Silicon Sam's Technology Resource (SSTR) - V3.86
Main Table of Contents (ToC)

Note: If you know of something that is incorrect or missing from this page or if you have any additions, please contact me via the Sci.Electronics.Repair FAQ Email Links Page.

Everything in SSTR is now accessible directly from the S.E.R FAQ Main ToC. It may be better to link there instead.

See What is the Sci.Electronics.Repair FAQ? if you are really not quite sure you should be here.

Please check out the Home and Mirror Site Locations page to access or download the latest versions of these documents.

The SSTR Expanded ToC lists ALL files of mine resident at this site. This may be convenient if you are attempting to locate or download a particular photo, schematic, or other file not referenced directly by the top level ToC or its Sub-ToCs.

Sci.Electronics.Repair FAQ Search on Drexel Mirror Site

The following provides a fast search facility but it is currently only present on the S.E.R FAQ mirror site at Drexel University which is maintained up to date almost daily.

For contact info, please see the Sci.Electronics.Repair FAQ Email Links Page.

Table of Contents

Introduction

These listings and links identify those web sites where I have some sort of control and attempt to maintain up-to-date versions of all the documents where possible. Additional options may be found at the mirrors info of the Sci.Electronics.Repair FAQ sites themselves. Some Web sites get updated more frequently than others. The latest versions of the S.E.R FAQ (including Sam's Laser FAQ) are at three Web sites, which are the absolute latest or updated almost daily:

- S.E.R FAQ Galactic Home
- S.E.R FAQ Drexel Mirror
- S.E.R FAQ UPenn Mirror

Zip files for downloading the complete FAQs may be found on the Drexel and UPenn mirror sites (direct links below).

Descriptions of the Various FAQ Collections

The Sci.Electronics.Repair (S.E.R) FAQ is an extensive set of documents on consumer electronics (and other) troubleshooting and repair, testing, general electronics, reference information, assorted schematics of interesting and sometimes unusual devices, links to over 1000 technology related Web sites, and more. It was developed specifically for the DoItYourselfer (DIYer) and tinkerer, hobbyist, experimenter, engineer, dentist, and poet. The S.E.R FAQ includes all of the material I have written (nicely formatted by Filipg G.) as well as many articles and references from others. To the best of my knowledge, this is the most comprehensive collection of information of its kind in the explored universe.

Note that the latest documents I have authored (see SSTR, below) are now linked from the S.E.R Main ToC. The older versions will eventually be phased out.

Sam's Laser FAQ (SLF) - A Practical Guide to Lasers for Experimenters and Hobbyists - contains extensive practical information on a variety of laser related topics. Sam's Laser FAQ is present at all S.E.R FAQ (and SSTR - see below) sites, but due to its nature and size, is also available as a self contained document and at other sites as well. Version may vary slightly by site but all are quite recent and nicely formatted including a full table of contents, list of all associated files, and extensive cross-links. The complete Sam's Laser FAQ may be downloaded for convenient high speed local access. See: Sam's Laser FAQ Local Installation for details.

The **Laser Equipment Gallery (LEG)** includes a collection of photos of various laser systems, power supplies, and components. Due to its size, the LEG is only present at selected sites and is NOT part of the FAQ distributions.

Silicon Sam's Technology Resource (SSTR) includes all the documents I have authored and are now linked from the main S.E.R FAQ ToC. They are nicely formatted and eventually the older similar documents of the S.E.R FAQ will be phased out. In other words, the latest versions of the S.E.R FAQ documents I have authored ARE exactly the same as what's in the SSTR directory. The complete SSTR collection may also be downloaded for convenient high speed local access. See: Silicon Sam's Technology Resource Local Installation for details. Note that while SSTR sites include Sam's Laser FAQ, it is NOT part of the SSTR download package and must be installed separately.

Copies of some of these documents, particularly the various repair guides of the Sci.Electronics.Repair FAQ, may be found at other totally independent sites. However, unless they are live links back to one of the sites below, the versions are likely to be quite old (relatively speaking, at least). There are also some additional sites which have copied and modified some of these documents to provide a more user friendly graphical user interface. So, if you stumble across something that looks vaguely familiar, you will know where it came from. In either case, if there is no acknowledgement of the origin in the links or at the beginning of the document, please let me know!

The Main Table of Contents (ToC) links, below, are the usual jumping off points for the good stuff for on-line viewing. :-) Those labeled as 'Zip' may be downloaded as a single compressed file and easily installed to create a local browser accessible copy. See the descriptions of the FAQs, above, for links to installation instructions.

Sci.Electronics.Repair FAQ Home Site

The latest versions of these documents are available at the Home site, Repairfaq.org.

(SSTR=Silicon Sam's Technology Resource, SLF=Sam's Laser FAQ, LEG=Laser Equipment Gallery.)

- USA-SC: S.E.R FAQ Home (RepairFAQ.org) - S.E.R. FAQ Main ToC | SSTR | SLF | LEG.

Sci.Electronics.Repair FAQ Mirror Sites

These sites have various versions depending on who maintains the content. For those where I have upload access at least, versions will be quite recent. UPenn is my "live" site - it's where I do all development and is thus guaranteed current (complete with screwups). Repairfaq.org and Drexel are updated from UPenn almost daily. Hopefully, some sites will have fully automatic mirroring but that is in the future (I've been saying this for about 10 years now!).

The primary mirror sites (Drexel and UPenn) are listed first, followed by the remainder in no particular order - maybe alphabetic, then EDU/COM, then USA/Foreign, then by distance, maybe. :)

(SSTR=Silicon Sam's Technology Resource, SLF=Sam's Laser FAQ, LEG=Laser Equipment Gallery, Zip=Zipped file for the preceeding FAQ collection.)

- USA-PA-E1: S.E.R FAQ Mirror (Sam, Drexel U. ECE) - Main ToC, Zip | SSTR, Zip | SLF, Zip | LEG.
- USA-PA-E2: S.E.R FAQ Mirror (Sam, U. of Penn CIS) - Main ToC, Zip | SSTR, Zip | SLF, Zip | LEG.

- USA-IL: S.E.R FAQ Mirror (David Gersic, NIU) - Main ToC | SSTR | SLF.
- USA-NH: S.E.R FAQ Mirror (Timothy. J. Quill, Dartmouth U.) - Main ToC | SSTR | SLF.
- USA-NY: S.E.R FAQ Mirror (Jameel Akari) - Main ToC | SSTR | SLF.
- USA-PA-W: S.E.R FAQ Mirror (Greg J. Szekeres, UPitt) - Main ToC.
- USA-CA: S.E.R FAQ Mirror (EIO) - Main ToC | SSTR | SLF.

- USA-FL: S.E.R FAQ Mirror (Chris Hoaglin) - Main ToC | SSTR | SLF
- CA (Canada): S.E.R FAQ Mirror (University of Alberta EECS) - Main ToC.
- DE-1 (Germany): S.E.R FAQ Mirror (Daniel Brune) - Main ToC | SSTR | SLF.

The entries marked 'Zip' provide a convenient way of creating a local browser-accessible copy of SSTR and/or Sam's Laser FAQ. See Silicon Sam's Technology Resource Local Installation and Sam's Laser FAQ Local Installation for details.

Sci.Electronics.Repair FAQ Archive

The complete Sci.Electronics.Repair FAQ (including information and links from other sources) may also be downloaded from the Circuit Cookbook Archive (CCA) sites. Both ASCII and local HTML versions are available but they are generally older than those at many other sites:

- CA (Canada): CCA Home (University of Alberta EECS) - Electronics FAQs | Repair FAQs - Zip.

Sci.Electronics.Repair FAQ Italian Translation by Antonio Cristiani

Most of the individual repair and testing documents (but not Sam's Laser FAQ) have been converted including the colloquial English phrases!

- IT (Italy): S.E.R FAQ in Italian (Antonio Cristiani)
- CA (Canada): S.E.R FAQ in Italian Mirror (University of Alberta EECS) - Main ToC.

Sci.Electronics.Repair FAQ French Translation by GUILBAUD Christophe (Tophe)

Portions of some of the individual repair and testing documents (currently just TVs and VCRs) have been converted. This site is under construction.

- FR (France): Tophe's Homepage and Table of Contents

Additional Sites with Silicon Sam's Technology Resource

(I'm not sure if this one is maintained.)

- USA-MA: GB7IPD's Web Site - SSTR | SLF.

Additional Sites with Sam's Laser FAQ

In addition to being included in the S.E.R FAQ and SSTR sites, there are several other sites which include Sam's Laser FAQ (SLF).

- USA-MD: K3PGP's Web Site - Experimenter's Corner | SLF | LEG.
- USA-PA: Don Klipstein's Web Site (Home) - Don's Laser Page | SLF.
- DE-2 (Germany): LaserFreak.net's Web Site - SLF | LEG.

Going to laserfaq.net or laserfaq.org will also work and are the same Web site.

Miscellaneous Sites with Sam Stuff

A variety of documents that I have authored or coauthored are available on: Don klipstein's Lighting Technology Web Site. (Most of these are also part of the S.E.R FAQ and SSTR collections.)

One of the latest versions of the document: "Notes on the Troubleshooting and Repair of Electronic Flash Units and Strobe Lights, and Design Guidelines, Useful Circuits, and Schematics" usually resides at:

- Don's Xenon Flash and Strobe Page - Strobe FAQ.

Fluorescent and discharge lamp info and troubleshooting documents:

- Don's Lighting Info Center - Fluorescent Lamps | DC-AC Inverters | Discharge Lamps.

High Voltage Stuff:

- Don's High Voltage Page - Simple HV Generator.
- Don's Plasma Spheres, Jacobs Ladders, and Other Things Page - Jacobs Ladders.

- Back to Home and Mirror Site Locations Table of Contents.

-- end V1.75 --

Silicon Sam's Technology Resource

Expanded Table of Contents (ToC): HTML, Photos, Diagrams, and Schematics

For contact info, please see the Sci.Electronics.Repair FAQ Email Links Page.

Introduction

This Expanded Table of Contents (ToC) provides links to all of the files of Silicon Sam's Technology Resource (SSTR). These pages may be used in place of the normal Main ToC, to identify those graphics files which are part of any given FAQ, or simply as a means of just looking at the pretty pictures. :-)

Note: There are *zillions* of additional diagrams and schematics included within the HTML files themselves. Those that are listed here are only the ones that are in .pdf, .gif, .jpg, or other graphics or compressed format.

Silicon Sam's Technology Resource

Including:

Electronics (and more) Repair Guides and Laser and Other Information

Welcome to Samuel M. Goldwasser's latest and most fabulous "Notes on the Troubleshooting and Repair of..." series of comprehensive repair guides for consumer electronic equipment and other household devices. Detailed diagnostic and repair procedures are provided for: small electrical appliances, audio equipment, TVs, VCRs, CD players, computer monitors, microwave ovens, even lawn mowers - and much much more! There are also articles on the testing of various types of electronic components without fancy test equipment, 100 complete repair briefs including diagnostic procedures - not just solutions, repair related stories, pinouts for common chips and hybrids, and the list goes on and on.

Basic information includes essential safety guidelines when working on high voltage and/or AC line powered devices as well as a complete document on getting started in electronics troubleshooting. Some of its topics are: diagnostic tips and rules-of-thumb; recommended tools, supplies, and parts inventory, test and ancillary equipment; schematics for some easy to build incredibly handy widgets(tm); soldering and desoldering; sources of information in print and on-line; parts sources; and how to perfect diagnostic and repair skills.

In addition, there is a great deal of other information on a variety of areas of technology.

Sam's Laser FAQ has a great deal of information on a variety of laser and optics related topics including a comprehensive treatment of diode, helium-neon, argon/krypton ion, and CO2 lasers as well as amateur laser construction including numerous examples of truly home-built lasers. Much of this is not available anywhere else either on-line or in print!

Also included are documents on video conversion, use of fixed frequency monitors on PCs, international power, fluorescent and discahrge lamps, many new schematics, salvaging useful parts, links to over 1,000 technology related sites - and much much more.

This resource was developed specifically for the Do-It-Yourselfer, electronics experimenter, hobbyist, technician, engineer, and possibly even including the dentist and poet! To the best of my knowledge, it represents by far the largest most in depth collection of on-line information of its type - anywhere.

Silicon Sam's Technology Resource Sites

The links below take you directly to the documents at this site:

- SSTR Main ToC - Comprehensive Repair Guides, FAQs, Testing Info, Assorted Schematics, etc.
- Sam's Laser FAQ - A Practical Guide to Lasers for Experimenters and Hobbyists.

The documents at Sam's Home (RepairFAQ.org) will normally be the latest and greatest. However, the large FAQs of the "Notes on the Troubleshooting and Repair of..." series located at the various Sci.Electronics.Repair FAQ sites under the "S.E.R FAQ Main Table of Contents" pages may be more nicely formatted with complete tables of contents, cross-linking, and feedback forms for comments as well as complements, corrections, or complaints. The most popular of these are also available in convenienct small segments or as a single file. There is also a lot of additional information and links beyond what I have written.

- Sci.Electronics.Repair FAQ Home Main Table of Contents - Everything nicely formatted plus much information from other sources.

For all of these documents, please check the Home and Mirror Site Locations page to identify the best site for your needs.

Please Read at Least Once

A word about the philosophy of this site: These pages are declared to be a fluff-free zone! There will be no unnecessary, superfluous, or useless graphics of any kind - including but not limited to: dancing, gyrating, or other animated icons, colored textured backgrounds that are impossible to read through, or forced downloading of bit intense pictures that may be of no interest to you. Nor, will I ever expect you to use a particular brand of Web browser to be able to effectively access these pages. There are and never will be any advertisements, cookies, or other impositions on your time and space. In the time that it may take wading through a single monstrosity of the professional Web page designers at other sites, you will be able to find out what you want to know, when you want to know it! What a concept. :-) (Note, however, that your browser needs to be configured properly to make sense of ASCII diagrams, schematics, and tables. See the document: Suggested Browser Settings for font and other related information.)

In return for this gold mine of information, please make a serious effort to find the answers to your questions before contacting me. It may take just a wee bit of effort and could stress a few neurons in the process, but there is an excellent chance that what you seek is covered at these sites. Should you be really stuck, I will respond to email in a timely manner. However, if your question indicates that you haven't even gotten past the Main Menu, AND I am in a good mood, you will get a somewhat polite reply to read the #$%& FAQs. On the other hand, if it is a bad day, and you are really really lucky, you will probably be ignored. In any case, I expect to be able to hit the reply key for my mail program and not get bounced email. I will not attempt to unjumble any anti-SPAM email addresses! I have posted over 20,000 articles to the USENET newsgroups using my true email address. (And, you won't pick up SPAM via private email anyhow.) Yes, SPAM is a pain but I tolerate the small amount I get so others will not be inconvenienced.

Note: I NEVER send email attachments. If you receive a message supposedly from one of my addresses with any sort of attachment, it is bogus and possibly a virus. Someone's address book includes my address and their computer is infected. Send me the complete headers and I'll attempt to check it out, or just delete it.

Where you have a model specific repair question, it will probably be more expedient to post a complete but concise description of your problem including manufacturer, model, symptoms, and what you have already tried, directly to the USENET newsgroup: sci.electronics.repair. I really don't have access to that much model specific service information - and that is probably what I will tell you to do anyway! See the document: Troubleshooting and Repair of Consumer Electronic Equipment for more information. Or, consult a **Tech-Tips** database to see if your specific problem has already been solved a million times. See the document: On-Line Tech-Tips Databases.

Troubleshooting and Repair Notes Introduction

Version 1.23

For contact info, please see the Sci.Electronics.Repair FAQ Email Links Page.

Table of Contents

- Back to Introduction Table of Contents.

Introduction to the Introduction

The most up-to-date public versions of these articles which constitute a major portion of the Sci Electronics Repair FAQ currently reside at the:

- RepairFAQ.org Home Site

Keep this in mind if you are reading this elsewhere as your versions may not be the latest. Major new releases come out every few months but minor corrections or additions may appear at any time.

- Back to Introduction Table of Contents.

Purpose of the "Notes"

The "Notes on the Troubleshooting and Repair of..." series was developed to provide a resource for the hobbiest, tinkerer, engineer, weekend mechanic, housewife, dentist, and poet. For you, I am doing this because I would like to help provide information that is not always readily available. The sincere appreciation I receive via personal email is generally enough of a reward to retain my interest.

The purpose of these articles is not only to help you repair your CD or VCR but more importantly, to educate. Therefore, they are not quite 'FAQs' but rather complete maintenance and repair guides. What this means is that you cannot depend on every problem to show up in the index. For example, if you have a problem with say, a breadmaker, but there is no entry for it in the guide for small appliance repair, think of what is inside such a device: power supply, controller, motor, heating element, etc. Then, find the sections on something similar. It is difficult enough to provide coverage for every type of device ever marketed in this sector of the galaxy let alone the more remote parts of the universe :-).

If all you want is a quick fix, the various 'Tech Tips' databases may be better alternatives. They will likely list the most common problems and solutions for your equipment. However, these seem to deal mostly with TVs, VCRs, monitors, and microwave ovens. For anything else, you are largely on your own. A quick fix may be possible but you will not learn much that can be applied to other problems in the future. In addition, you may end up replacing many parts that are actually good since you will have done little or no testing.

With the Notes, a quick fix may still be possible but you will have to do some leg work (or at lest finger and mouse work) on your own. How much you will benefit will be a direct consequence of how much effort you put in - but there should be a significant amplification or multiplication factor. Wherever possible, explanations of the equipment operating principles and likely causes of failures are provided. You will gain at least some understanding of 'what makes it tick' and be able to carry over general troubleshooting approaches from one brand to another and even one type of device to another.

I realize that not everyone will have the capability - or desire - to actually apply the information in these Notes towards a repair. However, awareness of the likely causes and remedies for a particular problem goes a long way toward being able to make an informed decision with respect to repair or replacement options. If you do take the unit to a service center or repair shop, this knowledge will enable you to deal with the sales droid or technician from a position of strength.

For those of you who are professional technicians in business for profit, much of the information contained in the Notes is no doubt familiar. However, if you are routinely referring to these documents, I expect that you consider them beneficial in some way. This probably means some combination of savings in terms of time and money - which translates to increased profits. I would hope you feel some minimal obligation to show your appreciation in some concrete way. I am not sure what form this should take but you must realize that maintaining this continuously evolving and expanding site is a very non-trivial and time consuming task for both Filip and myself. These Notes and other articles do not grow on trees or spontaneously sprout from the bowels of the Web server at this site!

- Back to Introduction Table of Contents.

Why do I do this?

I am an electrical engineer by profession. I have spent significant time in both academia and industry teaching and designing in the areas of the architecture and implementation of digital systems. The development of one particular special purpose high performance image and graphics processor with three of my students led to the creation of a business plan. I have done the startup thing, been taken over by a big company, spent some time there, and become bored with corporate life.

I also have always had a passion for fixing mechanical and electronic devices. As a kid, household appliances represented the beginning of my fascination with technology. It wasn't long before the workings of the TV were of more interest to me than the mostly stupid shows. Naturally, I had to see what was inside nearly everything. Mechanical clocks seemed to suffer the most at first but fairly soon I figured out that getting things back together again was generally not that much more difficult than disassembling them in the first place. This insatiable curiosity and unending search for challenges continues to this day.

For several years the obsession with repair kept me out of trouble. I was an independent engineering consultant but spent much of my time helping others on the Internet newsgroups, writing these guides and other articles, providing free repairs for those who cannot afford professional service, going to garage and tag sales in search of interesting technology to repair or restore, and bicycling when weather and time permited. For a while, this was more fun and much more rewarding than a real job. But, phases of my life tend to run in six (6) year cycles (counting from when I discovered USENET newsgroups in 1994)....

---

* Back to Introduction Table of Contents.

What I'm doing now

Since the last revision of this introduction, I've been spending an increasing percentage of my time developing Sam's Laser FAQ which is by far the largest collection of practical laser and optics information for experimenters and hobbyists in the entire Universe. I still maintain the repair FAQs including the "Notes" but my main emphasis is on lasers and I rarely get to do much fun repair anymore - only when something breaks and I have no choice!

I have also joined the faculty of Drexel University (Philadelphia, PA) as a Research Professor at the Center for Microwave and Lightwave Engineering in the Electrical and Computer Engineering Department. So, now I can do real laser work in a university setting. Should you care, the research involves high performance mode-locked and chirped solid state microchip lasers for millimeter wave communications, lidar/radar, and biomedical imaging.

I still do engineering consulting if the job seems like it will be fun and rewarding and I still spend a great deal of time developing Sam's Laser FAQ. The auction site, eBay, has largely replaced garage and tag sales but mostly for (usually junk) laser equipment and parts. I already have way too many CD players and VCRs in various states of health, rapidly decaying into obsolescence. :(

Since I am not into repair on a daily basis, if you have specific comsumer electronics questions that aren't addressed in the FAQs, please ask them directly on the usenet newsgroup: sci.electronics.repair. This will save us both a lot of time and aggravation since I don't have many service manuals and schematics and will probably just direct you to newsgroup.

Thanks.

--- sam

Introduction

Getting Into Troubleshooting

This document attempts to provide an entry to the world of consumer electronics troubleshooting and repair. It also covers test equipment selection, tools and supplies, parts, home made troubleshooting aide - Incredibly Handy Widgets(tm) - and safety.

Mostly, you will learn by doing. However, you do need to prepare.

There are many schools dedicated to electronics repair. Some of these are quite good. Many are not. This document, however, is written from the perspective of the motivated do-it-yourselfer, hobbiest, and tinkerer.

The Repair FAQs usually list suggested references for each area. Your local public or university library will probably have some of these or other repair oriented electronics books.

Above all read and understand the document: Safety Guidelines for High Voltage and/or Line Powered Equipment. Your life may depend on it. That fabulous large screen won't be of much use to you if you are dead.

Collect broken electronics and appliances from your friends, relatives, the dump, garage sales and flea markets, etc. Start on those that have been written off - you will screw up at first. We all did. As times passes, your batting average will improve. It may not happen overnight but it will happen if you apply yourself. There will be many relatively easy successes but the 'tough dogs' may make up for these triumphs. Don't let them get to you - not everything can be repaired. Sometimes, the basic design is flawed or someone before you messed up royally. Troubleshooting is like being a detective but at least the device is generally not out to deceive you.

Experience will be your most useful companion.

If you go into the profession, you will obtain or have access to a variety of tech tips databases. These are an excellent investment where the saying: 'time-is-money' rules. However, to learn, you need to develop a general troubleshooting approach - a logical, methodical, method of narrowing down the problem. A tech tip database might suggest: 'Replace C536' for a particular symptom. This is good advice for a specific problem on one model. However, what you really want to understand is why C536 was the cause and how to pinpoint the culprit in general even if you don't have a service manual or schematic and your tech tip database doesn't have an entry for your sick TV or VCR.

While schematics are nice, you won't always have them or be able to justify the purchase for a one-of repair. Therefore, in many cases, some reverse engineering will be necessary. The time will be well spent since even if you don't see another instance of the same model in your entire lifetime, you will have learned something in the process that can be applied to other equipment problems.

As always, when you get stuck, the sci.electronics.repair newsgroup will still exist!

Happy repairing!

Comments on How to Learn Repair

(From: Nicholas Bodley (nbodley@tiac.net).)

Here's how I see it:

By all means, do what you can to understand basic principles first. Your success will be much more likely when you understand how a device works. If you can, read Electronics Now and Popular Electronics, as well as Nuts and Volts (http://www.nutsvolts.com). Also have a look at the Radio Amateur's Handbook.

These periodicals are not carefully edited, unfortunately, and now and then things get into print that are simply wrong or misleading, but they are still useful; I learned quite a bit from their predecessors (Radio Craft and Radio News!).

I can't speak firsthand, but it might be a very good idea to become (eventually) a Certified Electronic Technician. Look up the I.S.C.E.T.

Hearsay and folklore sometimes indicate that you should replace a given part when certain symptoms occur, and in the case of frequent failures of such parts, this information might even be true. But that's no way to become a competent technician.

My personal take is that you have to know when to 'let go' of an hypothesis about what the cause of the trouble is. A tech. who persists beyond a certain point in his belief that such-and-such is causing the problem is stuck and spinning his wheels. (I'm sexist; I think women are far less likely to get stuck this way! I think it's a male trait. :)

Troubleshooting is a special field of knowledge and has its own special outlook on things. The device did work, after all.

Production testing and troubleshooting is different; you are likely to be the first person to apply power to a device, and the device has never worked before. If the assemblers aren't giving you excellent quality, you can have some remarkably-bizarre symptoms with a poorly laid-out board from solder shorts, for instance.

A variable toroidal autotransformer (universally known by what used to be a General Radio trade-name, Variac) is priceless for troubleshooting circuits that handle any amount of power and which are powered by the AC line. (Not all devices function at all at, say, half of rated AC input; I work on a poorly-designed amplifier that draws many amps at something like 70 volts with no signal and no load. Unfortunately, Variacs and their equivalents are horribly expensive, at least from some sources! If you get a used one, see that the contact area of the winding is undamaged; you might need to remove a knob and some covers to see it. If the knob is stiff, try some contact/control cleaner/lube; it did wonders for mine!

Learn how to operate a 'scope, and learn why you see what you do. I suspect that some techs are not too well-informed about what goes on inside a 'scope; learn from reliable sources!

Learn to use a digital multimeter, and an analog one as well; the latter is easily damaged if you don't know what you're doing, but it's a great trend indicator.

Learn to use a function generator, and use the triangle output as well! Nothing like a triangle to show a wee bit of clipping or limiting in an amplifier...

Learn how to solder! Solder is not an adhesive; it's a metallurgical bond, according to some sources I trust. It just about has to be with gold, at least! If you *really* want to learn soldering, NASA has developed training courses that will make you a disgustingly good solderer.

(From: Phillip R. Cline (pcline@iquest.net).)

I used to repair consumer electronics from VERY high end stereos down to lowly boom boxes. When repairing stereos there is no substitute for good troubleshooting techniques which come from empirical means. Good knowledge of circuit functions helps a great deal. VCRs are almost always a mechanical problem (70% or more in my experience). Audio stuff can be destroyed by the user and often times the design is just plain crap. All low and mid-fi Japanese stuff made within the last ten years isn't worth a crap from a design standpoint. Even a lot of the high-end stuff is junk. They have 71 volt rated caps running at 69 volts etc.... US and most European stuff is way better designed! There are exceptions. I once saw a Philips amp that had a transformer for the power amp supply that wasn't centertapped yet the supply was bipolar. They just rectified and filtered the AC with series caps and the common was the point they were connected to each other. This is fine if you rate the caps at more voltage than the power supply can deliver but these were rated at just over half the total voltage of the supply from rail to rail. One cap shorted and the other one exploded and launched the can sideways across the component side of the amp PC board. This basically did a nice job of depopulating the board along the ballistic path of the cap's can. I laughed for a good while after seeing this.

I gave up repairing stuff when the customers asked, and rightly so, why it costs $80 to fix something that costs $100 new. The OEM parts cost on some stuff was intended to make the customer go buy a new unit instead of repairing the old one. This basically made most of the stuff disposable.

My background was and still is as an electronic hobbiest so the theory of operation was not a big deal and circuit function wasn't either. I have a brother that was the person from whom I learned a great deal of what I know now about electronics.

Soldering ability cannot be overstressed in importance especially with SMT being very common nowadays. As for the guys that seem to be ripping you off in their pricing, they could be gouging you but most often the overhead in the shop and their cost on parts is the most likely cause of high pricing. While labor might seem high a great deal of repair can be accomplished in an hour by a competent technician and some shops have a flat rate for a given repair. This can work to the benefit of the shop sometimes and to the customer sometimes. Our shop was this way. We had the lowest pricing in town(Indianapolis) and the customers still bitched. Sometimes they would take their units after we gave them the price for labor and a estimate of parts cost. We didn't charge for estimates. They would storm out only to come back with their tail between their legs in a few days after checking around for labor charges elsewhere. Depending on their attitude we might go ahead with the repair. Often times we would decline by telling the customer that the other shops may have done something while checking the unit out.(This depended on the shop that the customer took the unit to.) Some of these places had some real winners for techs!! We really didn't feel like undoing some yoyo's handiwork just to get the unit back to it's original nonworking state!

An EE in electronics is useless by itself and will cause a lot of undue troubleshooting to the beginning tech. They will overlook the obvious easy stuff for some possible but unlikely fault. A few years of repairs under their belt though and they can find the most difficult electronic problems with relative ease.

The best way to become proficient is with hands-on training under an experienced tech. A good overall background in electronics doesn't hurt either.

(From: Michael Black (blackm00@CAM.ORG).)

I think one of the problems of home repair is fear. If you're willing to spend the money to have something repaired, then you may think that if you fiddled with it you may make it worse. On the other hand, if you are about to throw something out because it doesn't work, you have nothing to lose by playing around with it and trying to fix it. Or find some stuff other people have thrown out, and start with that.

You may not fix it, but your willingness to open the cover allows you a familiarity that you won't get from a book. You de-mistify the equipment, and by actually adjusting things and seeing the results, you will learn.

I picked up a VCR for cheap at a garage sale this past summer. I was buying it as a tuner for use with a monitor. The guy said it "must be the power supply because it keeps turning off". Actually, it kept turning off because the mechanics weren't working properly. By moving the parts by hand, I saw how they were supposed to work. With the first hand experience, the S.E.R FAQ made more sense than if I'd just read it first, and so did a book on VCR repair that I took out of the library. I saw that the belts needed replacing because I'd figured out how things were supposed to work, and saw that they weren't working that way.

(From: Malcolm MacArthur (malcolmm@rustic-place.demon.co.uk).)

I have two years' of an Electronic Engineering degree behind me (I gave up on the degree and became a computer programmer. ;) It has been little, if any, help. What you really need is experience... which you'll only gain by fiddling with things. I've been doing repairs since about age 13. After twelve years, I now have a fair success rate, but those first few years were not easy. Best thing to do is get hold of old equipment and just have a go with it (Beware of CRTs, though ;). Be warned, you may break quite a lot of stuff initially! But as the others have said, most of the problems are due to mechanical failures (including dry solder joints).

Tall repair stories time:

- The IDE hard drive, given free, with two broken pins. Fixed with bits of bent paper clip soldered in place of the original connectors.
- The record player which wouldn't play at the right speed, and there wasn't enough adjustment in the pot.

Fix: cover belt spindle in Araldite, leave to harden, machine down with scalpel.

- The VCR which wouldn't play. Roughened up drive tire with sandpaper, did same to spindles, worked a treat. Still working fine after 3 years. :)
- Another VCR, rejected by a repair shop as uneconomical to repair, and given back to my friend's aunt. Took it apart. found nothing wrong, cleaned it, reassembled. Still working fine (I have no idea what the "fault" the shop found was).
- A computer monitor with incorrect colour balance. Fixed by adjusting the guns at the back WITHOUT an insulated screwdriver (Hairy!). I didn't have one, so used a normal screwdriver taped with insulating tape to a (dry) 1 ft. wooden spoon. Oh, because of poor design, the CRT kept threatening to impact with the mainboard when I had the back off, so I had to hold it at the front with my other hand. Visions of 25,000 V going straight through my chest made it all a bit scary. :)
- First ever repair (this is true!): taught my mother how to wire up a household (e.g. at power meter) fuse because I'd watched my Dad do it (he's good at this sort of thing as well. :) Age? Five.
- A TV with a broken tuner, had been to a repair shop twice, they'd given up on it. Received it for free, found out the composite video in worked fine, so ran 20 ft. of cable to a spare video downstairs (there was no aerial in my room, see). Must fix that tuner sometime...
- A CDROM drive which couldn't read near the edge of some discs. Disassembled whole unit, (eventually) reassembled it, found out that I was the spring which holds the CD down. Fixed by plugging into computer, running a cdrom and wiggling the spring with my finger until I felt the least vibration. Still works fine, although I am replacing it soon with a faster unit.
- The dropped TV with a crack at the corner of the mainboard. Repaired all the cracks by patching with wire, TV nearly blew up in my face (hence, beware of CRTs). Thank goodness for the fuses... this little incident put me off repairing TVs for over a year. It was eventually chucked, a failure.

As you can see above, most of these repairs are pretty simple and can be accomplished with mechanical know-how, more than anything else. Be prepared to experiment - but also be prepared for the fact that some of your experiments might fail! I guess I've just been lucky, but few of my repairs even involved using a multimeter.

Have fun.

THE Question: To Repair or Not to Repair

One of the themes, repeated more than once in emails to me and in reader feedback from Poptronix/Electronics Now was of the following general flavor:

> "Why bother with repair of VCRs (or anything else) when I can buy a new model for $79.95?"

Actually, I've seen prices as low as $39.95 for a promotion (but not requiring the purchase of anything else)!

or:

> "This stuff may have been useful 5 years ago but now some/much of the material doesn't apply to newer VCRs."

While both of these deal with VCRs, it should be understood that it applies equally well to much other consumer electronics.

Depending on your background and interests, these statements may have some validity. Thus, the need for some objective (if possible) way of making a decision as to whether to bother at all, and whether to attempt the repair yourself.

So, when does it make sense to attempt *any* repair yourself rather than to toss the item in the trash or take it to a professional? People do this sort of stuff for several reasons:

1. For the challenge and rewards associated with success.

2. To save money.

3. Because they like a particular set of features or the controls or the styling of the equipment and don't want anything new!

4. To avoid cluttering land-fills.

The first of these is likely most relevant to the readers of the S.E.R FAQs.

It's quite difficult to suggest an approach in deciding when something is worth repairing. You have to decide how much the equipment is worth to *you* in terms of monetary, sentimental, or other value; how much time you are willing to put into a repair; and whether the failure represents a good excuse to upgrade! To what extent each of the factors is significant will also be determined by how much you enjoy troubleshooting and tinkering. If you'd rather be doing something else or keep thinking about all the time you are spending on this rather than something you can charge for, perhaps you should be doing that something else.

However, it is easier to identify specific situations where equipment probably *isn't* worth attempting to repair on your own (or possibly at all):

1. Serious damage due to water (especially salt water), fire or smoke. Even if the obvious faults can be found and corrected, there are likely to be latent failures just waiting to strike in a few weeks or months.

2. Lightning strike. Lightning is like the 900 pound gorilla - it can go anywhere it wants. Even if you can repair the obvious damage and get the equipment working, there could be hidden problems waiting to appear at a later time due to components that aren't totally fried but just weakened.

3. Extremely high electrical power surge like a 13,000 V feeder line falling across the 115 V wiring to your house. Similar comments as lightning apply.

Where any of these are covered by insurance, that is the best option where the settlement is at all reasonable. If the insurance company allows you to keep the damaged equipment, there is nothing to stop you from attempting repairs as a challenge - you may get lucky. But, it could also be a long drawn out and expensive frustration.

4. Serious physical damage, especially for equipment with mechanical parts like VCRs. It may be impossible to replace broken parts. Twisted metal can be straightened but there is a good chance there will still be erratic misbehavior.

5. Equipment where prior attempts at repair may have resulted in an undetermined number of new unidentified problems. At least when something breaks on its own, your only opposition is the device itself. But, if another person attempts a repair and they are a novice or just plain incompetent, the dumpster may be the best solution.

6. Equipment with known design or manufacturing problems. When we undertake a repair, one assumption that is usually made is that the equipment originally worked correctly and/or that the fault isn't something that was designed in before the name went on. :) For most things, this is a valid assumption. Even the famous RCA/GE/Proscan and Sony TV solder problems, while no doubt resulting in 100s of thousands of sets ending up in the trash, are repairable with modest effort at low cost. And, the result is a well performing reliable TV. However, some computer monitors may die when fed a particular scan rate or during boot when mated with a particular video card - a design flaw which may not have a (known) solution.

