inexpensive fans. Better units include a solid state motor speed control.

The light often included with the fan unit is usually just an incandescent fixture with 1-5 bulbs and a switch. This may be a simple on-off type, a selector to turn on various combinations of bulbs, or a dimmer with continuous or discrete control of illumination.

WARNING: Always check mechanical integrity of fan mounting when installing or servicing a ceiling fan. Original design and construction is not always as fail-safe as one might assume. Double check for loose nuts or other hardware, adequate number of threads holding fan to mounting, etc. These have fallen without warning. Only mount in ceiling boxes firmly anchored to joists - not just hanging from the ceiling drywall! Check that the fan is tight periodically. The constant vibration when running, slight as it is, can gradually loosen the mounting hardware. Furthermore, if pull chain type switches are used for the fan or light, constant tugging can also tend to loosen the entire fan.

Failures of ceiling fans can be divided into electrical and mechanical:

Electrical:

- **No power:** Use a circuit tester to determine if power is reaching the fan. Check the fuse or circuit breaker, wall switch if any, and wire connections in ceiling box.

- **Bad switch in fan:** with power off, check with a continuity tester. If wiring is obvious, bypass the switch and see if the fan comes alive. Jiggle the switch with power on to see if it is intermittent. For multispeed fans, exact replacements may be required. For single speed fans, switches should be readily available at hardware stores, home centers, or electrical supply houses.

- **Bad or reduced value motor start/run capacitor:** This might result in slower than normal speed or lack of power, a fan that might only start if given some help, or one that will not run at all.

  For an existing installation that suddenly stopped working, a bad cap is a likely possibility. An induction motor that will not start but will run once started by hand usually indicates a loss of power to the starting (phase) winding which could be an open or reduced value capacitor.

  This is probably a capacitor-run type of motor where the capacitor provides additional torque while running as well. Therefore, even starting it by hand with the blades attached might not work. With the blades removed, it would probably continue to run. Of course, this isn't terribly useful!

- **Bad motor:** If all speeds are dead, this would imply a bad connection or burned winding common to all speeds. There might be an open thermal fuse - examine in and around the motor windings. A charred smelly motor may not require further testing. A partially shorted motor may blow a fuse or trip a circuit breaker as well or result in a loud hum and no or slow operation as well.

Schematics for some typical ceiling fans can be found at Gary Tait's Ceiling Fan Wiring Diagrams Page. **Mechanical:**

- **Noise and/or vibration:** Check that fan blades are tight and that any balance weights have not fallen off. Check for worn or dry bearings. Check for sheetmetal parts that is loose or vibrating against other parts. Tighten screws and/or wedge bits of plastic or wood into strategic spots to quiet it down. However, this may be a symptom of an unbalanced fan, loose fan blade, or electrical problems as well. Check that no part of the rotating blade assembly is scraping due to a loose or dislodged mounting.

- **Sluggish operation:** Blades should turn perfectly freely with power off. If this is not the case, the bearings are gummed up or otherwise defective. Something may be loose and contacting the casing. (This would probably make a scraping noise as well, however).

Lubricating ceiling fans

(From: Chris Chubb (cchubb@ida.org).)

I use synthetic transmission lube, 80-130 (manual gearbox, not automatic transmission fluid which is very thin --- sam). I imagine that any similar lubricant, synthetic or not, would work as well, but the synthetic flows down in better and works well.

Do not use WD-40, 3-in-1 oil or any other lightweight oil. Motor oil is good as well, but it does not stick to the bearings as well. DO NOT use automatic transmission fluid - extremely thin.

Grease would be perfect, white lithium, divine! But, getting the grease down into the bearings would be very difficult.

Just about three or four drops should be all it takes. Getting it on the lower bearings of the ceiling fan will be tough. I have an oil can that I pump a drop to the tip of, then hold it against the bearings until they wick the oil inside. This is very slow. It takes about 15 minutes per fan to oil, clean the top of the blades, oil a little around the hanging ball, pull the globe off and clean the globe inside, and make sure everything is OK.

Variable speed ceiling fan on normal circuit

It is usually not possible to use a normal light dimmer to control the fan as this uses an AC induction motor. A dimmer can only be used on the built in light if a separate wire is available to power it.

Doing this will likely result in a nasty hum or buzz at anything other than full brightness (speed) or off. This is both annoying and probably not good for the fan motor as well. A dimmer works by reducing the power to the light by controlling when the voltage is applied on each cycle of the AC. If it is turned on half way through the cycle half the power is provided, for example. However, with cheap lamp dimmers, this results in sharp edges on the waveform rather as peak voltage is applied suddenly rather than with the nice smooth sinusoid. It is these sharp edges causing the coils or other parts of the fan to vibrate at 120 Hz that you are hearing.

Special speed controls designed for ceiling fans are available - check your local home center or ceiling fan supplier.

Here is another alternative:

(From: Rick & Andrea Lang (rglang@radix.net).)

Here's a potential solution if you don't mind spending a little more for a ceiling fan (If you already have one in that location, perhaps you can put it in another room). Ceiling fans with remote control are now available. They only require power to the ceiling fan (2 wire) and a remote control. With the remote you can dim the lights, slow the fan or both. You can then use the existing new wall switch as a power ON/OFF switch also. If you choose this route, be careful of interference with garage door openers. Usually, the remotes have at least 4 frequency selections to help avoid interference with other remote systems. I put one in that three of the four frequencies opened the garage door. I lucked out on the 4th one!

Throbbing noise from ceiling fan

This could be due to a mechanical problem - bad bearings or blades out of balance - or an electrical problem with the speed control.

(From: David Buxton (David.Buxton@tek.com).)

A quickie test. Get the fan turning at a speed that demonstrates the throbbing noise. Come up with a way to instantly remove power to the fan. If the noise continues for a little bit until the fan has slowed down enough, then you know the noise is in the mechanical dynamics, perhaps blades out of balance. If the noise quits instantly with power removal, then you need a better speed control better designed for fan motor control.

Ceiling fan motor speed control and capacitor replacement

(From: Kevin Astir (kferguson@aquilagroup.com).)

Ceiling fans are normally multipole, capacitor-run types. They normally run fairly close to stalled, the blades being big enough that the motor never gets anywhere near synchronous speed.

Speed control in three speed types is by switching the value of the cap in series with the quadrature windings. The caps normally have two sections of 3 and 6 uF, with a common connection between the two sections allowing connections of 3, 6, or 9 (3 in parallel with 6) uF total.

I have seen some caps of slightly different value, but they should be close, just translate my 3 and 6 to what you actually have in what follows.

The higher the capacitance the higher the stall torque, so the faster the fan runs against the non-linear (square-law) torque vs. speed characteristic of the blades. (remember I said it is always pretty much stalled)

If you miswired the cap, then you may be getting 3 or 6 and 2 (3 in *series* with 6 uF which would result in low speeds. This *is* the case if any 2 out of 3 speeds seem to be the same. The replacement caps are usually marked with what terminal is which, but originals often are not. I don't know if there is a standard color code, but manufacturers are under no obligation to adhere to it even if there was. If you are totally lost, there are only 6 possible ways to connect the capacitor. 2 of these will give you all 3 speeds (but one in wrong order). So if you keep good notes (essential here) then you could try all possibilities in 20 minutes or so...yes, you're probably working with hands over head, what you wanted easy too?

OK, here is how to get it in 3 tries max:

Identify the "common" capacitor lead (connects to both 3, and 6 uF sections, hopefully your replacement is marked). It is currently connected to the wrong place, so swap it with one of the other cap wires. If you now have three speeds in the correct order, then your done. If you have three speeds in the wrong order, then leave common wire alone, but swap other two. (correct order is: off-hi-med-lo usually)

If you *didn't* have three different speeds following the first wire swap, then swap that common wire with the one wire you haven't moved yet. Now you should have three speeds, now correct the order as described, if needed.

If you currently have three speeds, but all are too slow, then it is likely that your fan needed a higher value capacitor. another explanation might be that the old cap was getting leaky when it warmed up after start, and letting the fan have extra current, thus giving extra speed.

In my experience, the three speed types should run from just slow enough to follow with the eye, to fast, fairly noisy, and making a fair amount of wobble on the mounting.

Continuously variable speed types put a fixed 9 or 10 uF cap in series with the quadrature winding, and regulate voltage to both windings via lamp-dimmer style triac circuit.

Mike's notes on ceiling fan installation

(From: morris@cogent.net (Mike Morris).)

Depending on what wiring you have and what new wiring needs to be installed, I would install 14/3 cables for all ceiling lights. That way, you will be able to control ceiling fan and light from two separate switches.

Each time a new light has to be installed in our house, I make sure a 14/3 wire is installed. For three-way switches, I make it two 14/3 wires, even if I don't install a ceiling fan now. A 14/3 wire is not that much more expensive, and 10 years down the road, it might be useful.

The local high-end lights-and-fans shops have a handout that recommends that wherever a ceiling fan is to go have the following wiring:

1. Neutral.
2. Ground (if local code requires it, good idea anyway).
3. Switched hot for the lights.
4. Switched hot for the fan.
5. An extra wire - some brands need 2 hots for the fan, and if your brand doesn't need it, an extra conductor doesn't hurt.

Why two switched hots?

- It allows to run the lights and fan separately.

- You should not use a lamp dimmer as a motor speed control. While it may work to some extent, the motor will likely hum and long term reliability and safety are questionable.

Note that this does not preclude using a fan with built-in controls - unused wire is just that. And pulling in 5 conductors during construction or remodeling costs just a little more that pulling in 2 or 3.

The handout sheet also point out that adding a extra brace to the ceiling during any remodeling or new construction sized for a 100 pound dead weight is a good idea - it can be as simple as a couple of feet of 2x6" lumber and a couple of sheet metal fasteners. A wobbling fan can cause fatigue in a light duty metal brace rapidly. The extra cost is minimal, and it can prevent a fan from landing in the middle of the bed!

Ceiling fan construction

The following describes a basic capacitor run split phase induction motor, though the arrangement of pole pieces and coils is unusual compared to the typical squirrel cage variety.

(From: George Eccles (geccles@ibm.net).)

I just took ceiling fan motor apart. The (center) stator has 16 coils, in 2 concentric groups of 8, arranged around the circumference of a flat disk. The groups are offset from each other by (maybe) 20 or 30 degrees. Based on resistance readings, I think one group is all wired in series. (I think) the other group is arranged in different combinations, based on the speed setting. For highest speed, I think all are in series, though I don't know what the phasing is. For the lower speeds, 1 or 2 coil pairs have their phasing reversed.

The rotor (aka the housing) has no visible windings, and no permanent magnets. AFAIK, it's just a thin ring (maybe 1/2" thick vertically, 3/4" radially) of laminated (maybe 10 or 12) strips of ferrous metal, embedded in a slightly larger aluminum casing. The laminations are not insulated from each other. Along the innner cicumference, the laminations are interrupted with weird pattern of what might be just interlocking to the aluminum casing.

Air cleaners

Simple air cleaners are just a motor driven fan and a foam or other filter material. HEPA (High Efficiency Particulate Air) types use higher quality filters and/or additional filters and sealed plenums to trap particles down to a specified size (.3 micron). A clogged (neglected) filter in any air cleaner is probably the most likely problem to affect these simple devices.

Failure of the fan to operate can be a result of any of the causes listed above in the section: Portable fans and blowers.

Electronic air cleaners include a high voltage low current power supply and oppositely charged grids in the air flow. A failure of the solid state high voltage generator can result in the unit blowing air but not removing dust and particulate matter as it should. A typical unit might have 7.5 to 10 kV at 100 uA maximum (short circuit current, probably less at full voltage). Actual current used is negligible under normal conditions. This voltage is significant but the current would be just barely detectable, if at all.

The power supplies for smaller table top devices like the AirEase(tm) Personal Space Ionization Air Cleaner from Ion Systems, Inc. would probably generate similar voltages (possibly slightly lower) but at much lower current - perhaps only, 5 to 10 uA.

The modules are usually quite simple: a transistor or other type of switching circuit driving a step-up transformer and possibly a diode-capacitor voltage multiplier. See the sections: "Electronic air cleaner high voltage module schematic" and "Auto air purifier schematic" for an example of a typical circuit.

Where there is no high voltage from such a device, check the following:

- Make sure power is actually getting to the high voltage portion of the unit. Test the wall socket and/or AC adapter or other power supply for proper voltage with a multimeter.

- Excessive dirt/dust/muck/moisture or physical damage or a misplaced paper clip may be shorting it out or resulting in arcing or corona (a strong aroma of ozone would be an indication of this). With such a small available current (only uA) it doesn't take much for contamination to be a problem. Thoroughly clean and dry the unit and check for shorts (with a multimeter between the HV electrodes and case) and then test it again. Your problems may be gone!

- If this doesn't help and the unit is not fully potted (in which case, replacement is the only option), check for shorted or open components, especially the power semiconductors.

On the topic of high voltage power supplies/transformers:

(From: Marvin Moss (mmoss@mindspring.com).)

These transformers have a very large air gap in the core and are designed to be able to operate for an extended period of time when the output is short circuited. If you get a piece of dirt or aluminum foil or something conductive in the filter, it has to bear the short until you clean the filter. I found several sources of surplus high voltage power supplies in the range of 5,000 volts at 2 mA. or so for $14.95 and bought several of them. I did in fact replace one of my two supplies in my A/Cs with this unit and it has been working perfectly for about 10 years now. The voltage is not critical but too high a voltage will create excessive ozone. Too low a voltage will not filter well. I think that 3,500 to 6,000 volts is the range but I can give you more info if you want it.

Electronic air cleaner high voltage module schematic

At least I assume this cute little circuit board is for an electronic air cleaner or something similar (dust precipitator, positive/negative ion generator, etc.)! I received the unit (no markings) by mistake in the mail. However, I did check to make sure it wasn't a bomb before applying power. :-)

This module produces both positive and negative outputs when connected to 115 VAC, 60 Hz line voltage. Each is about 5 kV at up to around 5 uA.

The AC line powered driver and HV multiplier are shown in the two diagrams, below:

```
                   D1                                            T1  o

 Line      Power  .15 uF _|_     1.5K   |<|--+--'  |   4 A    o ::( 350 ohms
          IL1 LED   250V ---                _|_    |  +-------+ ::(
        +--|<|---+        |              C2 ---    |  |        )::(
        |   R1   |   R2   |        .0047 uF  |     |  | .1 ohm )::(
  N o---+--/\/\--+--/\/\--+                  +-----+--+        )::(
           470      3.9K  |                                +--+    +--+--o B
           1 W      2 W   |                                |    R4    |
                          +--------------------------------+---/\/\---+
                                                               2.2M
```

The AC input is rectified by D1 and as it builds up past the threshold of the sidac (D2, 100 V), SCR1 is triggered dumping a small energy storage capacitor (C1) through the primary of the HV transformer, T1. This generates a HV pulse in the secondary. In about .5 ms, the current drops low enough such that the SCR turns off. As long as the instantaneous input voltage remains above about 100 V, this sequence of events repeats producing a burst of 5 or 6 discharges per cycle of the 60 Hz AC input separated by approximately 13 ms of dead time.

The LED (IL1) is a power-on indicator. :-)

The transformer was totally potted so I could not easily determine anything about its construction other than its winding resistances and turns ratio (about 1:100).

```

                                 B o--+----------------------+
```

The secondary side consists of a voltage tripler for the negative output (HV-) and a simple rectifier for the positive output (HV+). This asymmetry is due to the nature of the unidirectional drive to the transformer primary.

From my measurements, this circuit produces a total of around 10 kV between HV+ and HV-, at up to 5 uA. The output voltages are roughly equal plus and minus when referenced to point B.

I assume the module would also operate on DC (say, 110 to 150 V) with the discharges repeating continuously at about 2 kHz. Output current capability would be about 5 times greater but at the same maximum (no load) voltage. (However, with DC, if the SCR ever got stuck in an 'on' state, it would be stuck there since there would be no AC zero crossings to force it off. This wouldn't be good!)

This module is probably for a device similar to the AirEase(tm) Personal Space Ionization Air Cleaner from Ion Systems, Inc. This unit has the positive output of its HV module connected to a 3/16" diameter electrode on the side of the case. This is in contact with a piece of foam (a cylinder about 2" in diameter by 5" high) which surrounds the entire unit. While it appears that this foam should be conductive, I could not detect any evidence of this with a multimeter. The negative output is connected to a 1-1/4" conductive foam disk on the top of the unit. Unfortunately, the HV module in the AirEase was totally potted so I could not determine anything about its internal circuitry.

Auto air purifier schematic

Well, maybe. :-) This thing is about the size of a short hot-dog and plugs into the cigarette lighter socket. It produces a bit of ozone and who knows what else. Whether there is any effect on air quality (beneficial or otherwise) or any other effects is questionable but it does contain a nice little high voltage circuit.

```
                                                                   DL1 +-+ |

  GND o---+--------+----------+--------------+--------------+
```

T1 is constructed on a 1/4" diameter ferrite core. The D (Drive) and F (Feedback) windings are wound bifilar style (interleaved) directly on the core. The O (Output) winding is wound on a nylon sleeve which slips over the core and is split into 10 sections with an equal number of turns (100 each) with insulation in between them.

DL1 to DL4 look like neon light bulbs with a single electrode. They glow like neon light bulbs when the circuit is powered and seem to capacitively couple the HV pulses to the grounded grid in such a way to generate ozone. I don't know if they are filled with special gas or are just weird neon light bulbs.

Bug zappers

You know the type - a purplish light with an occasional (or constant) Zap! Zap! Zap! If you listen real closely, you may be able to hear the screams of the unfortunate insects as well :-).

The high-tech versions consist of a high voltage low current power supply and fluorescent (usually) lamp selected to attract undesirable flying creatures. (Boring low-tech devices may just use a fan to direct the insects to a tray of water from which they are too stupid to be able to excape!)

However, these devices are not selective and will obliterate friendly and useful bugs as well as unwanted pests.

Here is a typical circuit:

```
         S1        R1         C1            C2            C1-C4: .5 uF, 400 V
  H o----o/ o--+--/\/\--------||---+--------||---------+  D1-D5: 1N4007
               |  25K        D1    |   D2        D3    |   D4
               |          +---|>|---+---|>|---+---|>|---+---|>|---+
              +-+         |        C3        |        C4        |
 AC Line      |o| FL1     +---+----||----+----+---+----)|----+----+--o +
              +-+ Lamp    |   |    R3    |        |    R4    |       500 to
               |          |   +---/\/\---+        +---/\/\---+       600 V
               |   R2     |       10M                  10M           to grid
  N o----------+--/\/\---+-------------------------------------------o -
                  25K
```

This is just a line powered voltage quadrupler. R1 and R2 provide current limiting when the strike occurs (and should someone come in contact with the grid). The lamp, FL1, includes the fluorescent bulb, ballast, and starter (if required). Devices designed for jumbo size bugs (or small rodents) may use slightly larger capacitors!

(From: Jan Panteltje (pante@pi.net).)

I have one, bought it very cheap: they are only $10 here :)

It comes with a 25 W blue lamp inside, with wires around it. The lamp did not last long, so I replaced that with a 7 W electronic fluorescent type, that now just keeps going and going and going. The bugs do not care, they just go for the light. Then they hit the wires.

Here, we have 230 V, in the lamp is a voltage doubler, with 2, 220 nF capacitors, 2 silicon diodes, and a 10 K Ohm series resistor in the mains. The whole thing cannot be touched by humans from outside. The voltage between the wires is something like 620 V. If an insect shorts the wires, the 10K limits the current until it is destroyed (the insect that is). The insect actually explodes, the 600 V cap discharges into it.

(From: (Abe Shultx) abe_shultz@hotmail.com).)

I grabbed a bug zapper from someone's garbage and opened it up. Instead of a voltage multiplier, there was a transformer. It had a capacitor across the output, and threw an approximately 3/4 inch loud blue arc. I don't know the cap values, because it was potted. :-(

Electric fences

Yes, I know, this isn't a common small appliance but....

(From: John Harvey (johnharvey@bigpond.com).)

Most DIY fence energizers use an automotive ignition coil and kits (generally minus coil) are available in Australia and probably elsewhere.

Commercial units operate on the capacitor discharge principle and are fired at a 1.2 second interval. Voltage O/P needs to be around 5 to 8 kV (which will drop under load). The energy O/P (pulse duration) is determined by the capacitor and 10 to 20 uF is about right for a small unit (up to 2km or so). They must use a pulse grade capacitor (which has a high dV/dt) to be reliable.

Appliance and light timers

There are two basic types: mechanical and electronic.

- Mechanical timers are simply a synchronous timing motor and gear reducer controlling a two prong (usually polarized) outlet.

  The most common problems relate to failure of the timing motor or gear train. With time, the oil and grease used inside the timing motor may gum up. Eventually, it gets so stiff that the motor stops - or more likely - doesn't start up after a power failure or the unit has been unplugged for a while.

  The cheap plastic gears may also break, chip, or loose teeth.

  Sometimes, disassembly, cleaning, and lubrication, will get the motor going - possibly for a long time. However, replacement parts are rarely worth the cost compared to a complete new timer.

- Fully electronic timers use digital clock-type circuitry to control a triac or other solid state switching device.

  These may fail in the same way as other electronic controls such as dimmers. Most likely problems are that they are either stuck off or stuck on. Aside from testing for bad connections or shorted or open components (with power OFF or disconnected!), repair is probably economical. Assuming it can be opened non-destructively at all, check the triac and other parts in its vicinity. The rest of the circuitry is probably in a proprietary chip - but these don't fail much.

  Also see the section: Warnings about using compact fluorescent lamps on electronic timers.

Warnings about using compact fluorescent lamps on electronic timers

You may have seen these warnings in the instructions or on the package of electronic (not mechanical) timers and/or compact fluorescents.

There are two issues:

1. Providing the trickle current to operate the clock circuitry in the timer.

   Where a solid state timer is used to replace a normal switch, there is usually no connection to the Neutral so it must derive all its operating power from current through the load (though at a very low current level).

   The type of circuitry in a compact fluorescent with an electronic ballast (or other equipment with a switching power supply like a TV, some VCRs, computer, etc.) may result in this current being too low or erratic. The result will be that the timer doesn't work properly but damage isn't that likely (but no guarantees).

   If it is installed with 3 wires (Hot, Neutral, Load), then this should not be a problem.

   In addition, interference (e.g., spikes) from the CF ballast may feed back into the electronic timer and this may either confuse or actually result in failure.

2. Damage to either or both of the devices dues to incompatibility.

The solid state switching device - usually a triac - in the timer unit may be blown by voltage spikes or current surges when the power goes on or off into an inductive or capacitive load like an electronic ballast (or normal magnetic ballast, for that matter.