7. Newer throw-aways. I can pretty much guarantee that a $39.95 VCR isn't worth any effort unless the problem is obvious. This junk is built as cheaply as possible with a lot of plastic parts, no thought given to access for testing or repair, and with attention only to the short term bottom line. There has been no miraculous invention to reduce construction cost of the relatively complex VCR mechanism - it comes out of reliability.

8. Equipment like cell phones, pagers, and other modern wireless devices as well as cordless phones; PC mainboards, peripheral boards, and disk drives; TV set-top, cable boxes, satellite receivers, etc. It is essentially impossible to obtain service information on any of these so unless the problem is an obvious broken connector or broken trace on the printed circuit board, or possibly a dead power supply, forget it. You don't have the documentation, test equipment, rework equipment, or any chance of buying many of the repair parts in any case.

9. Any situation where safety would be compromised by your repair. For example, attempting to reconstruct a smashed microwave oven door or jerryrigging a flyback transformer that has serious arcing. Where items (1) to (3) are involved, one must very carefully inspect for any possible safety related damage (like charred insulation in hidden areas) that may not have affected operation.

10. If you really don't know what you are doing, leave it to a professional! Not only is it dangerous to be poking around inside many types of equipment if you don't even know what not to touch, there is a strong likelihood that such attempts will cause additional, possibly fatal damage to the circuitry. Even if the equipment can be repaired, the ultimate cost will end up be much greater than had you not done anything in the first place, both in terms of labor (troubleshooting and repair) and parts. If you can't justify a professional repair, just set it aside until you have gained more experience and can deal with the equipment safely (for you and it).

11. Finally, don't attempt to repair a piece of equipment for which you are not equipped in the tools or test equipment department. Attempting to remove a part from a multilayer printed circuit board without proper desoldering equipment will just make an unsalvageable mess. Guessing at a replacement part ("I heard that the flyback transformer is a likely cause for a dead monitor.") will just end up being frustrating and expensive (unless you've won the Lottery recently in which case maybe your luck is still holding).

In the good old days when life and electronics were simpler and you could count the total number of transistors in a TV on your hands and feet, service information was included with the equipment or was readily available either from the manufacturer or Sams Technical Publishing (formerly Howard Sams) as Sams' Photofacts (no relation to me). There are still Sams' Photofacts for many TVs at least, but for anything else, obtaining schematics may be impossible or even if they are available, the cost may be excessive. Paying $100 for a mediocre copy of a service manual for a computer monitor that can be replaced for $250 may not be justified.

One way to get an idea of your chances of success for popular brands and models is to search the archives of the USENET newsgroup sci.electronics.repair via Google Groups (formerly Deja.com/Dejanews. There are other public USENET archives but even though this archive keeps changing its name, I see little reason to use others which may come and go and provide less reliable coverage.) Where others have experienced - and repaired - similar problems, your chances of success are greatly increased. Then, if you have detailed symptoms, asking for suggestions on that newsgroup may also be beneficial, especially if you have already done some initial testing. If, on the other hand, the consensus from the newsgroup is that your problem is hopeless, then you may be able to save a lot of time and frustration by giving up immediately (or at least postponing your efforts until you have more experience.

What about older equipment?:

The basic technology of TVs and VCRs hasn't changed significantly in 10 or 15 years. Yes, there are convenience features like "auto clock set" which are supposed to make life easier but often don't (if the station transmitting the clock information has their clocks set wrong or uses a feed from a source in a different time zone!). But as far as picture and sound quality, that VCR from 10 years ago will be just as good or better than one purchased today. Any, it will almost certainly be better constructed and more maintainable.

For example, Panasonic VCRs from the mid to late '80s were solid machines that could be kept in shape with a bit of periodic maintenance (cleaning, rubber parts replacement) and repair of known problems (failed electrolytic capacitors in the power supply after 10 years or so). One could not expect that $39.95 special to provide such service. If it lasts through the warranty period, you're probably ahead of the game. I'd still take a middle age Panasonic over any new low to medium priced model. And, even the high-end VCRs may be based on flimsy chassis.

Case studies:

Here are 4 examples of equipment that I did eventually repair but where serious consideration should have been given to the dumpster. The following can be found described in more detail at in the document: Sam's Repair Briefs/

1. **GE TV dropped:** (From: Repair Brief #69: GE Portable Color TV - Dropped.)

This TV had taken a nose dive off of a 4 foot shelf onto an unknown surface. And, of course, someone had probably attempted to operate after this with possible additional damage. While the exterior didn't show any major abuse, it was obvious that there was severe trauma as soon as the back was removed. The main circuit board was broken near the (heavy) flyback transformer. Several dozen traces were severed including some to surface mount parts.

A repair shop would be unlikely to want to tackle this for several reasons: (1) the obvious repairs to circuit board traces would take a couple hours at least, (2) there could be unseen damage to the CRT in form of a distorted shadow mask and this wouldn't be known until the circuit board was fixed, and (3) any repair might not catch everything so future problems could develop.

As it turned out, the only damage was to the circuit board and after 2 or 3 hours of soldering - and then finding additional traces to solder - the set was fixed, and has continued to operate reliably for several years.

2. **GE TV with 'rivlets':** (From: Repair Brief #59: GE 13AC1504W Color TV - Dead (with Other Problems)).

   In the early 1980s, some brilliant manufacturing engineer working for GE decided that a good way to save money on circuit boards would be to use what were dubbed 'rivlets' instead of actual plated through holes to connect top and bottom. A rivlet is basically a rivet which, the theory goes, is then soldered to the copper traces. That's the theory. In practice, due to the thermal mass of the rivet, soldering was never reliable. And, as a result of thermal cycling, cracks developed between the rivet and traces over time. Problems ranged from a dead set to loss of color depending on which rivlet happened to be unhappy on any given day.

   Attempting to repair just the problem rivlets was impossible because as soon as you found a bad one and soldered it, another in its vicinity would decide to fail. The only approach that worked was to reheat every one that could be located using a soldering gun. Since there were many dozens of these on the circuit board, this took quite awhile and it was easy to miss some. In fact, the only truly reliable repair would be to remove the solder from each rivlet, snake a bare wire through it, and solder the wire directly to the traces top and bottom. This repair would also take a couple hours and likely be too expensive for a small TV, though if the same chassis were used on a 27 incher, might be worth it.

3. **CD player restoration:** (From: Repair Brief #10: Pioneer PD5100 CD Player Trashed).

   Here is a case of a piece of equipment being partially destroyed by previous repair attempts. The Pioneer PD5100 is a basic solid CD player but this one had broken parts in the loading mechanism and was in unknown operational condition. If it were taken to a repair shop, the response would probably be something along the lines of: "Well, that certainly looks like a CD player.". It simply wouldn't be worth the time and effort to repair what was obviously broken with the possibility of finding more serious electronic problems after that.

   I had nothing better to do (!!) so decided to attempt to restore it to something usable. After repairing the mechanical damage, there was indeed a servo problem which ultimate required the replacement of a motor driver chip - for which I got lucky. The player would read the disc directory but was unable to seek to any track, even #1. One of the chips was getting hot. So, I replaced it and after servo alignment, the play problems were cured. If that hadn't worked, there was probably little more I could have done. Very likely, the servo chip was the original problem and the previous repair attempt created the mechanical mess.

4. **Sony TV with bad butchered soldering:** (From: Repair Brief #81: Sony KV-19TR20 Color TV - No Reception).

   The final example is of a Sony TV that had the infamous tuner/IF box solder problems. This is normally a fairly easy repair, especially for this particular model where the IF box (which was faulty in this case) is readily accessible without taking the whole thing to bits. Once repaired, like the RCA/GE/Proscan TVs with similar solder problems, the result is a solid reliable TV. However, the friend of a friend who had attempted to replace it, apparently used a Weller soldering gun to do the fine soldering, leaving nearly every pad detached or missing. Fortunately, only the pads appeared to have suffered and after 20 minutes and several jumper wires, this one was healthy again.

Repairs for the novice:

It would be way too easy to poison your future outlook on servicing by attempting to repairs multiple times and failing or making things worse.

Equipment that is good to learn on because there will likely be immediate or at least ultimate gratification might include: small appliances, power tools, remote controls, and basic audio equipment like tape decks and low power amplifiers (not big power amps!). And, while electronic troubleshooting of CD players and VCRs is definitely for the advanced course, they often have problems that can be easily remedied by a proper cleaning and/or general maintenance. Electronic problems are tough to diagnose but most are mechanical. Microwave ovens are generally easy to repair but due to the very serious safety issues, I'd suggest holding off on these unless you are experienced in dealing with high voltage high power equipment.

With reasonable care, PC troubleshooting involving basic swapping of components, can also be rewarding. But, don't expect to repair a mainboard with a peculiar failure of IRQ2 (unless you find a lockwasher that ate through to some PCB traces!).

Intermediate level troubleshooting and repair would add TVs since service information in the form of Sams' Photofacts is available for the majority of popular models. Video (not computer) monitors are also straightforward to deal with. And perhaps, audio amplifiers and receivers.

For those just starting out, there are some types of equipment to avoid (beyond those mentioned above). One in particular is modern computer monitors. With their wide scan rate range, microprocessor control, need for decent test equipment, dangerous voltages, and the general difficulty in obtaining service information, even professionals will stay away from many of these - particularly no-name or non-major brand models. Except for obvious problems like bad solder connections, a blown fuse (replace ONCE only, might have been a power surge), or the need for degaussing, they may not be worth the frustration, certainly not as your first project. TVs are not only much simpler than computer monitors, but as noted, complete service information is usually available.

If You Decide That You Don't Want to Bother Repairing Something

So, you already have 10 VCRs and really don't want to even pop the case on yet another one.

Don't just toss it in the trash. See if a local charity like the Salvation Army or Goodwill accepts broken appliances and electronics. They may have someone on staff who can perform at least simple repairs and then resell the item. Not only will this reduce clutter in the land fill, you may benefit on your taxes (and in the good deeds department). However, it really isn't proper to do this if you have already worked on the item and given up or reduced it to a pile of slag!

Smoking Around Electronic Equipment

Note: This is my token editorial but the effects on both people and equipment are very real.

If you still doubt the harmful effects of the chemical compounds in tobacco smoke on your health and that of others around you, whatever I say below probably won't matter and you may want to skip it since it may upset you. However, perhaps, you worry more about your fancy, costly, finely tuned electronic entertainment and computer equipment. In that case, read on.

The several hundred chemical compounds found in tobacco smoke have the following effects on electronic equipment. What isn't trapped in your lungs or in the lungs of those around you:

- coats the precision optics of CD and DVD players, CDROM and DVDROM drives, and other optical disc/k equipment AND the media they use.
- coats the read/write heads of floppy disk drives, Zip drives, tape drives, AND the media they use.
- coats the tape path of VCRs and audio decks including the audio, video, and control heads AND the cassettes and tape inside.
- coats mechanical parts and promotes the loss of lubrication in all equipment.
- may contribute to deterioration of plastic and rubber parts.
- coats the screens of TVs and monitors, display windows of VCRs and other devices, and the outside and inside of everything eventually resulting in ugly brown discoloration and a horrible stench.

This list of effects goes on and on.

The resulting film WILL eventually cause problems and is very difficult to remove. Damage done due to chemical action may require the replacement of costly parts. Increased maintenance will be needed or the equipment may simply fail before its time and not be worth fixing. Contamination will often find its way into critical places that are not accessible and to media which is irreplaceable.

When someone trys to get me to look at something that has been in a smoker's residence (I know because it will reek of stale tobacco smoke essence), my first inclination is to put it in a sealed bag to go out with the garbage. (I have been known to drop portable TVs directly into the nearest trash can under these circumstances.) If this isn't an option, my next objective is to get it evaluated and repaired or refused as quickly as possible. However, my concentration may not be at its peak for such equipment! It is a good thing that I don't need to do this for a living - I would have to refuse service to a good portion of the world's population :-(.

So, now you have a few more reasons to give up the stupid, disgusting, filthy, obnoxious, inconsiderate of others, costly, dangerous, killer habit!

Sorry, end of editorial. :-)

General Safety Considerations

Depending on the type of equipment you will be working on, there can be a variety of dangers - some potentially lethal:

- Electrical shock hazard from TV, computer and other video monitors, microwave ovens, the switchmode power supplies in some VCRs and computer peripherals, electronic flash units, some parts of audio equipment, hand and stationary power tools, large appliances, and even many small line powered appliances.

- Mechanical hazards from the moving parts of various appliances, computer peripherals, hand and stationary power tools, and especially gasoline powered yard equipment.

- Risk of CRT implosion from equipment using large CRTs.

- Vision hazards from the lasers in CD players and CDROM drives, DVD players and DVDROM drives, other optical data storage devices, and laser disc players.

It is imperative that you understand and follow ALL safety recommendations while working inside whatever equipment.

See the document: Safety Guidelines for High Voltage and/or Line Powered Equipment for general safety information.

See the SAFETY sections of the documents dealing with your equipment for additional safety information for your equipment.

- Back to Troubleshooting Table of Contents.

Basic Troubleshooting

Some of My Rules of Troubleshooting

1. Safety first - know the hazards associated with the equipment you are troubleshooting. Take all safety precautions. Expect the unexpected. Take your time.

2. Always think 'what if'. This applies both to the analytic procedures as well as to precautions with respect to probing the equipment. When probing, insulate all but the last 1/8" of the probe tip to prevent costly shorts. (If I had a nickel for every time I have been screwed not following this advice...)

3. Learn from your mistakes. We all make mistakes - some of them can be quite costly. A simple problem can turn into an expensive one due to a slip of the probe or being over eager to try something before thinking it through. While stating that your experience in these endeavors is measured by the number of scars you have may be stretching the point, expect to screwup - we all can point to that disaster due to inexperience or carelessness. Just make it a point not to make the same mistake again.

4. Don't start with the electronic test equipment, start with some analytical thinking. Many problems associated with consumer electronic equipment do not require a schematic (though one may be useful). The majority of problems with VCRs, CD players, tape decks, and answering machines, are mechanical and can be dealt with using nothing more than a good set of precision hand tools; some alcohol, degreaser, contact cleaner, light oil and grease; and your powers of observation (and a little experience). Your built in senses and that stuff between your ears represents the most important test equipment you have.

5. If you get stuck, sleep on it. Sometimes, just letting the problem bounce around in your head will lead to a different more successful approach or solution. Don't work when you are really tired - it is both dangerous and mostly non-productive (or possibly destructive).

6. Many problems have simple solutions. Don't immediately assume that your problem is some combination of esoteric complex convoluted failures. For a TV, it may just be a bad connection or failed diode. For a VCR, it may just be a bad belt or idler tire - or an experiment in rock placement by your 3-year old. For a CD player, a dirty lens or need for lubrication. Try to remember that the problems with the most catastrophic impact on operation - a dead TV or a VCR that eats tapes - usually have the simplest solutions. The kind of problems we would like to avoid at all costs are the ones that are intermittent or difficult to reproduce: subtle color noise, the occasional interference, or the dreaded horizontal output transistor blowing out every 3 months syndrome.

7. Whenever possible, try to substitute a working unit. With modular systems like component stereos and computers, narrowing down a problem to a single unit should be the first priority. This is usually safe to do in such cases and will quickly identify which unit needs work. This same principle applies at the electronic or mechanical parts level. Note that there is the possibility of damaging the known good part by putting it into a non-working device or vice versa. This risk is most likely with the power circuitry in amplifiers, TVs and monitors, power supplies, etc. With appropriate precautions (like the series light bulb) the risk can be minimized.

8. Don't blindly trust your instruments. If your get readings that don't make sense, you may be using your equipment in a way which is confusing it. DMMs are not good at checking semiconductors in-circuit or the power transistor you are testing may have a built in damper diode and/or base resistor. Your scope may be picking up interference which is swamping the low level signal you are searching for (TVs and Monitors, or low level circuits in VCRs and CD players). Your frequency counter may be double triggering due to noise or imperfect signal shape.

9. Realize that coincidences do happen but are relatively rare. Usually, there is a common cause. For

example, if a TV has no vertical deflection and no picture, it is much more likely that a common power supply output has failed than for parts in both the deflection and video subsystems to be bad. In other words, first look for a common root cause rather than trying to locate bad parts in separate circuits.

Exceptions include lightning, power surge, dropped, water, or previous repair person damaged equipment. However, multiple electrolytic capacitors in older equipment may be degrading resulting in failures of unrelated circuits. Determine if all the problems you are troubleshooting have just appeared - see below. It is very common to be given a device to repair which has now died totally but prior to this had some behavior which you consider marginal but that was not noticed by the owner.

10. Confirm the problem before diving into the repair. It is amazing how many complaints turn out to be impossible to reproduce or are simple cockpit error. It also makes sense to identify exactly what is and is not working so that you will know whether some fault that just appeared was actually a preexisting problem or was caused by your poking. Try to get as much information as possible about the problem from the owner. If you are the owner, try to reconstruct the exact sequence of events that led to the failure. For example, did the TV just not work when turned on or were there some preliminary symptoms like a jittery or squished picture prior to total failure? Did the problem come and go before finally staying bad for good?

11. Get used to the idea of working without a schematic. While service info for TVs is nearly always available in the form of Sams' Photofacts, this is hardly ever true of other types of equipment. Sams VCRfacts exist for less than 10 percent of VCR models and only the older ones include anything beyond (obvious) mechanical information. While a service manual may be available from the manufacturer of your equipment or another Sams-like source, it may not include the information you really need. Furthermore, there may be no way to justify the cost for a one time repair. With a basic understanding of how the equipment works, many problems can be dealt with without a schematic. Not every one but quite a few.

12. Whenever working on precision equipment, make copious notes and diagrams. You will be eternally grateful when the time comes to reassemble the unit. Most connectors are keyed against incorrect insertion or interchange of cables, but not always. Apparently identical screws may be of differing lengths or have slightly different thread types. Little parts may fit in more than one place or orientation. Etc. Etc.

13. Pill bottles, film canisters, and plastic ice cube trays come in handy for sorting and storing screws and other small parts after disassembly. This is particularly true if you have repairs on multiple pieces of equipment under way simultaneously.

14. Select a work area which is wide open, well lighted, and where dropped parts can be located - not on a deep pile shag rug. The best location will also be relatively dust free and allow you to suspend your troubleshooting to eat or sleep or think without having to pile everything into a cardboard box for storage.

15. Understand the risk of ESD - Electro-Static Discharge. Some components (like ICs) in solid state electronic devices are vulnerable to ESD. There is no need to go overboard but taking reasonable precautions such as getting into the habit of touching a **safe** ground point first.

WARNING: even with an isolation transformer, a live chassis should **not** be considered a safe ground point. This applies mostly to TVs, computer and video monitors, some AC operated strobe lights, and other line connected devices. You shouldn't be touching components with the device powered and plugged in (at least, not until you really know what you are doing!). Once unplugged, sheet metal shields or other ground points should be safe and effective.

Some Quick Tips or Rules of Thumb

- Problems that are erratic or intermittent - that come and go suddenly - are almost always due to bad connections - cold solder joints or internal or external connectors that need to be cleaned and reseated. It is amazing what a large percentage of common problems fall into the category.

  Pay particular attention to areas of the circuit board where there are large and/or high power components, connectors, or evidence of discoloration or actual charring due to excessive heat. Your eyeballs, a bright light, and magnifier will be the most useful test equipment for this purpose!

- Problems that change gradually - usually they decrease or disappear - as the equipment warms up are often due to dried up electrolytic capacitors.

  While capacitors will occasionally leak making diagnosis easy, in most cases, there are no obvious signs of failure. (Note: Don't be misled into thinking that the adhesive often used to anchor large capacitors and other components to the circuit board is leakage.) The most useful testing device for electrolytic capacitors is an ESR meter. However, heating suspect caps with a hair dryer may get the equipment going for the purposes of making a diagnosis. See the document: Capacitor Testing, Safe Discharging and Other Related Information.

- Problems that result in a totally dead unit or affect multiple functions are generally power supply related. These are usually easy to fix.

  Common failure items are the large hybrid power regulator ICs used in many VCRs and TVs, diodes and transistors, and remarkably - high value resistors that open up.

- Catastrophic failures often result in burnt, scorched, cracked, exploded, or melted components, or similar catastrophic consequences. However, some components run hot by design and slight discoloration on the circuit board in their vicinity, while not desirable, may be normal.

  Use your senses of sight and smell for the preliminary search for such evidence.

- Listen for signs of arcing or corona - snapping or sizzling sounds. A component on the brink of failing due to overheating may provide similar audible clues.

  Some discharge sounds are normal for a TV or monitor when powered on or off and occasional sounds of thermal expansion are nothing to worry about. The flyback, yoke, or other (usually) magnetic component may also emit a buzz or while constantly or intermittently without any other symptoms or implication of impending doom. However, repeated loud snaps or a sizzling sounds accompanied by the smell of ozone should be dealt with immediately since they can lead to more serious and expensive consequences.

- Most VCR problems are mechanical in nature. Worn or deteriorated rubber parts, gummed up lubrication, or abuse (bad tapes or toy or penut butter and jelly sandwich storage.).

  For any problem but a totally dead VCR, a check should be made for dirty or worn mechanical parts before even thinking about electronic problems or trying to locate a schematic - especially if the unit hasn't been cleaned in a few years.

- Many CD player problems are mechanical - dirty lens, worn or oily drawer belts, dirt/gummed up grease on sled tracks/gears, bad/partially shorted spindle or sled motor. Power problems with portables seem to be common as well. No matter what the symptoms, always make it a habit to clean the lens first - many peculiar failure modes are simply due to a dirty lens. Actual laser failure is relatively uncommon despite what the typical service shop may claim. CD players are also remarkably robust. Optical alignment should never be needed under normal conditions of operation.

- TV and monitor problems are very often power supply or deflection related. These tend to have obvious causes - blown posistor, rectifier diodes, filter capacitor, HOT, or chopper. Flyback with shorted windings or shorts between windings or in the voltage multiplier (if used) or screen/focus divider network are also common. Where the HOT or chopper is involved, operation should be observed after the repair as components in the vicinity may cause the new parts to fail. HOTs should generally not run hot. If they do, check for weak drive, excess B+, etc.

- Microwave oven problems are almost always power related. Faulty components in the microwave generator - magnetron, HV diode, HV capacitor, HV transformer - are relatively easy to identify. Sometimes, components on the primary side can cause baffling symptoms like the misaligned interlock switches that blow fuses or the weak triac that causes the oven to blow the main fuse only when the cycle *ends*. Control problems may be due to a spill in the touchpad, dried up electrolytic capacitors in the low voltage power supply, or failure confused state due to a power surge.

- Ink-jet printers are extremely reliable electrically. Look for simple problems such as caked ink in the 'service station' area, misaligned print-head contacts, or a nearly empty cartridge when erratic printing problems develop.

- Laser printers tend to develop problems in the fuser, scanner, or power control modules. These are often simple like a burned out lamp, bad motor, or bad connections.

- Turntables or record changer problems are very likely to be due to gummed up grease.

- Problems with audio tape decks like VCRs are mostly mechanical. Similar solutions apply. Where one channel is out, suspect a broken wire at the tape head before a bad chip.

- Telephone line connected equipment like modems and phones are susceptible to phone like surges. Where a device seems to respond to user commands but does not dial or pickup, suspect a blown part near the phone line connector.

- Sam's Magic Spit(tm). This approach - using a moistened finger to probe LOW VOLTAGE CIRCUITS has come to the rescue many times. Touching various parts of a circuit from the solder side of the board in an attempt to evoke some sort of response can work wonders. Once an suspect area has been identified, use a metal probe or nail to narrow it down to a specific pin.

The reason this works is that the reduced resistance of your moist skin and your body capacitance will change the signal shape and/or introduce some slight signal of its own.

- Logic circuits - marginal timing or signal levels will result in a dramatic change in behavior with a slight 'body' load. It has been possible to locate a race condition or glitchy signal on a 305 pin PGA chip using this approach in less time than it would have taken to roll the logic analyzer over to the system under test. Signals which have proper levels and timing are gnerally remarkably immune to this sort of torture.

- Analog circuits - behavior can again be altered. In the case of audio amps, probing with a finger is just as effective as the use of a signal injector - which is what you are doing - and the equipment is always handy. By evoking hum, buzz, clicks, and pops, locating the live or dead parts of a circuit is rapid and effective.

- Unknown circuits - where no schematics are available, it may be possible to get the device to do something or locate an area that is sensitive to probing. The function of a section of circuitry can often be identified by observing the effects of touching the components in that area.

  For example, I was able to quickly identify the trigger transistor of in a wireless door bell by using my finger to locate the point that caused the chimes to sound. This quickly confirmed that the problem was in the RF front end or decoder and not the audio circuitry.

- Bad bypass capacitors - touching the power/signal side of a good bypass cap should result in little or no effect. However, a cap with high ESR and/or reduced uF will not be doing its job bypassing the pickup from your finger to ground - there will be a dramatic effect in audio or video systems.

Don't get carried away - too much moisture may have unforeseen consequences.

Depending on the condition of your skin, a tingle may be felt even on low voltage circuits under the right conditions. However, this is pretty safe for most battery operated devices, TTL/CMOS logic, audio equipment (not high power amps), CD players, VCRs (not switching power supply), etc.

WARNING: Make sure you do this only with LOW VOLTAGE circuitry. You can easily fry yourself if you attempt to troubleshoot your TV, computer monitor, photoflash, or microwave oven in this manner!

On-Line Tech-Tips Databases

A number of organizations have compiled databases covering thousands of common problems with VCRs, TVs, computer monitors, and other electronic equipment. Most charge for their information but a few, accessible via the Internet, are either free or have a very minimal monthly or per-case fee. In other cases, a limited but still useful subset of the for-fee database is freely available.

A tech-tips database is a collection of problems and solutions accumulated by the organization providing the information or other sources based on actual repair experiences and case histories. Since the identical failures often occur at some point in a large percentage of a given model or product line, checking out a tech-tips database may quickly identify your problem and solution.

In that case, you can greatly simplify your troubleshooting or at least confirm a diagnosis before ordering parts. My only reservation with respect to tech-tips databases in general - this has nothing to do with any one in particular - is that symptoms can sometimes be deceiving and a solution that works in one instance may not apply to your specific problem. Therefore, an understanding of the hows and whys of the equipment along with some good old fashioned testing is highly desirable to minimize the risk of replacing parts that turn out not to be bad.

The other disadvantage - at least from one point of view - is that you do not learn much by just following a procedure developed by others. There is no explanation of how the original diagnosis was determined or what may have caused the failure in the first place. Nor is there likely to be any list of other components that may have been affected by overstress and may fail in the future. Replacing Q701 and C725 may get your equipment going again but this will not help you to repair a different model in the future.

One alternative to tech-tips databases is to search via Google Groups (formerly Deja.com/Dejanews) for postings with keywords matching your model and problem and the newsgroup sci.electronics.repair. See the section: Searching for Information from USENET Newsgroups.

Please see the document: On-Line Tech-Tips Databases for the most up to date compilation of these resources for TVs, VCRs, computer monitors, and other consumer electronic equipment.

Getting Inside Consumer Electronic Equipment

Note: the documents on specific equipment has additional 'getting inside' info as well.

Yes, you will void the warranty, but you knew this already.

Hint: The crowbar and 12 pound hammer are *laset* resorts! Really :-).

Manufacturers seem to take great pride in being very mysterious as to how to open their equipment. Not always, but this is too common to just be a coincidence. Opening the equipment non-destructively may be the most difficult and challenging part of many repairs!

A variety of techniques are used to secure the covers on consumer electronic equipment:

1. Screws. Yes, many still use this somewhat antiquated technique. Sometimes, there are even embossed arrows on the case indicating which screws need to be removed to get at the guts. In addition to obvious screw holes, there may be some that are only accessible when a battery or cassette compartment is opened or a trim panel is popped off.

   These will often be of the Philips variety. (Strictly speaking, many of these are not actual Philips head screws but a slight variation. Nonetheless, a Philips screwdriver of suitable size will work on them.) A precision jeweler's screwdriver set including miniature Philips head drivers is a must for repair of miniature portable devices.

Sometimes, you will find Torx or a variety of security type fasteners. Suitable driver bits are available. Sometimes, you can improvise using regular tools. In the case of security Torx, the center post can usually be broken off with a pair of needlenose pliers allowing a normal Torx driver to be used. In a pinch, a suitable size hex wrench can substitute for a Torx driver. Places like MCM Electronics carry a variety of security bits.

2. Hidden screws. These will require prying up a plug or peeling off a decorative decal. It will be obvious that you were tinkering - it is virtually impossible to put a decal back in an undetectable way. Sometimes the rubber feet can be pryed out revealing screw holes. For a stick-on label, rubbing your finger over it may permit you to locate a hidden screw hole. Just puncture the label to access the screw as this may be less messy then attempting to peel it off.

3. Snaps. Look around the seam between the two halves. You may (if you are lucky) see points at which gently (or forcibly) pressing with a screwdriver will unlock the covers. Sometimes, just going around the seam with a butter knife will pop the cover at one location which will then reveal the locations of the other snaps.

4. Glue. Or more likely, the plastic is fused together. This is particularly common with AC adapters (wall warts). In this case, I usually carefully go around the seam with a hacksaw blade taking extreme care not to go through and damage internal components. Reassemble with plastic electrical tape.

5. It isn't designed for repair. Don't laugh. I feel we will see more and more of this in our disposable society. Some devices are totally potted in Epoxy and are throwaways. With others, the only way to open them non-destructively is from the inside.

Don't force anything unless you are sure there is no alternative - most of the time, once you determine the method of fastening, covers will come apart easily If they get hung up, there may be an undetected screw or snap still in place.

The most annoying (to be polite) situation is when after removing the 18 screws holding the case together (losing 3 of them entirely and mangling the heads on 2 others), removing three subassemblies, and two other circuit boards, you find that the adjustment you wanted was accessible through a hole in the case just by partially peeling back a rubber hand grip! Been there, done that. :(

And on the still lighter side, from an IBM maintenance manual, circa 1925 (displayed in the Chicago Museum of Science & Industry):

> "All parts should go together without forcing. You must remember that all the parts you are reassembling were disassembled by you. Therefore, if you can't get them together again, there must be a reason. By all means, do not use a hammer."

When reassembling the equipment make sure to route cables and other wiring such that they will not get pinched or snagged and possibly broken or have their insulation nicked or pierced and that they will not get caught in moving parts. Replace any cable ties that were cut or removed during disassembly and add additional ones of your own if needed. Some electrical tape may sometimes come in handy to provide insulation insurance as well.

For those hard-to-open LCD panels:

(From: Onat Ahmet (onat@turbine.kuee.kyoto-u.ac.jp))

The LCD display housings are usually secured by plastic catches built into the case. They still may have a couple of screws that are positioned in the most innovative places! Obvious places are sides of the display, and under stickers (rub your finger over a sticker and see if you can feel the hole for a screw). Also, try to look around the hinge connecting the LCD to the main housing. Look with the LCD closed, and also open; rotating open the housing might hide some screws from view. Expect it to be awkward! BTW, do not forget small hatches, that do not look like one!

After that, it is patience, and knowing the right place to twist the case to pop it open. Try not to use screwdrivers; they leave unsightly marks along the seam.

Also, if it is your own unit, and you break a few of the catches along the way, do not worry; you can put the housing back together with a few spots of adhesive.

How to Build Obsolescence In Before the Name Goes On

The following would belong more in the humor department if it weren't for the fact that much of it is true by accident or design with modern appliances and electronics! However, memorizing this list will go a long way toward helping to understand by the piece of !@#$ is such a pain to repair! I don't believe we are divulging any secrets here - the manufacturers already have this list in their "Corporate Operations Manual". :)

These are in no particular order.

(Portions from various people including Alan Liefting (aliefting@ihug.co.nz), Heath Young (heathryoung@hotmail.com), Craig Osborn (eelcr@worldnet.att.net), Phil Allison (bilup@bigpond.com), Franc Zabkar (franczabkar@dingoblue.net.au), and Sam.)

1. Place metal shields around the power supplies without holes for air circulation. This will ensure power supply capacitors will dry out and make the power supply fail prematurely. And make sure not to use high temperature capacitors. Keeping the electros hot makes the ESR lower so cheaper ones will do.

2. Push as many capacitors as possible into the sides of heatsinks, power transistors, regulators, and power resistors - anything hot!

3. Do not bother with putting thermal conducting paste between heat sink and transistor. It only oozes and dries out anyhow.

4. Do not bother to solder the heavy components or joints subject to thermal cycling. Touch up selected connections by hand? You have to be joking.

5. The following components can be left out during manufacture: protection zener diodes, VDR's, spark gaps, decoupling capacitors, ferrite beads etc. If it works most of the time without them, the expense can't be justified.

6. Keep all factory tests as short as possible. If there isn't a dirt cheap solution to any problems found, don't test for them.

7. Buy the cheapest components from manufacturers who cannot guarantee the longevity of their product. It is easy to have a CRT fail within three years by using impure materials. This will make the cathodes oxide and reduce the emissions giving a dull, hard to read picture. The customer won't realize their TV or monitor has deteriorated but will see newer models with bright vibrant colors and just have to buy one.

8. Fit the so-called head cleaning device to VCR's. This will ensure numerous service calls increasing the customer frustration which will lead them to buy a new product. There is one born every minute.

9. Dispense with EMI/RFI components in the power supplies. As well as producing unacceptable interference, this will also mean that the power supply is more prone to damage from voltage spikes. These problems are by definition the responsibility of the customer anyhow so the result will only be a positive effect on the bottom line.

10. Use the softer plastics rather than the more wear resistant phenolic for kettles and toasters. This will guarantee the consumer will purchase a new product to replace the shabby appliance.

11. Make the covers of heat generating appliances out of painted instead of chrome-plated sheet metal. The paint will darken unevenly with use resulting in an old looking appliance in need or replacement.

12. Do not use spot welding on your heating elements. Spot welding makes a reliable connection. Crimped connections will fail within a short period. This is good (for the manufacturer) since spare parts are not available. The consumer will have to buy a new product and have been conditioned to not expect appliances to be repairable. People like to buy new things anyhow.

13. Install an Appliance Leakage Circuit Interrupter (ALCI) on the cord of the appliance. This is a one time use GFCI (or what I call a GFCK - Ground Fault Circuit Killer). When constructed with suitably cheap parts, it, rather than the appliance will fail but the customer will be informed that they must have gotten the appliance wet.

14. Use the cheaper carbon film resistors instead of the more reliable metal film resistor with better voltage ratings. What the customers can't see won't bother them.

15. Fasten heavy (or just random) parts to the PCB with that white/beige glue that decays after awhile to brown and conductive causing all sorts of nasty problems.

16. Use a design style which will rapidly look dated. This is another ploy in order to have the consumer purchase the latest style regardless of whether the item is working or not. People are slaves to fashion - and they love slaves.

17. Reduce the number of service agencies and the number of products the service agencies will repair for you. This will increase the sale of new products by frustrating the consumers efforts in order to have their item repaired.

18. Fit fast blow fuses inside sealed double insulated appliances that will fail from metal fatigue. (Why did they do this??? - it was sealed with heatshrink onto one of the wires?!)