In short, read and follow label directions! Although a given combination may actually work reliably for years even if it is not supposed to but you should be able to find a pair for which this shouldn't be a problem.

Wall thermostats

These can be divided into several classes depending on:

- Normal or setback (electronic or electromechanical).
- 24 VAC or self powered (thermopile or thermocouple) valve control.
- Heating, airconditioning, or combination.

It is not possible to cover all variations as that would require a complete text in itself. However, here is a summary of possible problems and solutions.

Conventional thermostats usually use a bimetal strip or coil with a set of exposed contacts or a mercury switch. In general, these are quite reliable since the load (a relay) is small and wear due to electrical arcing is negligible. On those with exposed contacts, dirt or a sliver of something can prevent a proper connection so this is one thing to check if operation is erratic. The following description assumes a single use system - heating or cooling - using 24 VAC control which is not properly controlling the furnace or air conditioner.

1. Locate the switched terminals on the thermostat. Jumper across them to see if the furnace or air conditioner switches on. If it does, the problem is in the thermostat. If nothing happens, there may be a problem in the load or its control circuits. Cycle the temperature dial back and forth a few times to see if the contacts ever activate. You should be able to see the contacts open and close (exposed or mercury) as well.

   (**CAUTION:** on an air conditioner, rapid cycling is bad and may result in tripped breakers or overload protectors so ideally, this should be done with the compressor breaker off).

2. Check for 24 VAC (most cases) across the switched circuit. If this is not present, locate the control transformer and determine if it is working - it is powered and its output is live - you may have the main power switch off or it may be on a circuit with a blown fuse or tripped breaker. I have seen cases where the heating system was on the same circuit as a sump pump and when this seized up, the fuse blew rendering the heating system inoperative. Needless to say, this is not a recommended wiring practice. The transformer may be bad if there is no output but it is powered. Remove its output connections just to make sure there is no short circuit and measure on the transformer again.

3. If 24 VAC is present and jumpering across the terminals does nothing, the heater valve or relay or air conditioner relay may be bad or there is a problem elsewhere in the system.

4. Where jumpering the terminals turns on the system, the thermostat contacts may be malfunctioning due to dirt, corrosion, wear, or a bad connection. For a setback unit, the setback mechanism may be defective. Test and/or replace any batteries and double check the programming as well. On those with motor driven timers operating off of AC, this power may be missing.

5. Where jumpering the terminals does not activate the system, check the load. For a simple heating system, this will be a relay or valve. Try to listen for the click of the relay or valve. If there is none, its coil may be open though in this case there will be no voltage across the thermostat contacts but the 24 V transformer will be live. If you can locate the relay or valve itself, check its coil with an ohmmeter.

6. If the previous tests are ok, there may be bad connections in the wiring.

Some additional considerations:

> **Type of control:**Most systems use a 24 VAC circuit for control. However, some use low voltage self powered circuits that require special compatible (sometimes called thermopile or thermocouple) thermostats with low resistance contacts and no electronics directly in series with the control wires. Erratic or improper control may result from using the wrong type.
>
> **Setback thermostats:** These may be controlled electromechanically by a timer mechanism which alters the position of the contacts or selects an alternate set. Newer models are fully electronic and anything beyond obvious bad connections or wiring, or dead batteries is probably not easily repaired. However, eliminate external problems first - some of these may need an additional unswitched 24 VAC or 115 VAC to function and this might be missing.
>
> **Heat anticipators:** In order to reduce the temperature swings of the heated space, there is usually a small heating element built into the thermostat which provides some more immediate feedback to the sensor than would be possible simply waiting for the furnace to heat the air or radiators. If this coil is defective or its setting is misadjusted, then erratic or much wider than normal temperature swings are possible. There will usually be instructions for properly setting the heat anticipator with the thermostat or furnace.

Units that control both heating and airconditioning are more complex and will have additional switches and contacts but operate in a similar manner and are subject to similar ailments.

Testing a thermostat

Where a heating appliance doesn't come on or go off as it should, a bad thermostat is possible.

- Failure to run could also be due to any number of other causes: bad wiring; defective motor/compressor or heating element, open thermal fuse, protector, or case interlock; and of course, no power! Easiest test is to jumper across the contacts of the thermostat (do this with the plug pulled!) and then plug in the appliance to see if it will run. CAUTION: This assumes a single set of contacts as with a space heater.

- Failure to cycle where the heating/cooling is operating correctly is very likely thermostat related. However, it just may be set too high or on 'continuous run', or the interior of the appliance may just need a proper cleaning (or defrosting) - the cold or heat may not be reaching the thermostat!

Most thermostats in refrigerators and freezers, air conditioners, heating systems, hot plates, fryers, and the like, are simple on/off switches activated by the bending of a bimetal strip (due to the differing expansion coefficients of the two types of metal) or by the expansion of a liquid filled bulb or capillary (often in cooling appliances).

- For motor driven appliances like air conditioners, there should be a distinct 'click' as the contacts open and close around the set-point. This snap action minimizes arcing at the contacts. And, there should be some 'hysteresous - the knob should have to be turned back somewhat past where it switched on for it to turn off and vice-versa.

- For heating appliances like waffle irons and toaster-ovens, there may be no click or very much hysteresous but it should be possible (see below) to determine that the contacts open and close reliably.

- If something seems broken or loose inside, the thermostat is probably bad.

Basic tests can be done with a container of hot, cold, or freezing water (depending on the application) and a multimeter (to check for the closing and opening of the contacts if it isn't visually or audibly obvious.

Fully open mechanisms (no enclosed switches) can be totally dunked in the water as long as they are dried thoroughly afterwards. This should be avoided where the bimetal activates an enclosed 'microswitch' since it is difficult to be sure of removing all the trapped water.

To test an air conditioner thermostat, for example, turn the knob to the highest (coldest) setting. The contacts should be closed. Then, cool the bimetal strip off with cold tap water. The contacts should open. The range can be determined with a thermometer and various combinations of hot and cold water.

- If resistance measurements are erratic - there should be no readings between 0 and infinity - but the contacts appear to be closing and opening properly (if visible or distinct click is heard), contact cleaner may help, at least temporarily. For enclosed switches, it may be possible to spray in through an existing opening or drill a tiny hole in the plastic case for this purpose.

- Where the contacts (if visible) are seriously pitted or burned, a temporary repair may be possible using a fine file or sandpaper but replacement will be needed. However, these drastic measures should be used as a last resort only - replacement will be needed.

Replacing a thermostat

The following applies to refrigerators and freezers, air conditioners, electric space heaters, as well as other small appliances.

Removing the thermostat (unplug AC line first!) and cleaning the contacts using contact cleaner NOT sandpaper or a file (except as a laser resor) - may help temporarily. Replacement is easy if the cold control is self contained using a bimetal strip. If it uses a liquid filled bulb, the tube may snake around inside the cabinet and may be more challenging. Still no big deal. An appliance part distributor or your appliance manufacturer should have a replacement.

Note that an exact replacement may not be needed as long as its electrical ratings (amps or HP) is at least as high, it is intended for the same application (e.g., freezer or space heater), the sensing element is similar, and it can be made to fit! This could come in handy if trying to repair a 30 year old air conditioner!

Electric space heaters

All types have one thing in common - they are nearly 100% efficient which means that just about every watt of power utilized is turned into heat. The remainder is used for any built in fans or the wasted light produced by glowing elements or quart lamps.

However, this does not mean that these are the most economical heating devices. Heat pumps based on refrigeration technology can be much less costly to run since they can have coefficients of performance - the ratio of heat output to energy input - of 3 or more to 1. Thus, they are in effect, 300% or more efficient. Note that this does not violate any conservation of energy principles as these simply move heat from one place to another - the outdoors is being cooled off at the same time.

Space heaters come in 3 common varieties:

- Radiant - heating element with polished reflector.
- Convection - heating element and small fan to circulate heated air.
- Oil filled radiator - heating element heats oil and metal fins.

Problems with space heaters are nearly always related to bad heating elements, problems with the thermostat, interlock switches, or fan (if any), or bad connections. Blown fuses or tripped circuit breakers are very common with these appliances as they are heavy loads - often the maximum that can safely be plugged into a 15 A outlet - and thus overloads are practically assured if **anything** else is used on the same circuit. Since we rarely keep track of exactly what outlets are on any given circuit, accidentally using other devices at the same time are likely since the same circuit may feed outlets in more than one room - and sometimes some pretty unlikely places.

Radiant space heaters

These use a coiled NiChrome, Calrod(tm), or quartz lamp heating element. There is no fan. A polished reflector directs the infra red heat energy out into the room. Radiant space heaters are good for spot heating of people or things. They do not heat the air except by convection from the heated surfaces.

Of course, first check that the outlet is live.

As with other heating appliances, the most likely problems are with burned out heating elements; defective on/off switches, thermostats, or safety interlock or tip-over switches, bad cord or plug, or bad wiring connections. Your continuity checker or ohmmeter will quickly be able to identify which of these are the problem.

Warning: do not be tempted to bypass any interlock or tip-over switches should they prove defective. They serve a very important fire and personal safety function. Never, ever cover the heater in any way as a serious fire hazard will result.

Convection space heaters

A small fan blows air over or through a heating element. This may be a NiChrome coil, Calrod(tm) element, or ceramic thermistor. This type is probably the most popular since it can quickly heat a small area. The ceramic variety are considered safer than the others (of this type) since they are supposed to operate at a lower surface temperature.

In addition to the problems covered in the section above: "Radiant space heaters", the fan can also become sluggish or seize up due to gummed up lubrication (as well as other fan-motor problems). Since it is running in a high temperature environment, disassembly, cleaning, and lubrication may be needed periodically despite what the manufacturer may say about permanently lubricated parts.

Oil filled electric radiators

These are also considered convection heaters but they do not have any fan.

The typical unit consists of a pair of heating elements providing 600, 900, or 1500 Watts depending on which are switched on. A simple bimetal adjustable thermostat is used for temperature control. The heating elements are fully submerged and sealed inside an oil filled metal finned replica of an old style radiator. The whole affair is mounted on wheels as it is quite heavy.

Depending on design, there may be one or two thermostats (oil and air) in addition to thermal and electrical protection devices.

Common problems with these have been the pair of power switches which tend to fail resulting in no or erratic operation. Note: if your heater is a Delongi, there has been a free (well $5 S&H) upgrade to replace the failure prone power switches and air temperature thermostat on some common models.

The heating elements are replaceable (as a set). Since they are immersed in the oil, you MUST have the radiator on its end with the terminals straight up while changing them or else there will be a mess. Replacement will be worth the cost and effort only if you require the high settings as it is unlikely for both elements to fail. If testing reveals an open element, you will just not have the heat ranges that use it. If an element shorts to the case, it must be disconnected to prevent a shock hazard though the other one can still be safely used. Parts should be available.

So, what about the Pelonus Disk furnace?

(From: Kirk Kerekes (kkereke@iamerica.net).)

It is a portable electric heater, using high-power thermisters as the heating elements. This technology was originally developed by TDK a few decades ago. The premise is that the power thermisters will automatically control the heating element temperature (the thermister), so that if the air flow is blocked, the heater won't cook. The manufacturers make efficiency claims, but these seem to be bogus. (All space heaters are nearly 100% efficient. See the section: Electric space heaters --- Sam.)

I have a bathroom version of this device, and it works.

Electric pencil sharpeners

AC powered pencil sharpeners consist of a small shaded pole induction motor, pencil sense switch, and some gears and cutter wheels. Aside from pencil shavings crudding up the works - which can be cleaned - the most common failure is of the cheap plastic gears. These can be easily be replaced if you can get them - the original manufacturer is likely the only source. The switch contacts may become dirty or level/bar may become misaligned or worn. Some clever repositioning or the addition of a shim may help in these cases.

Battery operated pencil sharpeners use a small DC motor for power. These tend to be whimpier than their AC counterparts but all other comments apply. Always try a fresh set of batteries first.

Blenders

A blender really is just a high speed motor mounted inside a base. Units with 324 speeds accomplish (this more or less useless marketing gimmick) through a combination of diodes, resistors, and multiple windings on the motor. Without addressing the ultimate utility of thousands of speeds, problems with these units are more likely to be in the motor itself - open or shorted windings, or bad bearings. However, the selector switches and electrical parts can fail as well.

The motors are typically of the series wound universal type. These have carbon brushes which are prone to wear. However, given the relatively short total usage of a blender, this is not usually a problem.

Disconnecting (and labeling!) connections one at a time may permit the source of a problem to be localized. Diodes can be tested with a multimeter (they should read open in one and only one direction) and resistors checked as well. Shorts in a motor with multiple taps on its windings may be difficult to identify or locate. Shorted windings can result in overheating, incorrect speeds, or even a blender that runs with the power switch supposedly in the off position as the wiring is sometimes sort of strange!

Bad bearings will result in any number of mechanical problems including excessive or spine tingling noise, vibration, a seized rotor or very sluggish rotation. Sometimes, disassembly, cleaning, and oiling will be effective but since these rotate at high speed, don't count on it. Unfortunately, cheap bronze bushings are often used instead of ball bearings. However, substituting a set from another similar unit might work since it is usually the bronze bushing and not the motor shaft that fails.

The most sophisticated units will have a variable speed control - similar to a light dimmer. If this goes bad - the blender always runs at full speed - then the active element (triac) has probably blown. Replacement is possible and the part types should be readily available.

Drip coffee makers

A drip coffee maker consists of several components:

1. **A heating element:** Combined or separate Calrod(tm, usually) types for operating the drip pump and then keeping the coffee warm.

2. **Thermal protector:** To prevent excess temperatures.

3. **Some kind of water interlock:** Prevents dripping when separate reservoir is used.

4. **Timer or controller:** The simplest are mechanical while programmable units with clocks and electronic timers are also available.

Many problems are be mechanical - clogged water passages or interlock. Extended use with hard/high mineral content water can also result in reduced heating effectiveness and/or increased heating times. It may be possible to flush the unit a couple of times with viniger.

If there is no heating, check the element and thermal protector with an ohmmeter. If the element is open, it is probably time for a new coffee maker. The thermal protectors can be replaced but the underlying cause may be a defective, shorted overheating element so it may not be worth the trouble. Timers can develop bad contacts and bad connections are possible on electronic controller circuit board wiring.

Drip coffee maker repair

(From: Niels Henriksen (ap294@FreeNet.Carleton.CA).)

I wish I had thought of this sooner rather than throwing out the first coffee maker and I had planned to throw this one out. For some reason I thought I would just look inside to see what was up.

Where I live the water is hard (well) and there is constant scaling and buildup of calcium. We heard that all you have to do is to run a mixture of vinegar through the coffee maker to rejuvenate.

A friend and the 2 of ours all started to leak very badly when the vinegar/water mixture when through. I though that the internal plumbing had corroded through the metal parts and the vinegar dissolved the calcium that was protecting the holes and therefore unrepairable. Who knows where these ideas come from.

Now for the technical solution.

The element that is used to boil the water and uses the bubbles to bring hot water to top of coffee maker is the same element that is used to keep the pot warm.

There is a metal tube attached to the metal warming element and this unit has a heating element embedded. There are 2 rubber hoses attached. One brings cold water to heater and the other brings boiling water to top. The cold water tube has a check valve that prevents the bubbling water from going to cold water reservoir.

When vinegar is added the calcium scales start to dissolve and in 3 of 3 so far, this blocked the metal tube. The water starts to boil and since the cold water inlet has a check valve the water pressure can only buildup to where the rubber tube is blown off the metal pipe. No damage to parts.

To fix:

1. Take bottom off to gain access to heater area.

2. Remove rubber tubes which are connected with spring clamps.

3. Run rubber tubes through your fingers to loosen scale buildup and flush out

4. Push a thin copper wire or other bendable wire through heating tube. This is to unblock and loosen some scale.

5. Pour straight vinegar into metal tube to dissolve calcium and use wire to loosen.

6. Repeat several times till clean.

7. Re-attach all parts and use.

The solution is to start a regular process of using vinegar BEFORE the calcium has buildup to the point where when loosened it will block the tube.

Coffee percolators

While largely replaced by the drip coffee maker, these are still available, particularly in large sizes. The components are similar to those in a drip coffee maker - element, thermal protector, possibly a thermostat as well. The element and bottom of the water/coffee container are likely one piece to provide the best thermal conduction for the 'pump' in the middle. Even if the element is removable, it may not be worth the cost of replacement except for a large expensive unit.

Electric kettles

These consist of a heating element, thermal protector, and possibly a thermostat and/or timer. See comments for coffee makers.

Electric (motor driven) clocks

While line operated clocks have mostly been superseded by electronic (LED or LCD) clocks on nearly every kitchen appliance, many of these are still in operation on older clock radios and ranges.

AC operated clocks depend on the AC line frequency (60 Hz or 50 Hz depending on where you live) for time keeping. The accuracy of a line operated clock is better than almost any quartz clock since the long term precision of the power line frequency is a very carefully controlled parameter and ultimately based on an atomic clock time standard.

Therefore, most problems are related to a clock motor that does not run or will not start up following a power outage. Once running, these rarely fail.

The most common problems are either gummed up oil or grease inside the motor and gear train, broken gears, or broken parts of the clock mechanism itself. See the sections on "Synchronous timing motors" for repair info.

Battery operated quartz clocks usually operate on a 1.5 V Alkaline cell (do not replace with NiCds as they do not have a long absolute life between charges even if the current drain is small as it is with a clock).

First, test the battery. Use a multimeter - usually anything greater than 1 V or so will power the clock though if it is closer to 1 V than 1.5 V, the battery is near the end of its life. The clock may run slow or fast or erratically on a low battery.

With a good battery, failure to run properly is usually mechanical - one of the hands is hitting against the glass front or something like that. Don't forget to check any on/off switch - these are not expected but are often present presumably to permit you to start the clock at precisely the right time. I had one case where the fine wire to the solenoid that operates the once per second clock mechanism broke and had to be resoldered but this is exceedingly rare.

If the clock consistently runs slow or fast with a known good battery, there is usually a trimmer capacitor that can be adjusted with a fine jeweler's straight blade screwdriver. Without test equipment the best you can do is trial and error - mark its original position and turn it just a hair in one direction. Wait a day or week and see if further adjustment is needed (right, like you also won the lottery!) and fine tune it.

If the hands should fall off (what a thought!), they can usually be pressed back in place. Then, the only trick is to line up the alarm hand with the others so that the alarm will go off at the correct time. This can usually be done easily by turning the hour hand counterclockwise using the setting knob in the rear until it is not possible to turn it further. At this point, it is lined up with the alarm hand. Install all hands at the 12:00 position and you should be more or less all set.

Rotisseries

The mechanism consists of a shaded pole induction motor and gear train. Clean and lubricate the gears. See the section: Shaded pole induction motors for motor problems.

Electric can openers and knife sharpeners

There consist of a shaded pole induction motor, gear train. and power switch. Likely problems relate to broken gear teeth, dirty or worn power switch, dull cutting wheel, and broken parts. Lubrication may be needed if operation is sluggish. Parts that come in contact with the cans and lids collect a lot of food grime and should be cleaned frequently.

Electric carving knives

A small motor operates a pair of reciprocating mounts for the blades.

AC powered carving knives include a momentary power switch, small motor (probably universal type), and some gearing. Congealed food goo as well as normal lubrication problems are common. The power switch is often cheaply made and prone to failure as well. The cord may be abused (hopefully not cut or damaged by careless use of the knife!) and result in an intermittent connection at one end or the other. For motor problems, see the appropriate sections on universal motors.

For battery powered knives, bad NiCds cells are a very likely possibility due to the occasional use of this type of appliance.

See the section: Small permanent magnet DC motors and the document: AC Adapters, Power Supplies, and Battery Packs for information on repair.

Electric scissors

Similar to electric carving knives except for the linkage to the blades. All other comments apply.

Portable and stationary food mixers

These consist of a universal motor which usually features a continuously variable speed control or a selection of 3 to 5 speeds, a gearbox to transfer power to the counter-rotating beaters, and a power switch (which may be part of the speed control).

Sluggish operation may be due to cookie dough embedded in the gearing. Fine particles of flour often find their way into the gears - clean and lubricate. There may be a specific relationship that needs to be maintained between the two main beater gears - don't mess it up if you need to disassemble and remove these gears or else the beaters may not lock in without hitting one-another.

The speed control may be a (1) selector switch, (2) mechanical control on the motor itself (a governor/spring/switch arrangement), or (3) totally electronic. Parts may be replaceable although, for portables at least, a new mixer may make more sense.

For sluggish operation (non-mechanical), sparking, burnt smells, etc., see the section: Problems with universal motors.

Food processors

A powerful universal motor is coupled to interchangeable cutters of various types. In most respects, food processors are similar to any other universal motor driven appliance with one exception: There will be a safety interlock switch to prevent operation unless the cover is on properly and secured. This switch may go bad or its mechanical position adjustment may shift over time resulting in difficulty in engaging power - or a totally dead unit.

As usual, cord and plug problems, bad bearings, burnt motor windings, and broken parts are all possibilities.

Steam and dry irons

Most modern irons (does anyone really use these anymore?) can be used dry or with steam.

An iron consists of a sole plate with an integrated set of heating coils.

Steam irons will have a series of holes drilled in this plate along with a steam chamber where a small amount of water is boiled to create steam. A steam iron can be used dry by simply not filling its reservoir with water. Those with a spray or 'shot of steam' feature provide a bypass to allow hot water or steam to be applied directly to the article being ironed.

Over time, especially with hard water, mineral buildups will occur in the various passages. If these become thick enough, problems may develop. In addition, mineral particles can flake off and be deposited on the clothes.

A thermostat with a heat adjustment usually at the top front of the handle regulates the heating element. This is usually a simple bimetal type but access to the mechanism is often difficult.

Where an iron refuses to heat, check the cord, test the heating element for continuity with your ohmmeter, and verify that the thermostat is closed.

An iron that heats but where the steam or spray features are missing, weak, or erratic, probably has clogged passages. There are products available to clear these.

Newer irons have electronic timeout controllers to shut the iron off automatically if not used for certain amount of time as a safety feature. Failure of these is not likely and beyond the scope of this manual in any case.

When reassembling an iron, take particular care to avoid pinched or shorted wires as the case is metal and there is water involved - thus a potential shock hazard.

Toasters

In addition to a fine heating element, there is a controller to determine the length of time that the bread (or whatever) is heated. A solenoid or bimetal trip mechanism is used to pop the bread up (but hopefully not totally out) of the toaster then it is 'done' and turn off the heating element at the same time.

Since most of these are so inexpensive, anything more serious than a broken wire or plug is probably not worth repairing. The heating element may develop a broken spot - particularly if something like a fork is carelessly used to fish out an English muffin, for example. (At least unplug it if you try this stunt - the parts may be electrically live, your fork is metal, you are touching it!). They may just go bad on their own as well.