19. Manufacture equipment as a collection of modules - example. Optics train in certain models of projectors - instead of replacing just a hot mirror ($15 or so) you have to replace the lot! (All optics and LCD screen etc as a module) Now, try getting the poor serviceman to explain why the projector that cost the customer $5,000 costs $3,000 to fix.

20. Encourage consumers to purchase the cheapest items so when someone does make a good product, no one will buy it, and the company will go out of business.

21. Make your spare parts very expensive or do not bother with having spare parts available.

22. When the prototype has been built and working correctly, start removing components until it fails to work properly. Then manufacture it with the minimum parts required to make it work. In mid production run, change selected over designed components to their border line equivalents.

23. If a government regulating agency forces a major recall due to a severe fire hazard, close the current brand name, and start a new brand with a redesigned outside shell that emulates an ergonomic look but with the same internals as before. Add words like "New, Improved, Upgraded, and Leading Edge" to the new marketing slogan.

24. Don't make service manuals or circuit diagrams available. If you do, ensure that only your service agents get one, or price them so highly that the job becomes uneconomical. Think of it this way: Instead of buying the equipment which was the usual way of doing business in the past, the purchase price is now actually only a rental fee for the duration of the warranty. After that, the manufacturer may let the smoke out at any time without notice and thus there is no reason to support repairs. :)

25. Don't identify yourself as the manufacturer. Hide behind your OEM resellers who of course will have no facilities to repair anything except by total replacement.

26. Scrape the numbers off your IC's, or have them stamped with obscure in-house part numbers. You don't want to make repairs too easy for the end user or for a third party repairer who would otherwise be able to source these $1 garden variety parts from any electronics store.

27. Don't stock parts that could reasonably be expected to fail or wear out like battery contacts, flex PCBs, remote control keypads, curly cords. If you must supply them, then do so as part of a complete, uneconomically priced assembly.

28. Use flimsy non-standard (and hence unavailable) connectors for attaching expensive proprietary AC adaptors, chargers, and accessories.

29. Use expensive sealed units which cannot be opened for service without being damaged, and which are powered by an inexpensive internal battery.

30. Have a single solid wire between circuit boards and anything that moves, e.g. sockets at the back of VCRs, or almost any part of a remote control, especially the battery connection. This means that the

soldered connection will give up.

31. Have flimsy hinged flaps on a remote control that break after a short time.

32. On a remote control, have rows and rows of identical buttons that have functions that are almost never needed. Also omit functions that would be very handy.

33. Make sure the coax to the tuner of the VCR or TV has no proper mechanical anchorage to the chassis so it takes little more than the house cat to trip on the cable and yank the active innards from the tuner.

34. Make sure all large metal components (particularly the audio in/out sockets at the rear of amplifiers) are only soldered to the same degree as the flimsy IC pins - just soldered sufficiently to pass the production final test.

35. Don't use fiber reinforced plastic gears if you can use plain plastic types.

36. Never use keys to lock shafts to plastic pulleys.

37. Always use etched copper film thin ribbon board interconnects wherever there is maximum flexing such as in laptop screen hinges.

38. Never make rubber drive belts accessible by just removal of the back plate.

39. Use as many non-standard components as possible.

40. Don't use 2 boards if you can mount components on both sides of one board.

41. Always use the smallest possible wattage for a resistor: if the dissipation is 2 watts, then use a 2 watt resistor.

42. Take advantage of exciting new legislation in creative ways to make it illegal for others to make compatible user-replacable parts. No more third party batteries, inkjet cartridges, etc.

43. Add useless complexity to accessories like batteries and inkjet cartridges to make it more difficult for third parties to manufacture replacements. Include warnings about the risks of using third party accessories.

44. Shorten product introduction cycles so that by the time the end-user requires a repair to the item, it's already obsolete.

45. Set the cost of the repair to greatly exceed the cost of a new model of the same type of equipment, which, you just happen (surprise surprise) to have in stock and for sale.

- Back to Troubleshooting Table of Contents.

Tools, Test Equipment, and Other Stuff

Hand Tools

Invest in good tools. If you are into garage sales, you can often pick up excellent well maintained tools very inexpensively but be selective - there is a lot of junk out there. In the end, substandard tools will slow you down and prove extremely frustrating to use. Keep your tools healthy - learn to use a wetstone or grinding wheel where appropriate (screwdrivers, drill bits, etc.) and put a light film of oil (e.g., WD40) on steel tools to prevent rust.

Some basic hand tools.

- Screwdrivers of all types and sizes including straight, Philips, Torx. Security bits for some video games, PS2s, etc. Notched straight blade for VCR mechanical tracking adjustment - make or buy.

- Jewelers screwdrivers - both straight and philips. These are generally inexpensive but quality is also quite variable.

- Small socket driver set.

- Hex key wrenches or hex drivers. Miniature metric sizes for VCRs.

- Pliers - long nose, round nose, curved. Both smooth and serrated types are useful.

- Adjustable wrench (small).

- Cutters - diagonal and flush. Linesman's pliers.

- Wire strippers - fixed and adjustable. Crimp tool.

- Alignment tools - (at least a standard RCA type for coils).

- Files - small set of assorted types including flat, round, square, and triangular.

- Dental picks - maybe a reason to go to the dentist? :-) These are useful for poking and prodding in restricted areas (but you knew that).

- Locking clamps - hemostats - for securing small parts while soldering etc.

- Magnetic pickup tool - you can never tell when you will drop something deep inside a VCR. If you keep a strong magnet stuck to your workbench, you can use it to magnetize most steel tools such as screwdrivers. Just keep anything magnetized away from the tape path and magnetic heads.

- Hand drill, electric drill, drill press - one or all. A small benchtop drill press (e.g., 8") is invaluable for many tasks. A good set of high speed bits (not the 1000 bits for $9.95 variety). Also, miniature bits for

PCB and small plastic repairs.

- Soldering and desoldering equipment. An entire chapter is devoted to this topic with the name, you guessed it: "Soldering and Desoldering Equipment and Techniques".

Emergency Screw Removal

While a good quality selection of straight, Philips, Torx, and hex-head drivers should handle most screws found in consumer electronic equipment, a couple of other types do turn up and can really be a pain in the you-know-where to remove intact. See the section: About Those Other Funny-Headed Screws.

It may be possible to remove such screws even if nothing in your driver assortment quite fits (short of buying the proper tool, that is - what a concept!). There is also the situation (very common) where someone (we won't say who) has pre-mangled the screw head! Here are a few approaches to try when you are stuck at 2:00 AM on a Sunday morning with an uncooperative screw:

1. Select a driver type (usually Philips) and size that privides the best grip. Then apply as much pressure as is safely possible without destroying anything and attempt to turn the screw. What you want to avoid is slippage - once the blade slips, the head will be quickly destroyed and then you are left with options (2) or (3), below. For a jeweler's type screwdriver, clamping something larger to its shaft can provide valuable additional leverage.

2. Use a hand grinder (e.g., Dremel tool) or thin file to create a slot in the screw head which one of your straight-blade screwdrivers will fit. Obviously, take care to avoid damage to adjacent parts and dam off the area to prevent grinding chips from getting over everything.

3. Grab the center and edge of the screw with a pair of sharp diagonal cutters and turn it. This, of course, also damages the screw head and if you are too forceful, will break your cutters as well.

4. Drill out the screw using a bit just large enough to sever the head from the shank of the screw. Then, use a pair of needlenose pliers to unscrew what remains. For large screws, drill only part way and then use a screw extractor like Easy-Out(tm).

5. Superglue the screwdriver or some other suitable tool to what's left of the screw. Wait till it hardens and turn.

6. There are also products available for the purpose of improving the grip of screwdrivers. For example: ScrewGrab.

7. For screws into plastic holding metal covers, remove all other screws so the cover can be used to pull on the screw and heat the screw with a soldering iron. With care, it will melt its way out but the plastic will solidify to a smaller hole that can be used to install a new screw. Where the cover is also plastic, it may melt first so probably not a good idea.

Note: some of these screws have had some material like Lock-Tight(tm) (which looks like colored nail polish) applied to the top to prevent the screw from loosening on its own. This also prevents the blade of a screwdriver from properly seating, so removal is essential before attempting removal.

Plastic Screw Thread Repair

Where a screw no longer tightens into a threaded plastic hole, here are a few suggestions:

1. Install a larger screw in original worn hole. :) For repairs where the appearance isn't important, this may be the best solution.

2. Use a soldering iron from the hidden side to "adjust" the hole. Doing this with the screw in place will result in proper threads being preformed.

3. Fill the hole with a mixture of the same type of powdered plastic and solvent or other similar material. When dry, drill a pilot hole and then install the original screw.

4. Glue a metal nut to the underside of plastic and use a machine screw.

There are many other possibilities.

To avoid this problem in the future, realize that plastic is very soft and it is essential to gently start the screw into the hole to get a feel for it properly mating with the existing threads. The use of an undersized screwdriver to get the screw started may be helpful in that it won't accidentally apply too much torque and strip the threads. Something that is less obvious is that screws for plastic are often made with a wide thread and a narrow thread wound that alternate, sort of like a deformed hunk of DNA. :) With these, there is only one proper way for them to mate with an existing hole and forcing them is asking for stripped threads and a fine strand of plastic being pulled out along with the loose screw.

About Those Other Funny-Headed Screws

(From: Tony Duell (ard@p850ug1.demon.co.uk).)

As well as Phillips, there are Pozidriv and JIS:

> Pozidriv screws can be recognized by the 'starburst' - the little lines on the head between the main slots. These are very common (certainly in Europe) in all sorts of equipment.

- There are also JIS (Japanese Industry Standard) heads. These _look_ just like Philips, but the screwdriver is a little flatter on the end. Not surprisingly these do turn up in Japanese stuff.

A Philips screwdriver won't even appear to fit a Pozidriv head. It will appear to fit a JIS head, but it will also damage it if it's at all tight. JIS screwdrivers are not easy to get, either. I think I have a small set made by Acu-Min (?).

It's not uncommon for all 3 to be used in the same equipment, especially if subassemblies were made by different companies.

(From: Robert McPherson (rm502@bellsouth.net).)

There is a type of screwdriver called a "Reed & Prince" which fits these screws which are similar in appearance to Phillips screws. Cooper tools makes them.

Workbench and AC Power

Perhaps this isn't as immediately essential as a pair of wire strippers but for any serious electronics - be it construction or repair - some dedicated place to do it is essential. It doesn't need to be a $2,000 professionally designed "work unit". Any large sturdy flat surface will suffice as long as it doesn't need to be cleared off for meals. :)

A size of 3 x 6 feet should be adequate, longer is better if you have the space. Workbench height is typically 36 inches. Make sure the legs are sturdy and rigid - some equipment can be quite heavy. Get yourself a comfortable stool to sit on for those marathon troubleshooting sessions.

The surface can be laminate, particle board, plywood, butcher block, or some other insulator. It shouldn't have a dramatic pattern though since small parts will be hard to find. Wood products should have multiple coats of varnish or polyurethane. Using a cheap material that can be replaced will enable the surface to be rejuvenated after it gets pitted and burnt - as it invariably will after awhile. An antistatic surface is desirable but probably expensive to put on the entire workbench so just get an antistatic matt for use when needed. (An antistatic surface isn't quite a perfect insulator but has just enough conductivity to minimize the buildup of static electricity, essential for any work with devices like CMOS ICs and laser diodes that can be destroyed by even a small static discharge.)

Install a shelf or shelves along the back that are about half the depth of the workbench surface to hold smaller pieces of test equipment, power supplies, parts cabinets, and other odds and ends. Add a shelf or shelves underneath for storage.

Install AC outlets along the rear edge, vertically so debris can't fall into the holes. How many? The more the merrier - they will all get filled no matter how many are there! At a minimum, one every 6 inches or a duplex every foot, double this won't hurt. Power the workbench from two branch circuits fed from opposite sides of the 115-0-115 VAC (in the U.S.A.) Consider including at least one 230 VAC outlet (in the U.S.A.). Providing some outlets that are switched with power indicator lamps and protected by fuses or circuit breakers. Most outlets, particularly those used to plug in equipment being worked on, should be GFCI (Ground Fault Circuit Interrupter) protected for safety. But a few - clearly marked "NOT GFCI PROTECTED" - should be available for equipment that will not function reliably on a GFCI with the understanding that these lack such protection. Most test equipment and power supplies with properly wired grounded power cords do not need to be GFCI protected but won't complain if they are. However, some equipment may nuisance trip (immediately or at random) GFCIs even if functioning properly.

The total cost can be well under $100 for all of this even if the materials and parts are purchased new. With some reasonable scrounging abilities, it can be a lot less.

Basic Test Equipment

Obviously, you can load up on exotic test equipment. What follows are those that are most used. You might at first not consider all of these to fit the category of test equipment but an old TV can provide as much or more useful information about a video signal than a fancy waveform analyzer in many cases. And, basic reliable easy-to-use test equipment is more important than sophisticated instrumentation laden with features you will never need.

- DMM and/or VOM. I prefer to have both. A good old Simpson 260 is better in many ways than a cheap digital multimeter. For most measurements, I still use a 25 year old Lafayette (remember them?) VOM. I only go for the DMM when I need to measure really low ohms or where better accuracy is needed (though this can be deceptive - just because a DMM has 3-1/2 digits does not mean it is that accurate - check you manual, it may prove enlightening). The Simpson 260 also has a nice 5000 V AC/DC scale which the others lack.

  A fancy expensive multimeter is not needed, at least not while you are just starting out (and likely to make some occasional mistakes like attempting to measure line voltage on the ohms scale.) However, if someone offers to give you a nice Fluke DMM, don't turn it down :-).

  Scales for transistor, capacitor, frequency counter, etc. are not really essential. A diode test function on a DMM is needed, however, to properly bias semiconductor junctions. Even this is not useful for in-circuit tests or for some power transistors or transistors with built in damper diodes and/or base resistors.

  Make sure you have a good well insulated set of test probes. This is for your own safety as you may be measuring relatively high voltages. Periodically inspect for damage and repair or replace as needed. If the ones that came with your multimeter are substandard - flimsy connectors or very thin insulation, replace them as well.

  A high impedance high voltage probe is sometimes useful for TVs and monitors. You can build one of these which will suffice for most consumer electronics work.

- AC clamp-on ammeter. This permits the measurement of currents in appliances or electrical wiring without having to cut any wires. At most, you will need an easily constructed adapter to permit access to a single conductor of a line cord. This may be an option for your multimeter.

- Oscilloscope - dual trace, 10 to 20 MHz minimum vertical bandwidth, delayed sweep desirable but not essential. A good set of proper 10x/1x probes. High vertical bandwidth is desirable but most consumer electronics work can be done with a 10 MHz scope. If you get into digital debugging, that is another story - 100 MHz and up will be required. If money is no object, get a good digital storage scope. You can even get relatively inexpensive scope cards for PCs, but unless you are into PC controlled instrumentation, a stand-alone scope is much more useful.

  I would recommend a good used Tektronix (Tek) or Hewlett Packard (HP) scope over a new scope of almost any other brand. You will usually get more scope for your money and these things last almost forever. Until recently, my 'good' scope was the militarized version (AN/USM-281A) of the HP180 lab scope. It has a dual channel 50 MHz vertical plugin and a delayed sweep horizontal plugin. I have seen these going for under $300 from surplus outfits. For a little more money, you can get a Tek 465 or 465B (slightly newer but mostly similar specifications) 100 Mhz scope ($200 to 600) which is what I use now. The HP-180 is still fine but I couldn't pass up a really good deal. :) The Tek 465/B or other similar model will suffice for all but the most demanding (read: RF or high speed digital) repairs. (See the additional comments below on the Tek 465 as well.) From my experience with this scope many years ago and now as well, I really do agree with some who say that this is the best scope Tektronix ever designed.

Auctions like eBay can sometimes be a source of good used Tek and other scopes at reasonable prices though sometimes the bid price goes way beyond what is reasonable. :) A search for "oscilloscope" will typically turn up several hundred hits. However, to have any confidence in the operational condition of a scope, the seller must be reputable and know something about testing them. A warranty may be of limited value since a major part of the cost of a used scope is likely to be the shipping and you'd end up having to pay that both ways. Check out Phil's Tek Scope Prices on eBay List as well as catalog pages of surplus test equipment dealers. A Web search (e.g., Google) will usually turn up enough sites for any specific model to provide both specifications and typical prices from surplus equipment dealers (which are usually high!).

My instant checklist for a used scope:

- Bright, sharp trace, no screen burns, short warmup time.
- Vertical amp(s) operational on all ranges.
- Horizontal timebase(s) operational on all ranges.
- Stable triggering at low and high end of frequency range.
- Switches and controls reasonably noise-free (may need cleaning though).
- Decent cosmetic condition, all knobs and buttons present, no signs of major trauma.

You don't absolutely need an oscilloscope when you are just starting out in electronics but it would help a great deal. It need not be a fancy one at first especially if you are not sure if electronics is for you. However, being able to see what is going on can make all the difference in your early understanding of much of what is being discussed in the textbooks and the newsgroups. You can probably find something used that will get you through a couple of years for less than $100. An oldie but goodie is much better than nothing at all even if it isn't dual channel or high bandwidth!

And a note about digital versus analog scopes: Analog scopes are what we used to think of as an oscilloscope: The CRT *is* the place where the waveform is generated. Digital scopes use a fast A/D converter to capture data in memory in the form of 1s and 0s and then display this on a raster-scan CRT (like a computer monitor screen). Digital scopes are automatically storage scopes and are great for analyzing waveforms. However, most older digital scopes are really poor at real time display and in addition, appear to have been designed by computer programmers, not test equipment engineers. Ever try to play a menu-driven piano? :) For general electronics and troubleshooting, I'd rather have a 20 year old Tek analog scope than a 5 year old digital scope costing 25 times as much. The inherent real-time presentation of an analog scope can be invaluable when attempting to observe the subtle characteristics of a waveform. Those who go through school never having touched a true analog scope have missed out on a great experience.

- Logic probe - for quick checks of digital circuitry for activity. A logic pulsar can be used to force a momentary 1 or 0. Some people swear by these. I consider them of marginal value at best.

- TV set (color is desirable) and/or video monitor for testing of video equipment like VCRs, camcorders, laserdisc players, etc. I have an old CGA monitor which includes an NTSC input as well.

A great deal of information can be gathered more quickly by examining the picture on a TV or monitor than can be learned from the video waveform on displayed on a scope.

- VCR or other video signal source for testing of video monitors and TVs. These will have both RF (F connector) and baseband (RCA jacks) outputs.

- Stereo tuner or other audio signal source for testing of audio equipment.

- Audio signal generator. A function generator (sine, square, triangle) is nice as well. The usual audio generator will output from a few Hz to about 1 MHz.

- Audio amp connected to a loudspeaker. The input should be selectable between line level and mic level and be brought out through a shielded cable to a test probe and ground clip. This is useful for tracing an audio circuit to determine where a signal is getting lost.

- Signal injector. A readily accessible portable source of a test tone or other signal (depending on application) that can be introduced into the intermediate or early stages of a multistage electronic system.

  For audio, a simple transistor or 555 timer based battery powered oscillator can be built into a hand held probe. Similar (but generally more specialized) devices can be constructed for RF or video testing.

- RF signal generator. For serious debugging of radio and tuner front-ends. These can get quite sophisticated (and expensive) with various modulation/sweep functions. For most work, such extravagance is unnecessary.

- LCR meter - a capacitor tester is desirable but I prefer to substitute a known good capacitor rather than trusting a meter which will not test under the same conditions as exist in-circuit.

- Adjustable power supplies. At least one of these should bo of the totally indestructable variety - one you can accidentally short out without fear of damage. Mine is a simple 1 amp 0-40 V transformer and rectifier/filter cap affair with a little Variac for adjustment.

- The following book has a number of simple test equipment projects you can build with readily available parts:

Jerry's Comments on Used Scopes and the Tek 465

(From: Jerry Greenberg (jerryg50@hotmail.com).)

If you are buying a used 465, look for the 465B. It is a better unit, and is the same price most of the time. Take care that this scope is about 20 years old, and there is no support from Tek on it. The replacement parts are not available if something blows. I used to have a few of them. One needed a CRT, and the other I sold while it was still working. For consumer electronics, you will get by with a 100 MHz unit, but it is preferable to have over 200 MHz bandwidth if you want to do front end service on consumer FM radio receivers. Read up on Nyquist and you will see the answer.

If you also call Tektronix technical services, tell them that you are looking for a used Tek scope to be used for hobby purposes. They will be very helpful in giving you any information you require. They will even recommend models and what to look for. If you talk to their sales people, they will sometimes even give you their authorized dealers who handle used Tek equipment so that you can shop around.

If you go a bit more for your used scope you can get a 200 or 300 MHz unit that is a newer version of an analog scope. It will have improvements over the 465 series. Look at the 2000 analog series scopes. These have a lot of enhancements like on the screen display. This will be very handy for precise work. When buying any type of scope, I would stress that the Tektronix is the best. If you find a good working used one, you will have a very high quality product, and it should give you years of service. Most of the analog scope that they made include the TV sync options.

Even if you buy a used one, and the parts are not available, it pays then to buy a second used one and you will have spare parts. These scopes used to cost in the many thousands of dollars when new, and you are probably paying between eight hundred to fifteen hundred for a used one (somewhat cheaper now, even from surplus companies. --- Sam). These scopes will be far superior to even the newer ones from the consumer level scopes. In 1978 I believe my company paid over $8,000 for the 465B scope new. A new Chevy fully loaded was less!

Repairing Tectronix 400 Series Scopes

As noted above, the Tektronix 465 and 465B 100 MHz scopes are among Tek's best ever made, and very desirable and affordable for troubleshooting and general electronics work. The Tek 485 is a nice 350 MHz scope. There are many other 400 Series Tek scopes, almost any of which would make a fine service scope. However, they are showing their age dating from the '70s to the early '80s and many are appearing with power supply problems at even more affordable prices. :(While Tek custom parts are no longer available for these scopes (and you couldn't afford them anyhow!), many power supply problems which often result in a totally dead scope (but may also just cause specific sections like the timebase to be non-functional), can be repaired with readily available parts at little cost.

The most likely causes are shorted tantalum "dipped" capacitors dragging down one or more power supply rails. Apparently, Tek used a batch of unreliable caps on the some of the 400 Series scopes and while aluminum electrolytics usually just dry out with decreased capacitance and increased ESR, these dipped tantalums go short circuit. Fortunately, the design of the switching power supplies in these scopes is such that the controller shuts down from a serious overload or short rather than letting its smoke out. If the overload is on only one voltage rail and not severe (e.g., through a resistor), only that voltage may be low or absent resulting in loss of functionality but not a totally dead scope.

So, the first step is (WITH POWER OFF) to check the resistance of each voltage test point to ground with a multimeter. While the expected resistances may not be known except from a service manual (if that), anything very low (e.g., 10 ohms) is suspect. Here are typical values measured on a Tek 485 using a Fluke 87 DMM with the black lead on ground: +50 V, 2.1K ohms; +15 V, 89 ohms; +5 V, 70 ohms; -5 V, 222 ohms; -15 V, 152 ohms. The resistance for +5 V changes significantly depending on front panel settings and which incandescent indicator lamps should be lit and may go below 35 ohms. On this scope, the -15 V rail originally measured about 10 ohms due to a bad cap. Where one of these is found, attempt to determine the location of the short to a specific circuit board. Then, trace the wiring on that board to locate the possible bad caps. A good DMM or milliohmmeter can help to track down the cap since PCB foil resistance is high enough to be measured and the resistance to ground will be lowest at the location at the bad cap. At this point, unsoldering one lead of each cap and checking its resistance is the safest approach. With care, this can be done from the component side of the board which is fortunate since removing some of these large PCBs can be a royal pain. Heat the lead with a soldering iron and pull it free. Then, use a vacuum desoldering tool ("SoldaPullet") to clear the hole. Check the resistance of the cap and/or across the supply rail to determine if you found the correct one. The bad cap mentioned above was found in about 5 minutes in this manner. There are typically only a few of these caps on each board but it's possible for the bad one to be on a board that isn't easily accessible.

Where this approach doesn't work or for the lazy but daring among us, the alternative is to apply voltage from an external adjustable current limited supply to the bad power rail. If the bad part isn't a perfect short circuit, it will dissipate heat and let its smoke out or explode. Wear safety glasses! If this doesn't happen, it may actually be possible to power up the scope with the external voltage applied to determine functionality. In either case, I won't be responsible for any destroyed equipment should this be done.

So You Can't Afford a $20,000 Transient Event Recorder?

You know the situation - an intermittent that happens once an hour for 1/2 second! In industry, you would use a fancy logic analyzer with associated digital scope to capture the event.

However, there may be no need for such extravagance. If you have an oscilloscope and camcorder or video camera/VCR, you probably have all that is needed.

For a TV or monitor, point the camera at the CRT and the scope screen so that they are both in the picture and record on a 6 hour tape. Then, when your event takes place, you have a permanent record!

That old video camera will be perfectly adequate. It doesn't need a 100X digitally stabilized enhanced reprocessed zoom or 1/10,000th second shutter. It doesn't even need to be color!

Sure, this won't capture the 1 ns glitch. But, for the occasional flash in the picture, it is more than adequate to eliminate a video signal line as the source of the problem.

Extensions to more convoluted problems are left as an exercise for the student!

Transformers - Isolation and Variable

Isolation transformers are *essential* to safely work on many types of equipment with exposed AC line connections or live chassis. Variable transformers provide a convenient way to control the input voltage to equipment to determine whether a fault still exists or to evaluate performance at low or high line voltage.

Isolation Transformers

An isolation transformer is very important for safely when working on live chassis equipment. Make it a habit to use an isolation transformer whenever possible. Portions of TVs, monitors, switchmode power supplies, and many other types of equipment are generally fed from a direct connection to the AC line without a power transformer (which would provide the isolation function). The DC power rails will typically be between 150 and 300 V with momentary current availability of multiple amps!

Since Earth Ground and the Neutral of the power line are connected together at your service panel (fuse or circuit breaker box), grounds like cold water pipes, test equipment chassis, and even a damp concrete floor make suitable returns for the line voltage (Hot or live wire). Since this is just as true with the conductor being being a wire or your body, such a situation is very dangerous.

An isolation transformer as its name implies provides a barrier such that accidental contact with an earth ground results in negligible current flow (only due to the parasitic capacitance and inductance of the transformer) - a slight tingle at worst. This also protects your test equipment as well as the device you are troubleshooting since a similar accidental contact can result in a short circuit, sparks, smoke, and many destroyed parts.

The schematic for a typical isolation transformer is shown below:

```
                   _        1:1
    H o-----/ ----- _------+    +-----------o 115 V
           Power  Fuse      )||(
           Switch           )|| +-----------o 105 V
                            )||(
                            )||(
                    Primary )||( Secondary
Tied together at            )||(
service panel               )||(
|                           )||(
|                           )||(
+-> N o----------+---------+ |  +---+--------o Return
|                |  4.7 M*   |      |
|                +---/\/\----|------+
|                            |
+-> G o----------------------+--------------o Ground
```

Note: Ground is included on the secondary side. This is actually needed for safety with certain types of equipment like microwave ovens where the HV return is to the chassis. Most other consumer electronic equipment and appliances will only have a 2 wire cord and thus not use the Ground. However, a potential safety hazard can arise if some other piece of equipment develops a ground fault resulting in a live, non-isolated part being user-accessible so this must be taken into consideration in deciding whether to ground the secondary side.

The resistor (*) is desirable to permit any static charge to leak off to ground. Since it is quite large - 2 M ohms - no perceptible current will flow between the secondary and primary sides but this value is low enough to dissipate any static charge. CAUTION: The resistor must be a high voltage rated type (as in 4,200 V isolation, large size light blue color to assure that arc over will not result due to voltage differences that may be present when the isolation transformer is being used in its normal manner.

Although the power line Neutral and Ground wires are tied together at the main service panel (fuse or circuit breaker box), the transformer prevents any significant current flow between any of its outputs and earth ground should a fault occur.

Even if you were standing with bare feet in a puddle of salt water on a concrete floor (noting that this is definitely NOT recommended) and were to touch something connected to the secondary of the isolation transformer or its return, or equipment circuitry attached to these, there is no direct return path for current to flow through you.

However, this shouldn't encourage a false sense of security. If you were to touch two points at different potentials on the secondary side, you could still be fried! And some equipment like microwave ovens use their chassis, and thus ground, as the high voltage return so an isolation transformer is of limited value for these whether it passes ground through or not.

Isolation transformers can be purchased or constructed from a pair of similar power transformers connected back-to-back. I built mine from a couple of old tube-type TV power transformers mounted on a board with an outlet box including a fuse. Their high voltage secondary windings were connected together. The unused low voltage secondary windings can be put in series with the primary or output windings to adjust voltage. See the section: Typical Homemade Isolation Transformer.

For super critical applications like in hospitals where every microamp of leakage counts, special isolation transformers are available (no doubt at equally super cost) which have shielding between the primary and secondary to minimize the inter-winding capacitance and inductance as well. This should not really be necessary for general servicing.

Note: Not all definitions of the term 'isolation transformer' are created equal! For some purposes, this may mean just preventing line born electrical noise from passing to the equipment. So, if you acquire something called an 'isolation transformer' on its nameplate, confirm that the primary and secondary are indeed not tied together by a low resistance. If they are, it can probably be modified for service needs by disconnecting a jumper but it may not have the insulation ratings desirable for high voltage isolation.

(From: Filip "I'll buy a vowel" Gieszczykiewicz (filipg@repairfaq.org).)

Ever wonder how those guys repair HV transformers running 200 kV without shutting off the power lines feeding the city? They use *very well isolated* cherry pickers! The guy on that platform is working on ONE wire which - since he's not connected to the ground - is at ZERO potential! That wire has no reference at all so no current flows. And he prays each morning that it stays that way or he goes off with a flash! [ugh!].

You're doing something like that on a much safer level. :)

Typical Homemade Isolation Transformer

The schematic for a homemade isolation transformer a pair of back-to-back power transformers from ancient tube-type TVs is shown below:

```
                                +-------------------------o 109 V
                                |
                                |     +-------------------o 121 V
                                |     |
                                | +---------------+
                                | |   |           |
                   || +--o NC   | |   +---+ ||    |

            | Transformer 1    2M*    Transformer 2 |
            +------------------/\/\-----------------+
```

Note that there should be a fuse in the primary to protect against faults in the transformer as well as the load. A slow blow type should be used in the primary circuit. The inrush current of the transformer will depend on the part of the cycle when the switch is closed (worst is actually near the zero crossing) as well as the secondary load. To protect the load, a fast blow type in the secondary is recommended. However, the inrush current of the degauss coils in TV sets and monitors, for example, will often pop a normal or fast blow fuse when no actual problems exist. (It is probably a good idea to disconnect the degauss coils while testing unless they are suspected of being the source of the problem.)

The 2 M resistor (*) is to bleed away any static charge as described above.

The power/VA ratings of the transformers you use need to be greater than your expected load. And, since some equipment like TVs and computer monitors draw a lot of current at power-on (from the degauss circuit), the isolation transformer will limit the peak current and may cause problems during startup (though overall, the limited current may prevent some types of disasters!). In any case, don't expect a pair of 6.3 VAC, 1 A transformers wired back-to-back to be useful for testing much of anything!

Also see the section: Isolation Transformers from Dead Microwave Ovens.

(From: David Moisan (dmoisan@shore.net).)

It's not as hard as you think to find inexpensive isolation transformers. At the next hamfest, look for someone selling dead UPS's (Uninterruptible Power Sources) or other power conditioning equipment. Isolation transformers are often sold for use in the computer industry; that's how I got mine. 250 VA for $20, and I could have gotten 1000 VA for $50 if I wanted. Definitely increases my safety *and* confidence level!

Isolation Transformers from Dead Microwave Ovens

The high voltage transformers from dead microwave ovens (failures are rarely due to the transformers) can also be used. These are probably much easier to locate (try your local appliance repair shop or dump) and will have a nice high capacity - usually 5 to 10 A or more.

However, note that microwave oven transformers are usually designed with as little copper as possible in the primary winding and do go into core saturation at normal line voltage with no load. For example, measurements using a clamp-on AC ammeter of a transformer from a mid-size microwave oven shows:

```
  Input VAC   Input Amps
------------------------
     80           .3
     90           .6
    100          1.1
    110          2.0
    115          3.0
    120         >4.0
```

At 115 VAC input, that's about 350 VA - probably close to 350 W with nothing connected to its secondaries! It also had a very noticeable hum above about 100 VAC.

Thus, this sort of approach isn't recommended unless you really need the high capacity - testing of other microwave ovens or ion laser power supplies, for example!

A pair of these trnasformers can be connected in a similar manner to the tube-type TV power transformers described in the section: Typical Homemade Isolation Transformer, there are a few more things to keep in mind:

- These transformers are DANGEROUS. Their high voltage output is between 1,500 and 3,000 VRMS at AMPS - an instantly deadly combination. Therefore, thoroughly insulate the connections between the HV secondaries.
- The high voltage returns are connected to the cores so these must be tied together AND to earth ground for safety.
- These transformers may not be rated for continuous duty operation. So, they should probably not be left plugged in when not in use.
- The more limited capacity of a small isolation transformer can sometimes protect you from yourself -

preventing the burnout of a horizontal output transistor due to excessive load or carelessness. You will have no such guardian looking over your shoulder with a microwave oven monster!

A better way to use these is to take the primary (low voltage) windings from two similar transformers and mount them on a single core. Then, there is no high voltage to worry about, the unit is more compact and lighter in weight, and the performance is better (less voltage droop at high loads). Of course, disassembling the cores may prove interesting especially if they were originally welded!

How Safe is a Homemade Isolation Transformer?

Some people will claim that because it is homemade from salvaged parts, it *cannot* be as safe as a commercial unit.

Keep in mind that I am not talking about using something that has been rusting away in a damp basement for 20 years. The power transformers from tube-type TVs or audio amplifiers must have been designed with isolation requirements in mind to obtain regulatory approval in the first place since they are used in equipment where the user may come in contact with metal parts.

Also, the use of an isolation transformer is no excuse to ignore the other aspects of safe troubleshooting.

It is easy to test for AC and DC leakage - and this should be done - to be sure that your transformers are in good condition. With two transformers, the probability of a failure is even smaller - 1/(P*P). Personally, I would trust the homemade transformer over a cheap import any day!

Variable Autotransformers

A variable autotransformer (Variac is the trade-name of one popular brand) enable the AC input to an appliance or piece of electronic equipment to be easily varied from 0 to full (or greater than full) line voltage. Your first Variac doesn't need to be large - a 2 A unit mounted with a switch, outlet and fuse will suffice for most tasks. However, a 5 amp or larger Variac is desirable. If you will be troubleshooting 220 VAC equipment in the US, there are Variacs that will output 0 to 240 VAC from a 115 VAC line. **WARNING:** A Variac is NOT an isolation transformer!

The internal wiring of a typical Variac is shown below:

```
           _                1
    H o---- _-----/ ------>o--+     Tap 1: 0 to 115 VAC
         Fuse 1  Power      2  )||
        (Input)  Switch    o--+ ||  Tap 2: 0 to 140 VAC
                               )||
                               )||      _
Tied together at               )<------- _--------o Adjustable output
service panel           Power  )||     Fuse 2
|              220       LED   )||    (Output)
|          +--/\/\--|>|--|>|--+ ||
|          |                   )||
```

```
+-> N o----+-----------------+-|----------------o Return
|                              |
+-> G o------------------------+----------------o Ground
```

WARNING: Direct connection between input and output - no isolation since the power line Neutral and Ground are tied together at the main service panel (fuse or circuit breaker box)!