Being a high current appliance, the switch contacts take a beating and may deteriorate or melt down. The constant heat may weaken various springs in either the switch contact or pop-up mechanism as well. Sometimes, some careful 'adjustment' will help.

Controllers may be thermal, timer based, or totally electronic. Except for obvious problems like a bent bimetal element, repair is probably not worth it other then as a challenge.

Automatic toaster will not drop bread

If it really is old, then your problem is almost certainly mechanical - a spring sprung or gummed up burnt raisin bread. You will have to do a little investigative research meaning: take the thing apart! Try to determine what the bread does to cause the support to drop down. It is possible that putting the bread in is supposed to trip a microswitch which activates a solenoid, and the switch or solenoid is now defective - bad contacts or broken wires, bad coil in the solenoid, or grime.

The following applies directly to several Sunbeam models (and no doubt to many others as well).

(From: John Riley (jriley@calweb.com).)

I will assume that the toaster is either a model ATW or possibly an older model 20 or the like.

When you drop the bread in the toaster it trips a lever that is attached to the bread rack. This lever pushes in on the contacts inside of the thermostat (color control switch) which actually turns the toaster on. In "most cases" adjusting the screw on the bottom of the toaster will do the trick. The proper adjustment is to adjust the carriage tension so that the bread rack in the side where it marked for a single slice of bread comes just to the uppermost limit of its travel. Any more is overkill.

If you have adjusted it as mentioned above and it still won't go down, there is one more thing you can try. Take the toaster a sort of BUMP it down onto the table rather firmly. Sometimes a piece of crumb will get in between the thermostat contacts. A couple of good "bumps" on the table will usually dislodge the particle.

If all of the above doesn't work, and you know the cord isn't bad, them you may very well have a thermostat that has gone south. They are still available for replacement on most models. Suggest you check with your local SUNBEAM AUTHORIZED SERVICE for price and availability.

Toaster oven (broilers)

I really liked the old original style GE toaster oven. It was very versatile and convenient for baking and toasting. The newer types seem to have lost some of these qualities. The pop open door and oven tray have apparently not been retained in any modern models that I am aware of.

Modern toaster oven (broilers) use Calrod style elements - usually two above and two below the food rack. Depending on mode, either just the top (top brown/broil), just the bottom (oven), or both sets (toast) will be energized. Each pair may be wired in series meaning that a failure of one will result in both of the pair being dead. Very old units may use a coiled

NiChrome element inside a quartz tube.

Thermostats are usually of the bimetal strip variety with an adjustment knob. A cam or two on the shaft may also control main power and select the broil function in the extreme clockwise position.

There may be a mode switch (bake-off-broil) which may develop bad contacts or may fuse into one position if it overheats. These are often standard types and easily replaceable. Just label where each wire goes on the switch before removing it to take to an appliance repair parts store.

Newer models may use an electronic timer for the toast function at least. I assume it is not much more than something like an IC timer (555) operating the trip solenoid. However, I have not had to deal with a broken one as yet.

Testing is relatively straightforward. Check the heating elements, thermostat, mode switch,, cord, and plug. While replacements for heating elements and thermostats are often available, removing the old one and wiring the new one may not be straightforward - rivets may be used for fastening and welds for the wire connections. You will have to drill the rivets with an electric drill and replace them with nuts, bolts, and lockwashers. Crimp splices or nuts and bolts can be used for the wiring. Take extra care in reassembly to avoid any bare wires touching the metal cabinet or other parts as well as insulation being cut by sharp sheetmetal parts. The high temperature fiberglas or asbestos insulation is not very robust. In the end, it may not be worth it with full featured toaster oven/broilers going for $20-30 on sale.

Some more details and comments are provided in the section: Troubleshooting a toaster oven.

Troubleshooting a toaster oven

You might expect that there would be a way of obtaining a schematic. Forget it, there is no such thing. :(However, these aren't designed by rocket scientist so it should be possible to draw one out if you really need it.

Before doing this, there are basic things to check:

1. Toaster ovens usually operate in three modes:

   - Oven (both top and bottom should be on)
   - Toast (same)
   - Top brown (only top elements)

   The broiler option is similar to top brown.

   Thinking about which elements need to be powered for which mode, and whether the thermostat is involved (not for toasting), will help to narrow down the area of attack.

   If a heating element is found to be bad either by inspection or the ohmmeter check, it can be replaced though this may only make sense from a cost perspective if you have one that can be salvaged from another appliance. If the length and resistance are similar, it should work. Attaching the cut wires may be a challenge unless you are into welding. However, a mechanical connection with a screw and nut will work though for how long is anyone's guess. Also see below. Solder can't be used.

2. A typical toaster oven has 2 sets of elements - either a pair of the Calrod(tm) type, top and bottom, with each pair usually wired in series or, a coil or pair of Nichrome coils, top and bottom.

   Visually inspect the heating elements. Failure of a Calrod(tm) type often results in an external wart of blemish where the internal coil shorted and melted the cladding. Nichrome (wire) elements fail by breaking somewhere along their length.

And/or measure the resistance of each of the elements. Typical values are 10 to 12 ohms for a single Calrod type or 20 to 25 ohms for a complete Nichrome coil. (Your measurements will vary depending on the actual wattage of the oven. These values are typical in the U.S.A. for operation on 115 VAC.)

3. If the elements are good, both top and bottom, another likely place for failure are the contacts of the mode switch(es) and thermostat. Check each of these sets of contacts and make sure they are moving appropriately and decisively - I have seen the springs lose some of their springiness over time resulting in some not working. Sometimes they can be bent back into service.

4. Broken/deteriorated wiring is very common since everything gets very hot during use. All connections in a toaster oven are likely welded but you can replace them with either a nut and bolt or high temperature crimp. Soldering will also work if the location of the failure isn't too close to the elements.

5. The thermostat on some of these units senses via a riveted attachment to the oven wall. If these rivets loosen with age, the oven may run hotter than normal. Drilling them out and using nuts and bolts or pop-rivets may work in this case.

6. On newer units that have electronic controls, parts can fail but the most likely problems are probably due to cold solder joints on the little wiring board that sits in a hot area so check for these before trying to locate a datasheet for an obscure chip.

(From: Terry (tsanford@nf.sympatico.ca).)

Get a 'wire-nut' connector. Not one of the usual ones with a wire spiral inside it; but one of the ones that has a brass insert with a screw to secure the wires. See 'Note' re set screw. Throw away the plastic outer shell. Put end of the element heating wire and the end of a short piece of heat resistant wire into the wire nut brass insert and tighten the screw; real tight cos it's going to get somewhat hot! Dress the wire and/or suspend what is now your brass connector so that it is clear of everything or use some woven 'glass' heat resistant tubing to cover the connection. Repeat at other end as necessary. Probably last for quite a while. Note: Look for one that has a set-screw that can be tightened with a hexagonal 'Allen' wrench rather than a straight edge screwdriver. With these it would seem you can get the screw and therefore contact with the wires much tighter! Another connection that might work, but have not used for this is to clip the screw terminals off the end of a duff oven element and use those as screw terminals to secure a connection to the toaster heating element wire? Those oven element terminals do get hot in normal use anyway!

Circuit diagram of typical toaster oven/broiler

Here is a schematic of a typical 'dumb'toaster oven/broiler - one without a P5-1000 chip if you can believe such a thing exists. :) Most of the complexity of these simple devices is actually in the sheet metal of the toast release mechanism! Like the more elaborate unit described in the section: Circuit diagram of Toastmaster toaster oven/broiler with electronic controls, there is a knob for control of the oven/broiler functions and another for toast Light/Dark. A separate lever engages the toast function which terminates when the toast is done. You will note that other than that unit having an IC for toast timing, the basic circuits are almost the same.

Apparently, the only real difference between a "toaster oven" and a "toaster oven/broiler" is that the latter has a means of disabling the bottom heating element while in oven (non-timed) mode - and, of course, the price!

- The heating elements are either Calrod(tm) type or Nichrome wire coils, possibly enclosed in quartz tubes.
- A single knob selects OFF (full CCW, S1A open), oven temperature S1B opens at selected temperature), and

BROIL (full CW, S1C open). Some models may have a separate both/top only switch.

- The Toast Timer can be a mechanical timer and/or a bimetal or other toast temperature sensor. Individual details will vary but when the toast is ready, they will both release the Toast Lever and open S2 as well as possibly signaling with a bell. The Light/Dark control may vary time or the temperature at which toast is considered 'done'.

This diagram is not based on any particular model.

Circuit diagram of Toastmaster toaster oven/broiler with electronic controls

Well, for toast, at least! :)

Aside from the CMOS IC based toast timer, this is a fairly basic design:

- Toastmaster Toaster Oven/Broiler Schematic

The toast function and oven/broiler are controlled separately. A single Power/Temperature/Broil knob controls the oven/broiler. This is entirely electro-mechanical with a conventional bimetal thermostat. Toast darkness is based only on time using CD4541B timer chip to release a manually activated Toast lever. Older 'dumber' toasters often were more sophisticated in their operation using a combination of time and temperature. Not this one.

Its conventional counterpart would be identical except using a mechanical and/or toast temperature sensor in place of the IC timer. Despite what you might think, the most likely failures are NOT in the 'high-tech' electronics but the usual burnt out heating element(s), bad cord or plug, broken wires, and tired switches.

Convection oven noise

Unlike a regular (non-microwave) oven, convection ovens are not totally silent. There is a small fan used to circulate the hot air (thus the name: convection oven). Depending on the oven's design and age, these fans may be anywhere from nearly silent to objectionably noisy.

If you notice an increase in motor noise (whining or squealing, grinding, knocking) then the motor and fan should be inspected and parts replaced if necessary. Sudden failure is unlikely but if it were to happen - seized bearings, for example -

an overtemperature thermal protector should shut down the heating element or entire oven. Some of these may not be self resetting (thermal fuse).

Hot plates, waffle irons, broilers, deep friers, rice and slow cookers, woks

These are all just a single or dual heating element, thermal protector (not all will have one), and an adjustable (usually) thermostat. As usual, check the cord and plug first, and then each of the other parts with an ohmmeter.

Where a NiChrome coil type heating element is used, a break will be obvious. If it is very near one end, then removing the short section and connecting the remainder directly to the terminal will probably be fine. See the section: Repair of broken heating elements.

For appliances like waffle irons, burger makers, and similar types with two hinged parts, a broken wire in or at the hinge is very common.

Note that since these operate at high temperatures, special fiberglass (it used to be asbestos) insulated wiring is used. Replace with similar types. Take extra care in reassembly to avoid shorted wires and minimize the handling and movement of the asbestos or fiberglas insulated high temperature wiring.

Popcorn poppers (oil type)

An Oil popper is basically an electric frying pan with a built-in stirrer and cover. The internal parts are accessed from the bottom: Heating coil, thermostat and thermal protector, and small gear-motor similar to that used in a clock or timer. Take care to note the orientation of the motor when removing and to not damage any seals (you don't want oil seeping down under!).

As always, check for bad connections if the popper is dead or operation is erratic.

Problems with heating can arise in the heating element, thermostat, and thermal protector.

If the stirrer doesn't turn, a gummed up motor or stirrer shaft (since these are only used occasionally) may be the problem. See the chapter: Motors 101.

Popcorn poppers (air type)

Air poppers combine a heating element and blower to heat corn kernels without the need for any unhealthy oil. Of course, you probably then drown the popcorn in butter and salt, huh? Admit it! :-).

As always, check for bad connections if the popper is dead or operation is erratic.

Problems with heating can arise in the heating element, thermostat, and thermal protector.

The motor is probably a small PM DC type and there will then be a set of diodes or a bridge rectifier to turn the AC into DC. Check these and for bad bearings, gummed up lubrication, or other mechanical problems if the motor does not work or is sluggish. See the chapter: Motors 101.

Electrical heating tape

This is the stuff used to keep your pipes from freezing when it is -25 degrees F in the Sun. :-) They come in various lengths and plug into a normal 115 VAC outlet. There may or may not be a thermostat (you may serve that purpose!).

Obviously, if you can disassemble the unit to the point of access to the connections to the heating element, a simple continuity check of each component (heating element, thermostat/switch, fuse if any, line cord, etc.) will identify whether there is a bad part. Similarly, if there is no switch, thermostat, or any other accessible parts - the entire thing is a sealed glob with a line cord - if there is no continuity, it is bad.

However, for the more general case, there are two ways to test a heat tape if whether it is alive or not isn't obvious by feel and you can't get inside. If you cannot get to the connection to the actual heating element, then the tests need to be performed with any power switch or thermostat in the 'on' position. However, it may not be possible to get a thermostat to go on if you are inside a nice heated house. It may need to be bypassed or the tests run where it is cold!

1. Check for continuity at the plug. If you have an 'on' indicator that is a neon bulb (or no indicator), it won't affect this reading. However, if it is an incandescent bulb, go to (2).

2. Test for heating action. What a concept? :) Put the sensing end of a thermometer against the heat tape and wrap the whole thing in an insulating material like fiberglass or even bubble wrap or styrofoam peanuts. Let the temperature stabilize and record it. Then turn the heat tape on or off depending on what state it was in. If it is working you should see a perhaps small, but noticeable change in temperature.

The actual resistance element in the heating tape really cannot be repaired safely so replacement is the only option if you find a problem there. The only possible repair would be to a cord that got cut or damaged resulting in a break in the wire or a faulty thermostat.

Automatic bread machines

These are actually kind of clever and according to Consumer Reports, may actually make quite decent bread. In a nutshell (whether there are nuts in your bread or not), you dump in the raw ingredients, close the lid, and the bread machine does the rest, signaling when done. Unfortunately, sometimes things go wrong and you are left with a half-baked or half-beaten mess to clean up.

The basic components of a bread machine are:

- The bread/dough chamber. This is likely made of stainless steel and about the size and shape of the finished loaf. It is surrounded by a heating element and has a stirrer/beater/kneader sticking up from the bottom.

  Common problems: Blown thermal fuse (screwed to outside of chamber in series with everything, open heating element, leaking stirrer seal, bad or stuck release solenoid.

- Stirrer motor and belt drive.

  Common problems: Bad belt or one that has popped loose, bad motor or motor in need of lubrication.

- Controller with electronic touchpad and LCD display.

  Common problems: Blown triacs, contamination in touchpad due to overzealous cleaning, faulty microprocessor, surge or lightning damage.

It should be straightforward to locate bad parts not related to the actual microprocessor - test the heating element(s) and motor for continuity and shorts. Tset the triacs (if any) for shorts as well (the resistance between any pair of pins should be more than a few ohms). However, it may be hard to be sure that something else wasn't the cause if a bad part is found. For example, a blown thermal fuse (a very common failure) may be an isolated event (these things can just grow tired of life) but could also mean that the electronic thermostat sensor isn't working or a triac or relay is stuck in the 'on' position.

Like any other electronic device, a power surge or lightning strike can wipe out the controller rendering the bread machine dead as, well, a loaf of bread. Unless there are obviously blown parts AND you get very lucky, the only solution with any likelihood of success is a total brain transplant (controller board replacement) - which is probably more expensive than a new bread machine.

Sewing machines

Moth mechanical and electrical problems are possible. (Note: we are not going to deal with fancy computerized equipment as this is probably better left to a professional except for the more obvious problems like a bad cord or plug.)

I have a 1903 Singer foot-pumped sewing machine which we have since electrified and still runs fine. A couple of drops of sewing machine or electric motor oil every so often is all that is needed. They were really built well back then.

Although the appearance of the internal mechanism may appear intimidating at first, there really is not that much to it - a large pulley drives a shaft that (probably) runs the length of the machine. A few gears and cams operate the above (needle and thread) and below (feet and bobbin) deck mechanisms. Under normal conditions, these should be pretty robust. (Getting the adjustments right may be another story - refer to your users manual). Sometimes if neglected, the oil may seriously gum up and require the sparing use of a degreaser to loosen it up and remove before relubing.

If the motor spins but does not turn the main large pulley, the belt is likely loose or worn. The motor will generally be mounted on a bracket which will permit adjustment of the belt tension. The belt should be tight but some deflection should still occur if you press it gently in the middle.

If the motor hums but nothing turns, confirm that the belt is not too tight and/or that the main mechanisms isn't seized or overly stiff - if so, it will need to be cleaned and lubrication (possibly requiring partial disassembly).

The electric motor is normally a small universal type on a variable speed foot pedal (see the section: Wiring a sewing machine speed control).

If the motor does not work at all, bypass the foot pedal control to confirm that it is a motor problem (it is often possibly to just plug the motor directly into the AC outlet). Confirm that its shaft spins freely. All normal motor problems apply - bad wiring, worn brushes, open or shorted windings, dirty commutator. See the section: Problems with universal motors.

Wiring a sewing machine speed control

This assumes a basic sewing machine (nothing computer controlled) with a normal universal series wound motor (115 VAC).

The common foot pedals are simply wirewound rheostats (variable resistors) which have an 'off' position when the pedal is released. They are simply wired in series with the universal motor of the sewing machine (but not the light) and can be left plugged in all the time (though my general recommendation as with other appliances is to unplug when not in use.

While not as effective as a thyristor type speed controller, these simple foot pedals are perfectly adequate for a sewing machine. There are also fancier speed controls and using a standard light dimmer might work in some cases. However, there are two problems that may prevent this: the sewing machine motor is a very light load and it is a motor, which is not the same as a light bulb - it has inductance. The dimmer may not work, may get stuck at full speed, or may burn out.

Shavers

A variety of types of drive mechanisms are used in electric shavers:

1. **Vibrator (AC only):** These (used by Remington among others) consist of a moving armature in proximity to the pole pieces of an AC electromagnet. The mass and spring are designed so that at the power line frequency, the armature vibrates quite strongly and is linked to a set of blades that move back and forth beneath the grille.

   If dead, check for continuity of the plug, cord, switch, and coil. IF sluggish, clean thoroughly - hair dust is not a good lubricant. Sliding parts probably do not require lubrication but a drop of light oil should be used on any rotating bearing points.

   Note that since a resonance is involved, these types of shavers may not work well or at all on foreign power - 50 Hz instead of 60 Hz or vice versa - even if the voltage is compatible.

2. **Universal motor (AC or DC):** Very small versions of the common universal motors found in other appliances. A gear train and linkage convert the rotary motion to reciprocating motion for shavers with straight blades or to multiple rotary motion for rotary blade shavers. These may suffer from all of the afflictions of universal motors; bad cords, wires, and switches; and gummed up, clogged, or worn mechanical parts. Also see the sections on the appropriate type of motor. Take care when probing or disassembling these motors - the wire is very fine any may be easily damaged - I ruined an armature of a motor of this type by poking where I should not have when it was running - ripped all the fine wires from the commutator right off.

3. **DC PM motor:** Often used in rechargeable shavers running of 2 or 3 NiCd cells. These may suffer from battery problems as well as motor and mechanical problems. One common type is the Norelco (and clone) rotary shaver. See the chapters on Batteries and AC Adapters as well as the sections on "Small permanent magnet DC motors".

   A shaver that runs sluggishly may have a dead NiCd cell - put it on charge for the recommended time and then test each cell - you should measure at least 1.2 V. If a NiCd cell reads 0, it is shorted and should be replaced (though the usual recommendation is to replace all cells at the same time to avoid problems in the future).

   Note that in terms of rechargeable battery life, shavers are just about optimal as the battery is used until it is nearly drained and then immediately put on charge. The theoretical 500 to 1000 cycle NiCd life is usually achieved in shaver applications.

Comments on Norelco shaver maintenance and repair

The following applies to newer models that have more computing power in their battery chargers than 5 month old PCs, not those with just a bridge rectifier for electronics. :)

(Merged comments from: Jerry Greenberg (jerryg50@hotmail.com) and Paul Grohe (grohe@galaxy.nsc.com).)

I used to service some of the Philips models of shavers. These are the same as the Norelco. When the batteries are dead the shaver will not run. The shaver has a sophisticated uPC (for what it does) that manages its operation. When it sees the batteries as dead, it will inhibit the shaver from being able to run. If the batteries are shorted, nothing will even light up at all.

The little "power supply" does not have enough "juice" to run the motor. The motor runs off the cells. If the cells are *dead* (shorted), nothing will work.

You can "test" the power supply by either listening carefully, or, holding it up to an AM (MW) radio tuned off to the end (no station) while plugging the razor in.

If the charger is okay, but the cells are shorted or weak, you will hear a quick "ping" followed by a stretched-out, "constipated" squeal. This is the little switching power supply quitting under the "dead weight" of the cells.

A "good" razor will have a nice, steady squeal (or "hiss" on the radio).

Once the shaver is opened, if you are mechanically skilled, it is worth the effort to disassemble the top head assembly where the motor goes in to, and do a thorough cleaning. You can lubricate the gears and shafts with a very light silicon lubricant. The motor is held in position with two spring clips. Care must be taken to not break the plastic pieces.

Everything snaps together. Opening the case is usually the toughest part.

And take it apart over a paper towel. Powdered hair will fall out all over the place as you take it apart. Keep a dust-buster or vacuum near by to suck up any escaping "dust". The stuff is worse than wallboard dust!

If you do any soldering, do it in a well ventilated place. Burning hair is not a pleasant smell! I would take the shaver completely apart (like a watch) and clean all the pieces, including the circuit board and display. Everything would be dried off, mechanical parts lubricated, new batteries installed, new blades, and then the complete re-assembly would be done. Once used to this type of work, a complete overhaul takes less than about 30 to 40 minutes. Most of the time, it only needed new batteries and blades. The shaver would be good for another few years. This especially pays for the more expensive models.

I'm on my third set of cells after 12 years. Last month I installed new 1200 mA/H NiMh cells.

Also: While you have the motor removed - it is a good idea to "clean" the motor brushes by connecting it to an adjustable power supply and slightly over-voltaging it to make it run faster than normal (with no load). Run it full-out for about 5 minutes (or until it runs smoothly). Run it in both directions, too. This will eliminate any "chugging", stalling or rough starts you may be experiencing with older units.

As for original parts, Norelco will supply them if the shaver model is less than about 5 to 7 years old. Usually the replacement parts are not expensive in relation to replacing the shaver. As for replacement parts, they would only supply the complete circuit boards, batteries, and any mechanical parts if they are defective.

Mine is as good as new now!

Electric toothbrushes

These are basically similar to any other small battery operated appliance or tool such as a screwdriver or drill. The permanent magnet motor runs off of rechargeable NiCd batteries and cause the bristles or whatever to oscillate, rotate, or vibrate. Interchangeable 'brush' units allow each member of the family to have their own. Coupling to the internal battery is often via a 'contactless' mechanism using a pair of coils to transfer AC inductively. Inside the hand unit, this is rectified to charge the NiCd (usually) battery. See the section: Inductively coupled charging circuit for an example of one such design.