CAUTION: Keep any large transformer of this type well away from your monitor or TV. The magnetic field it produces may cause the picture to wiggle or the colors to become messed up - and you to think there is an additional problem!

Note: the 'Power LED' circuit is soldered directly to a winding location determined to produce about 6 VAC.

- Sam's Rule #61453: Your lab or shop can never have too many Variacs!
- Sam's Rule #61454: If you only have a single Variac, it should be LARGE!

Wiring a Variable Autotransformer

Typical variable autotransformers (e.g., Variacs) may be wired so that either clockwise or counterclockwise shaft rotation increases the output and for either 0 to 115 VAC or 0 to 140 VAC from a 115 VAC line (0 to 230 VAC or 0 to 280 VAC for units designed to operate on a 230 VAC line). There are also some Variacs that can produce 0 to 280 VAC from a 115 VAC line with the proper wiring (but they must have been designed for this!). Intermediate taps on the winding provide these options. The one for the LED, I add myself. :)

Wiring is straightforward if you have acquired a bare unit (the following assumes a 115 VAC line, the extension to 230 VAC should be obvious):

- Decide on the output voltage range and direction of rotation (clockwise should always be used to increase output as far as the user is concerned but depending on mounting, actual direction of the shaft with respect to the body of the unit may be either way):

  - For 0 to 115 VAC output, Hot and Neutral go between the ends of the winding with Neutral at the terminal where the wiper will be when you want the output to be 0 VAC; The output goes between Neutral and the wiper.

  - For 0 to 140 VAC output, Hot is moved to the tap about 20 percent away from the terminal where the wiper will be when the output is at 140 VAC; The output goes between Neutral and the wiper as above.

  - For some (mostly small) Variacs that do not have intermediate taps, it may still be possible to add a tap to permit 140 VAC operation. However, this will reduce the number of turns on the primary and could lead to overheating from core saturation if the design is marginal. Most of these are overdesigned and this shouldn't be an issue. But, nonetheless, if you try this, monitor the temperature of the *unloaded* Variac for, say, an hour to make sure it doesn't get excessively hot.

- Include a primary-side power switch and power-on indicator lamp. In the old days, a neon lamp would be used (e.g., NE2H with a 47K ohm resistor). Nowadays, neon lamps may be hard to find. An alternative as suggested above is to add a tap on the Variac winding at about 6 to 10 VAC and use an LED and current limiting resistor.

- Provide fuses for **both** input and output. They should be the same rating as the Variac. The fuse for the input protects against primary side shorts. The one for the output protects the Variac winding from excessive load. Commercial units may only have one fuse but fuses are inexpensive and the added protection won't hurt.

- Use an adequately rated grounded cordset and mount everything in a well insulated box. The Variac frame and box (if made of metal) should be grounded.

Variable Isolation Transformers

This should probably be your basic setup for troubleshooting. You don't need to buy a fancy combination unit. A Variac can be followed by a normal isolation transformer. (The opposite order also works. There may be some subtle differences in load capacity.)

Variac/Isolation Transformer with Current Limiting

For the well equipped troubleshooter, there are also devices (Variacs and/or isolation transformers or combos) with adjustable (electronic) current limiting. This is particularly useful to protect the equipment being tested from excessive current - somewhat like the series light bulb but easily settable for each particular situation.

Constant Voltage Ferroresonant Transformer

These provide very good line voltage regulation (typically +/-1% output change for a +10/-20% input change) without any active components. They also are very effective at suppressing line noise, spikes, and harmonics. SOLA is probably the most widely known manufacturer of these devices. A complete FAQ can be found at .

Note that while isolation may be provided, it is NOT inherent in this technology. Some types may use autotransformers and thus have no isolation.

(From: Dave Martindale (davem@cs.ubc.ca).)

The simplest version has fairly ordinary-looking primary and secondary windings wound on the centre leg of a shell-type transformer core. Unlike a normal transformer, where the primary is wound over the secondary (or vise versa), the primary and secondary windings are physically separated. Magnetic shunts (chunks of transformer steel) are inserted between the centre and outside legs of the core at a point between the primary and secondary winding. These magnetic shunts provide a flux path around the primary that bypasses the secondary winding, producing lots of leakage inductance. This is what limits the current when the secondary is shorted.

Meanwhile, the secondary winding is in parallel with a capacitor, chosen to make the secondary resonant at 60 Hz. The resonance drives the portion of the core inside the secondary winding into saturation, which limits the amplitude of the secondary voltage. Changes in primary voltage have almost no effect on secondary voltage over the regulating range.

Now, the above is actually a simplification. In real CV transformers, the secondary actually has enough turns to step up the voltage by a factor of several, so the capacitor is operating at several times line voltage. This allows the capacitor to be lower capacitance for resonance, which is physically smaller and cheaper than what you'd need at 115 V. The actual output voltage is obtained from a tap on the secondary where the voltage is 115 V or so.

Also, the transformer I've described so far outputs a pretty square waveform. That's great for the input stage of a DC power supply, but not for some AC loads. The commercial CV transformers I see use a "harmonic neutralized" design that gives an output closer to a sine wave. Instead of one secondary winding, there are two, with another pair of magnetic shunts between the two secondaries. The capacitor is connected across the two secondary windings in series. The output voltage is taken from just the "middle" secondary winding. In the Sola transformer, there's also an air gap in the centre leg of the core, at the end where the 3rd winding is. I don't understand how the extra winding and shunt cancel some of the 3rd harmonic output, but they do.

The Series Light Bulb Trick

When powering up a TV (or any other modern electronic devices with expensive power semiconductors) that has had work done on any power circuits, it is desirable to minimize the chance of blowing your newly installed parts should there still be a fault. There are two ways of doing this: use of a Variac to bring up the AC line voltage gradually and the use of a series load to limit current to power semiconductors.

Actually using a series load - a light bulb is just a readily available cheap load - is better than a Variac (well both might be better still) since it will limit current to (hopefully) non-destructive levels.

What you want to do is limit current to the critical parts - usually the horizontal output transistor (HOT). Most of the time you will get away with putting it in series with the AC line. However, sometimes, putting a light bulb directly in the B+ circuit will be needed to provide adequate protection. In that location, it will limit the current to the HOT from the main filter capacitors of line connected power supplies. This may also be required with some switchmode power supplies as they can still supply bursts of full (or excessive) current even if there is a light bulb in series with the AC line.

Actually, an actual power resistor is probably better as its resistance is constant as opposed to a light bulb which will vary by 1:10 from cold to hot. The light bulb, however, provides a nice visual indication of the current drawn by the circuit under test. For example:

- **Full brightness:** Short circuit or extremely heavy load - a fault probably is still present.
- **Initially bright but then settles at reduced brightness:** Filter capacitors charge, then lower current to rest of circuit. This is what is expected when the equipment is operating normally. There could still be a problem with the power circuits but it will probably not result in an immediate catastrophic failure.
- **Pulsating:** power supply is trying to come up but shutting down due to overcurrent or overvoltage

condition. This could be due to a continuing fault or the light bulb may be too small for the equipment.

Note: for a TV or monitor, it may be necessary (and desirable) to unplug the degauss coil as this represents a heavy initial load which may prevent the unit from starting up with the light bulb in the circuit.

The following are suggested starting wattages:

- 40 W bulb for VCR or laptop computer switching power supplies.
- 100 W bulb for small (i.e., B/W or 13 inch color) TVs.
- 150-200 W bulb for large color or projection TVs.

A 50/100/150 W (or similar) 3-way bulb in an appropriate socket comes in handy for this but mark the switch so that you know which setting is which! Or, for the ultimate in troubleshooting convenience, see the section: Combination Variable Isolation Transformer and Series Light Bulb Unit.

Depending on the power rating of the equipment, these wattages may need to be increased. However, start low. If the bulb lights at full brightness, you know there is still a major fault. If it flickers or the TV (or other device) does not quite come fully up, then it should be safe to go to a larger bulb. Resist the temptation to immediately remove the series light bulb totally from the circuit at this point - I have been screwed by doing this. Try a larger one first. The behavior should improve. If it does not, there is still a fault present.

Note that some TVs and monitors simply will not power up at all with any kind of series load - at least not with one small enough (in terms of wattage) to provide any real protection. The microcontroller apparently senses the drop in voltage and shuts the unit down or continuously cycles power. Fortunately, these seem to be the exceptions.

Combination Variable Isolation Transformer and Series Light Bulb Unit

If you plan on doing a lot of electronics troubleshooting consider building a box which includes:

- A Variac and isolation transformer or variable isolation transformer. Include a power switch and BIG RED power-on indicator as well as primary and secondary fuses or circuit breakers.

- A series light bulb bank consisting of 25, 50, 100, and 200 W light bulbs in parallel with individual switches for each. By selecting an appropriate combination of switch positions, any wattage from 25 to 375 W can be set up in 25 W increments. An additional switch in parallel with the light bulbs can be used to bypass them entirely. The light bulbs should be outside any enclosure so (1) they are clearly visible and (2) their heat won't cook the components inside the case!

- AC voltmeters on the isolation transformer output and final output; AC ammeter in series with the load.

Using a Light Dimmer or Similar Device as a Variac?

The quick answer is: No, get a proper Variac!

The behavior of a phase control device like a light dimmer depends critically on what sort of load it sees. If the dimmer sees mostly a resistive load, it will work reasonably well and survive. However, most electronic equipment doesn't fall into this category. If the dimmer is attempting to drive a piece of equipment with a lot of capacitance or inductance, at the very least it will behave strangely with the control range squashed to one end or the other, or the output voltage will change suddenly rather than smoothly. But more likely, it will self destruct and/or damage the equipment due to the strange waveform, which may result in a peak output voltage that approaches full line voltage even at relatively low settings. There's also usually a minimum load below which it won't do anything predictable. In short, get a proper Variac. You know my motto: "You can never have too many Variacs!". :) Surplus Variacs are readily available including on eBay.

What About the Scope Ground?

In general, scopes SHOULD be earth grounded. The only time this is not the case is if you are attempting to measure signals in a line-connected device such as found in many TVs and switching power supplies and are not using an isolation transformer. However, this is a very dangerous setup and should be avoided if at all possible. With line-connected equipment, the return or ground reference is not at earth ground potential due to the bridge rectifier or voltage doubler often used in the power supply front-end.

Without an isolation transformer, connecting the scope ground clip to the return will result in a short through the ground lead between the equipment and earth ground. There will be smoke and possibly blown components as well. Disconnecting the scope from ground allows its case to float which will prevent the melt-down but is EXTREMELY DANGEROUS since the entire scope cabinet is effectively connected to the power line. You (or someone else not familiar with your foolishness) may casually touch or lean against the scope cabinet and be thrown across the room if it is a lucky day or worse. Don't do it! Invest in an isolation transformer. It is very cost effective insurance.

Basic Ancillary Equipment

Various common items are useful for testing of the following consumer electronics and computer devices. These will normally be used before and during use of any actual test equipment. (Some of these were already listed under the heading of 'test equipment'). However, this is kind of inverted identifying what is needed for each type of equipment being repaired.

- TVs: VHF and UHF antennas and/or VCR or other video source with both RF and baseband (RCA plugs) outputs.

- VCRs: a small TV (preferably color but a monochrome TV will suffice for many tests) and/or NTSC/PAL video monitor, antenna, known good video tapes at both SP and SLP speeds. Also, a couple of blank cassettes for record tests.

- Camcorders: same as VCRs but in addition, a test chart, tripod, and lamps for indoor testing.

- CD and Laserdisc Players: - a garbage CD and test CD (or laserdiscs). A garbage disc is one you do not care about if it gets scratched. A test disc does not need to be an official (and expensive) test disc - any known good disc will do for most tests. The garbage CD can even be an outdated CDROM - an audio CD player will often read the directory of a CDROM just like an audio CD.

  Special cut-down miniature test CDs can be made to view the lens motion while focusing and to permit access to adjustments blocked by normal CDs in many portable players. See the document: [Notes on the Troubleshooting and Repair of CD Players and CDROM Drives] for details.

An IR detector will be needed to confirm laserdiode operation.

An audio amplifier with speakers or headphones will be needed for the audio tests, or headphones if the unit has a headphone jack. A TV or video monitor will be needed for Laserdisc video tests.

- Audio Equipment - a set of known working stereo components consisting of at least a tuner, amplifier, and speakers. Headphones are also useful. For most purposes, an inexpensive setup is preferred since there is no telling what kind of abuse it may need to endure during troubleshooting. I suppose that a turntable may even be needed occasionally. A couple of prerecorded audio cassettes are handy when testing tape decks. One of these should have a tone of known frequency recorded on an accurately calibrated deck for setting tape speed. Also, a couple of blank cassettes for record tests.

- Microwave Ovens - a cup of water for a load. You don't need special microwave approved water - tap water will do :-) A thermometer for power tests. Neon or incandescent bulbs with their leads shorted together can serve as microwave detectors inside the oven (though these may not always survive for very long).

- PCs and components - a working basic PC is useful to serve as a testbed for trying suspect components. I use an old 286 mainboard with just enough to boot from an old hard drive. A set of known working basic PC peripheral boards is useful - SA, IDE and MFM HD and FD controller, I/O ports, sound card and speakers, 5-1/4" and 3-1/2" floppy drives, etc. A spare power supply - even one that is not an exact mechanical match - is also handy for testing. An old laptop (commonly used as a door stop) is useful for testing printers on location.

- Computer Monitors - a test PC is useful as a video source. Of course, it will need to support whatever scan rates and video types the monitor is designed to accept. Programs are available to display purity, convergence, focus, color, and other test patterns.

- Telephones, answering machines, faxes - a phone line simulator is useful for initial tests. For many purposes, a DC power supply or battery and 600 ohm resistor will be all you need. A pair of normal phone lines will of course also work but you will need to provide jacks where you are working and access (which may be difficult with teens in the house).

Incredibly Handy Widgets(tm)

These are the little gadgets and homemade testers that are useful for many repair situations. Some of these can also be purchased if you are the lazy type. Here are just a few of the most basic:

- Series light bulb for current limiting during the testing of TV sets, monitors, switching power supplies, audio power amplifiers, etc. I built an outlet box with two outlets wired in series, switch, and indicator. A lamp or other load can be plugged into one outlet and the device under test into the other. Clearly label the special outlet box so you (or someone else) will not attempt to use it for other purposes!

  A typical schematic is shown below:

```
H o-------/ ---+-------+
       Power   |       | H     N
       Switch  /       +--|   |--+  Current limiting load
               \                 |
           47K /           o G   |
               \                 |
               |       +---------+
              +++      | H     N
         NE2H |o|      +--|   |--+  Device under test
        Power |o|                |
        Light +++          o G   |
               |           |     |
N o-----------+----------------+
                           |
G o------------------------+
```

Note: Ground connections normally not used for equipment likely to be tested using this device.

See the repair guides for specific equipment for more details on the use of the series light bulb.

- Capacitor discharge tool. This device provides a safe and low stress (for your spouse - no zap) way of discharging the capacitors found in TV sets, monitors, microwave ovens, electronic flash units, etc. An indicator can easily be built in as well to provide a visual confirmation as the voltage decays.

  Safety note: always double check that capacitors are fully discharged with a voltmeter before touching any high voltage terminals!

  See the document: Capacitor Testing, Safe Discharging and Other Related Information for additional information.

- Video cassette cheater. This is the shell of a VHS or Beta cassette with all of the innards removed and most of the top and bottom cut out to permit access to the reel spindles and other rotating components of a VCR during operation. You can also purchase these at grossly inflated prices.

  See the document: Notes on the Troubleshooting and Repair of Video Cassette Recorders for additional construction details.

- Degaussing coil. Make or buy. The internal degaussing coil salvaged from a defunct TV doubled over to half it original diameter to increase its strength in series with a 200 W light bulb for current limiting, (use the series light bulb widget for this), fuse, and momentary switch will work just fine.

  See the document: TV and Monitor CRT (Picture Tube) Information for additional information on CRT magnetization and degaussing techniques.

- Tape head demagnetizer. This could just be a coil wrapped around a common nail with its end protected with tape. Connect to low voltage AC. However, these are so inexpensive that you should just buy one.

  See the documents: "Notes on Troubleshooting and Repair of Audio Equipment and other Miscellaneous Stuff" and "Notes on Troubleshooting and Repair of Video Cassette Recorder (VCR)" for additional information on tape head demagnetizing.

  Caution: do not use a demagnetizer on video heads unless specifically designed for them. Some are strong enough to damage the fragile ferrite cores. Video heads generally do not require demagnetizing anyhow.

- IR detector. This can be a photodiode/LED circuit or IR sensitive card. Use for testing remote controls, IR LEDs in photosensors, and CD laserdiodes.

  See the document: Notes on the Troubleshooting and Repair of Hand Held Remote Controls for construction details.

- Flyback tester. I use a 12 V chopper with a 10 turn coil to excite the flyback under test. This will identify most primary and secondary short type faults under near-operating conditions.

  See the document: Testing of Flyback (LOPT) Transformers for additional information.

- High voltage probe for your multimeter. This will come in handy when testing the high voltage circuits of TVs, monitors, and microwave ovens (though extreme care will be needed, particularly with the latter). See the document: Simple High Voltage Probe Design for details on basic high voltage probes you can construct from (relatively) readily available parts. These will be satisfactory for DC voltages but compensation to get any kind of high frequency response can be tricky. However, that will handle most consumer electronics needs.

- Not-so-fantastic current probe. When diagnosing TV and monitor deflection problems, a current probe may be desirable to view the current waveforms in the yoke and flyback. You cannot view the high voltage signals without a high frequency high voltage probe.

  If you have a current probe for your scope, this can be used to monitor the various current waveforms. I have used my Tektronix current probe to view the yoke current on TVs. The rendition of the horizontal deflection current waveform is quite good. However, the vertical suffers from severe distortion due to the low frequency cutoff of this probe.

  You can build a not-very-fantastic (but quite usable) current probe using a split ferrite core of the type used on keyboard and monitor cables (preferably one that snaps together). The following will work:

  - Wrap seven turns of insulated wire around one half of the core.
  - Solder a 2.2 ohm resistor across the two leads to act as a load.
  - Connect to the vertical input of your scope via a coaxial cable or probe.

  You can experiment with the number of turns and load resistor value for best results.

To use your fabulous device, insert one and only one of the current carrying wires inside the ferrite core and clamp the two halves together.

For a typical TV horizontal deflection yoke, this results in about a .3 V p-p signal. The shape was similar to that from my (originally) expensive Tektronix current probe. Enjoy the show! Due to its uncompensated design, this simple probe will not work well for low frequency signals.

- Quick and dirty curve tracer. A curve tracer is useful for displaying the I-V characteristics of semiconductor and other devices. See the sections on curve tracer design in the document: Basic Testing of Semiconductor Devices.

  There is info on useful devices for your scope that you can construct in about 10 minutes. These won't replace a fancy Tek 576 but may be all you need (or at least can justify on a finite budget).

- Handy-dandy phone line tester. The inexpensive variety is just a pair of LEDs in series with a resistor for each line attached to an RJ11 connector. However, this is much more convenient than fumbling with a multimeter! You can buy one at Radio Shack (about $7) or easily build your own. See the document: Notes on the Troubleshooting and Repair of Audio Equipment and Other Miscellaneous Stuff, specifically the section: "Handy-dandy phone line tester" for details.

- High voltage diode and neon bulb tester. This is a line powered low current voltage doubler producing up to about 300 VDC to test (in conjunction with a Variac and multimeter) for reverse blocking of high voltage rectifiers, diodes, and ratings of high voltage zeners, neon and other small discharge lamp characteristics, and so forth.

  WARNING: Use an isolation transformer with this device since it is line connected without isolation. The maximum sustained (short circuit) current is only 4 or 5 mA but this is still enough to be dangerous so respect it even with the isolation transformer!

```
          C1                    D2
AC H o----||-------------+----|>|----+-----+----o +DC

Cheater Cords

In the good old days, before VCRs, before most solid state TVs, before the Net, and before newsgroups, most electronic equipment had a sort of interlock to prevent operation when the cover was removed. Normally this consisted of the line cord plugging into the chassis via a plug fixed to the cover. Then, emoving the cover automatically disconnected power to the equipment. So, a cheater cord was needed for testing and had an AC plug at one end and this special plug at the other to bypass the interlock and allow you to get a shocking experience. :)

Exactly why this is no longer done except to save money isn't quite clear. Chassis of modern equipment like TVs, computer monitors, microwave ovens (especially microwave ovens) are very dangerous. Perhaps the manufacturers figure that at least for the first two, not using vacuum tubes, most of their voltages are lower. More likely, since they provide the warning "no user serviceable parts inside", they figure that they can't be sued and it is isn't worth spending the 10 cents for the extra plug. :)

Where your equipment actually has this sort of interlock, it is usually possible to pop off a retaining clip and use the original cord for this purpose. Just make sure you understand the safety issues. Modern devices may not have several hundred volts sprinkled all over the chassis like those using vacuum tubes, but there may be non-isolated line voltage, 25 kV or more for the CRT, or 5,000 V at AMPs in a microwave oven. You can be just as dead from these!

Monitoring Current Consumption from Batteries

When a problem develops in a battery powered deviced - it might be totally dead or drain batteries too quickly - it is desirable to be able to measure the current from the batteries. A simple way to do this is to construct a gadget that can be inserted between two cells or between a cell and the battery holder terminal so that a multimeter can be installed in series with the battery output.

(Portions from: Raydon Berry (rayberry@pt.lu).)

Take a small piece of stiff plastic (e.g., as used in blister packs) and attach strips of self adhesive copper or aluminum foil to both sides. Shape one end of the strip into a sort of finger, narrow enough to slip between the AA or AAA batteries or batteries and the contact when they are installed in the holder. If the foil is copper, wires can be soldered to each side at the other end. If aluminum, cut away a portion of the foil in opposite locations on both sides so clip leads from a multimeter can be attached without shorting.

This device is used (frequently by me) for checking the current consumption of all battery powered equipment - it's very simple and very cheap.

For example, with remote controls, insert between batteries and put the multimeter on a range of about 25 mA and when you press each button, the code being sent will show up as a wagging needle on a VOM or an average current for a DMM. If the ceramic filter or the IR diodes have failed, the current remains very low, but if OK, you should see pulses of 5 to 10 mA.

For other devices, select an appropriate range. It might not be a bad idea to check new/working equipment as well to obtain a "signature" of health which is recorded on a slip of paper glued inside the battery compartment. Then, if the device should fail, a comparison can easily be made.

Miscellaneous

- Clip leads. Like woodworking clamps, you can never have too many of these.

- Patch cords for audio, video, and telephone interconnection.

- Parallel (Centronics) printer, serial (breakout box desirable), other computer cables.

- Insulating sheets - for separating circuit boards when removed from the chassis. These can be cardboard, fiberglas, plastic, etc.

- Insulating sticks - for prodding to locate intermittents.

- Small parts tray and container. I always use a film canister or pill bottle for storing the screws, washers, and springs removed during disassembly. An icecube tray or egg carton makes a handy parts bin for temporary storage of small parts while you are working.

Making a Bench Power Supply from a PC Power Supply

The power supply from a long obsolete PC can be the basis for a low cost unit useful for a variety of design and troubleshooting applications. The typical 200 W PC power supply will provide +5 V at 20 A, +12 at 8 A, and low current -5 V and -12 V outputs. However, these are not that well filtered - at least not where low noise analog circuits are concerned. They are fine for digital and power circuits as is. For analog work, additional post regulation (e.g., LM317s) and filtering may be needed.

- Typical (but not always) color codes for PC power supplies:

  Red: +5, Yellow: +12, Black: Gnd (Probably case as well).
  White: -5, Blue: -12, Orange: Power_good (output).

  (Some newer supplies may have a +3.3 output as well which may be green).

- PC power supplies (as well as most other switchers) need a minimum load on +5 and possibly on +12 as well. An amp (e.g., 5 ohms on +5) should be enough.

  I use an old dual beam auto headlight. It adds a touch of class as well to an otherwise totally boring setup :-). You can also use auto tail light bulbs or suitable power resistors or old disk drives you don't really care about (you know, those boat anchors).

- There are no sense lines. There is a 'Power_Good' line which is an output from the power supply to the mainboard and can be ignored unless you want to connect it to an indicator to let you know all the outputs are within specs (it may need a pullup and I don't know its drive capability).

- Pinout for the standard PC and clone connector (some companies like Compaq do NOT use this type of connector, however.). Black (Gnd) wires together for the P8 and P9 connectors when installed to mainboard.

```
    J8: Pin 1 = Power_Good   J9: Pin 1 = Gnd
    Pin 2 = +5               Pin 2 = Gnd
```

```
Pin 3 = +12                 Pin 3 = -5
Pin 4 = -12                 Pin 4 = +5
Pin 5 = Gnd                 Pin 5 = +5
Pin 6 = Gnd                 Pin 6 = +5
```

Note: for an XT only, J8-Pin 1 is Gnd, J8-Pin 2 is no connect.

- The peripheral connectors are: Pin 1: +12, Pin 2 and 3: Gnd, Pin 4 = +5.

Soldering and Desoldering Equipment and Techniques

Solder is Not Glue

The ease and quality of your work will depend both on proper soldering as well as desoldering (often called rework) equipment.

However, the purpose of solder is not to physically anchor connections - they must be mechanically secure first to assure reliability. When properly done, solder actually combines with the clean metal surface of the wires, pins, and terminals assuring a low resistance connection.

While there are several conditions must be satisfied to achiev good reliable solder connections, with a little practice, soldering will become essentially automatic and you will know immediately when the results are satisfactory.

There have been entire handbooks written on proper soldering technique. Organizations like NASA take this seriously - after all, a service call to the one of Jupiter's moons would be quite costly!

Aditional information on soldering techniques and equipment can be found at:

- The Basic Soldering Guide

CAUTION: You can easily turn a simple repair (e.g., bad solder connections) into an expensive mess if you use inappropriate soldering equipment and/or lack the soldering skills to go along with it. If in doubt, find someone else to do the soldering or at least practice, practice, practice, soldering and desoldering on a junk unit first!

Soldering Equipment

- A low wattage (25 W) iron for delicate components including discrete semiconductors, ICs, other small parts).

- A medium wattage (40-50W) iron for heavy duty circuit board work including power components, power plane connections, and large transformers).

- A 100-140 W soldering gun for chassis connections.

Three wire grounded soldering equipment is recommended but I do not consider it essential for this type of repair work. However, a temperature regulated soldering station is a really nice piece of equipment if you can afford it or happen on a really good deal.

I consider fine gauge rosin core solder (.030 or less) to be best for most applications (e.g., Ersin Multicore).

- Desoldering pump - SoldaPullit or similar 'solder sucker' for removing components easily and usually nondestructively. SolderWick is also handy for cleaning up desoldered connections.

A vacuum rework station is not needed unless you are removing your soldered in 500 pin Intel P6!

Soldering Techniques

Soldering is a skill that is handy to know for many types of construction and repair. For modern small appliances, it is less important than it once was as solderless connectors have virtually replaced solder for internal wiring.

However, there are times where soldering is more convenient. Use of the proper technique is critical to reliability and safety. A good solder connection is not just a bunch of wires and terminals with solder dribbled over them. When done correctly, the solder actually bonds to the surface of the metal (usually copper) parts.

Effective soldering is by no means difficult but some practice may be needed to perfect your technique.

The following guidelines will assure reliable solder joints:

- Only use rosin core solder (e.g., 60/40 tin/lead) for electronics work. A 1 pound spool will last a long time and costs about $10. Suggested diameter is .030 to .060 inches for appliances. The smaller size is preferred as it will be useful for other types of precision electronics repairs or construction as well. The rosin is used as a flux to clean the metal surface to assure a secure bond. NEVER use acid core solder or the stuff used to sweat copper pipes! The flux is corrosive and it is not possible to adequately clean up the connections afterward to remove all residue.

- Keep the tip of the soldering iron or gun clean and tinned. Buy tips that are permanently tinned - they are coated and will outlast countless normal copper tips. A quick wipe on a wet sponge when hot and a bit of solder and they will be as good as new for a long time. (These should never be filed or sanded).

- Make sure every part to be soldered - terminal, wire, component leads - is free of any surface film, insulation, or oxidation. Fine sandpaper or an Xacto knife may be used, for example, to clean the surfaces. The secret to a good solder joint is to make sure everything is perfectly clean and shiny and not depend on the flux alone to accomplish this. Just make sure the scrapings are cleared away so they don't cause short circuits.

- Start with a strong mechanical joint. Don't depend on the solder to hold the connection together. If possible, loop each wire or component lead through the hole in the terminal. If there is no hole, wrap them once around the terminal. Gently anchor them with a pair of needlenose pliers.

- Use a properly sized soldering iron or gun: 20-25 W iron for fine circuit board work; 25-50 W iron for general soldering of terminals and wires and power circuit boards; 100-200 W soldering gun for chassis and large area circuit planes. With a properly sized iron or gun, the task will be fast - 1 to 2 seconds for a typical connection - and will result in little or no damage to the circuit board, plastic switch housings, insulation, etc. Large soldering jobs will take longer but no more than 5 to 10 seconds for a large expanse of copper. If it is taking too long, your iron is undersized for the task, is dirty, or has not reached operating temperature. For appliance work there is no need for a fancy soldering station - a less than $10 soldering iron or $25 soldering gun as appropriate will be all that is required.

- Heat the parts to be soldered, not the solder. Touch the end of the solder to the parts, not the soldering iron or gun. Once the terminal, wires, or component leads are hot, the solder will flow via capillary action, fill all voids, and make a secure mechanical and electrical bond. Sometimes, applying a little from each side will more effectively reach all nooks and crannies.

- Don't overdo it. Only enough solder is needed to fill all voids. The resulting surface should be concave between the wires and terminal, not bulging with excess solder.

- Keep everything absolutely still for the few seconds it takes the solder to solidify. Otherwise, you will end up with a bad connection - what is called a 'cold solder joint'.

- A good solder connection will be quite shiny - not dull gray or granular. If your result is less than perfect reheat it and add a bit of new solder with flux to help it reflow.

Practice on some scrap wire and electronic parts. It should take you about 3 minutes to master the technique!

Desoldering Techniques

Occasionally, it will be necessary to remove solder - either excess or to replace wires or components. A variety of tools are available for this purpose. The one I recommend is a vacuum solder pump called 'SoldaPullet' (about $20). Cock the pump, heat the joint to be cleared, and press the trigger. Molten solder is sucked up into the barrel of the device leaving the terminal nearly free of solder. Then use a pair of needlenose pliers and a dental pick to gently free the wires or component.

For stubborn joints or those connecting to the power planes (surface or multilayer boards), you may need to add some fresh solder and/or flux and then try again. Generally, if you only get part of the solder off the first time, repeated attempts will fail unless you add some fresh solder.

Other approaches that may be used in place of or in addition to this: Solder Wick which is a copper braid that absorbs solder via capillary action; rubber bulb type solder pumps, and motor driven vacuum solder rework stations (pricey).

(Portions from: Pat Brunner (Brunner@ieee.org).)

I have used a SoldaPullet for 30 years but found an inexpensive improvement. Add a 1 inch length of silicone tubing (or something else that won't be damaged by the heat, 1/8" ID x 1/4"OD) over the SoldaPullet tip leaving 3/16" to 1/4" extending past the tip. This absorbs the downward force when the SoldaPullet is fired reducing damage to the PCB, provides a better seal around the component lead so it's often possible to clear a hole in one operation that might otherwise require several, and it prevents the plastic tip of the SoldaPullet from being damaged.

Nick's Comments on Successful Desoldering Techniques

These directly apply to the destructive (i.e., you don't care about saving the part) removal of IC chips. However, the basic techniques work for discrete parts as well.

(From: Nicholas Bodley (nbodley@tiac.net).)

A few points to keep in mind...

Try to get cutters that will let you snip individual leads on the IC. Get tool catalogs! I like Contact East, in the USA; not sure about Canada. Jensen, in Arizona, I think, tends to be costly.

If you snip all the leads on one side, you can bend the IC back and forth to break the other side free, but be sure to do the bending next to the plastic (it's harder to do there).

When you cut the IC leads, do your best to leave most of each lead sticking up above the surface of the board.

Set your iron to about 770 deg. F (400 deg. C). (This assumes a modern soldering station with a temperature control, and a relatively-slender tip.) Be sure that the tip is clean and shiny and properly tinned. Any oxidation is just no good. (DON'T file modern plated tips! You'll remove the plating!). Be fanatical about ensuring that the tip always idles with a decent coating of solder.

Hotter temps run a real risk of spoiling the adhesive bond that holds the copper foil to the board. DO NOT use a higher temp to make up for an improperly-tinned tip!! (You might need a higher temp for holes in the middle of ground planes, however. These will sink the heat away effectively; but do those separately.)

You must get each pad hot enough to be well above the melting point, so that the cold air won't make the solder resolidify when you slurp it up.

To transfer enough heat, you must have a fillet of solder between the tip and the pad. If necessary, add a bit of solder to ensure this!

After hitting these points so hard, I'll relax and say that you'll really do better if you remove each lead stub individually with assembly tweezers (AA style are good) or thin needle-nose pliers.

Once they're all out, then you need to be concerned about heating the pads enough. Now you can desolder. The other messages in this post have good advice on that.

You need to maintain your desoldering tool, too. It might not have good vacuum if ignored.

It's tricky to hold the iron on the pad while getting the nozzle close enough, but a decent desoldering tool will work if tilted somewhat to let the tip contact the pad.

If a hole doesn't open, but some solder has been slurped up, you could try good solder wick (Solder-Wick (Soder-Wik?) brand is good); it can sometimes pull up solder from underneath by capillary action. (I didn't believe this until it happened!) Poor solder wick isn't fluxed sufficiently, or might be subtly corroded. It should soak up solder like a sponge.

It might be quicker to refill the hole with a bit of solder and repeat; there could be a good blob of it on the other side, which you might, or might not, be able to get to.

(If you can get to both sides, and have five hands, you could apply heat to one side, let the tip dwell for a few seconds to melt all the solder, and slurp from the other side.)

If things become messy, apply liquid flux (seems not to be too easy to find in small quantities; I use a flux pen, which seems not overpriced). Reheat the pad, and the flux should do a great job of tidying things up. It tends to let capillary action make the holes open wider, when most of the solder has been picked up.

I think it's well worth the effort to cut the leads free from the IC body and remove them one at a time, then go over the pads a second time to remove the solder.

I have very recently removed a 16-pin DIP twice from a location without damaging the pads at all by these principles.

It's much harder, or impossible, to do good work with poor tools. Do try to get good tools, and learn to take care of them.

Soldering Pins in Plastic Connectors

The thermoplastic used to mold many common cheap connectors softens or melts at relatively low temperatures. This can result in the pins popping out or shifting position (even shorting) as you attempt to solder to them to replace a bad connection, for example.

One approach that works in some cases is to use the mating socket to stabilize the pins so they remain in position as you solder. The plastic will still melt - not as much if you use an adequately sized iron since the socket will act as a heat sink - but will not move.

An important consideration is using the proper soldering iron. In some cases, a larger iron is better - you get in and out more quickly without heating up everything in the neighborhood.

Comments on Repairing Damage to Printed Circuit Boards

Two common problems are discussed here: damaged traces and damage from overheated components.

- Traces may be damaged due to poor soldering or desoldering techniques or by acting as fuses due to short circuits. Where there is just a gap in a trace, it may be possible to scrape off any protective coating (the solder mask) and then soldering a bare jumper wire to bridge the gap. DO NOT just put a blob of solder there - it won't last. However, it is often better to remove the remains of the trace entirely and solder a wire between the two end-points.

- When components overheat, they can also damage the PCB material underneath them. If the PCB is just slightly discolored, then probably it can be cleaned up and reused. This will often happen under hot components even with properly functioning equipment after many years of operation and doesn't cause problems.

  But if there is actual damage to the board material itself, then the carbon that is present and can't be removed will result in a conductive path which may result in circuit failure or erratic behavior. It would be best to replace the entire PCB if possible. But a more realistic alternative is to cut out the bad section and build the missing circuitry on a separate prototyping board.

- Back to Troubleshooting Table of Contents.

Supplies and Parts

Lubricants, Cleaning Agents, and Other Liquidy or Slimy Stuff

- Light oil such as electric motor oil or 3-In-One. WD40 may be useful for cleaning or freeing rusted screws but it is not a general purpose lubricant despite what is claimed on the label.

- Light grease suitable for fine electronics - must be plastic-safe.

- Isopropyl alcohol (91 % medicinal or better preferred though rubbing alcohol (70 percent) can be used in a pinch as long as it doesn't contain any additives).

  - Q-tip swabs (you may know them as cotton buds) for cleaning of everything BUT the video heads on VCRs and other helical scan tape transports.

  - Chamois covered head cleaning sticks for video heads.

  Note that sometimes plain water will work better for sugar based coatings. Tape head cleaner can be used for head cleaning as well.

- Contact cleaner in spray can. This is used for switches and relays.

- Control cleaner in spray can. This is used for potentiometers and will probably include some type of non-drying lubricant.

- Tuner cleaner and lubricant in spray can. The stuff sold by Radio Shack works fine.

- Degreaser in spray can. Use with care around plastics.

* WD40 in spray can. NOT for lubrication in most cases. However, WD40 is an intermediate strength solvent that comes in handy for cleaning, removing labels and label goo, coating tools to prevent rust, etc.

* Liquid flux for helping in tough soldering and desoldering jobs.

* Flux remover. Isopropyl alcohol will work but there are also spray cans of this stuff.

* Silicone heat sink compound. A little goes a long way. You don't need to goop it on - just the thinnest film to fill voids. Here are some numbers:

  (From: Asimov.)

  Thermal resistance (°C/W) for silicone heatsink compound:

```
 Insulator           Without   With
------------------------------------
 None                  0.20     0.10
 Anodized Aluminum     0.40     0.35
 Mica                  0.80     0.40
 Teflon                1.45     0.80
```

Note that using no insulator is always better than one with heatsink compound for these materials (no data on BeO which may be the exception).

(From: Gavin Parrish (the_big_geez@ameritech.net).)

Kano Labs makes a number of exceptional products which are only available directly through them. They are not cheap, but all that I have tried have met or exceeded my expectations. Their premier product is "KROIL" a penetrating oil that breaches a space as small as one millionth inch. No fooling! Throw away that WD whatever-its-called stuff. If it's stuck, this will unstick it.

While they have a lot of really big industrial customers, they give attentive service even if you only buy 1 can. The only drawback is they keep sending you somewhat amusing flyers every month or so. You already get a lot of this so it's no big deal.

For info or ordering contact: (what? no URL?!): Kano Laboratories, 1000 Thompson Ln., Nashville, TN 37211-2627. Phone: 1-615-833-4101, Fax: 1-615-833-5790.

(The above is not a paid promotion, merely data I hope you find useful.)

(From: Rich Grise (richardgrise@yahoo.com).)

Which solvent to use depends on what you're trying to dissolve. For a something like a cruddy motor, I'd try, in order from least aggressive up:

1. Isopropyl alcohol - good on most oils and greases, fairly innocuous chemically.

2. Ethyl alcohol - as good a solvent, or better than isopropyl, but much too valuable as a beverage.

3. Methyl alcohol - don't even touch this crap - if you even just get it on bare skin, it can blind you. (Actually, this is an extreme position, methyl alcohol is mainly dangerous if ingested. --- Sam.)

4. Naphtha (lighter fluid) - the only solvent I've ever seen that can get chewing gum out of your hair. Not too good on aliphatic greases, however.

5. Mineral spirits or turpentine - still flammable, makes good paint thinner, but seems to leave a greasy residue when used for cleaning.

6. Toluene/xylene - excellent cleaner, but it could attack the insulation on the windings. Breathing the fumes can cause a sort of intoxication that I think isn't very good for you.

7. Acetone/MEK - MEK is less volatile, but still quite aggressive. Very flammable, but evaporates completely without residue. Acetone is the only thing I've ever seen that can dissolve acrylic plastics like Plexiglas.

The chlorinated/fluorinated solvents sit somewhere in the middle of the range - someone else pointed out the difference between trichloroethylene and trichloroethane; I guess TCA is much friendlier than TCE - but we used them in the Airforce to clean up hydraulic fluids that nothing else would even touch.

I've heard that Vaseline makes a superb lubricant for bike bearings; it also makes a reasonable vacuum seal, and it's incredibly tenacious - one day, I used it on a gasket, and when I needed to make a change, I couldn't find anything in the shop that would clean it up completely.

Don't use WD-40 as a cleaner; it gums everything up. I inherited an old Baudot teletype once and thought I'd clean it with a WD-40 spray. HAH! Spent the next week disassembling the thing and cleaning all the gunk off the intricate little parts with TCA or something. WD-40 is good for door hinges.

Carburetor cleaner is a mixture of solvents in a spray can which may include acetone, toluene and methanol but it's extremely flammable and it seems to wash greasy dirt away as if it weren't even there.

Adhesives

- Two part Epoxy. Epoxy is one of the strongest and most versatile all around adhesive and bonds well to most materials except some plastics. I recommend separate tubes, not the combined syringe type. With tubes, it's much easier to get exactly what is needed. The syringes invariably dispense about 10 times the desired quantity and then last for only a few uses.

    - Fast curing (5 minute) Epoxy is most convenient for quick repairs but may not be as strong as the slow curing (1/2 to 1 hour) type.

    - It is generally easier to do a neat job with clear Epoxy but white or metal types work as well.

    - Conductive (silver filled) Epoxy may be useful for repairing printed circuit board traces and remote control pads but is no substitute for metal wires.

    - There is also special Epoxy for plastics which may form a stronger bond to certain types of plastics than normal Epoxy.

- Industrial quality cyanoacrylate like Loctite 401. The common types (Crazyglue, Superglue) work but stick to everything you don't want stuck together and the tubes never seem to keep the unused portion in decent condition. Loctite 401 comes in a nice bottle with applicator and proper recloseable top. This is probably best for instant repairs.

- General purpose adhesive like Duco Cement.

- Semi-flexible adhesive like windshield sealer.

- Flexible adhesive like weather strip cement or silicone sealer or RTV. Note: some types may be corrosive to metals upon curing - test first. One example of a suitable product would be Dow Corning #736 RTV though I don't know first hand if it is acid-free.

- Solvent type plastic cement or plastic model cement.

- Rubber cement.

- Plastic electrical tape.

- Masking tape.

- Clear plastic tape.

Electronic Sealers and Potting Compounds

These may be needed to insulate a high voltage connection or to encapsulate a circuit for reliability (or to keep it from prying eyes!).

Ordinary silicone window and bathtub caulk has the right mechanical and electrical properties (tough, flexible, excellent insulator especially for high voltage), but it secretes acetic acid upon curing and this may damage the electronic circuitry (but not always the case). Some types claim to be safe for this or that (e.g., aluminum) but unless it states specifically that it is safe for electronics, use at your own risk.

(From: Ralph L. (ralphl@keycomp.net).)

You can also use an RTV that is safe for oxygen sensors that are used on most computer controlled cars. It does not produce that acetic acid (vinegar smell) during the curing process and will not harm electronics.

(From: Greg Szekeres (gjs@prophet.pharm.pitt.edu).)

Yes, Permatex Ultra Blue is safe, available at most auto parts stores. I have also been using polyurethane instead of silicone, although is has problems with some materials.

(From: RadMan (radcom@comnet.ca)).

Some agents require UV to cure, some need heat. You can also try Miller-Stevensen 907 available at Future/Active, and it pots with a heat gun very fast (30 minutess).

(From: Bob Wilson (rfwilson@intergate.bc.ca).)

Dexter makes Hysol Epoxy which is a potting compound that totally encapsulates the circuits. There are easily available commercial coloring compounds intended for this purpose, and are available from the supplier of the Epoxy. An alternative is to mix some laser copier toner (dry powder) with the epoxy if making it opaque is desired.

Mind you, all that potting does as a means of security, is to keep he amateurs out. Depotting an electronic assembly is pretty easy. All that is needed is judicious application of a small welding torch flame to locally heat the epoxy above its glass temperature (whereupon it becomes rather "crunchy" and easy to remove), and a little patience.

(From: Brian Symons (brians@mackay.net.au).)

The products normally safe to use are labeled "neutral cure" or at least they are here in Australia.

Any acid cure product is certainly dangerous around electronics. I cam across some PCB's that had had the wires glued in place by a run of acid cure silastic across the board.

When looking for the fault, I peeled up the silastic and found every track under the silastic was completely eaten away.

BTW. Over here, It is quite common for ovens to have a from glass viewing window that is glued in position with a silastic material that can handle the high temps.

When a warrantee guy ordered in a tube of the silastic, they supplied a tube of the silastic that is available here at car parts suppliers and service stations to repair windscreen seals. They were only charging about eight times the price though. This silastic is a black product. I have used it successfully for oven glass repairs for several years.

Electronic Parts

I was going to attempt to make a basic list of recommended parts but this quickly got out of hand. The list below is just a start. The idea is to have enough parts available so that you do not need to raid the local electronics store every time you want to try something.

A good source for many of the basic parts is dead equipment - their organs can live on at your workbench. Parts like small resistors are so inexpensive that this doesn't warrant a lot of time. However, power resistors, potentiometers, power semiconductors, some ICs, etc. are well worth saving. Used electrolytic capacitors will generally still be functional but these do deteriorate with time and heat so testing them first and avoiding the use of really old ones for the permanent repair is probably wise. The majority of my parts inventory is from salvage. Think of them as 'pre-owned burned in components' :-).

- Resistor assortment. A variety of resistor packs for digital termination.
- Potentiometers (variable resistors), assorted values.
- Capacitor assortment - ceramic and electrolytic. Large high voltage electrolytics for power supplies.
- Rectifiers - 1N4007s for primaries of power supplies. Microwave oven rectifier. Fast recovery rectifiers - for switching supplies.
- Diodes - 1N4148 signal diodes.
- Transistors (bipolar): small signal, medium power, high power audio, and horizontal output transistors. Obviously, this list could get quite long. A few basic types will suffice in a pinch.
- Fuses - 3AG size (1-1/4"x1/4") - .5, 1, 2, 3, 5, 10 amp. You can always solder these across the smaller 5x20 mm fuses often found in consumer equipment these days.
- LEDs and indicator lamps.
- Wire: assorted colors of #24, #18, and #14 stranded and solid insulated wire. 75 ohm coax for video. Shielded cable for audio. Fine wire (e.g., #30, bare and insulated) for PCB repairs.
- Assorted small switches - toggle, pushbutton, etc.
- Line cords, plugs, and other electrical components.
- Lamp sockets, single and three-way switch/sockets, plugs, etc. for small appliance repair.
- Various jacks and plugs such as RCA, phono, F, BNC, etc.
- Small loudspeakers, headphones.
- etc., etc., etc.

Mechanical Parts

- Hardware assortment including English machine screws and nuts, Metric machine screws (mostly for replacement use, and Metric nuts are rare), and flat and lock washers.

- Plastic split washer assortment. Despite dire warnings to the contrary, these can often be reused. However, they are easily lost.
- E-clip and C-clip assortment. These can be reused but very often go 'pling' into never-never land when removed.
- Spring assortment.
- Several thicknesses of steel wire.
- Various bits of plastic, wood, and metal to fabricate splints or other emergency repairs.
- Dial cord material.

Plastic Parts Repair

When a little plastic part breaks, repair can be a time consuming, frustrating, and ultimately futile task unless the failure was from abuse. The reason is that when a part breaks under normal operating conditions, the plastic gives way at the areas of maximum stress. Simply gluing the part won't work because the strength after the repair will probably not be as great as it was originally even if the proper adhesive is used.

Note that there are quite a variety of what we call "plastics". An adhesive that bonds with extreme strength to one may not even stick at all to another. (Nylon and polyethylene are difficult to glue; styrene is easy.) This is especially true of the 'welding' adhesives like MEK.

However, using the most appropriate glue can make a very significant difference:

- MEK (Methyl Ethyl Ketone) is the stuff in plastic solvent used for 'welding' styrenes. This results in a truly adequate repair only under very special conditions (which I've yet to encounter).
- Plastic model cement contains allyl Isothiocyanate (oil of mustard, huh?), and is good for styrene and acrylic plastics. Not recommended for polyethylene or phenolic plastics or for styrofoam (which it will eat).
- Duco Cement(tm) and similar all purpose glues are decent for many plastics including phenolics. Windshield sealer is similar but results in a semi-flexible repair.
- Tenex 7R is recommended for joining dissimilar plastics.
- SuperGlue(tm) and its clones (Cyano-acrylics) are only good on some plastics and only where the fracture is clean with a perfect fit upon reassembly. However, they are excellent for sticking thumbs to foreheads. :)

WARNING: The vapors from all of these adhesives are harmful to health if inhaled. Work only in a well ventilated area.

CAUTION: Spills from some of these will also damage paint and other plastic surfaces (including eyegless lenses!) even if wiped up immediately.

- RTV Silicon works well on a variety of plastics where a flexible repair is acceptable.
- Epoxies, wood glues, white Elmers glue, and library paste :) in general **do not** work well for plastics.

Where possible, I add reinforcement to plastic parts - either with plastic or metal. Or, fabricate all metal replacements. I've heard of people successfully adding bits of metal to replace plastic gear teeth. I have several clock radios with a mechanical clock where the little plastic pin in the number changing mechanism invariably broke after 5 years or so on all similar models. I replace them with a piece of steel wire (from a large paper clip) glued in place. This repair has worked for over 20 years. I bet the manufacturer saved a fraction of cent on each unit though! And, when someone forebly removed a paper jam on an HP DJ1000 printer and broke several pressure roller spring levers, stiff steel wire came to the rescue once again.

- Back to Troubleshooting Table of Contents.

Sources of Information and General Comments

This set of sections deals with ways of locating general electronics repair information as well as problem specific specifications, datasheets, manuals, and tech-tips. Since we first presented this set of topics several years ago, there have been two major trends which are worth noting, one good, one bad:

- The Internet, specifically the World Wide Web, has become THE preferred avenue for obtaining device datasheets and related information. While it may still be possible to obtain printed databooks, the convenience of typing in the part number to a search engine like Google and having its datasheet link appear almost instantly as one of the top 3 results cannot be overemphasized. This applies to virtually any widely used commercial discrete semiconductor or IC. Unfortunately, those with "house numbers" and more specialized ICs found in consumer electronics will probably not yield with this ease.

  For those of you without Web access at home or work, this may not sound like good news. However, libraries and other institutions are increasingly providing this service, and one can't hide from the future forever!

- The number and type of equipment that can be effectively and economically repaired is dwindling. VCRs, CD and DVD players, cell phones, pagers, and much other newer equipment is simply not designed to be repaired by anyone but the authorized service company - or not at all. Much A/V equipment is constructed so cheaply that it's lucky to last the warranty period. Compact high-tech devices are put together using surface-mount technology (SMT) and ICs that simply cannot be identified so anything beyond an obvious bad connection probably means it is junk. Absolutely NO service information is available in any form and the manufacturer, assuming they can be identified, couldn't care less about helping.

  PCs have been of this type for many years where anything beyond swapping modules is probably a futile exercise. Well, guess what? Devices lie digital set-top boxes, digital video recorders, video game consoles, and digital flat-screen TVs can be added to this list. Except, that they aren't going to use anything resembling standard modules like PCs still do to some extent. So, forget about achieving any significant success rate repairing this and similar equipment.

Manufacturer's Service Literature

Service manuals are still available for a great deal of consumer electronics. Once you have exhausted the obvious possibilities or mechanical problems, the cost may be well worth it. Depending on the type of equipment, these can range in price from $10 to 50 or more. Some are more useful than others. However, not all include the schematics so if you are hoping to repair an electronic problem try to check before buying.

Identifying OEM Manufacturer - FCC Numbers

Only a few manufacturers actually produce the vast majority of consumer electronic equipment. For example, Radio Shack, Magnavox, and Emerson do not make their own VCRs (I can tell you are not really surprised!). House brands are nearly always the products of well known manufacturers identical or very nearly identical to their standard models but repackaged or at least relabeled to reflect the store chain's name and logo. This is one reason why such lower cost products may be a good deal (but not always).

How do you determine the actual manufacturer? For most types of consumer electronic equipment, there is something called an 'FCC ID' or 'FCC number'. Any type of equipment that may produce RF interference or be affected by this is required to be registered with the FCC. This number can be used to identify the actual manufacturer of the equipment.

A cross reference and other links can be found at:

- FCC ID Numbers Cross Reference

Sams' Photofacts

Sams' (no relation) is Sams Technical Publishing (formerly Howard Sams & Company) who publishes circuit diagrams and service info for just about every TV sold on this planet since the 1940s.

Sams' Photofacts schematics and service literature are published by:

- Sams Technical Publishing

5436 W. 78th St.
Indianapolis, IN 46268-3910
Phone: 1-800-428-SAMS
Fax: 1-800-552-3910
Email customercare1@samswebsite.com or customercare2@samswebsite.com
Web: http://www.samswebsite.com/

You can search the Web site to determine if they have a folder for your model. Service info (EFacts) for most models manufactured after 1992 is available in electronic form (currently) about $11. These are similar to the print PhotoFacts but may be ordered on-line and will arrive via email within 1 business day.

These folders of service information have been published for over 45 years (I don't know for how long but I have a set for a 1949 portable 3 inch Pilot TV - about as portable as an office typewriter if you remember what one of those was like) and are generally the best most consistent source of service info for TVs, radios, some VCRs and other consumer electronics. There are some Computerfacts but the number of these is very limited. The VCRfacts are also somewhat limited and the newer ones tend to have strictly mechanical information.

Even if they don't list your model, they may have a folder for one using the same chassis so search by chassis number as well. Even if this doesn't help, there still may be a folder for models that are similar enough to be of value (though you really have to be in the library to be able to determine this by looking at the circuit diagrams or photos) so check out folders for other model numbers that are close to the one you really want.

Sams' Photofacts are often available (for photocopy costs) from you local large public library which may subscribe to the complete series. If not, a large electronic distributor can order the selected folder for you.

One advantage of the Sams' info is that it is compiled in a very consistent format so that once you are familiar with one model TV, it is easy to transfer that knowledge to any other. They provide waveforms at key locations and DC voltage measurements almost everywhere. Additional info such as IC pin to ground and coil resistances are often provided as well. The manufacturer's service manuals are generally not nearly as complete.

Note: I have heard that some of the Photofacts recently purchased directly from Sams Technical Publishing/Howard Sams have been poor photocopies with illegible scope waveforms rather than original printings. If this is the case, it is truly the end of an era and too bad. In any case, try to confirm the quality before you buy or get your info from the library.

Inside Cover of the Equipment

Television sets and even old radio often have some kind of circuit diagram pasted inside the back cover. In the old days, this was a complete schematic. Now, if one exists at all, it just shows part numbers and location for key components, occasionally some test points and voltages - still very useful. Some TVs - as late as 10 years ago, maybe even now - included a complete schematic with the product information and owner's manual. I have a 1984 Mitsubishi which came with a very nice high quality multi-page schematic. However, this is the very occasional exception rather than the rule anymore for A/V equipment.

Microwave ovens do almost always have a schematic diagram of the microwave power generation circuitry pasted inside the sheetmetal cover. This will generally include at least the high voltage transformer, interlocks, rectifier, capacitor, and magnetron. Since most microwave oven problems are in these areas, this is all you are likely to need. The controller, especially electronic units, is often omitted or only covered superficially.

Additional Sources for Service Information and Manuals

Where service information on your equipment isn't available as a Sams' Photofact (or even if it is), NAP is another possibility. They aren't that expensive, Maybe $25 for a set of 6 microfiches (well, you can't have everything!) that covers a variety of models including the one you are specifically interested. NAP's phone number for parts is 1-800-851-8885. They will look up your model in their database and identify the microfiche set(s).

As of Winter, 2002, I have confirmed that all the following Web sites for manuals and schematics are active. However, I have NOT checked email or snail mail addresses. Note that since these sorts of sites come and go, I'd advise downloading and archiving whatever you might possibly need when you find them - don't just save the links. You may be sorry later!

(From: William E. Miller (eagle@trader.com).)

Besides the used Sams TV Repair Manuals I sell, here are a few good sources for various flavors of service manuals.

- A.G. Tannenbaum
  Electronic Service Data
  P.O. Box 386, Ambler, PA 19002
  Phone: (215) 540-8055
  Fax: (215) 540-8327
  E-Mail: k2bn@agtannenbaum.com
  Web: http://www.agtannenbaum.com/

  "Parts and Service Data, 1920s to the present". Lotsa stuff!

- Michelle Troutman
  47 No. Bain Street, Brewer, ME 04412-2007
  Email: mtroutm@michelletroutman.com
  Web: http://www.michelletroutman.com/

  Sams Photofacts and service manuals for older TVs, stereos, and radios, as well as test equipment, vacuum tubes, electronics books, and magazines.

  (From: Mike Kaufman (makaufman@jps.net).)

  > "This is an excellent source for very reasonably priced repair manuals, especially out-of-date manuals,. Michelle's prices are on the order of $2.50 per manual plus $1.50 shipping - hard to beat."

- Marty Gasman
  Email: mgasman@tiac.net
  Web: http://www.tiac.net/users/mgasman

  He has a LOT of AUDIO service manuals for sale. Check his full list at his web site.

- Microtech - John Gallawa
  Email: microtech@gallawa.com
  Web: http://www.gallawa.com/microtech/

  "We will be happy to help anyone who needs a schematic or parts breakdown for virtually any make and model (commercial or residential) microwave oven."

- Mauritron Technical Services
  Phone: 01844-351694
  Email: mauritron@dial.pipex.com Web: http://dialspace.dial.pipex.com/mauritron/

  "Suppliers of Technical Books and Servicing Information to the television, video and computer repair trade"

- Manuals sometimes turn up at auctions - on-line (e.g., eBay) and others, as well as estate sales and the like, though these would hardly be regarded as a way of finding exactly what you want!

The U.S. Military has an extensive library of test equipment and related manuals, some of which are in the public domain:

(From: Dino (kl0s@cox.net).)

Go to: U.S. Army Logistics Support Activity. Select "Publications and Forms" which should get you to LOGSA Publications and Forums. Then select "Electronic Technical Manuals Online" which will roll you down to "Go to Electronic Technical Manuals Online". Click on this link which takes you to http://www.logsa.army.mil/etms/online.htm. If you accept their terms, click on "I accept" which takes you to http://www.logsa.army.mil/etms/welcom1.htm Choose "Enter the Site" [Note the disclaimer that you have to login if accessing anything but public release manuals and that you have to have 128 bit encryption engaged. That should bring you to: http://www.logsa.army.mil/etms/find_etm.cfm. which is the search page; click on "TM Title Text" and enter, for example, "Tektronix" and scroll down to hit "Search" which should get you to: http://www.logsa.army.mil/etms/show_etm.cfm where if you scroll down and look CAREFULLY you'll find lots of material in .PDF format which you can then download.

You may have to go through this entire process to establish the fact that you accept their terms. There's probably a cookie in my system that lets me go straight to the search page. I've found a number of good references here for text equipment.

Canadian Schematics Source

(From: John R. Hepburn (jhepburn@recorder.ca).)

I use a source in Canada for cheap schematics. I have to mention that they have limited coverage in the last while due to some O.E.M. holdbacks. There is nothing at all on monitors. It is:

- R.C.C. (Radio College of Canada)
  Lewcor Communications
  Phone: 1-416-971-4170
  Fax: 1-416-971-4173
  Email: lewcor@hookup.net

What they do cover is inexpensive, typically 5 schematics + data in one $19.50 manual ($14.00 U.S.). An example, I just received a manual the other day that I ordered to service a Sony VCR. It contained the following.

1. Citizen TV model JCTV-0204/JCTV-3097
2. Citizen VCR model JVHS-3931
3. Hitachi TV model CY07 C#G9LXU1M
4. Hitachi VCR model VT-M262A

5. Sony VCR models SLV-340/380/440/441

I suggest ordering their master index. They have 2 of them, pre-1973 and 1973 to present. You will need it for crossing anyway and it will give you a better idea what value their resources will be to you. Cost for an index is $5.00 (Can).

Reverse Engineered Schematics

A number of companies are in the business of generating schematics either from samples of the equipment or by 'other means' (which we won't go into). One such company that claims to have over 3,000 such schematics is:

- Bomarc Services
  P.O. Box 1113 Casper, Wyoming 82602
  Phone: 307-234-3488
  Email: rollo@trib.com
  Web: http://w3.trib.com/~rollo/bomcat.htm

I have no idea of their cost, reliability, quality, or accuracy but this type of source may be worth checking if you are desperate! One risk is that he wants $5 for catalogs of at most 3 categories from the following before you can order: audio, auto/air/marine, computer, detection, industrial, lighting, medical, phone, power supplies, radar, radio, security, tape/disk, telemetry, television, test equipment, time, toys & games, video, potpourri (misc).

Here is another company which has some reverse engineered schematics:

- Eagan Technical Services
  408 Northland Drive #304
  Mendota Heights, MN 55120
  Phone: 1-651-688-0098
  Web: http://www.eagantech.com/
  Email: dcarlson@eagantech.com

They have some PS/2 and other PC and monitor related schematics but not nearly the selections it would seem as Bomarc, above. I do not know anything more about this company.

Reverse Engineering Your Own Schematics

Of course, most of us have had need to reverse engineer equipment. This is probably not realistic for a multilayer PC mainboard. But for even something as complex as a TV or computer monitor, it may not be that difficult - and in some cases, the only option. I generally do this by going component by component and determining all connections to each one. The initial drawing will be a total mess - a spaghetti diagram. :) Once the wiring has been determined, I redraw the circuit (you've seen enough of them in these pages!). Everyone who does this more than once probably has their favorite technique to make the task easier.

(From: Jeff Zurkow (jeff@atrox.com).)

Here's a trick I'm using for reverse engineering: Put the board on a color photocopier, set the copier for "mirror image", and make a copy. This gets you a top view of the underside, as if the board were transparent. You can tape a piece of drafting mylar over the copy, and draw in the topside components and traces with colored pencils. In fact, I sometimes use multiple mylars: top traces on one, components on another, component values on a third, and a final one on which I check off components and solder joints as I draw them on the schematic. It helps to have a light box :)

The layered drawing can also serve as a component-location key for future troubleshooting. Just assign new component identifiers (the ones silk-screened on the board are often obscured by the components), and draw them in on both the mylar and the schematic. Makes it real easy go from the schematic back to the circuit board.

Mark's Approach to Finding Information

The first skill you need when you want to design something is digging up the databooks. This applies to troubleshooting and repair as well. A well stocked literature shelf (f cabinet) is an invaluable time saver. Don't assume you can get EVERYTHING on the net just yet!

Take the lowly 2N3055 power transistor, for example.... (Most of us have its specs engraved on some radiation-hardened neurons safely tucked away in a forgotten part of our brains but for the freshly minted EE or technician....

(From: Mark Zenier (mzenier@netcom.com).)

Places to look:

The web, at sites for companies that make power transistors.

Good bets would be Motorola (http://www.motorola.com/), Philips (http://www.semiconductors.philips.com/) Note: only 1 'L' in Philips, and SGS-Thomson (http://www.st.com/). (A whole bunch more people make 2N3055s, down to some little 50 employee companies that you've never heard of, but they may not have a web site yet). Or start with one of the web directories like http://www.xs4all.nl/~ganswijk/chipdir or Grey Creagers pages on http://www.scruznet.com/~gcreager. (Hope I got my spelling right on all those URLs).

The sales rep, sales office, or company literature department. Look in the phone book or on the web page for the phone number of a company or their local or regional sale representative or office. Call them up and ask. It's their job to provide customer support and if you sound like you halfway know what you're doing (saying you're a student works, too) AND it doesn't cost them much (don't get greedy) they'll often be more than willing to send you information. (These days, it might be a CD-ROM of their whole product line. Cheap, but not that easy to use, IMHO.) If they won't help you, ask them where there is someone who can. Like the nearest distributor.

Electronics distributors. Larger ones often fill the same literature distribution role as the sales rep. Other distributors like Jameco, JDR Microdevices, Future Active sell databooks as a catalog item. Or a local distributor that caters to the walk in trade will have a databook shelf and allow (or have a nominal fee for) photocopies. (The big distributors are closed operations, mostly using phone salesmen and UPS for distribution, visitors aren't necessarily welcome.)

A good library. Like one at a university with an electrical engineering program, or a large city library.

Used book stores, a big unselective 'book dump' often will have a good stock of old databooks. Ones that you can't get from the manufacturer and more. Likewise, electronics surplus stores (most big cities should still have one or two) often have them.

Parts Information and Cross References

I have found that one of the most useful single sources for information on semiconductors, especially for troubleshooting and repair, to be the ECG Semiconductors Master Replacement Guide. (ECG is now merged with NTE.) It used to be about $6 and may possibly be available for download free now from the NTE Web site (but it's huge). SK and others have similar manuals but NTE, especially with its acquisition of ECG, now appears to dominate the industry. The manual will enable you to look up U.S., foreign, and many manufacturer's 'house' numbers to identify device type, pinout, and other specifications.

Also see the section: House Numbers.

Here is the current Web site for NTE:

- NTE (NTE Electronics, Inc)

(From: Gregg (greggIns@ix.netcom.com).)

> "NTE's device numbers are the same as ECG's, and their cross-ref guide can be downloaded from http://www.nteinc.com/.
>
> It's free but they do want you to register. If you want to bypass this, go to ftp://nteinc.com/pub/ and download the windows version of the guide, ntesetup.exe. Don't bother with the dos version; the file named dosdisk2.exe is bad, and won't unzip."

I am not necessarily recommending using NTE (or other generic) replacements if the original replacements are (1) readily available and (2) reasonably priced. (Note that very often the original replacement part will be less expensive than the equivalent from NTE. Therefore, it should be used if available.) However, the cross reference can save countless hours searching through databooks, seaching the Web, or contacting the manufacturers. Even if you have a wall of databooks, this source is invaluable. However, there are a couple of caveats:

1. Some crosses have been known to be incorrect - the specifications of the generic replacement part were inferior to the original or totally wrong with different pinout or even function!

2. Don't assume that the specifications provided for the generic part are identical to the original. Since a single NTE part may replace multiple standard parts, it may actually be better in some ways. Thus, using one of these cross references to determine the specifications of the parts in your junk bin can be risky.

I often use the replacement guide to determine upper bound specs but as noted above, rarely buy any generic parts (sorry NTE). Then I find industry standard parts that have equal or better specs. Dalbani's catalog (see the section: Mail Order Parts Sources) has a sort of inverse cross-reference from NTE to 2S/2N/BU/whatever that isn't a bad starting point (though probably not to be trusted without confirmation of actual specs). Of course, this doesn't necessarily help with some tricky HOTs and choppers....

Note that while Howard Sams of Sams' Photofact fame publishes a semiconductor cross reference manual (or used to), it would appear to just be a compilation of the ECG, NTE, SK, and Radio Shack manuals - and much more expensive ($25 or so).

For standard ICs, IC Master can often provide quick access to complete data. Full access to their Web site is currently free but they do require registration. However, with their print version, ICs no longer manufactured were not listed. I assume the on-line version will be similar. Thus, it may be of only limited value for older equipment.

Transistor Designations

Unfortunately, there is no such thing as a universal part number!

- U.S. made semiconductors used to be mostly of the 'nN' variety - 2N with a 3 or 4 digit number for bipolar transistor, for example. This is called the Joint Electron Device Engineering Council (JEDEC) standard numbering but seems to have been replaced by letter prefixes which may be manufacturer dependent although the same part may be available from multiple sources. These numbers are becoming less common and are rare in consumer electronics.

    - 1N: diodes.
    - 2N, 3N: bipolar transistors.
    - 4N, 5N: optocouplers.

- Many devices in consumer electronic equipment are marked with a letter (A, B, C, D, F, J, K) and a 3 or 4 digit number. Add a '2S' in front of this and the result is likely to be the complete (Japanese) part number (the '2S' is nearly always absent from the package label). You can often use this number to find a suitable cross from NTE. However, most of the common '2S' devices are available from places like MCM Electronics and Dalbani.

    - 2SA, 2SB: PNP bipolar.
    - 2SC, 2SD: NPN bipolar.
    - 2SF: thyristor.
    - 2SJ, 2SK: FET/MOSFET.

    There are many other '2S' prefixes but these are by far the most common.

    Suffixes may denote package type or some special feature like an internal damper diode (D, for horizontal output deflection transistors), enhanced gain, special speed sort, etc.

    A cross reference of sorts is availabe at Transistors Japonais (French). Don't worry, the device numbers are the same in French and English. :)

- Less common are designations which look similar to the Japanese 2S numbers (a capital letter followed by a 3 or 4 digit number and optional suffix) but are actually Korean part numbers to which you add a 'KT' (Korean Transistor or Type?) instead of a '2S'. So D998 becomes KTD998. These components typically have a capital 'K' on top in addition to the part number starting with the letter (e.g., A,B,C,D). However, sometimes the only way you will know is that ordering the 2S version gets you a device that isn't even close (like a tiny TO92 small signal transistor rather than the 200 W, TO3 type you expected)!

There may be other examples but these are the exceptions (at least for now).

- Note that some components (usually ICs) may be labeled in a similar manner (like C4558C which is actually a dual op-amp) but this IS the complete part number - just something else to confuse you! Some of these such as one labeled C1003 may actually be a uPC1003 so if what you find in a datasheet doesn't make sense, try these other possibilities!

Aside from the VERY expensive D.A.T.A. semiconductor reference series (don't even ask), which includes virtually all types and flavors of devices, there are various Japanese Semiconductor Reference manuals available through places like MCM Electronics for around $20. Some of the text may be in Japanese but the relevant data is in English so these are handy if you want more detailed or precise specifications for these devices than provided by cross references such as NTE.

More on Transistor Designations

A common labeling scheme for MOSFETs consists of a 2 digit number followed by "N" or "P" followed by another 2 digit number: II T VV. This may be embedded in a much longer part number.

- II denotes the current rating in amps.
- T will be either N for N-channel or P for P-channel.
- VV denotes the D-S voltage rating in V/10.

(From: Mark Robinson (mark-r@snow_white.ee.man.ac.uk).)

We are lucky with transistors that, apart from a few oddities which I'll talk about later, most markings follow one of these codes. ICs are more tricky as you're often dealing with custom chips or mask programmed devices with manufacturers individual codes. A quick hint though: always look for known numbers (e.g., 723, 6502, 2764) etc. between the suffix and prefix, and beware of the date code.

Right... Back to transistors. The three standard transistor marking schemes are:

1. **Joint Electron Device Engineering Council (JEDEC).**

   These take the form:

   Digit, letter, serial number, [suffix]

   where the letter is always 'N'.

   The first digit is one less than the number of legs, (2 for transistors unless they're crippled although I'm not sure about 4 legged transistors maybe they get a 3) except for 4N and 5N which are reserved for optocouplers.

The serial number runs from 100 to 9999 and tell nothing about the transistor except its approximate time of introduction.

The (optional) suffix indicates the gain (hfe) group of the device:

A = low gain
B = medium gain
C = high gain
No suffix = ungrouped (any gain)

See the data sheet for the actual gain spread and groupings. The reason for gain grouping is that the low gain devices are fractionally cheaper than the high gain devices, resulting in savings for high volume users.

Examples: 2N3819, 2N2221A, 2N904.

2. **Japanese Industrial Standard (JIS).**

These take the form:

Digit, two letters, serial number, [suffix]

Again, the digit is one less than the number of legs.

The letters indicate the application area and flavour of the device according to the following code:

SA: PNP HF transistor
SB: PNP AF transistor
SC: NPN HF transistor
SD: NPN AF transistor
SE: Diodes
SF: Thyristors
SG: Gunn devices
SH: Unijunction transistor
SJ: P-channel FET/MOSFET
SK: N-channel FET/MOSFET
SM: Triac
SQ: LED
SR: Rectifier
SS: Signal diodes
ST: Avalanche diodes
SV: Varicaps
SZ: Zener diodes

The serial number runs from 10 to 9999.

The (optional) suffix indicates that the type is approved for use by various Japanese organizations.

NOTE. since the code for transistors always begins with 2S, it is sometimes (more often than not is seems) omitted so, for example, a 2SC733 would be marked C733.

Examples: 2SA1187, 2SB646, 2SC733.

3. **Pro-Electron.**

These take the form:

Two letters, [letter], serial number, [suffix]

The first letter indicates the material:

A = Ge
B = Si
C = GaAs
R = compound materials

Needless to say the biggest majority of transistors begin with a B.

The second letter indicates the device application:

A: Diode RF
B: Variac
C: Transistor, AF, small signal
D: Transistor, AF, power
E: Tunnel diode
F: transistor, HF, small signal
K: Hall effect device
L: Transistor, HF, power
N: Optocoupler
P: Radiation sensitive device
Q: Radiation producing device
R: Thyristor, Low power
T: Thyristor, Power
U: Transistor, power, switching
Y: Rectifier
Z: Zener, or voltage regulator diode

The third letter indicates that the device is intended for industrial or professional rather than commercial applications. It is usually a W,X,Y or Z.

The serial number runs from 100-9999.

The suffix indicates the gain grouping, as for JEDEC.

Examples: BC108A, BAW68, BF239, BFY51.

Apart from JEDEC, JIS and Pro-electron, manufacturers often introduce their own types, for commercial reasons (ie to get their name into the code) or to emphasize that the range belongs to a specialist application.

Some common brand specific prefixes are:

MJ: Motorola power, metal case
MJE: Motorola power, plastic case
MPS: Motorola low power, plastic case
MRF: Motorola HF, VHF and microwave transistor
RCA: RCA
RCS: RCS
TIP: Texas Instruments power transistor (plastic case)
TIPL: TI planar power transistor
TIS: TI small signal transistor (plastic case)
ZT: Ferranti
ZTX: Ferranti

Examples: ZTX302, TIP31A, MJE3055, TIS43.

Many manufacturers also make custom parts for large volume OEM use. These parts are optimized for use in a given part of a given circuit. They usually just have a manufacturers stamp and an untraceable number. Often when a company goes bankrupt, or has surplus at the end of a production run, these transistors find their way into hobbyist bargain packs. There is no way that you can trace data on these devices, so they are only suitable as LED drivers, buffers, etc, where the actual parameters are not important. Check carefully before buying.

Once you have identified your part, a trip to the data sheet or equivalents book is called for (anyone know of an on-line equivalents list?).

Surface Mount Parts

Due to their small size, very little information is printed on the actual package for diodes, transistors, capacitors, and other discrete devices.

- Resistors are often labeled with 3 or 4 itty-bitty digits where the last one is the multiplier (10 to the Nth power).

- Capacitors are often totally unlabeled but larger electrolytics may have both capacitance and voltage rating. Non-electrolytic types often have a brown body. Electrolytics may be black, yellow (tantalum), or some other color.

- Discrete semiconductors can often be identified by the number of pins using an ohmmeter at least in a rough sort of way. However, the only way to determine their specifications (and often even the type) or to find a cross reference for the abbreviated markings like 1A, B2, 2J, is to look them up since there is no logical relationship between the marking and the actual part number (unlike the 2S discrete parts, for example). This can be done if you have the manufacturers databooks or possibly even their abbreviated catalog (e.g., Motorola's "Master Semiconductor Selection Guide". NTE does cross a few of these SMT parts but their coverage is not nearly as comprehensive as for normal (through-hole) counterparts.

  The Web sites of semiconductor manufacturers may also have some information but this varies widely from company to company.

  There is an on-line list at:

  - Surface Mount (SMD) Transistors/Diode FAQ

  This is also somewhat incomplete. And, a very nice one at:

  - The SMD Code Book

  There used to be SMT marking codes info at:

  - Siemans Semiconductors

  However, since the semiconductor division changed their name to Infineon, I haven't been able to locate the page if it exists.

- ICs. The only option for many of these is to locate the databook or Web site with the datasheet. Even if the part number is similar to a through-hole version, the pinout may differ. However, common TTL/logic chips and op-amps will usually have identical pinouts and specifications. It is often possible to partially confirm this by checking the location of the power pins or known signal connections.

House Numbers

These are the cryptic numbering like 121-1025 or 113234 that may be the only marking on that critical part you need to replace or identify.

Are house numbers used just to make life difficult?

It certainly seems that way from the perspective of repair. Give me industry standard numbers anyday. However, house numbers are a fact of life.

The house number is what you need to order a replacement from the original manufacturer of the equipment but that may not always be desirable due to the likely high cost and possible difficulty in locating a suitable distributor that carries the manufacturer's replacement parts.

As noted in the section: "Parts information and cross references", a Master Selection Guide like NTE may be able to give you some idea of the specifications even if you don't want to use their generic replacement semiconductors. Their web sites have (or should have in the future) some amount of cross reference information for industry standard and house numbers. However, don't expect to detailed IC specifications or even pinouts in most cases there or from the disks they may also offer. The hard-copy Master Selection Guides which these companies sell have been better in the past (though this may be changing) but even these won't give you all the details. However, if you do repair work regularly, these 'telephone book' thickness guides worth the few bucks that is charged.

Also see the section: Parts Information and Cross References.

Generic Parts (Mostly Semiconductors)

NTE (which now includes ECG) offers an extensive selection of discrete devices and integrated circuits which are replacements for thousands of industry standard as well an house numbered semiconductors. Should you consider them? My general feeling is: not unless you have to. They are often more expensive than the parts they replace and quality is not always quite as high as an original standard part. However, in most cases, these parts will work just fine.

Other common components including flyback transformers, belts and other rubber parts, and RF modulators may also be available from these sources but they tend to be used less often and quality may vary even more.

There are some other similar companies like SK (part of Thomson Consumer Electronics) but NTE now appears to dominate the industry for these generic replacement semiconductor and other electronics components.

HP-to-Industry Standard Semiconductor Cross Reference

(From: Walter Shawlee 2 (walter2@sphere.bc.ca).)

This will help decode all those odd 1820-xxx numbers!

http://www.sphere.bc.ca/test

Also HP and Tek repair parts and equipment on line, plus helpful FAQs and links to all kinds of test gear sites.

We also have a big used equipment site on line for Canadians.

Internet Sources of Information

Most manufacturers of electronic equipment are now providing info via the World Wide Web. The answer to you question may be a mouse click away. Perform a net search or just try to guess the manufacturer's home page address. The most obvious is often correct. It will usually be of the form "http://www.xxx.com" where xxx is the manufacturers' name, abbreviation, or acronym. For example, Hewlett Packard is hp, Sun Microsystems is sun, Western Digital Corp. is wdc. It is amazing what is appearing freely accessible via the WWW. For example, disk drive manufacturers often have product information including detailed specifications as well as complete jumper and switch settings for all current and older harddrives.

Tandy (Radio Shack) has a nice web resource and fax-back service. This is mostly for their equipment but some of it applies to other brands and there are diagrams which may be useful for other manufacturers' VCRs, TVs, CD players, camcorders, remote controls, and other devices. The Tandy Product Support Page has links to each type of equipment.

In addition to Tandy products, there are a couple Sony models. Furthermore, since Tandy does not manufacture its own TVs, VCRs or camcorders - they are other brands with Realistic or other Radio Shack logos - your model may actually be covered. It may just take a little searching to find it.

Are There Schematics of Consumer Electronic Equipment on the Web?

Well, yes and no.

You are searching for the Holy Grail. Everyone is, but it isn't going to happen on a large scale - at least not for free. Schematics are copyrighted by the equipment manufacturers who sell them as part of their service manuals or license them to organizations like Sams Technical Publishing (Sams' Photofacts) and others.

- If you reverse engineer - trace - the schematic of a piece of equipment from the unit itself - and can prove it - and then make it available at your Web site, that is probably legal. You'll have a hard time proving it though for something like a TV or VCR.

- However, if you scan a service manual or Sams' Photofact and make that available at your web site, you may eventually find yourself in court. For schematics from original service literature of obsolete equipment, the chances of the manufacturer wanting to spend a lot of money on lawyers is small but for newer equipment, they may indeed - or just to make an example at your expense. A scanned Photofact is likely to be a problem regardless of age.

That is my take, at least.

Having said that, there are many Web sites with schematics that may or may not have been legally copied and made publicly available. See the section: Additional Sources for Service Information and Manuals.

Taking the Unit to a Repair Shop

As with medical problems, an accurate diagnosis can only be made with good complete information. Use your senses to their fullest. If you do decide to have the unit professionally repaired - and depending on your level of experience and confidence, this may be the wisest choice - the more complete your description of the problem the easier (and cheaper) it will be to locate the problem. Include functional behavior or lack thereof, mechanical and electronic sounds it makes, anything that is related at all to the operation of the unit. Sometimes seemingly unrelated factors can be important. For example, the fact that your officemate rearranged their desk and you monitor's image is now shaking. Don't omit anything - even what you feel is inconsequential - leave that judgement to the repair person. Also, what may have changed in your setup, did you move the equipment recently or add a component? What about your cable connections? Did you rearrange the furniture? When was the last time you know it worked properly? What were you trying to do at the time of the failure?

To paraphrase a famous quote: 'The only stupid or useless information is that which is not provided'. However, unless you really are sure of what you are talking about, don't try to tell the repair person what you think the problem is likely to be. Don't bombard them with technobabble full of buzzwords - any competent tech will see right through that. You can be sure that if you mention that you suspect the expensive flyback is toast, it will be diagnosed as bad. Let them do their job. Listen carefully to their diagnosis. You should be able to tell if it makes sense.

Searching for Information from USENET Newsgroups

USENET newsgroups are on-line bulletin boards or discussion groups that cater to every interest from soup to nuts and beyond. There are over 20,000 active newsgroups in existence though for our purposes one is of most interest: sci.electronics.repair.

There is an excellent chance that your question has come up and resulted in information being passed back and forth on sci.electronics.repair (or other appropriate newsgroup). For example, if you have had problems with a late model RCA/GE television, there have been dozens if not hundreds of postings on this subject over the last couple of years. There is no need to add to the clutter.

Google Groups (formerly Deja.com/DejaNews) includes a USENET newsgroup searching facility. It has been archiving newsgroup articles since March, 1995. By going to their web site, you can invoke a search of over 45,000 newsgroups (hundreds of GB of data!) for any set of words, names, or email addresses. Within *seconds*, they will provide a list of postings that satisfy your search criteria. Try using Google Groups at least once - you will be instantly hooked. :(Some of the relevant site URLs are:

- Google Groups Homepage
- Usenet Advanced Search

Specifically for the sci.electronics.repair newsgroup:

- Articles on Sci.Electronics.Repair

This results in listing of threads by date. However, going through the Search page provides many many options to locate specific articles relevant to your problem or just your curiosity.

While postings typically drop off of your local server in a few days or less, Googlegroups maintains them *forever* so that locating an entire thread becomes a trivial exercise in identifying a search string that will narrow down the postings to those relevant to your needs.

There are many other services available via Google Groups including newsgroup posting (under constructio apparently during the transition from Deja.com).

Speaking of posting:

Posting to the Sci.Electronics.Repair Newsgroup

This is a bit different than attempting to tell the tech at a repair shop how to do their job - speculation is safer. There is enough cross- checking such that any gross errors in analysis will be uncovered. There is also generally no profit motive. If your speculation is totally bogus, you will find out quickly enough, turn various shades of red - and learn from the responses.

Even if your ISP doesn't provide USENET newsgroups or allow posting for some reason, you can always access them (read, search, and post) via Google Groups. See the section: Searching for Information from USENET Newsgroups.

No matter how you do it, however, here are some tips that will get you what you want without unnecessary flame wars:

- Please read the on-line repair FAQs or repair guides first. Your problem may be covered. Even if an exact solution is not provided there, the additional information may allow you to ask your questions more concisely and intelligently and therefore arrive at a solution more quickly.

  The FAQs can be found at:

  - Sci.Electronics.Repair FAQ (RepairFAQ.org)

  and its mirror sites. First read the README and Mirrors links to identify the best way for you to access the information from your location.

- Put the type of device (i.e., VCR, CD player), manufacturer, and model number in the subject header as this will get the attention of the professionals. If you do not provide this info, the first reply you will receive will be to provide it. Avoid this waste of Net bandwidth. For general questions, such info may be unnecessary, but it will not hurt.

- As with professional repairs, provide as much relevant information as possible. Ambiguity can lead to totally bogus advice. For part identification, include both the designator (e.g., R324, Q1) and type (e.g., 330K, BU407D) if available.

- Don't just ask for repair tips - describe in chronological order what you have done so far in terms of troubleshooting approach and tests performed but don't fill screen upon screen with details. People don't want to read a lot of filler. Include only the essentials.

- Turn off any fancy formatting like HTML or WORD! Use plain ASCII text since everyone can read that, formatting adds NOTHING to the content, takes up space, and is very confusing for those people whose news readers cannot interpret it.

- Take a bit of time to make sure what you have typed is legible. Spell checking it won't hurt. DO NOT use ALL CAPS - that is like shouting in cyberspace and a good way to be ignored.

- A bit of courtesy won't hurt as well. Many people who reply won't care about the use of *please*, *thank you*, and *any help much appreciated*, but none of these will hurt and don't take much effort.

- If a little circuit diagram will help, provide it in ASCII if possible. ASCII takes up almost no space and everyone (with a fixed width font) can read it. Here are some basic guidelines for creating legible ASCII schematics:

1. Use a fixed-width font like Courier, Lucida Console, Quick Type Mono, etc.
2. Make sure your line length is set to 78 characters or less.
3. Use SPACES rather than TABs - TABs interpret differently depending on terminal or newsreader settings and the alignment gets messed up when text is included in a news posting.

For numerous examples of ASCII schematics that should look fine, see: Various Schematics and Diagrams.

Large binary files are not supposed to be posted on these newsgroups. In addition, you will upset people who are forced to download a 1 MB file they have no interest in but may not know it until they see the description. Some ISPs charge for connect time and bits transferred. If you have a large scanned schematic and you think it really will help with a diagnosis of or solution to your problem, offer it via email, upload it to your Web site, or post it to the newsgroup: alt.binaries.schematics.electronic (but not all news servers carry this group).

- You need to be patient. Not everyone sits at their computers all day. Some news servers may be days behind in their postings. If you truly get no replies of any kind (to the newsgroup or email) in a few days, repost your question with a note that it is a repeat. The net isn't perfect and due to finite disk space, many servers will miss postings or purge them after a day or less. Sometimes, your posting may not have made it out of the bowels of your computer system. You should be able to check this via - see below.

- Don't ask for help on 25 problems in the same posting - that is taking advantage of the generosity and time of others. Dribble them out and reciprocate by replying to other people's problems as well if you can but not to just say something. If you act immature, you will end up in everyone's kill file.

- Don't ask for help on problems that you could just as easily solve on your own by checking a databook you should have or a Web site that you should know about.

- Don't ask for an email response. First of all, it is very impolite. Sci.electronics.repair was not created for your benefit. We do this because we like to help people but at the same time do not want to feel like we are being taken advantage of or taken for granted. We are not your private consulting service. In addition, others will know when an adequate response to your query has been provided and will not need to waste their time repeating the same information. And, everyone will learn something in the process.

  More importantly for you, receiving replies via email will circumvent one of the most important functions of the newsgroup - cross-checking to locate errors in responses either because the responder didn't know what they were talking about or made an error in interpretation. Perhaps, they were just being a bozo and sent a totally bogus or even dangerous response. And, some people may have hidden agendas that aren't in your best interests. If that was the only reply, you would never know. While there is a lot of high quality information available via the Internet, there is also a lot of noise. Yes, you will need to read the newsgroup for a few days. That will be a small sacrifice and well worth the effort.

  If your news feed is indeed poor - as many are - and you are honestly afraid of missing the responses, then phrase your request for an email reply in such a way that it doesn't sound like you are totally immature and lazy.

Another alternative is to search for replies at:

  - Google Groups (formerly Deja.com/Dejanews.)

This service will enable you to search for only the postings you are interested in and seems to be pretty reliable. They subscribe to a half dozen news feeds just to avoid missing *your* postings!

Many people will send you a CC of their posting anyhow so avoid getting flamed for poor netiquette. However, take note below.

- Use your true full name and email address in the 'Reply-to' field of your posting. It is unreasonable to expect us to reformat a bogus email address that you might use to avoid SPAM. It is quite annoying to try to help people only to receive bounced mail. While the 'delete' key works quite well in dumping the returned message, you don't get your questions answered. The regulars on the sci.electronics.xxx newsgroup hierarchy all use their real names and email addresses. Please do us a favor by being mature and do the same. Spammers lurking around these sci newsgroups get pummeled anyhow and don't survive for long. :-)

- Don't accept the first response as the definitive word. Gather a few replies and followups and then you will be able to make an evaluation of which to believe and act upon. Post a question for clarification, if needed.

- If you do receive email responses, reply to the senders as well as posting to the newsgroup *and* indicate to the senders that you are posting a copy to the newsgroup.

  It is very annoying to reply via email only to find that the same question appears a little later on the newsgroup requiring a repeat response.

  In any case, once your problem has been resolved (or you have given up), it is polite to post a concise summary of the problem, suggestions, the solution or frustration, and appreciation to those who have helped you.

Private Discussion Groups and Email Listservers

In addition to USENET newsgroups, there are a number of private bulletin boards (may also be called forums) on repair related topics. These are accessible via the Web rather than through a News server. New ones come and old ones disappear regularly. :) I personally see little point in using these - traffic is usually very low, and the experts all hang out on the relevant USENET newsgroups anyhow! And, very often the private ones are related to a commercial enterprise as (1) you don't know how whether the replies are slanted toward selling something in some cases and (2) there is often objectionable (at least in my opinion) advertising on the site.

There are also a few repair related email listservers. These require that you subscribe by sending a special email message and/or filling out a form. Some may have merit in that experts are more likely to be subscribers and they are forced to at least receive all emails (even the next stop is the bit bucket!).

Sorry, given the relatively low interest in both private discussion groups and email listservers, I can't justify attempting to keep up with their arrivals and departures! :) Both of these can be found through the various tech-tips sites as well as by searching postings on the Sci.Electronics.Repair Newsgroup via Deja.com. A few may also be listed in my Bookmark File.

Having said that, popular services like Yahoo often host at least a few niche discussion groups that simply due to the number of users, have a volume of traffic worth noting. For example, go to Yahoo Groups and search for "Tektronix". Two groups for Tektronix oscilloscopes will pop up, one for general postings and the other for documentation like schematics.

Dealing with a Repair Shop in an Efficient and Professional manner

When all else fails and you are forced to admit defeat.... OK, I'll try that again: Should you end up taking the equipment to someone else for service, here are some tips for getting it fixed with minimal hassle.

(From: Rex (bopeep@prysm.net).)

I have been asked to give tips for dealing with repair shops. It is sometimes difficult for the average consumer to convey their needs to shops or technicians.

- Limit the scope of the problem to the actual problem you are having with your product.

  Avoid getting into dialog about children, grandchildren, holidays, bad mouthing other shops or manufactures, "I can get a new one for that", vacations, school functions, how seldom you have used the product or anything that that has nothing to do with you product's failure.

- Ask for an ESTIMATE, but realize that an ESTIMATE can and MAY be raised or lowered. You MUST be advised of any change to the estimate before you are billed for a unapproved amount.

- Avoid GUILT, RUSH (unless you are willing to pay for it), and pressure to the shop. Be polite and EXPECT to be treated politely and you should be given the respect that any business should give their customers.

- If the repair does not meet your standards:

  - Ask for and expect, that something will be done as quickly as possible.

  - If the shop fails in its obligation to you, call the BBB, consumer affairs agencies or any other place that can help you resolve the problem if the shop refuses to honor its warranty.

    CAUTION: Be VERY sure what the warranty is. Most repairs are covered for the work done, not the entire operation of the product. Read the shop warranty and ASK questions.

  - Do NOT expect a shop to clean up or repair problems from other repair attempts (including your own), or to be able to repair a product that has be abused.

* Back to Troubleshooting Table of Contents.

Parts Sources

Where to Go for Parts

Large electronics distributors like Allied, Digikey, Mouser, Newark, and others stock tens of thousands of types of electronic components. Even Radio Shack can be used in a pinch.

However, none of these places have even the most basic service parts for consumer electronic equipment. You won't find a single rubber belt, RF modulator, posistor, or video head, nor most Japanese semiconductors within their thick catalogs.

It may be possible to go direct to the manufacturer of the equipment but expect to spend many times the true price of a part to get it from the horses mouth. In most cases, a totally identical part - with the manufacturer's logo and everything - meeting identical specifications is available elsewhere at a fraction of this cost.

Web Parts Information and Ordering

Many manufacturers are now providing a great deal of *useful* information on the Web. For example, Panasonic has a web site you can enter your model number and get a parts list with list prices and part descriptions:

* Panasonic Parts & Service Online

This site includes support for Panasonic, Technics, and Quasar consumer electronics. However, my quick visit only showed accessory type items (e.g., replacement original remote controls, cables, etc.). Encrypted credit card protection presumably makes it possible to order parts directly.

Mail Order Parts Sources

See the document: "Major Service Parts Suppliers" for some companies that I have used in the past and others that have been recommended. (These lists have now been consolidated into that document.)

And, Don't Forget Radio Shack

Radio Shack may be the most abused chain on the sci.electronics.xxx newsgroup hierarchy but they ARE good when it is after business hours for your normal distributors, you need a resistor or capacitor, and just have to have it NOW!

In addition, Tandy, the parent company of Radio Shack is worldwide and may actually offer a USEFUL selection of components:

(From Ted Gondert (vcrepair@bbs.industrynet.net).)

Tandy (aka Radio Shack) has a new catalog available at your local Radio Shack; "Tech America" "Your Electronics Resource". This is special mail order catalog with many parts available from a different division of Tandy. There is no minimum order and parts are sent directly to your house. Shipping is $4.00 for components orders only or various rates up to $13 for orders of $500.

Call 1-800-877-0072 between 7 a.m. to 11 p.m. M-F Central Time, 9 a.m. to 8 p.m. Saturday, 11 a.m. to 7 p.m. Sunday. Fax 1 800 813-0087. Mail: Tech America, PO BOX 1981 Fort Worth, Texas 76101-1981.

This catalog, Sept 1997 has 546 pages with capacitors, resistors, transistors, IC, coils, wires, antennas, test equipment, tools, radios, security equipment, books, etc.

The capacitors include high temperature, 105C electrolytics. The integrated circuits and transistors are mostly American type part numbers, digital, op-amps, etc. not the Japanese type used in most consumer electronics today. But should be many parts that electronics techs can use.

For example; 1000ufd 16 volt 105C electrolytic capacitor is only 39 cents. (pg 14) That's popular size in use in Panasonic SMPS. Also has MJ15024 audio output transistor for $4.59 (pg 49) and surface mount transistors.

Radio Shack also has catalogs in stores for RSU, Radio Shack Unlimited. Those show Japanese semiconductors, special batteries, phono stylus, equipment, etc. that your local Radio Shack can order.

(I haven't ordered anything yet but after checking my inventory and budget will probably stock up on some capacitors, etc. Get most of my parts from MCM, MAT Electronics, etc and some local distributors.)

- Back to Troubleshooting Table of Contents.

Troubleshooting of Intermittent Problems

These are the ones everyone dreads - equipment that is tempermental, working or not working apparently depending only on its own mood. Behavior may appear to be totally random but in most cases, there will be some correlation with physical, environmental, or external interference. Careful observation and perhaps a bit of detective work will ultimately allow a repair to be successful. Troubleshooting such problems is a primary cause of hair loss in engineers and technicians. :) However, with a methodical approach and patience, it should be possible to identify the cause and repair misbehaving equipment. Here are some examples of intermittent problems:

- A computer monitor that erratically loses one of its primary colors (red, green, or blue).

- TV reception that turns to slow and then returns to normal apparently at random. Or one that turns itself on at maximum volume in the middle of the night.

- A car radio or tape deck that misbehaves on rough roads.
- A TV that turns itself on in the middle of the night.
- A CD player that is prone to aborting or skipping at random times
- A microwave oven that blows its main fuse once in 10 days.
- A TV that exhibits annoying herringbone patterns at certain times of day.

This section deals mostly with TVs and monitors since they appear to be most prone to these sorts of problems. This is partially due to the higher power levels and associated heat generation inside of them, and partially due to the cost pressures which result in manufacturing quality control problems. Other equipment like VCRs and CD players also may suffer from intermittent behavior, but it is usually not due to bad soldering (though there are exceptions) but rather due to mechanical problems or dirty or worn internal position sensing switch contacts.

TV and Monitor Manufacturing Quality and Cold Solder Joints

Low cost no-name (or unknown name) computer monitors tend to be particularly prone to bad solder connections. However, so are many models of name brand TVs including those from RCA/GE/Proscan and Sony. We'll touch on these at the end of this article.

Any intermittent problems with monitors that cause random sudden changes in the picture brightness, color, size, or position are often a result of bad connections. Strategically placed bad connections can also cause parts to blow. For example, a bad connection to the SCR anode in a phase controlled power supply can result in all the current passing through the startup resistor, blowing it as well as other components. I had a TV like this - the real problem was a bad solder joint at a pin on the flyback. Thus, erratic problems, especially where they are power or deflection related, should not be ignored!

Bad solder joints are very common in TVs and monitors due both to poor quality manufacturing as well as to deterioration of the solder bond after numerous thermal cycles and components running at high temperature. Without knowing anything about the circuitry, it is usually possible to cure these problems by locating all bad solder connections and cleaning and reseating internal connectors. The term 'cold solder joint' strictly refers to a solder connection that was either not heated enough during manufacturing, was cooled too quickly, or where part pins were moved before the solder had a chance to solidify. A similar situation can develop over time with thermal cycling where parts are not properly fastened and are essentially being held in by the solder alone. Both situations are most common with the pins of large components like transformers, power transistors and power resistors, and large connectors. The pins of the components have a large thermal mass and may not get hot enough during manufacturing. Also, they are relatively massive and may flex the connection due to vibration or thermal expansion and contraction.

Why Can't TV Manufacturers Learn to Solder Properly?

I can think of several potential reasons - all solvable but at higher manufacturing cost.

1. Mass of large component leads (like shields) does not get adequately heated during manufacture leading

to latent cold solder joints. While they may look OK, the solder never actually 'wetted' the heavy pins and therefore did not form a good mechanical or electrical bond.

2. Thermal cycles and differential thermal coefficients of circuit boards, traces, and solder. While it is not easy to do anything about the material properties, using plated through-holes or a similar mechanical via would greatly increase the surface area of the joint and prevent the formation of cracks.

3. Vibration. This is also directly related to the single sided circuit boards without plated through-holes to strengthen the joints.

4. Lack of adequate mechanical support (single sided circuit boards without plated through-holes (vias).

I believe that the single most significantimprovement would come about by using plated through-holes but this would add to the cost and apparently the consumer is not willing to pay more for better quality and reliability! Some designs have used rivlets - mechanical vias instead of plated ones. While this is good in principle, the execution has often been flawed where cold solder joints resulted between the rivlets and the circuit board traces due to lack of adequate process control.

The Sony and RCA/GE tuner shield problem is interesting because this could have been solved years ago at essentially no additional cost as other manufacturers - and their own repair procedures - have proven.

Attacking intermittents

First, determine whether the problem is internal or external.

The most common external causes would be electro-magnetic interference, either through the air or via the power line. For more on these in particalur, see information on interference in the documents on TV and monitor repair. But, suffice it to say, changing the location or electrical power source will usually help to narrow it down.

If internal, it may be physical, heat related, or mode related. Gentle whacking (yes, whacking is an acceptable diagnostic technique but don't go for the 12 pound hammer!), pressing, flexing, cable wiggling, etc., can and should be used in an attempt to confirm at least that there is a physical cause inside the unit. Doing these tests just as the problem comes or goes is the best time as whatever is marginal, will be most marginal then.

If the problem appears or disappears, or does both, over a period of time after the equipment is turned on, then temperature is almost certainly a factor as the circuit board and components expand.

The most common physical problems are bad (cold) solder joints, connectors that need to be cleaned and reseated, and bad cables or cable connections. Perhaps surprisingly, though components may fail internally and result in erratic behavior, this is probably lower on the list of likely causes than those listed above. Some exceptions would be mechanical relays in audio power amplifiers, phone equipment, and elsewhere; hybrid power amplifiers, and other power devices.

The whacking, etc., can be done without taking the cover off the equipment and may or may not reveal anything. In either case, you will have to go inside. But if there is an effect, then you will know that the problem IS inside and further tests will need to be done to identify the specific cause.

Once the cover is off, there still may be quite a challenge to find the specific solder connection or contact that needs attention. Knowing something about how the actual circuit area relates to the symptoms will help narrow it down. For example, if there is a loss of vertical deflection in a TV or computer monitor, the most likely areas to attack will be the vertical deflection output stage and its power supply feed.

For popular consumer electronic equipment, intermittent problems are often present in many (or even most) samples of a particular model over the course of its life. Therefore, checking a tech-tips database or asking on the USENET newsgroup sci.electronics.repair may reveal a common cause and an easy solution ("resolder the flyback pins"). There are a list of tech-tips databases at my Web site, www.repairfaq.org.

(From: Phil Buble N1GTZ (muttnik@ecr.net).)

A note on whacking as a troubleshooting technique, at home and in the shop.

I'm not what you would call a full time electronic repairman though I have made a living doing it commercially. I can be just helping a friend out at home but usually it's been an adjunct to my main work as assembler/post flow touch-up and I'm pretty good at it. Therefore most of my repair experience is with new equipment that doesn't work correctly the very first time it's powered on. (and yes when *will* that wave-solder machine learn to solder? :) Running that thing is a art-form I'm glad to avoid)

Naturally in such a situation I'm a great believer in "swap-out with NGP testing" since there's usually lots of them in an assembly shop but this cannot always be easily done. Especially at home, with obsolete units or those so small or cheaply made not a vacuum tube, IC or module is to be found in a socket. My funniest experiences with whacking regard these - one commercially and one at home. The commercial one first:

It involved a totally obsolete and smallish sensor board used in the ground-water monitoring industry to measure water pH deep down in wells. Even carefully sealed you can imagine the condition it was in after years of hard use. Only a few had ever been made by the company long before and the engineer who designed it equally long gone. A young, recently hired engineer was given the task of finding out what was wrong. It was giving rather useless and erratic readings and needed to be repaired in a hurry. I cleaned it and reflowed all joints, just in case, then turned it over to him since it still didn't work. After hours of frustration and attempts to get "into the head of the designer" he gave up and I asked to give it a try. By then I had a hunch. I made a routine test to make sure all was getting power - then gave the PCB a whack and a little twisting action. It began working perfectly as long as the PCB had a slight twist to the right. This literally took me all of about 5 minutes. You have never seen such a dumb-founded engineer! They do need to get out more! Even with the failure mode detected the cracked trace could not be found in a reasonable time so I had the honor of transferring all the parts to a new PCB. Amazing they even had one.

The second funny situation occurred many years before the above and happened at home. A neighbor brought over a old (even for the time) but nice condition 19" tube-type B/W TV hoping I could fix it. Fully half this set was point-to-point wiring, no PCBs at all. I'm old enough to have one foot in the all tube and "condenser" era and one foot in the transistorized world so it didn't matter to me that it was tubes. As long as my friends are willing to pay for the parts and hopefully locate a schematic I'm willing to at least try. It's all done in a casual sort of way. (Side note: You'll have to pry my Heathkit AA-100 Vacuum Tube Stereo Amp from my cold dead hands, it still sounds great 41 years after it was built)

This one located the Sam's Photofacts for it, complete with schematic and pin voltages. A resistor in the B+ line to the plate of the Horizontal output tube had burned out. That was replaced and all DC pin voltages then looked OK - yet no picture. Sure, the H Oscillator wasn't oscillating! The next logical thing to do was to swap-out the H output tube with another to see what happened. I told my neighbor we needed to locate a tube, and a rather expensive one, to go any further. He didn't bother, it wasn't worth the effort or expense. 5 *YEARS* later he trots out that same TV hoping, once again, I could get it to work. I tell him we still needed that tube. He shrugs, plugs it in, turns it on and gives it a good whack. It came on and worked perfectly! That's all it needed all along, my power-supply repair had fixed it 5 years before but no one ever whacked it to get it started again.

Selective circuit whacking's been one of my most productive and time saving

Inspection and Power Off Tests for Intermittents

Assuming these don't help (or you consider letting someone else solve your problem to be cheating), a detailed visual inspection is the next step. This may be all it takes. With the unit unplugged) and after confirming that power supply capacitors are discharged!), remove the cover.

- Start with the pins on devices like power transistors, transformers, and large or high current connectors. These are most likely to cause marginal solder connections to break apart due to thermal and physical stress. Hairline cracks at solder joints is a primary cause of intermittents, especially in TVs and monitors with their power supply, deflection, and video circuitry that may run hot.

  Make the inspection under a bright light. If your closeup vision isn't perfect, use a good magnifier - these may literally be hairline cracks and their visibility may be obscured by reflections from the solder joint. Use a pointed stick (not something metal if possible) to gently prod any suspicious looking pins to see if they move. Look for discolored patches on the circuit board. Such discoloration isn't in itself a problem unless it is severe but indicates that hot components live there or nearby and bad solder joints are very likely.

- Check for tan or brown glue on the top and bottom of the circuit boards. A rigid adhesive may be used to attach various components but some varieties decompose and become conductive with heat and age. Some very weird problems have been linked to decayed glue! So, carefully scraping it away and replacing it with non-acidic RTV Silicone or similar adhesive may be prudent. However, I don't know how to tell which types are a problem.

- Check for loose or damaged cables (particularly in user serviced equipment like PCs!).

- Remove, inspect, clean (if necessary), and reseat all internal connectors. Even if they don't seem to be in an area of the circuitry that is relevant, they could be feeding a power or control signal. Check for discolored or fatigued contacts as well as physical damage to the wires and improperly made crimps. If any components (like transistors or SIMM memory modules) plug in, do the same for them.

Where a problem is found, don't assume there is only one! In many cases, bad solder connections or bad crimps are caused by poor manufacturing process control and will be repeated in many locations. So, correct what was found and then continue to inspect the entire unit. Sometimes, manufacturing is so poor that resoldering the entire board is the only solution with any chance of long term success.

- If a suspicious area is located, it may be possible to use an ohmmeter between selected pins to determine if a connection is intermittent. To increase the chance of detecting a momentary change in resistance that may be too brief to register on a meter, connect the input of an amplified speaker (or audio amp and speaker) in parallel with the meter probes.

Power On Tests for Intermittents

If none of this produces a breakthrough, the next step is to power up the equipment. WARNING: Depending on the particular equipment, lethal voltages or other hazards may exist. Make sure you understand and follow what's in the document: Safety Guidelines for High Voltage and/or Line Powered Equipment.

- Using an insulated stick, start gently prodding likely areas of the circuitry in an attempt to make the problem come and go. If you are successful, don't assume the journey is over! Pressing at a corner of the board may have an effect at the opposite side. In fact, you may find that pressing *anywhere* appears to have about the same effect. It may take some vary very light tapping, flexing, etc., to locate the culprit. Until a physical cause if actually located (e.g., a visibly cracked solder joint where the pin can be see to move!), don't assume you're home free even if the problem appears to clear up. In fact, it is very common for an intermittent problem to go away as soon as troubleshooting begins not to reappear for several days or more - but it will reappear!

  Once a particularly sensitive area is located, use a stick thin enough to just touch a single pin at a time. Sometimes, a probe with a pointed metal tip, insulated for all but the last 1/16" or so, will be useful as it can get into the area between the pin and solder pad where cracks may have developed but are not visible. The metal tip will bridge the gap causing a change in behavior.

- If the cause is heat related, no amount of prodding (or cursing) may result in the problem occurring with the cover off. In this case, a heat gun (or blow dryer) may be needed to carefully warm up selected areas of the circuitry in an effort to identify the culprit. A blower with no heat may be used for cooling. Or, "circuit chiller" or "cold spray" may be used for more aggressive spot cooling. However, simply removing the cover may have altered something physical. For example, one of the cabinet screws may be to long and is shorting out something - this may be either from improper prior reassembly after repair or a manufacturing or design defect.

- The hardest intermittent problems to locate are those that occur infrequently and for only a short time with no chance of making a measurement. There are fancy and expensive recording analyzers for just such occasions (but you can buy a nice car for what one of these costs!). However, there may be no need for such extravagance. If you have an oscilloscope and camcorder or video camera/VCR, you probably have all that is needed.

  For a TV or monitor, point the camera at the CRT and the scope screen so that they are both in the picture and record on a 6 hour tape. Then, when your event takes place, you have a permanent record!

  That old video camera will be perfectly adequate. It doesn't need a 100X digitally stabilized enhanced reprocessed zoom or 1/10,000th second shutter. It doesn't even need to be color!

  Sure, this won't capture the 1 ns glitch. But, for the occasional flash in the picture, it is more than adequate to eliminate a video signal line as the source of the problem.

Don't rush this process. It may take several diagnostic sessions to finally resolve the problem. Even if one or more cracked solder joints are found and fixed, it may be worth waiting a few days to reinstall those 10 shields that had to be removed in order to access the underside of the main board! However, do replace the cover so that the internal temperature will be similar to normal during extended operation.

Now the question comes up: How can the re-occurrence of intermittents be prevented? For cracked solder joints, in addition to using proper soldering techniques for repair, it should be possible to add some "reinforcements" in the form of bare wire wrapped around the pin and extending out to the circuit board trace or even to an adjacent component pin. This will be better than just using more solder. For the CTC175 etc. cases discussed below, there is also special "elastic" solder that supposedly should be used. But, there are mixed reviews on whether this really helps.

Some equipment may also benefit from a small amount of additional cooling. A small fan can be added to draw air out of the cabinet. This will improve reliability since most components are happier being cool but will also reduce the extent of the thermal cycles reducing the likelihood of bad solder joints developing in the future.

RCA/GE/Proscan and Sony TVs

One of the classic examples of an intermittent problem that is present in an entire product line are the RCA/GE/Proscan TV chassis starting with CTC175 and running at least through CTC187, possibly beyond. A very large percentage of these TVs are destined to have cracked solder joints in the area of the tuner/controller resulting in erratic picture and sound. If not corrected, this eventually results in bad data being written into the EEPROM that stores the TV's parameters causing total failure to turn on. Until recently, Thomson Electronics was covering at least part of the repair costs. There may also be at least one class action lawsuit pending in regards to this problem.

Some Sony TVs suffered from a similar set of bad solder joints, usually in the tuner or IF (metal) boxes. The most common location for the problem for many of these was to one pin of a coil inside the IF box which always seemed to lack adequate solder.

Much more information on the RCA/GE/Proscan and Sony solder problems and solutions, see the documents: RCA/GE TV CTC175-187+ Solder Connection and EEPROM Problems and Sony TV Tuner and IF Solder Connection Problems.

Other makes and models of TVs have similar problems with solder joints but not to the extent of these.

- Back to Troubleshooting Table of Contents.

Perfecting Your Skills

Where to Find Equipment in Need of Repair or Abuse

Now that you have read all the previous sections, perhaps some of the Repair Briefs, followed the sci.electronics.repair newsgroup for a while, built your handy widgets(tm), and loaded up on test equipment, where should you go to find broken stuff to play with and practice on? Of course, you probably have closets bulging with broken VCRs, TVs, stereos, and small appliances. You may not may not want to practice on these just yet.

- One obvious source are accomodating relatives, spouses, and collegues. However, again, you will want to hold off on this until you have some success under your belt.

- Garage, yard, driveway, porch, etc. sales (also tag and house sales but this may be higher class more expensive junk) can be veritable bonanzas of dead appliances. With a little restraint (don't buy the first items you see until you have a feel for what the going rates are) you should be able to buy excellent dead items for next to nothing. For example, I usually don't pay more than $5 for a dead VCR - maybe $10 for a late model in excellent physical condition. I bought a 26" RCA Colortrak TV for $5 and a late model 20" color TV for $3. CD players with problems typically go for $2 to $7. Sometimes they will just give you the stuff so they do not have to haul it to the dump. Much of this can be repaired inexpensively once you have some experience. If you mess up some of the patients, so be it. You will have learned a great deal and sacrificed little.

  Always check to see that you got all the accessories - remote controls, cables, attachments, etc. Often, they will have long since disappeared but it won't hurt to ask.

  Try to find out what the symptoms were from the owner if possible. With a little knowledge, this could improve your bargening position as well - or make you decide to try for a lesser challenge:

  > "Jonny stuck a peanut-butter-and-jelly sandwich in the tape slot and when his pet hamster wen't to eat the sandwich it got stuck. They have both been there for a couple of years now. I put the VCR in this plastic bag to protect it from moisture. It really is a great VCR".

  or:

  > "Well, there was this lightning strike, the modem exploded and 6 foot flames leaped out of the monitor so I dumped a pitcher of lemonade on it to put out the fire. What is left of the PC is still melted to the floor but I figured someone could use the monitor."

  I would skip those.

  Another high risk would be a piece of equipment that had been worked on by someone not competent to change a light bulb:

  > "My VCR wouldn't play my Rambo tape so I opened it up and found this silver thing was out of line - you know, all cockeyed. So I tried to straighten it with a pair of Vise Grips(tm) but I must not have done it quite right as now all I get is snow and it makes these crunching noises. Maybe you will have more luck"

  or:

  > "I tried to repair this amplifier but while I was making some adjustments, my screwdriver

> slipped and there were these HUGE sparks and bubbles appeared on several of those black things that look like cochroaches and parts flew off of those clips glued to this plate at the back. You wanted a challenge, right?"

or:

> "Duh, I thought I would get cool music in my car but for some reason I cannot fathom, the jumper cables I used got really hot and my portable CD player now smells really bad and doesn't work on the normal transformer anymore. I will throw in the jumper cables for nothing."

I would pass on these as well.

In addition to melted or scorched cabinetry and the wonderful aroma of charred circuitry, look for the absense of cover screws and chisel or chainsaw marks!

- Moving sales are similar and better in some ways as the owners are usually very motivated to move out as much junk as possible.

- Flea markets may yield simliar types of items but expect to pay more. Where do you think they obtain all their merchandise?

- Thrift stores, Goodwill's, and similar outlets may also yield suitable candidates in some cases for free. Find out when their 'drop-off' days are and camp out. :)

- Auctions have potential as well but you better know even more about what you are bidding on, set a hard upper limit for you bids, and be prepared to spend the day.

  I like to swoop in and swoop out - thus my preference for garage sales.

- The curb, local dumpsters, and the town dump can also be sources but confirm that whatever you are taking is really up for grabs! One recommendation is to drive around a college campus at the end of the term when students are packing up and throwing away anything that they will not be taking home. There are even supposed to be USENET newsgroups on these topics. For example, alt.dumpster though I've not actually found it.

The most annoying situation is when after haggling over the price of a 'dead' VCR, you get it home with great expectations of the challenge ahead only to find that it works perfectly or your Mark-I thumb is all it takes to clean a supposedly trashed video head (but you do have to know the proper technique and incantations!) I ended up with a couple VCRs like that. A 'dead' CD player for $5 magically cured itself on the back of my 10 speed bicycle. Often problems are simple and easily remedied resulting in quick gratification. However, there will be real dogs which could more than make up for the easy fixes (like the GE TV with the never ending string of bad solder connections). At least, if you sell the easy ones, this will help pay for your 'habit'.

- Repair shops. They will literally have walls of beyond hope, dogs, or unclaimed equipment - TVs, VCRs, CD players, etc. It might be worth asking if you can buy some of these for a modest fee. While I am always tempted to save everything on the off chance that a part will be useful in the future, realiztically, this rarely turns out to be useful and they may be happy to part with what they consider junk especially if they have more than one of the same or similar model cluttering up their back wall.

I do not know how viable an option this typically is since I have never tried it. (However, I used to trash pick mostly replaced vacuum tubes - nearly always tested good - back in those days when such things were common.) If they consider you a threat to their business, you may get the cold shoulder. If they consider you a future employee - or suspect you will make whatever you are working on worse and increase their business that way, you may be forced to take a whole pallet load of stuff off their hands :-).

Note that this could turn out to be very frustrating if by chance you end up with partially cannibalized equipment without realizing it. "This VCR does not load the tape around the video drum. Come to think of it, what happened to the video drum...?" Or, "There seems to be a big hole in the front of the TV. Now, what could possibly be missing...?"

- (From: Jerry Penner (jpenner@sentex.net).)

  Make friends with several local apartment superintendants When they clean house after someone moves, they toss out all kinds of working/non-working stuff the folks left behind. Some supers make a little extra cash by fixing and reselling this stuff, some just give it the heave-ho.

One note: inspect whatever you take home. Cockroaches and other unwelcome visiters may have made a comfortable home in that old TV. I once picked up a nice toaster oven but found that I was baking more than I expected or desired and had to completely disassemble and clean it before the cockroaches stayed away permanently.

Paul's Comments on the 'Well Equipped Garage or Flea Market Sale-er'

Only read the following if you are serious about this! Note: these comments apply more to the electronic flea markets or ham fests found around high tech parts of the country but can be adapted for the back woods as well.

(From: Paul Grohe) grohe@galaxy.nsc.com).)

Ah! If you are really serious about buying equipment, carry one of those little 200W 120VAC inverter bricks *with you* in your backpack, along with a cigarette socket to car battery clip adapter. Keep a small marine or gel-cell battery in your car (or with a friend who has a table).

This way, when you "roll up" on a good deal, ask the seller if you can borrow his cigarette lighter, or car battery, for a few minutes. If you can't use his car (and if you have time), run back and get your battery.

If he refuses...There's your answer!

I keep an 8-cell "AA" battery holder and an assortment of pigtail power connectors in my backpack. This way, I have an adjustable 1.5 to 12V power source to test things there on the spot (I'm planning on making a complete test box, complete with ammeter and current limiting).

I also carry a bunch of "AAA" and "C" cells in my backpack ("C" cells can be shimmed into "D" holders with a few coins between the batteries).

The same rule applies, If they won't let you test it.....etc,etc,etc.

Will they give you their business card or phone number? Make it clear you will not bother them unless absolutely necessary (secretly write down their license plate number, for "Justin Case").

Also carry a pocket DMM (This is a *must* for any flea enthusiast - NEVER buy batteries w/o testing them first!) and a small, bright flashlight (for "inspections").

Smell the equipment too! This can be a big clue as to it's condition. Does it smell like something blew up? Does it smell musty or moldy?

Another clue I have found is the physical condition of the unit. Sometimes the "cleanest" unit of the bunch is the one that failed prematurely and got stuffed on a shelf or back in the box. Whereas the "used looking" units were just taken out of service.

More importantly than "functional", is "complete".

Nuthin' worse than getting something and finding out a piece, or a board, or a module, or an expensive or rare IC is missing. Now you know it's not functional, and there may be little chance of it even becoming functional again.

I always assume "dead" until happily proven otherwise. Follow your instincts! If you have doubts, there's a reason! I always consider the scrap value of the item also. Any expensive goodies in it? The power switch may be worth more than the item!

Some of my best deals were the "I don't know if it works...Oh,..five bucks" deals.

It's a gamble...Ya' win some, ya' loose some!

Caveat Emptor!!!!!

(Let duh buyer beware!)

Cheers.

And, How Paul Equipped His Home Lab

(From: Paul Grohe) grohe@galaxy.nsc.com).)

That's me! Flea Markets/Surplus Stores/Salvation Army/Goodwill/thrift stores/Garage-yard Sales/etc...And there is *lots* of good stuff around this area!

I call it "going' Junkin'".

I arrive at about 5:30 AM, so that requires a combo krypton spotlight/fluorescent lamp flashlight (a $3 Goodwill special :^).

I carry with me the aforementioned 8 cell battery pack, 8 "C" batteries, a bright krypton penlight, one of those all-in-one screwdriver/knife/pliers/scissors/bottle opener contraptions ("fishermans friend"?) and a small pocket DMM. All about 5-7 pounds total. I carry it all in a backpack that I wear "backwards" on my chest (for easy access). During the "lull" (around 9 AM), I go back and "load transfer" to the car.

I got it down to a science!! ;^)

After some lucky "scores", and a few *hundred* hours of troubleshooting, I have a *very* well stocked home lab... :^)

My home lab is graced with a Tek 576 Curve tracer (bad Xfmr), HP 5345 Freq cntr (bad NPN trannie), HP3456 DMM (bad ROM), Radiometer 106 RF Generator (stuck keys), Genrad 1688 Digital RCL meter (another bad ROM) and a "few" other assorted goodies...

The Tek 576 is my favorite. This unit was the one of the bunch that failed early and was shelved. It was dusty, dirty, full of spider webs, and missing one little knob, but in otherwise perfect shape. I got it for $200. Guys were offering me $750 for it "as-is" on the way back to the car! To top it off, two tables down from where I got the 576, someone was selling a *complete* set of the transistor/diode plug-in fixtures. Score #2!

It was a good day..... I used up all of my allocated "luck" for that year. :^)

The 576's collector supply transformers primary was dead-shorted. Eventually I was lead to Dean Kidd, who sold me a *brand new* one for $75! Tek even took the bad transformer back for failure analysis!

The HP frequency counter was the longest fix (~2 months). It's all jelly-bean TTL logic (some ECL), but no "brains" at all! Board swapping with a friends unit and some "shotgunning" brought it to back life. The eventual root failure was a single NPN transistor, in a buffer between two stages of the main 500MHz counters, whose beta had dropped significantly. I stuck a 2N2222 in there to check it out, and "there" it remains to this day!

> "If it's no longer broke, Quit fixin' it!" - Paul Grohe ;^)

The Genrad was the "hair-puller" (really made me begin to doubt my troubleshooting skills!). It would continually fail it's self check at the same step. The failure code indicated a certain section of the analog section, which I *knew* was okay. There is not much to the analog section anyways! It is mostly jelly-bean, off-the-shelf 74C series digital logic sitting around a 6502 uProc. After checking *every* analog part (most out-of-circuit), and swapping all of the digital chips, I concluded it *must* be the ROM. It was the only part left that had not been replaced! I posted for a "brain donor" and got a reply. He had two dead units and offered to send me the ROM's to compare and read. I took him up on his offer and copied the ROM, and then transferred it to an EPROM. Voila! The f#@&!#g thing worked! I chased my tail for weeks! It turns out that a few bits in the ROM were corrupted, and the error was subtle enough to cause it to just "trip-up" at that phase of the self-test, even though the hardware was fine. Arrrgghh!! I sent him his ROM's back, with a little "thank-you", and eventually helped him revive his two units. This was one of those "fun" repairs.

Everything else I have was dead, dying or crippled (er, "functionally challenged"). I even had to repair my 475A O'scope before I could use it! (It's a "P-I-T-A" to troubleshoot a scope w/o a scope!)

Too Bad About the Good Old Days

(From: Mike Diack (moby@kcbbs.gen.nz).)

In the days before 'Weirdstuff Warehouse' stopped being weird and simply became boring, a lot of the junkus electronicus they sold bore a sticker stating:

This equipment is guaranteed not to work - should you find that it does, we will be happy to exchange it for something that doesn't.

Treat fleas the same.

(From: Paul Grohe (grohe@galaxy.nsc.com).)

Yep! I bought a lot of "goodies" with that little orange and black sticker!! I resisted the temptation to take it back if it worked. If it did work, I broke it, then fixed it, so then I would not feel so "guilty". ;^)

Harrie's Notes on Repair

(From: Harrie Gulikers (hgu@oce.nl).)

Just want to share my experience on repairing electronic devices in general. After many (most successful) repairments I've concluded the following:

- If I need a schematic, then I'm really desperate, probably have spent too many hours by now on the device.
- Most of the problems were due to bad wiring between components. You must interpret this very general: bad solderdots (most common problem), bad contacts in connector, etc.
- 10 years ago and earlier, warm components were soldered with with straight leads to the solder-dots. After a few years these solder-dots come loose, or make bad contact because the leads vary in length due to temperature variations. Mostly you can see this with the bare eye. Just re-solder all big (warm) components, like transistors attached to heatsinks, big capacitors, coils etc. This works also preventive for future problems. Also, try to bend straight leads.

These bad contacts were the cause for, say 75% of all devices I have repaired for the past 16 years. If (and IF) a component was damaged, it was because of bad contacts.

Take this advice in mind and I hope you can profit from it. Repair shops probably will throw a stone towards my head ;-)

Roger's Comments on Troubleshooting

(From: Roger Pariseau (grinder@west.net).)

The closest I ever came to bench tekking was when I would service electronic organs at a dealer's warehouse. If I spent all day there I'd normally fix upwards of 20 instruments and "check out" several others. Normally I just "ran traps" at churches, auditoriums, schools and homes where I got to five or six instruments a day.

I dealt with intermittents via a little rubber mallet and a can of cold spray!

And, I learned a couple of things:

1. 'Shotgun' a bad circuit.
2. If an amp's outputs are blown, check/replace the speakers also
3. Digital circuits are *not* logical!
4. Never hurry.
5. Check *all* supply voltages first.
6. Check all signal generation and their paths (some organs derived their rhythm section's clock from a generated note - there are similar circuits in TVs).
7. Burn-in your work - it can go out the next day.

It was a great little business until the mid '80s when the Casios and the Yamahas became popular. Now I mostly repair computers with the occasional piece of HiFi gear hitting my bench. Like that damned Sony 100-disc CD player that I can't find parts values for!

Safety Guidelines for High Voltage and/or Line Powered Equipment

Version 1.32

For contact info, please see the Sci.Electronics.Repair FAQ Email Links Page.

Table of Contents

* Safety Tests for Leakage Current on Repaired Equipmen

---

* Back to Safety Guidelines Table of Contents.

Introduction

Consumer electronic equipment like TVs, computer monitors, microwave ovens, and electronic flash units, use voltages at power levels that are potentially lethal. Even more so for industrial equipment like lasers and anything else that is either connected to the power line, or uses or generates high voltage.

Normally, these devices are safely enclosed to prevent accidental contact. However, when troubleshooting, testing, making adjustments, and during repair procedures, the cabinet will likely be open and/or safety interlocks may be defeated. Home-built or modified equipment, despite all warnings and recommendations to the contrary - could exist in this state for extended periods of time - or indefinitely.

Depending on overall conditions and your general state of health, there is a wide variation of voltage, current, and total energy levels that can kill.

Microwave ovens in particular are probably THE most dangerous household appliance to service. There is high voltage - up to 5,000 V or more - at high current - more than an amp may be available momentarily. This is an instantly lethal combination.

TVs and monitors may have up to 35 kV on the CRT but the current is low - a couple of milliamps. However, the CRT capacitance can hold a painful charge for a long time. In addition, portions of the circuitry of TVs and monitors as well as all other devices that plug into the wall socket are line connected. This is actually more dangerous than the high voltage due to the greater current available - and a few hundred volts can make you just as dead as 35 kV!

Electronic flash units and strobe lights, and pulsed lasers have large energy storage capacitors which alone can deliver a lethal charge - long after the power has been removed. This applies to some extent even to those little disposable pocket cameras with flash which look so innocent being powered from a single 1.5 V AA battery. Don't be fooled - they are designed without any bleeder so the flash can be ready for use without draining the battery!

Even some portions of apparently harmless devices like VCRs and CD players - or vacuum cleaners and toasters - can be hazardous (though the live parts may be insulated or protected - but don't count on it!

This information also applies when working on other high voltage or line connected devices like Tesla Coils, Jacobs Ladders, plasma spheres, gigawatt lasers, hot and cold fusion generators, cyclotrons and other particle accelerators, as well as other popular hobby type projects. :-)

In addition, read the relevant sections of the document for your particular equipment for additional electrical safety considerations as well as non-electrical hazards like microwave radiation or laser light. Only the most common types of equipment are discussed in the safety guidelines, below.

- Back to Safety Guidelines Table of Contents.

Safety Guidelines

These guidelines are to protect you from potentially deadly electrical shock hazards as well as the equipment from accidental damage.

Note that the danger to you is not only in your body providing a conducting path, particularly through your heart. Any involuntary muscle contractions caused by a shock, while perhaps harmless in themselves, may cause collateral damage. There are likely to be many sharp edges and points inside from various things like stamped sheet metal shields and and the cut ends of component leads on the solder side of printed wiring boards in this type of equipment. In addition, the reflex may result in contact with other electrically live parts and further unfortunately consequences.

The purpose of this set of guidelines is not to frighten you but rather to make you aware of the appropriate precautions. Repair of TVs, monitors, microwave ovens, and other consumer and industrial equipment can be both rewarding and economical. Just be sure that it is also safe!

- Don't work alone - in the event of an emergency another person's presence may be essential.

- Always keep one hand in your pocket when anywhere around a powered line-connected or high voltage system.

- Wear rubber bottom shoes or sneakers. An insulated floor is better than metal or bare concrete but this may be outside of your control. A rubber mat should be an acceptable substitute but a carpet, not matter how thick, may not be a particularly good insulator.

- Wear eye protection - large plastic lensed eyeglasses or safety goggles.

- Don't wear any jewelry or other articles that could accidentally contact circuitry and conduct current, or get caught in moving parts.

- Set up your work area away from possible grounds that you may accidentally contact.

- Have a fire extinguisher rated for electrical fires readily accessible in a location that won't get blocked should something burst into flames.

- Use a dust mask when cleaning inside electronic equipment and appliances, particularly TVs, monitors, vacuum cleaners, and other dust collectors.

- Know your equipment: TVs and monitors may use parts of the metal chassis as ground return yet the chassis may be electrically live with respect to the earth ground of the AC line. Microwave ovens use the chassis as ground return for the high voltage. In addition, do not assume that the chassis is a suitable ground for your test equipment!

- If circuit boards need to be removed from their mountings, put insulating material between the boards and anything they may short to. Hold them in place with string or electrical tape. Prop them up with insulation sticks - plastic or wood.

- If you need to probe, solder, or otherwise touch circuits with power off, discharge (across) large power supply filter capacitors with a 2 W or greater resistor of 100 to 500 ohms/V approximate value (e.g., for a 200 V capacitor, use a 20K to 100K ohm resistor). Monitor while discharging and/or verify that there is no residual charge with a suitable voltmeter. In a TV or monitor, if you are removing the high voltage connection to the CRT (to replace the flyback transformer for example) first discharge the CRT contact (under the insulating cup at the end of the fat red wire). Use a 1M to 10M ohm 1W or greater wattage resistor on the end of an insulating stick or the probe of a high voltage meter. Discharge to the metal frame which is connected to the outside of the CRT.

- For TVs and monitors in particular, there is the additional danger of CRT implosion - take care not to bang the CRT envelope with your tools. An implosion will scatter shards of glass at high velocity in every direction. There is several tons of force attempting to crush the typical CRT. Always wear eye protection. While the actual chance of a violent implosion is relatively small, why take chances? (However, breaking the relatively fragile neck off the CRT WILL be embarrassing at the very least.)

- Connect/disconnect any test leads with the equipment unpowered and unplugged. Use clip leads or solder temporary wires to reach cramped locations or difficult to access locations.

- If you must probe live, put electrical tape over all but the last 1/16" of the test probes to avoid the possibility of an accidental short which could cause damage to various components. Clip the reference end of the meter or scope to the appropriate ground return so that you need to only probe with one hand.

- Perform as many tests as possible with power off and the equipment unplugged. For example, the semiconductors in the power supply section of a TV or monitor can be tested for short circuits with an ohmmeter.

- Use an isolation transformer if there is any chance of contacting line connected circuits. A Variac(tm) (variable autotransformer) is not an isolation transformer! However, the combination of a Variac and isolation transformer maintains the safety benefits and is a very versatile device. See the document "Repair Briefs, An Introduction", available at this site, for more details.

- The use of a GFCI (Ground Fault Circuit Interrupter) protected outlet is a good idea but may not protect you from shock from many points in a line connected TV or monitor, or the high voltage side of a microwave oven, for example. (Note however, that, a GFCI may nuisance trip at power-on or at other random times due to leakage paths (like your scope probe ground) or the highly capacitive or inductive input characteristics of line powered equipment.) A GFCI is also a relatively complex active device which may not be designed for repeated tripping - you are depending on some action to be taken (and bad things happen if it doesn't!) - unlike the passive nature of an isolation transformer. A fuse or circuit breaker is too slow and insensitive to provide any protection for you or in many cases, your equipment. However, these devices may save your scope probe ground wire should you accidentally connect it to a live chassis.

- When handling static sensitive components, an anti-static wrist strap is recommended. However, it should be constructed of high resistance materials with a high resistance path between you and the chassis (greater than 100K ohms). Never use metallic conductors as you would then become an excellent path to ground for line current or risk amputating your hand at the wrist when you accidentally contacted that 1000 A welder supply!

- Don't attempt repair work when you are tired. Not only will you be more careless, but your primary diagnostic tool - deductive reasoning - will not be operating at full capacity.

- Finally, never assume anything without checking it out for yourself! Don't take shortcuts!

- Back to Safety Guidelines Table of Contents.

Safety Tests for Leakage Current on Repaired Equipment

It is always essential to test AFTER any repairs to assure that no accessible parts of the equipment have inadvertently been shorted to a Hot wire or live point in the power supply. In addition to incorrect rewiring, this could result from a faulty part, solder splash, or kinked wire insulation.

There are two sets of tests:

- DC leakage: Use a multimeter on the highest OHMS range to measure the resistance between the Hot/Neutral prongs of the wall plug (shorted together and with the power switch on where one exists) to ALL exposed metal parts of the equipment including metallic trim, knobs, connector shells and shields, VHF and UHF antenna connections, etc.

  This resistance must not be less than 1 M ohm.

- AC leakage: Connect a 1.5K ohm, 10 Watt resistor in parallel with a 0.15 uF, 150 V capacitor to act as a load. Attach this combination between the probes of your multimeter. With the equipment powered up, check between a known earth ground and each exposed metal part of the equipment as above.

  WARNING: Take care not to touch anything until you have confirmed that the leakage is acceptable - you could have a shocking experience!

  The potential measured for any exposed metal surface must not exceed 0.75 V. This corresponds to a maximum leakage current of 0.5 mA.

  Note: A true RMS reading multimeter should be used for this test, especially where the equipment uses a switchmode power supply which may result in very non-sinusoidal leakage current.

If the equipment fails either of these tests, the fault MUST be found and corrected before putting it back in service (even if you are doing this for your in-laws!).

Checking for correct hookup of the Hot, Neutral, and Ground wires to the AC plug should also be standard procedure. There's no telling how it may have been scrambled during a previous attempt at repair by someone who didn't know any better or by accident. Unlike logic circuits, black is NOT the standard color for ground in electric wiring! :)

Sam's Repair Briefs - Complete: 1 to 100

Version 2.00e

For contact info, please see the Sci.Electronics.Repair FAQ Email Links Page.

Table of Contents

- Back to Sam's Repair Briefs Table of Contents.

What are the Repair Briefs(c)?

This series presents case studies of selected repair problems from my archives. (Archives sounds more impressive than scribbled notes and schematics, doesn't it?). I hope that these summaries are useful for those of you are interested in tackling your own repairs. These will NOT be of the form: "replace C418 when vertical size is reduced on HyperTech TV chassis HT312". Rather, they will document specific but common problems with TVs, VCRs, CDs, computer peripherals, etc. The symptoms, testing, diagnostic procedure, repair procedure, and comments will be included so that you can learn from my approach (and my screwups). If you want specific solutions to well known or repeat problems with your RCA or Zenith, then the repair professionals who frequent this group will be in a better position to help since they work on many of the same line of equipment on a regular basis. However, if you want to develop a general diagnostic approach, then this series may provide some tips and insight based on theory and experience. Not all of these are exciting cast-of-thousands repairs. Many tend to be mundain but address common problems with consumer electronic equipment. You will no doubt recognize some as directly pertaining to some appliance or electronic device that you had repaired (or junked) in the past. There will probably even be some of those 'dogs' that we all hate - the problems that never seem to go away. In any case, these will all be based on my true experiences with minimal embellishment.

Repair Brief #1: Daisy Wheel Printer - Carriage Gets Stuck

Patient: Panasonic KX-P3131 Daisy Wheel PC printer.

Symptoms: After some random amount of printing, the carriage would get stuck and just twitch instead of moving across the platen.

Testing: Using its internal test function, I let it print out until the problem ocurred.

Once the problem ocurred, the carriage would just kind of twitch back and forth. Grabbing it, it was obvious that the stepper motor was providing no effective power. Since this is usually indicative of a missing phase to the stepper motor, I immediately suspected either:

- Bad connection - cable or soldering.
- Bad driver.
- Bad motor.

Since it was intermittent with no relationship to time, heat, position, etc., this is most likely (1).

I then removed the cover to gain access to the circuit board and motor connections. It was necessary to defeat the cover interlock to get it to come one. Now, to get it to screw up again.

I left it printing out the ASCII character set and got a byte to eat. When I came back it was busy gouging a hole in the paper. So now for the critical test: Will pressing on the stepper motor connector cause a change? The answer is --- Yes! The carriage started moving again meaning that it is likely a bad connection.

Of course, to gain access to the underside of the circuit board required removing a zillion screws and the entire mechanical assembly. But once this was accomplished - immediate gratification. There were obvious bad solder joints around several pins of the stepper motor connector. I resoldered these and few others that were suspicious and inspected the rest of the board. If only I could remember which screws went where! Apparently, the continuous vibration of the assembly eventually caused the connections to fail. This is not likely a heat related problem though it could be just plain bad quality control.

Once reassembled, I left it happily printing out page after page of ACSII characters. Then, just to be sure, I connected an old laptop and printed a few pages of Repair Notes.

Comments: This is one of those dream problems since their solution is so obvious and so definitive. There is no doubt that the cure will last. Unfortunately, the tough 'dogs' are the ones you lose hair over.

- Back to Sam's Repair Briefs Table of Contents.

Repair Brief #2: Panasonic PV1461 VCR with Dead Power Supply

Patient: Garage Sale Panasonic PV1461 VCR (Asked $10, offered and accepted $5).

Symptoms: The power supply had been identified as being bad by the seller.

Testing: I plugged it in - nothing as expected. This was to verify that all functions and display were dead.

I removed cover and found that the main fuse had been removed. Hmmm, this usually means catastrophic power supply problem. This is the typical Panasonic switching power supply. Well, I have completely rebuilt these, so no biggie. (Of course, there was one I blew up, but that is another story).

The hardest part was removing the power supply. It is buried underneath the bottom circuit board necessitating the removal of this board and the front panel. Do you think they design these things this way to discourage tampering? There was plastic in specific places to prevent removal from the top even though it would have been trivial to design for easy removal. I disconnected power supply from VCR. Fortunately, this was just a connector.

I tested across switchmode power transistor with ohmmeter - dead short C-B-E.

I looked in ECG for 2SC3890 - ECG379 with that infamous # indicating an electrical but not mechanical match.. Since I had some BU406s, I looked this number up in ECG guessing that the BU406 would be have similar ratings and be usable in a small switcher - guess what, ECG379. The difference is that the 2SC3890 is totally plastic while the BU406 is a metal tab TO220. OK, so I cut out a bit of mica to serve as an insulator and used a nylon screw. This is temporary as I intend to get the proper replacement (2SC3890 - $2.15 from MCM Electronics).

I also checked continuity from the main filter cap to the C and E leads of the transistor to rule out a blown fusable emitter resistor. I checked other semiconductors as well - all fine as far as my VOM was concerned. Fortunately, the only casualty seems to have been the transistor and the fuse was fast enough to prevent any damage due to its shorting.

To power up the supply, I initially used a Variac with a 25 W light bulb in series with the line. Note that since I do not have any 1.6 A fuses, the fuse is shorted. The light bulb will provide the current limiting for now. I use my dual outlet widget box plugging in the supply to one outlet and a lamp with the 25W light bulb into the other (the outlets are wired in series for exactly this sort of application). This whole rig was plugged into an isolation trasformer for safety.

I then identified the primary output and connected my VOM to this. It would be in the range 5-15 V, probably 12 V based on the filter capacitors (16 V).

All set? Crank up power. Output comes up to about 13 V at around 50 VAC in. Light Bulb hardly flickered. If it had not stopped in the 12 V range, this would either indicate that there was a problem in the regulation or that a load was needed. Had this happened, I would have put a 22 ohm 5W resistor on this output and retested. Cranking up the Variac to full voltage causes no noticeable change to output.

OK, connect VCR. Lights, VCR, power! Nothing. Light bulb is now glowing but there is no indication of life from front panel and no action from motors.

Hmmmm.

Examining the nameplate, the expected power consumption is 29 W which is way more then one can get through a 25 W light bulb. (Expect to be able to draw maybe half of the bulb's ratings). So I go hunting for a 60 W light bulb.

This time the motors twitch and the front panel comes alive. Inserting a tape and holding my breath - tape starts to load but then aborts with poweroff. Go for it! The Variac had been set at about 90 VAC, so I crank it up to 120. Now everything works. I go dig up a TV and verify that the basic functions are ok. Doesn't appear to even need much cleaning. Even the idler tire appears to be in good condition.

Add a 2SC3890 and box of 1.6 A fuses to my next MCM order.

Comments: this is the sort of repair that might not pay for a professional shop to undertake. The time to disassemble the VCR, identify the problem, replace the transistor and fuse, and verify correct operation could be excessive, or at least has the potential to be excessive. If it turned out to be more than a transistor and fuse or was beyond repair, they might have to eat the cost in time and materials. In addition, there is no real way to guarantee that other marginal components won't cause the problem to repeat a week or month in the future. Upgrade/repair kits are available for these supplies and would probably represent the lowest risk investment for a permenant repair. No doubt, the previous owner had taken it in for repair and been quoted a rediculous price to replace the entire power supply module.

- Back to Sam's Repair Briefs Table of Contents.

Repair Brief #3: USR Data Modem Won't Dial

Patient: USR 14.4 K baud external data modem.

Symptoms: Modem works in most respects but when it goes to dial, the tones are superimposed on the dialtone which never goes away.

Testing: I plugged it into an old laptop kept for the specific purpose of testing of random external peripherals. Indeed, the AT commands worked just fine but tone dialing did not work. Interestingly, pulse dialing would work 90% of the time but a connection was never completely established.

At this point, I put a scope on each side of the 600 ohm coupling transformer. A normal 2 or 3 volt p-p signal was present on the logic side of the transformer during dialing. However, a much attenuated signal was present on the phone line side - probably .2 V p-p or so. I probably could have used a set of crystal headphones to just listen to the relative amplitudes of the logic and phone line side signals instead of a scope. (Magnetic headphones would have too low an input impedance.)

On a hunch, I did try replacing the transformer with one from my junkbox but as expected, this produced no change.

The phone line is a nasty place for electronic components - 90 V ringing signal, lightning strikes, pickup of EMPs (from nuclear bombs), etc. The first place to look for fried components is therefore the phone line circuitry. For a modem and no schematics, with the possible exception of the power supply, it is also probably the only place where there is any real chance of finding a problem.

Since there are a manageable number of discrete parts that connect the phone line to the transformer, an ohmmeter check was in order. Unfortunately, many of them were really itty bitty surface mount parts. After a couple of go-arounds, this proved to bear fruit as an SO23 device marked on the circuit board as a diode turned out to be shorted though I seem to have missed it on my first pass. Carefully unsoldering the almost microscopic part confirmed that it had turned into a dead short.

Note: markings for these devices were not always complete. Nonetheless, basic ohmmeter checks could be made with enough confidence to tentatively eliminate all except the single shorted diode.

Removing the diode and retesting proved that dialout was possible and that normal communications at 14.4 K baud was normal. The markings on the diode did not permit me to identify whether it was a simple diode or a zener. I still do not know what function the diode actually served.

I replaced it with a 1N4148. The modem has been tested to confirm that it is not damaged by the ringing voltage. Since the application does not require dial-in access, I do not know if there is still a problem with this mode.

Comments: Where a problem can be narrowed down to a small section of circuitry, ohmmeter tests can prove successful in identifying parts that have failed shorted or open. This may be the only option when confronted with a device for which obtaining a schematic would be difficult or impossible - or not worth the effort. While we might consider a modem to be a throwaway item these days, the time need to do basic testing of the phone line side components is minimal and, as in this case, may be all that is needed.

- Back to Sam's Repair Briefs Table of Contents.

Repair Brief #4: RCA 26" TV Very Dead

Patient: RCA 26" TV, Chassis CTC131A/M. Garage sale acquisition ($5). Previous owner explained that it failed to work after power was restored following a power outage due to a thunderstorm. They were more than happy to have me remove it from their garage.

Symptoms: Dead. Located fuse - blown due to short (not overload). Blackened inside glass. Note: appearance of blown fuses is very significant.

Testing: Replaced fuse. This was in hindsight a mistake without using a series light bulb to limit the current. The new fuse did not blow but the lights dimmed momentarily. Apparently a fusable resistor had sacrificed itself to protect the fuse.

Without schematics, I decided to trace the AC line circuits. These were partially buried inside a metal box with some big fat resistors on a separate board.

Measuring across the power resistors revealed that one 2.7 ohm resistor was now open. That explained the new failure. Some further searching located a TO3 power transistor inside the metal shield. Measuring C-E came up 0 ohms. This was not the horizontal output transistor but was rather in the power supply - a flyback switching supply separate from the deflection circuits.

The transistor was marked with an RCA part number. My handy dandy ECG Semiconductor Master Substitution guide listed it as a typical 350/800 volt switching transistor. I did not have an exact replacement but figured that a horizontal output transistor would probably work at least temporarily in this application, so I used my favorite BU208A in its place.

As a temporary substitute for the fusable 2.7 ohm resistor, I put in a regular power resistor with the understanding that a safe replacement would be installed before the TV was buttoned up.

Now for the test. This would be classic use for a series light bulb and/or variac for the initial power on. However, for whatever reasons, I did not bother - and lucked out in this case. The TV came on just fine. The only adjustments needed were to focus and horizontal position - totally unrelated to the original problem.

The recommended ECG replacement for the chopper transistor was an ECG385, a 350 V 10 A switching transistor. I elected to put in an ECG386 to give myself a little extra margin. The ECG386 is rated at 500 V and 20 A. Other specifications were similar or superior.

Comments: Since most modern consumer electronics are powered all the time even if the power switch is off, it is always a good idea to unplug everything during a lightning storm or if a blackout occurs. A nearby lightning strike can easily impose huge transients on the AC line. When power is restored following a failure, the initial power-on may not be clean including mini-brownouts, spikes, multiple cycles, etc. These are all hard on switching supply based equipment. Now, I fully realize that few of ua actually follow this advise. (Of course, other screwups can result in similar damage. I once was given a bag of dead stuff from a friend of a friend who had been doing a little wiring in his house. Somehow he managed to connect 240 V to a 120 V circuit - only for a second....)

This is one example where a failure with the most catastrophic impact on performance (it was dead, after all) has among a very simple solution (transistor, resistor, fuse). I much prefer these to the 'color noise on channels in the UHF band' variety.

- Back to Sam's Repair Briefs Table of Contents.

Repair Brief #5: Pioneer CD Changer will not Recognize Disc

Patient: Pioneer PDM601 6 Disc CD Changer rejects all CDs.

Symptoms: Disc is loaded from cassette, disc spins at various speeds for about 5 seconds, then it gives up, unloads this disc and loads next until there are no more.

Testing: Testing consisted of removing cover and observing behavior. Everything appears to happen normally except that disc directory is never read.

This is one of those problems that has an obvious cause and solution once experienced, diagnosed, and repaired the first time. I will outline my approach the first time I came across this one describing this particular case history from the perspective of the novice wannabe repair expert.

Since the disc is loaded and spins, it is likely that the laser and focus servo are functioning (though perhaps no guarantee, but I hope to get to that in another episode).

At first, I suspected (incorrectly) that an adjustment was needed, so I did what I always now warn against - turning any of the internal controls. I thought that they had been returned to the original settings but was not positive.

Pioneer CD players usually include a test function - a button on the main circuit board marked 'TEST'. Normally, test functions are invoked either by simply depressing the button or by holding it depressed when power is turned on. In this case I discovered that if this button were depressed when the unit was switched on, the display would change and certain front panel buttons would now function controlling the servo circuits directly.

(Note that the approximate duration of the previous paragraph was about 1 year as I put the thing aside unable to make any headway during the first go-around.)

After some experimentation with the front panel controls, I came to the conclusion that:

- STOP turns all servos OFF.

- TRACK FWD enable FOCUS servo (and loads disc 1 in changer).
- PLAY enables SPINDLE servo.
- PAUSE enables TRACKING servo (and PLAY mode).
- MANUAL SEARCH FWD or REV to move Laser head.

Playing with these for awhile revealed that it was possible to move the laser pickup, engage the focus servo, and make the disc rotate, Further experimentation confirmed that the internal controls were more or less in their correct positions - tracking offset could make the pickup slew from one end to the other, for example.

All this was leading nowhere until I accidentally happened to engage all servos in the middle of a CD - and the track display suddenly appeared. I reached for my headphones and confirmed that the CD was playing, just fine.

A little further investigation allowed me to determine that the CD would play fine from about the middle to the end but would get progressively noisier when moving toward the starting track and would be totally unplayable at the very start.

Now, what could depend so fundamentally on track position? Well, there are two possibilities: spindle motor speed and PLL frequency. A little careful tweaking of PLL center frequency had little effect.

One thing I noticed was that one of the servo driver ICs was running quite hot. This should have raised a red flag but again, this was the first time I had seen this problem. I also observed that putting a heatsink on the IC and blowing on this would permit the disc to play error free much closer to its start.

So now, you are saying, "what a moron, everyone knows that Pioneer CD spindle motors are crap". The confusing thing here was that the spindle motor was not dead, just marginal. So, all basic observations came up negative.

Anyway, back to the saga. Suspecting the driver IC, I obtained a replacement from MCM Electronics and swapped it. No change. Measuring motor voltage showed a maximum of 1.7 V or so at any time including startup. Since the driver is known now to be good and power was confirmed to be stable, I started to suspect the motor.

Disconnecting the spindle motor and cycling the player revealed that the driver was putting almost 10 V on the motor terminals but the motor was no doubt partially shorted and dropping this to less than 2 V with the consequential high power dissipation in the driver.

Now for the long shot. While the player was attempting to spin up and read the disc directory, I gave the motor a squirt of degreaser through its ventilation holes. The motor took off - went totally overspeed. Power off. Wait for degreaser to evaporate. Try again. Now, the directory came up the first time even though my internal controls were still no doubt not perfectly tweaked. All functions worked perfectly. For the first time is about 2 years, the player was producing music (without the help of TEST mode!

I then performed a normal alignment of the internal controls (but this is another story).

Measuring the motor voltage now showed greater than 5 V at spinup and a range of 2-.5 V between start and end of disc.

Comment: At this point the proper course of action would be to replace the spindle motor. However, since this is my CD player and replacing spindle motors is sometimes a pain, I will just keep an eye on performance. A pretty good indication of the motor's state is the time to spinup. If this deteriorates again I will be forced to replace the motor. For now, it continues to be satisfactory.

The initial confusion here was due to the fact that the motor was not totally dead, just weak enough to cause a problem with the inner tracks and more importantly, the directory. This is one of those cases where the old style turntable with a bad weak motor would have been much easier to troubleshoot,

---

Repair Brief #6: Dead Power One 400 W Multiple Output Switcher

Patient: Power One multiple output 400 W switching power supply.

Symptoms: Totally dead. No schematics available.

Testing: Applying power produces no output. Only observation is that lights flicker indicating the input filter capacitors are charging so this eliminates a blown line fuse as a possibility.

Unfortunately, this unit is not what I would call a 'simple switcher'. In addition to the main switchmode transistor, there are 2 other power transistors, a uA723 IC regulator, countless discrete transistors, resistors, capacitors, some components I cannot identify. This is all on the primary side of the transformer. Tracing the circuit is virtually out of the question due to its complexity. The only good news is that I have several identical units so I can compare readings between the bad one and a working unit. Powering with a Variac produces similar lack of any output. This is not a case of the outputs shutting down - there is simply no startup.

First check: power to main filter caps, continuity of thermal protector, power to uA723, power to switchmode power transistor. These all are fine.

Next, checked components around input including power transistors, large resistors (suspecting a startup problem), capacitors, etc. All ok.

Finally, about to give up, I decide to just test resistance across a more or less random selection of components. Everything is identical until I put my meter across a 6.8 M ohm resistor. On the good unit, this measures above 1 M ohm. On the bad unit, it measures about 40 K ohms. I unsolder components around this resistor until I located a 2N4124 transistor that makes a difference when removed. Testing on the x1 range of my VOM it tests fine but on the x1K scale, there is significant leakage in the reverse biased junctions. Comparing with a nearby 2N4124, this is definitely not the normal characteristics of a 2N4124. The 2N4124 is a general purpose transistor so I replaced it with a handy 2N3904.

Powering with a Variac, the supply now comes up fine. I have no idea of the function of the bad transistor.

Comments: This might be called a blind repair. Like bad connections, the failure mechanism and function of the bad part will probably never be known. It is not known whether the transistor was marginal to begin with and ts characteristics just drifted over time, or whether it went bad.

The basic assumptions which permit this technique to work at all are that for a sudden change in behavior in a system with mostly discrete parts, one of these parts has changed its resistance enough that an ohmmeter check has a chance to find it and that the circuitry is interconnected enough that checking a relatively small subset of node combinations has a good chance of locating the bad part.

---

Repair Brief #7: Goldstar CR820U TV with no Color

Patient: Goldstar model CR820U 19" color TV. Paid $1 at garage sale. If I can repair it cheaply, it will be given to someone in need free or for a nominal charge.

Symptoms: Basically operational except absolutely no color - not even any color noise between channels. Color and Tint knobs have no effect. In addition, brightness control has very limited range - brightness slightly too high. Several other minor problems including cracked tuner knob, dirty tuner, broken antenna wires.

Testing: This involved tuning local strong channels, adjusting fine tuning, tweaking AGC, etc. Under no circumstances was there any hint of color in the picture or between channels.

Fortunately, such symptoms narrow down the possible area of investigation to the chroma decoder circuitry. Searching the circuit board for a likely subsystem, I found that the set uses a TA7608P chroma chip. Fortunately, this chip is listed in my ECG Semiconductor Master Replacement Guide with a cross to ECG1532. Naturally, I suspect the IC at this point but know better than to just go out and find a replacement - I have been burned in this way with an RCA TV color problem - maybe I will say more on that in another Repair Brief. While the ECG does have a pinout, this does not really provide enough information to probe the circuit.

Off to the library to obtain the Sam's Photofact for this set. $0.75 poorer, I copied the complete schematic and another interesting page - a chart showing the resistances to ground for all pins on all of the intergrated circuits used in the TV. One item I forgot to look for was the block diagram that may have been included of the TA7608P chip. Oh well.

One thing I did try once armed with the Sam's was to attempt to tweak the subbrightness control. Even this had very little effect. OK, on to the fun stuff.

First test: confirm that the resistances of the circuit match those printed on the resistance chart. The chart specifies a DMM that applies less than .1 V on the ohms scales (to prevent forward biasing of any semiconductor junctions). Hopefully, my DMM satisfies this requirement. First step: make sure the main filter capacitor is discharged before making any resistance measurements. Done. Unfortunately. these tests do not reveal anything amiss.

Tests of this type are not guaranteed to find any problems. However, there is a fair chance that a shorted or open part would show up as a bad reading in the near that part. In my case, if there were any bad parts, the circuit topology prevented this simple resistance test from detecting them.

Now for the live tests. I don't have a color bar generator so I just have to hope that a broadcast channel will provide a signal that is close enough.

In the interest of safety, all the following tests are made with the set powered off of my isolation transformer.

Voltage measurements were inconclusive. Although some where off by 20%, this could be due to my non standard input signal. There did not appear to be any particular pattern.

Next, I used a scope to look at the testpoints for which Sam's supplied waveforms. Again, these will be different than the ones using a standard colorbar signal but the overall appearance should enable me to determine if a particular output is dead or the amplitude is way off.

All the waveforms looked reasonable except one - the output of what I deduce to be a gated chroma amplifier. Its output is almost dead. The color reference oscillator (3.58... MHz) looks fine as do the chroma input and color burst gating pulses. All the supply voltages and decoupling pins look fine as well. This doesn't look good for the chip. The signal seems to be getting in but the chroma amp would seem to be dead. Fortunately, I could not locate an inexpensive replacement from my usual sources. The TA7608P is probably obsolete. Even the ECG1532 is not available from MCM Electronics or Dalbani. I did not get to the point of trying ECG directly. You will see why I say 'fortunately' in a moment.

When confronted with a situation of this type, I usually try some experiments.

What would happen if I apply the chroma signal directly to the point in the circuit that is the output of that dead chroma amp? I take a 10K resistor and jump the input of the chip to the chroma amp output (and input to the chroma demodulator.) Now, I have colored stripes on the screen indicating that the chroma demodulator circuit is probably functioning. (Without the color burst to phase lock, I could not hope for anything more). So, it still looks like that bad amplifier. Well, one last desperate effort....

I use my Sam's patented magic spit. This has served in on numerous occasions mostly when locating clock noise, marginal timing, or glitches in high speed digital systems but hey, the world is really analog anyhow. I am not joking. Those who have done serious debugging know exactly what I am talking about. Moisten your finger. Run it up and down the pins on a suspect device. If something changes you have either (1) found a particularly critical or high impedance but normally behaving circuit (for example the frequency determining LC network of an oscillator) or (2) something that is open or on the edge.

Magic spit to the rescue: running my finger (one hand in my pocket, isolation transformer, etc.) over the two rows of pins on the chroma chip proved to yield immediate results. Around the low number pins, the color suddenly appeared grossly overloaded but with some indication of correlation with the picture. This is the first time I have seen any indication of picture related color. Hum.... OK, now to narrow it down. I take an insulated wire, and strip both ends. Holding one bare end with my fingers, I touch each of the pins in turn of the chip. Touching pin 6 has the most dramatic effect producing the distorted colors. What is connected to pin 6? According to the schematic, it is a 2.2 M ohm resistor to pin 3 and a decoupling capacitor to the power supply. It is unlikely that the capacitor would fail in such a way as to cause this behavior. So it must be the resistor. Rummaging around in my resistor cabinet I come up with a 2.2 M ohm resistor. and tack it across pins 3 and 6 (with power off!).

Now I get distorted color but this looks a lot more like a color TV than what I had before. Time for a better antenna. That helped a little but the picture is way too dark. Well, I did fiddle with the sub-brightness control back when it had minimal effect. Locating the sub-brightness control again, it now functions as expected having more than a sufficient range. When adjusted to produce a picture of normal brightness (with the user control mid-range), the color appears normal. Some additional fiddling with the Color and Tint controls yields a fine looking color picture.

Removing and testing the original 2.2 M ohm resistor confirms an open circuit. Soldering in my replacement completes the repair.

Now to clean the tuner, wipe down the case, repair the knob and antenna....

Total cost $1.77 including original purchase price (I threw in a hypothetical $.02 for the resistor).

As I am writing this, I am watching the Goldstar TV - my trusty RCA has just died after 14 years with no picture (raster and sound ok - that will be another Repair Brief).

Comments: It is always tempting to suspect the expensive or unavailable part first. Very often, as in this case, this proves to be erroneous. Had the TA7608P been readily available at reasonable cost, I would have probably replaced it only to find no change in behavior. This would, however, have saved time.

Be warned that the "Sam's Magic Spit(tm)" approach must be used with caution. You must understand the safety implications of touching *any* live circuit especially with moistened fingers. I use an isolation transformer for debugging. However, even with this precaution, I would think twice before doing this on a live chassis (the Goldstar signal circuits are isolated from the power line).

Repair Brief #8: Panasonic PV3720 VCR with Erratic Horizontal Video Noise

Patient: Panasonic PV3720 3 head VCR.

Symptoms: Band of what looked like tracking noise would come and go depending on tape being played, speed of tape, whether at start or end, etc. The noise was confined to the top 1/3 of the picture. Its height could vary from just a couple of video lines to a band occupying 20 % of the screen.

Testing: Several tapes were played initially. Problem would be nearly absent with some but severe on others. It was generally worse with EP recorded tapes compared to SP tapes.

I generally do not like problems of this type because one of the more likely possibilities is of a worn video head. This is one of the classic symptoms yet it could have a number of other causes. The approach must be to eliminate as best as possible the alternative causes until the risk of purchasing a new video is minimized.

Alternate #1: dirty heads. Head cleaning with a wet cleaning tape followed by a manual cleaning had little effect.

Alternate #2: tape path alignment. Visual inspection of the tape movement showed nothing out of the ordinary. Tape motion was very smooth and uniform with no wiggling, wavering, or wondering. All tape guides were properly positioned, perfectly vertical (where appropriate) and the tape appeared to be riding at the correct height on the video head cylinder.

Alternate #3: backtension. Insufficient backtension could result in similar problems. Inspection seemed to indicate that backtension was normal. Manually increasing backtension by gently pressing the backtension level to the left made a slight improvement. Increasing the spring tension did the same. However, these were not dramatic effects and backtension is not a critical setting to obtain a clean picture (though it is important to be accurate to minimize head wear and clogging).

Alternate #4: roller guide height. Although visual inspection of the of the tape path alignment proved negative I decided to confirm roller guide height by careful adjustment of the supply side roller guide - carefully noting its original position. (Problems at the top of the picture would be related to the supply side roller guide.) Optimal position for both EP and SP was at the original setting.

This left the video head as a likely candidate and at this point based on the age of the machine, a new video head cylinder (MCM Electronics, ERH433) was ordered and installed. Success! There was no doubt about the improvement. The noise bards completely disappeared and the normal backtension provided more then adequate head-tape contact.

Comments: Subtle problems that eventually point to the video heads are among the more difficult to diagnose with enough confidence to risk ordering an expensive video head and find out that the problem was elsewhere. This was a case of video head wear (as opposed to a mechanical or electronic failure of the heads). The chance of having an identical video head available to swap - which is the best test - is quite small, especially for a 3 head type. If this were a 4 head machine, some meaningful comparisons could be made during playback since a different set of heads is often used depending on tape speed and mode.

Thus, unless there is visible damage to the video heads or something like an open winding that could be revealed by simple testing, it comes down to eliminating as best as possible the alternatives until only the head remains a likely possibility.

Repair Brief #9: Original ATT Touch Tone Phone will not Dial

Patient: Classic ATT Touch Tone Wall Phone. 'Battlewagon' usually considered indestructible.

Symptoms: Everything worked fine except dialing. For some buttons, dial tone would not go away. For others, tones would be accepted but would be erratic and incorrect digits. Certain tones sounded weak or single frequency.

Testing: All buttons were tested. It was found that the problem was not even consistent as some buttons would not work all the time.

While the internal wiring of one of these old phones is intimidating, the basic tone dialing circuitry is an amazing example of simplicity. About the only things that fail yet still permit some tone generation are the pot core coils that determine tone frequency. Therefore, this is the first thing to check.

Sure enough, the core that deals with rows has split where the two halfs are joined. This seems to be a common problem due to both the age and brittle cement used on some revs of this model phone, and probably, as a result of rough treatment when hanging up the handset.

These cores must be aligned before being glued back together. In addition, there is an adjustment plug which may need to be tweaked. I align by ear as follows: Put a known good tone dialing phone and the bad phone on the same phone line. Depending on which core is bad, depress either an entire (same) row or column of buttons on both phones. (Adhesive tape is handy to hold down the buttons unless you have four hands.) By depressing the entire set of buttons, you are disabling the other tone generator so you hear a pure tone. Without turning the fine adjustment plug (assuming it was not disturbed; if it was, set it mid-range or the same as the one in the other core), rotate the loose core top until a zero beat is obtained. As your rotate the core, you will hear the tone change. As it approaches the correct setting, you will hear the tones beat against each other. When you are set correctly, the pitches will be equal and the beat frequency will go to zero. Mark the position of the core with a pen or pencil and then glue with Epoxy or other general purpose adhesive (around the outside - not on the mating surfaces as this will affect the tone frequencies). After the glue sets, confirm and adjust the plug core if needed. These cores use a strange triangular core tool - I made mine by filing down an aluminum roofing nail (do not use a ferrous material).

Comments: Those classic ATT touch tone phones are virtually indestructible. However, broken cores (or actually, just broken joints on the cores) are common but easily repaired once you know what to look for. Setting the tones by referencing a known good phone seems to be a very reliable technique as the zero beat permits an adjustment to better than .1%. Note that if the reference phone is a more modern (and flimsy digital one), then pushing multiple buttons may not work as it does with the old analog models. Setting the frequency using the normal dual tones will work - it is just not as easy.

Repair Brief #10: Pioneer PD5100 CD Player Trashed

Patient: Pioneer PD5100 single disc CD player in really sad shape. Garage sale acquisition paid $2. Probably paid too much. This episode is more aptly called a restoration rather than a repair. Perhaps a feature length saga. The challenge was irresistible.

Symptoms: Tray wasn't even on track, just sitting inside; Flapper ripped off of mountings, electronic condition unknown. It is obvious that the owner had attempted something - it would be generous to call it a repair - and was unable or did not bother to get it back together.

Testing: Not applicable at this point. With loose parts removed, power was applied to determine if there was any hope at all. At least the front panel came alive and pressing Eject resulted in the tray loading motor spinning.

In order to attempt to play a disc, the controller needs to think that the tray is closed. It will then go through its startup cycle. In the case of this player, there is a limit switch - somewhere. Rather than trying to locate it, I decide to put the tray back on its tracks. This is easy but there is still something wrong as it jams when the Eject button is pressed. So be it, leave that for later. At least the limit switch will be activated. Rummaging around in the pile of lonely parts removed from the carcass, I locate the clamper cover with the magnet. I pop in a garbage CD, put the clamper cover on top (make a mental not to press Eject under any circumstances as the tray, disc, cover, and anything else that is not screwed down would probably fly across the room) and press the power button. Some success - the disc spins and the directory is correctly displayed. The display came up rather quickly indicating that most of the optics and servos cannot be far out of alignment. This is quite remarkable!

With mounting anticipation, I connect the audio outputs to my amplifier and press play. The disc spins and makes repeated attempts to start playing at track 1 but it is obvious that something is terribly wrong. Attempting to play other tracks results in similar behavior.

The pickup appears to actually move to the general vicinity of the correct track but is unable to locate and lock onto the time/track that is selected. Pioneer CD players perform a very audible search to home in on the correct disc location; there was no evidence of this search.

I next attempt careful adjustment of the servo controls. Note that I do not expect this to help the problem based on how quickly the directory was displayed. However, the tracking could still be off and with care, there should be little risk of making things worse. Who knows what controls the owner touched in a misguided hope of performing a miracle. First, I marked the *exact* position of each control with a felt tip pen. This will get me back to the supposedly good positions no matter what. The only controls that would likely have an effect are those related to tracking. Careful tweaking of tracking balance, tracking offset, and tracking gain have no detectable effect. I put them back in their original position and verify that the player still recognizes the disc. So far so good?

At least the moron who butchered this thing does not seem to have touched the electronic adjustments.

At this point what do we know? Well, we know that all of the major components of the optical deck work including the laser, photodiode array, fine focus and tracking voice coil actuators, and spindle motor. These are all needed to read the disc index. The spindle motor, a common problem in Pioneer CD players is fine as its toughest task is at disc startup where the speed is greatest. Since the disc index is located at the very inner extent of the disc, we do not know if the sled servo (coarse tracking) is working correctly, only that it is doing something - it resets to the inner track if manually moved away and it does move to the approximate position of the selected track.

Well, Pioneer CDs have a TEST mode. Where is the button? I hunt all over for the little button and am about to give up when there it is! Hidden by the cables to the front panel.

OK, press TEST while switching on power. Now I have control of the servos. A little experimentation confirms that focus and spindle rotation seem to be functional: (of course, we knew that, right?) With no disc in place, the focus search routine is initiated by pressing TRACK FWD. The disc will only spin if focus lock is achieved and this is confirmed with a disc in place. So far nothing new. I am able to move the pickup back and forth on its tracks by pressing SEARCH FWD and REV.

However, when entering the correct sequence to play at an arbitrary point on the disc, weird things happen. If I use the SEARCH FWD and REV buttons to move the pickup to a particular spot on the disc, press TRACK FWD to close the focus servo, PLAY to start spindle rotation, and then PAUSE to actually start playing, the track and time info is only displayed for an instant. Then, the pickup seems to move toward and bump against the inner limit. Sometimes, a couple of times are displayed in rapid succession which are not sequential as they should be. In fact, they nearly always are far apart and the second is usually a lower time than the first. Then the display is blank.

Hum, I don't have a schematic so this could be the end of the line. But, I do see one chip on the circuit board that is getting unusually hot and I know from past experience that it is a servo driver - TA8410K. I have absolutely no idea if it is related in any way to the problem or really, for that matter, what the problem is. I only know that (1) it has only 10 pins and is easy to replace, (2) I have a replacement in my parts box, and (3) it is getting hot (which may or may not be a fault since I know these type of chips to run at least warm).

Getting to the bottom of the circuit board proves to be a bit harder than anticipated requiring removal of most of the snap type connectors. I guess these are cheaper than real connectors for Pioneer but a pain for servicing (cables are terminated in tinned wires and placed in the connector housing, then a cover is pressed down to lock them in place). I manage to only mangle one of these (cosmetic damage only).

Replacement goes smoothly. Getting all the connectors back in place is loads of fun but the effort is worthwhile! Now, the disc plays on the first attempt. There are still some tracking problems but this is a distinct improvement. In all honesty, I am not sure that the chip made the difference - it could have been a bad connections at one of the connectors. The new chip runs warm, perhaps not quite as hot as the old one, I am really not positive. I put a heatsink on it in any case (as I always do with these chips - just for insurance.

Next I tackle the mechanical restoration. First step: get the tray to move smoothly. Without going into terrible detail, the tray consists of two parts whose relative motion raises and lowers the disc. There appears to be something missing which controls when this raising and lowering takes place as the disc is lowered even before the tray moves into the machine. Sometimes there is a ball that controls this and a little examination reveals a grease trail where such a ball could have been. A corresponding hole in the tray bottom confirms this. I didn't notice any such ball in the parts pile but it could have easily been lost (I later found it near a corner of my workbench) but for now, I located a similar sized steel ball in my steel ball collection. With the ball in place, the tray now moves smoothly in and out and the disc is raised and lowered at the proper time.

Now for the clamper.

This is a much sorrier affair as the clamper is mounted to the deck sheetmetal with a couple of plastic standoffs that have been totally snapped off at their bases. First I try simply glueing them but this does not appear to be solid enough. In addition to the glue, I am able to clamp one down with a metal scrap that I carefully shape and screw down. For the other, I made a splint using a screw through a drilled hole into a neighboring strut. Now the clamper moves up and down at the proper time but the cover disk with the magnet seems to hit the tray. The part that seems to help out has totally disappeared so I take a brass rod and mount it in its place. Even without the rest of the mechanism, this seems to work fine. This rod, wrapped with electrical tape to prevent damage to the disc, prevents the disc from flopping around too much. Disc loads; disc unloads; all is well.

I then went through the electrical servo adjustment procedure as outlined in the CD Player Notes, final tweaking by maximizing the amplitude and stability of the 'eye' pattern. I made the mistake of attempting to touch the 'tangential adjustment' (at least that is what I think it is - without a proper alignment disc, this appears to be very difficult) and spent some frantic minutes until I was able to restore it to its original position. Beethoven's Ninth Symphony comes in handy as it runs almost to the edge of the disc (74 minutes) necessary to access the tangential adjustment. I even risked careful adjustments of the LD - laser power just to determine that it was not at the limit of its power. It was not. I am fairly confident at this point that the adjustments are pretty much where they should be - and they are very close to their original position.

Now the CD player works fairly well though it does not seem to have as much disc defect tolerance as I would expect. I do not know if there is still a fault either optical, mechanical, or electronic as all tests that I can perform without service info seem satisfactory. Considering what the player went through, this has still been a rewarding experience.

Comments: I consider this to be more of a learning experience than a repair. At the outset, I did not expect to be able to get nearly as far as I did. It was fun as such things go.

While I am in favor of home repairs, this is an example of a situation where whoever attempted the repair of a problem due most likely to the bad servo driver IC, totally destroyed any possibility of a professional even going beyond looking at the unit and stating: "Yup, that was a CD player once upon a time long long ago. To whom should I send the flowers?"

- Back to Sam's Repair Briefs Table of Contents.

Repair Brief #11: Yamaha R8 Receiver with AM/FM Tuning Problems

Patient: Yamaha R8 stereo receiver, about 4 years old at the time of the failure.

Symptoms: Fm reception is totally dead. Station numbers change erratically, not possible to save presets. Some AM stations work but most do not. This happened without warning - turned it on one day and it was sick.

Testing: This involved methodically checking to see what functions are operational. Incrementing and decrementing of FM station frequencies is not operational in seek mode, only in manual. There is not reception on any FM station frequencies. Incrementing or decrementing AM station numbers across certain boundaries (I forget the exact locations) causes a sudden jump of 800 kHz and may actually jump to an illegal station frequency. Various other modes are non functional including saving of memory presets. Even the hard reset does not store the factory presets.

I purchased the service manual for this unit - a nice piece of documentation and very reasonable - about $12. However, this is an example of modern technology where even schematics, pin descriptions of the various LSI chips, parts lists, etc. are not really adequate when so much depends on firmware (in 3 microcontrollers) which is not provided. It turned out to be difficult to even determine where each function is centered.

Some electrical tests that were performed:

Power supply voltages were verified.

Waveforms were checked on frequency synthesizer chip (LC7210).

Function of PLL charge pump was verified in both AM and FM. Output (VCO control voltage) was consistent with frequency display when reception was possible but not at other times. However, this could not be a problem with the charge pump, only the digital control.

Intermediate 4 bit busses were checked for stuck-at faults - there were none.

The first real clue is that since even some manual tuning functions are faulty, this is probably a digital fault. Presumably in manual, the station display is driven by the microcontroller that drives the synthesizer chip rather than being returned by that chip after a station search. Even in this mode (for AM), there is the issue of the 800 kHz jump. This is not approximate but exact and probably due to a stuck bit representing the 800 place value. The question then became: where was the bad bit? It is not on one of the intermediate busses as these were tested.

Could it be in the tuning microcontroller? Maybe, but then I would expect other functions controlled by this chip to be faulty (like mode setting, etc.) This is not the case. Could it be in the frequency synthesizer chip? Probably as only station tuning functions are defective. Could it be elsewhere? There do not appear to be any other busses or digital control lines that could cause the set of problems that are present.

However, not confident enough of the diagnosis of the faulty LC7210 synthesizer to spend the $25 or so that Yamaha would probably charge and not finding this part in any of my normal mail order sources, I set the receiver aside for a while. I dig out my garage sale NAD for use in the meantime.

A couple of MCM catalog editions later - what's this? LC7210 - $6. I will spring for that. Next MCM order arrives, solder in a socket as I always do where possible. Replacement chip cures all problems!

With 20/20 hindsight, it is almost possible to identify the place inside the LC7210 where the 800s bit bus fault occurs based on the symptoms and the rudimentary block diagram provided in the service manual.

Comments: Although not evident from the description above, this was a frustrating experience even with the service manual because there really was not enough information present to make the logical inferences needed to come to a definitive conclusion as to the defective part. Modern consumer electronics include more and more microcontrollers where the intelligence is buried in firmware and not the hardware itself. Without firmware listings, a microprocessor is just a black box even with pins listings and internal block diagrams. It would be nice if the service manual would at least provide better indications of which functions is located where - identifying the functions of each of the components. (It would also be nice if they were written or at least edited by Americans (in the case of a manual destined for the U.S. market). Some of the translations are, well, a bit strange.

- Back to Sam's Repair Briefs Table of Contents.

Repair Brief #12: Sylvania TV with no Horizontal Sync

Patient: Sylvania Color Television, about 20 years old.

Symptoms: Suddenly, the picture lost *all* horizontal hold. There was no evidence of any kind of attempt at lock in. I do not know whether this happened at power-on or while in use.

Testing: With strong signal, it was determined that horizontal hold had no effect. It is as though the H sync is not making it to the lock circuitry. Adjusting horizontal hold makes picture move across screen. Angle of sides of picture changes but there is no lock - even incorrect - at any setting.

Using my isolation transformer, I prepare to scope the relevant signals. I obtain the Sam's for the set. I check for the sync signal at the input to IC400 (I think). It is there. This should be a snap - bad IC! Well, that is exactly what happens - a careless slip of the scope probe and not only a snap, but a crackle