Problems can occur in the following areas:

- **Motor, battery pack, connections, on/off switch:** As with any other similar device.
- **Power train:** Gummed up lubrication, broken, or other mechanical problems.
- **Charging station or circuitry:** The fault may be with the base unit or circuitry associated with the battery pack. See the section: Braun electric toothbrush repair, below. Since these must operate in a less than ideal environment (humid or actual waterlogged!), contamination and corrosion is quite possible if the case is not totally sealed. Some

of the switches may be of the magnetic reed type so that there don't need to be any actual breaks in the exterior plastic housing. Even so, the motor shaft probably passes through a bushing in the housing and this will leak eventually.

Of course, getting inside may prove quite a challenge and in general one must consider the hand unit to be a throw-away item since it is generally glued together - permanently. While it is possible to use a hacksaw to carefully cut around the case, the resulting repair once the thing is put back together will be decidedly of the 'Jerry-rigged' type and sealing will be difficult and long term reliability and safety would be questionable.

(From: Jeff & Sandy Hutchinson (sandy2@flatoday.infi.net).)

It's darned near impossible to replace the batteries on the Interplak toothbrush without destroying the recharging circuit. The base of the hand unit has a little pickup coil in it, and when you unscrew the cap to get at the batteries, you break the connections to the pickup coil. Best to do an exchange with the factory.

(From: Bill Finch (alioth@ix.netcom.com).)

I've done this twice. Use a tubing (or pipe) cutter at the seam. Rotate and tighten the cutter slowly until the thing falls apart. Fish out the guts and resolder a new battery in place. Slip everything back into the lower tube. Glue the top back on with PVC pipe sealant. It helps to make a simple jig to hold the top steady while the PVC cement sets. Try not to get excess cement on the external plastic or you wife will complain. A good trick here is to mask with drafting tape or whatever.

If this fails just buy a new toothbrush.

(From: Chip Curtis (ccurtis@zilog.com).)

I had a problem with my Braun and found that the unit's PCB was rather wet. After drying it out and coating it the unit still turned on from time to time and I noticed that during the false runs the transistor was not saturating. It didn't take long to see that the problem is caused by the transistor's base being left wide open. Any noise on the base or small current flow from PCB leakage will cause the transistor to fire and the brush noise is enough to keep it triggering and running on.

The fix; tack a 1M or whatever (no smaller than 47K) resistor from the base of the transistor to ground. The pull-down won't hurt current consumption when the unit is off because the reed switch is open, and the small bias won't make much of a difference when the unit is running.

Inductively coupled charging circuit

This was found in an Interplak Model PB-12 electric toothbrush but similar designs are used in other appliances that need to be as tightly sealed as possible.

A coil in the charging base (always plugged in and on) couples to a mating coil in the hand unit to form a step down transformer. The transistor, Q1, is used as an oscillator at about 60 kHz which results in much more efficient energy transfer via the air core coupling than if the system were run at 60 Hz. The amplitude of the oscillations varies with the full wave rectifier 120 Hz unfiltered DC power but the frequency is relatively constant.

The battery charger is nothing more than a diode to rectifier the signal coupled from the charging base. Thus, the battery is on constant trickle charge as long as the hand unit is set in the base. The battery pack is a pair of AA NiCd cells, probably about 500 mA-h.

For the toothbrush, a 4 position switch selects between Off, Low, Medium, and High (S1B) and another set of contacts (S1A) also is activated by the same slide mechanism. The motor is a medium size permanent magnet type with carbon brushes.

Braun electric toothbrush repair

(From: David DiGiacomo (dd@Adobe.com).)

This Braun electric toothbrush (original model) would turn itself on and keep running until its batteries were discharged.

The toothbrush can be disassembled by pulling the base off with slip joint pliers (do not pull too hard because there is only about 1" of slack in the charging coil wires). With the base off, the mechanism slides out of the case.

There is a simple charging circuit, charging LED, 2 NiCd cells, and a reed switch driving the base of an NPN transistor. The transistor collector drives the motor.

I charged the battery, but the problem of the motor running with the reed switch open didn't recur until I held my finger on the transistor for about 10 seconds seconds. Grounding the transistor base turned it off again, and I could repeat this cycle. Since there wasn't anything else to go wrong I decided to replace the transistor. I couldn't read the marking, but it's in a SOT89 package and the motor current is 400-700 mA so it must be something like a BC868. However, I didn't have any surface mount or TO92 transistors that could handle the current, so I used a 2SD882 (small power tab package), which I was able to squeeze into some extra space in the center of the charging coil.

Hand massagers

These are simply motors with an off-axis (eccentric) weight or electromagnetic vibrators. If the unit appears dead, check the plug, cord, on/off switch, internal wiring, and motor for continuity. Confirm that the mechanical parts turn or move freely.

Some have built in infra-red heat which may just be a set of small light bulbs run at low voltage to provide mostly heat and little light (a filter may screen out most of the light as well). Obviously, individual light bulbs can go bad - if they are wired in series, this will render all of them inert.

At least one brand - Conair - has had problems with bad bearings. Actually, poorly designed sleeve bearings which fail due to the eccentric load. If you have one of these and it becomes noisy and/or fails, Conair will repair (actually replace) it for $5 if you complain in writing and send it back to them. They would like a sales receipt but this apparently is not essential.

Hair dryers and blow dryers

A heating element - usually of the NiChrome coil variety - is combined with a multispeed centrifugal blower.

First determine if the problem is with the heat, air, or both.

For heat problems, check the element for breaks, the thermal protector or overtemperature thermostat (usually mounted in the air discharge), the connections to the selector switch, and associated wiring.

Newer models may have a device in the plug to kill power to the unit should it get wet. See the sections: "What is a GFCI?" and "The Ground Fault Circuit Killer (GFCK)".

For air problems where the element glows but the fan does not run, check the fan motor/bearings, connections to selector switch, and associated wiring. Confirm that the blower wheel turns freely and is firmly attached to the motor shaft. Check for anything that may be blocking free rotation if the blower wheel does not turn freely. The motor may be of the induction, universal, or PM DC type. For the last of these, a diode will be present to convert the AC to DC and this might have failed. See the appropriate section for problems with the type of motor you have.

The Ground Fault Circuit Killer (GFCK)

Note: I have heard that the official name for these disasters is: Appliance Leakage Circuit Interrupter (ALCI). I like mine better. :)

This safety 'enhancement' must have been designed by engineers with too much time on their hands (or the wrong sort of incentive bonus plan). Get a few drops of water on one of these appliances and it goes in the garbage.

The irony is that once the GFCK blows, the owner is likely to just cut off the GFCK plug and replace it with a normal plug (rather than throwing the appliance away or having it properly repaired, as was no doubt the intent), thus eliminating the protection altogether!

The GFCK (my designation) is a device contained in an oversize plug which is part of the cordset of some newer hand-held (at least) appliances that may be used in wet areas like kitchens and baths but where there may be no GFCI protection (see the section: What is a GFCI?. I first ran across one of these on a late model Conair blow dryer (which is why this section on GFCKs is here rather than with the GFCI information).

In a nutshell, the GFCK permanently disconnects power to the appliance - at the plug - should electrical leakage of more than a few milliamps be present within the appliance. Unlike a GFCI, ther is NO reset button and no way to get inside short of drilling out the rivets holding the plug together! In fact, the unit I dissected uses an SCR to grossly overdrive and blow out a normal resistor which by its placement holds a mechanical latch in place for a pair of contact releases that disconnect the plugs prongs from the wires of the cord. With the resistor gone, the prongs of the plug go nowhere so everything beyond them becomes totally dead, electrically - forever. Thus, even if dropped into a bathtub, the appliance will not cause electrocution. Sorry, these can't be used as part of murder mystery plots!

Admittedly, the GFCK works regardless of whether the outlet the appliance is plugged into is 2-prong, 3-prong, correct or reverse polarity, or GFCI protected, and thus provides a high level of safety. But, this may be taking cost reduction to an extreme rather than providing a resettable basic GFCI (just H-G faults). Having said that, there is merit to disabling the appliance permanently since there is no way to know how much damage may have been done internally by the water (or whatever caused the GFCK to trip) and it's safety may always be suspect.

All this is mounted inside the plug:

```

* R1 is positioned to hold the latch for CB1 and CB2 in place until it vanishes in a puff of smoke. It is interesting to note that R1 is NOT a flameproof resistor - it looks like an ordinary 1/8 W carbon composition type.

The Ground wire in the cord (G) goes from the circuit in the plug back to the metal parts of the dryer (though as usual with a modern appliance, it is mostly made of plastic). Note that there is no Ground wire to the outlet - just to the appliance. The theory goes that should the device get wet, current is more likely to flow to the nearby metal parts and via the cord's Ground wire to the GFCK than to some other earth ground (including a person touching an earth ground). In fact, this device does NOT sense a current imbalance like a true GFCI - just leakage to its internal Ground wire, but under realistic circumstances, this should be a reliable indication of a fault.

A fault condition would result in current flowing between H and G in the cord. When this exceeds about 3 mA, the

SCR (Q1) triggers putting R1 essentially across the line (maybe limited a bit by L1). R1, which was physically holding the latch for the plug circuit breakers CB1 and CB2, now explodes releasing both these contacts. Power is shut off to the appliance - permanently! Hopefully, the plug doesn't catch fire in the process! :)

As noted, cutting off this fancy plug and replacing it or the entire cordset with a conventional one provides the same level of safety IF AND ONLY IF the appliance is used ONLY in a GFCI protected outlet (the cord Ground wire is left disconnected in this case or can be attached to the third prong of a three prong plug). The alternative of installing a 3-prong plug on the appliance and then only using it in a properly grounded 3-prong outlet doesn't provide the same protection as there can still be enough leakage to be lethal without blowing a fuse or tripping a breaker (and the ground wire in the sample I have wouldn't be adequate to carry a major fault current anyhow).

And, guess what? This Conair blow dryer died not because the GFCK had been activated, but because the soldering to the R1 was defective and it pulled loose!

Curling irons

These are just a sealed heating element, switch, and thermal protector (probably). Check for bad connections or a bad cord or plug if there is not heat. A failed thermal protector may mean other problems. While these are heating appliances, the power is small so failures due to high current usually do not occur.

VCR cassette rewinders

Cassette rewinders typically consist of a low voltage motor powered from a built in transformer or wall adapter, a belt, a couple of reels, and some means of stopping the motor and popping the lid when the tape is fully rewound.

Note that some designs are very hard on cassettes - yanking at the tape since only increased tension is used to detect when the tape is at the end. These may eventually stretch the tape or rip it from the reel. I don't really care much for the use of tape rewinders as normal use of rewind and fast forward is not a major cause of VCR problems. Sluggish or aborted REW and FF may simply indicate an impending failure of the idler tire or idler clutch which should be addressed before the VCR gets really hungry and eats your most valuable and irreplaceable tape.

Problems with tape rewinders are usually related to a broken or stretched belt or other broken parts. These units are built about as cheaply as possible so failures should not be at all surprising. The drive motor can suffer from any of the afflictions of similar inexpensive permanent magnet motors found in consumer electronic equipment. See the section: Small permanent magnet DC motors. A broken belt is very common since increased belt (and tape) tension is used to switch the unit off (hopefully). Parts can pop off of their mountings. Flimsy plastic parts can break.

Opening the case is usually the biggest challenge - screws or snaps may be used. Test the motor and its power supply, inspect for broken or dislocated parts, test the power switch, check and replace the belt if needed. That is about it.

Vacuum cleaners, electric brooms. and line powered hand vacs

Despite all the hype surrounding vacuum cleaner sales, there isn't much difference in the basic principles of operation between a $50 and $1,500 model - and the cheaper one may actually work better.

A vacuum cleaner consists of:

1. **A cordset:** Broken wires or damaged plugs are probably the number one problem with vacuums as they tend to be dragged around by their tails! Therefore, in the case of an apparently dead machine, check this first - even just squeezing and bending the wire may produce an instant of operation - enough to verify the cause of

the problem.

2. **A power switch:** This may be a simple on/off toggle which can be tested with a continuity checker or ohmmeter. However, fancy machines with powered attachments may have interlocks or switches on the attachments that can also fail. Where multiple attachment options are present, do your initial troubleshooting with the minimal set as this will eliminate potential sources of additional interlock or switch complications. With 'microprocessor' or 'computer' controlled vacuum cleaners, the most likely problems are not the electronics.

3. **A high speed universal motor attached to a centrifugal blower wheel:** As with any universal motor, a variety of problems are possible: dirt (especially with a vacuum cleaner!), lubrication, brushes (carbon), open or shorted windings, or bad connections. See the section: Problems with universal motors.

4. **A belt driven carpet brush (uprights):**. The most common mechanical problem with these is a broken rubber belt. (One person who shall remain nameless, mistook the end of the broken belt for the tail of a mouse and promptly went into hysterics!). Replacements for these belts are readily available.

5. **Power nozzles and other powered attachments:** Some of these are an attempt to give canister type vacuum cleaners the power of an upright with its directly powered carpet brush. Generally, these include a much smaller motor dedicated to rotating a brush. Electrical connections are either made automatically when the attachment is inserted or on a separate cable. Bad connections, broken belt, or a bad motor are always possibilities.

6. **A bag to collect dirt:** Vacuum cleaners usually do a poor job of dust control despite what the vacuum cleaner companies would have you believe. Claims with respect to allergies and other medical conditions are generally without any merit unless the machine is specifically designed (and probably very expensive) with these conditions in mind. If the vacuum runs but with poor suction, first try replacing the bag.

Vacuum cleaner mechanical problems

1. **Poor suction:** Check the dirt bag and replace if more than half full. Check for obstructions - wads of dirt, carpet fibers, newspapers, paper towels, etc.

2. **Poor pickup on floors:** Broken or worn carpet brush belt. There should be some resistance when turning the carpet brush by hand as you are also rotating the main motor shaft. If there is none, the belt has broken and fallen off. Replacements are readily available. Take the old one and the model number of the vacuum to the store with you as many models use somewhat similar but not identical belts and they are generally not interchangeable. To replace the belt on most uprights only requires the popping of a couple of retainers and then removing one end of the carpet brush to slip the new belt on.

3. **Vacuum blows instead of sucks:** First confirm that the hose is connected to the proper port - some vacuums have easily confused suction and blow connections. Next, check for internal obstructions such as wads of dirt, balls of newspaper, or other items that may have been sucked into the machine. Note that it is very unlikely - bordering on the impossible - for the motor to have failed in such a way as to be turning in the wrong direction (as you might suspect). Furthermore, even if it did, due to the design of the centrifugal blower, it would still suck and not blow.

4. **Broken parts:** Replacements are available for most popular brands from appliance repair parts distributors and vacuum/sewing machine repair centers.

Vacuum cleaner electrical problems

>

1. **Bad cord or plug:** This is the number one electrical problem due to the abuse that these endure. Vacuum cleaners are often dragged around and even up and down stairs by their tails. Not surprisingly, the wires inside eventually break. Test with a continuity checker or ohmmeter. Squeezing or bending the cord at the plug or vacuum end may permit a momentary spurt of operation (do this with it plugged in and turned on) to confirm this diagnosis.

2. **Bad power switch:** Unplug the vacuum and test with a continuity checker or ohmmeter. If jiggling the switch results in erratic operation, a new one will be required as well.

3. **Bad interlocks or sensors:** Some high tech vacuum cleaners have air flow and bag filled sensors which may go bad or get bent or damaged. Some of these can be tested easily with an ohmmeter but the newest computer controlled vacuum cleaners may be more appropriate to be repaired by a computer technician!

4. **Bad motor:** Not as common as one might think. However, worn carbon brushes or dirt wedged in and preventing proper contact is possible and easily remedied. See the section: Problems with universal motors.

5. **Bad internal wiring:** Not that likely but always a possibility.

Vacuum cleaner hose damage

> "We have been quoted a price of $100 to replace the hose on our Panasonic (Mc-9537) vacuum cleaner. It has a rip in it; next to the plastic housing where the metal tubing starts. Does anyone know if there is a more economical way to solve this problem?"

I have always been able to remove the bad section and then graft what is left back on to the connector. Without seeing your vacuum, there is no way to provide specific instructions but that is what creativity is for! :-) It might take some screws, tape, sealer, etc.

$100 for a plastic hose is obviously one approach manufacturers have of getting you to buy a new vacuum - most likely from some other manufacturer!

Note: Some vacuum cleaners with power nozzles use the coiled springs of the hose as the electrical conductors for the power nozzle. If you end up cutting the hose to remove a bad section, you will render the power nozzle useless.

High tech vacuum cleaners?

Excerpt from a recent NASA Tech Brief:

> "The Kirby Company of Cleveland, OH is working to apply NASA technology to its line of vacuum cleaners. Kirby is researching advanced operational concepts such as particle flow behavior and vibration, which are critical to vacuum cleaner performance. Nozzle tests using what is called Stereo Imaging Velocity will allow researchers to accurately characterize fluid and air experiments. Kirby is also using holography equipment to study vibration modes of jet engine fans."

I suppose there will be degree-credit university courses in the operation of these space age vacuums as well! --- sam

Dustbusters(tm) and other battery powered hand vacs

These relatively low suction battery powered hand vacuums have caught on due to their convenience - certainly not their stellar cleaning ability!

A NiCd battery pack powers a small DC permanent magnet motor and centrifugal blower. A simple momentary pushbutton power switch provides convenient on/off control.

Aside from obvious dirt or liquid getting inside, the most common problems occur with respect to the battery pack. If left unused and unplugged for a long time, individual NiCd cells may fail shorted and not take or hold a charge when the adapter is not plugged back into the wall socket. Sluggish operation is often due to a single NiCd cell failing in this way.

See the appropriate sections on "Batteries" and "Motors" for more information.

Dustbusters left on continuous charge and battery problems

The low current trickle charger supplied with these battery operated hand-vacs allow Dustbusters and similar products to be be left on continuous charge so long as they are then not allowed to self discharge totally (left on a shelf unplugged for a long time). Older ones, in particular, may develop shorted cells if allowed to totally discharge. I have one which I picked up at a garage sale where I had to zap cells to clear a shorts. However, it has been fine for several years now being on continuous charge - only removed when used.

While replacing only selected cells in any battery operated appliance is generally not recommended for best reliability, it will almost certainly be much cheaper to find another identical unit at a garage sale and make one good unit out of the batteries that will still hold a charge. It is better to replace them all but this would cost you as much as a new Dustbuster.

The NiCd cells are soldered in (at least in all those I have seen) so replacement is not as easy as changing the batteries in a flashlight but it can be done. If swapping cells in from another similar unit, cut the solder tabs halfway between the cells and then solder the tabs rather than to the cells themselves if at all possible. Don't mess up the polarities!

In the case of genuine Dustbusters, where a new battery is needed and you don't have a source of transplant organs, it may be better to buy the replacement cells directly from Black and Decker. They don't gouge you on NiCd replacements. B&D is actually cheaper than Radio Shack, you know they are the correct size and capacity, and the cells come with tabs ready to install. They'll even take your old NiCds for proper re-cycling.

Floor polishers

A relatively large universal motor powers a set of counter-rotating padded wheels. Only electrical parts to fail: plug, cord, power switch, motor. Gears, shafts, and other mechanical parts may break.

Heating pads

Heating pads are simply a very fine wire heating element covered in thick insulation and then sealed inside a waterproof flexible plastic cover. Internal thermostats prevent overheating and regulate the temperature. The hand control usually provides 3 heat settings by switching in different sections of the heating element and/or just selecting which thermostat is used.

There are no serviceable parts inside the sealed cover - forget it as any repair would represent a safety hazard. The control unit may develop bad or worn switches but even this is somewhat unlikely. It is possible to disassemble the control to check for these. You may find a resistor or diode in the control - check these also. With the control open, test the wiring to the pad itself for low resistance (a few hundred ohms) between any pair of wires). If these test open, it is time for a new heating pad. Otherwise, check the plug, cord, and control switches.

Extended operationg especially at HIGH, or with no way for the heat to escape, may accelerate deterioration inside the sealed rubber cover. One-time thermal fuses may blow as well resulting in a dead heating pad. One interesting note: Despite being very well sealed, my post mortems on broken heating pads have shown one possible failure to be caused by corrosion of the internal wiring connections after many years of use.

Electric blankets

As with heating pads, the only serviceable parts are the controller and cordset. The blanket itself is effectively sealed against any repair so that any damage that might impact safety will necessitate replacement.

Older style controllers used a bimetal thermostat which actually sensed air temperature, not under-cover conditions. This, it turns out, is a decent measurement and does a reasonable job of maintaining a comfortable heat setting. Such controllers produced those annoying clicks every couple of minutes as the thermostat cycled. Problems with the plug, cord, power switch, and thermostat contacts are possible. The entire controller usually unplugs and can be replaced as a unit as well.

Newer designs use solid state controls and do away with the switch contacts - and the noise. Aside from the plug and cord, troubleshooting of a faulty or erratic temperature control is beyond the scope of this manual.

Humidifiers

There are three common types:

1. **Wet pad or drum:** A fan blows air across a stationary or rotating material which is water soaked. There can be mechanical problems with the fan or drum motor or electrical problems with the plug, cord, power switch, or humidistat.

2. **Spray:** An electrically operated valve controls water sprayed from a fine nozzle. Problems can occur with the solenoid valve (test the coil with an ohmmeter), humidistat, or wiring. The fine orifice may get clogged by particles circulating in the water or hard water deposits. In cleaning, use only soft materials like pointy bits of wood or plastic to avoid enlarging the hole in the nozzle.

3. **Ultrasonic:** A high frequency power oscillator drives a piezo electric 'nebulizer' which (with the aid of a small fan) literally throws fine droplets of water out into the room. Problems with the actual ultrasonic circuitry is beyond the scope of this manual but other common failures can be dealt with like plug, cord, fan motor, control switches, wiring, etc. However, if everything appears to working but there is no mist from the output port, it is likely that the ultrasonic circuitry has failed. See the section: Ultrasonic humidifiers for more details.

Ultrasonic humidifiers

(From: Filip "I'll buy a vowel" Gieszczykiewicz (filipg@repairfaq.org).)

The components of the typical $45 unit are:

- Piezo transducer + electronics (usually in a metal cage - we are talking line current here - not safe!).

- Small blower/fan.

- Float-switch.

- Water tank.

The piezo transducer sets up a standing wave on the surface of the water pool. The level is sensed with a float-switch to ensure no dry-running (kills the piezo) and the blower/fan propels the tiny water droplets out of the cavity. A few manufacturers are nice enough to include a silly air filter to keep any major dust out of the 'output' - do clean/check that once in a while.

Common problems:

- Low output:
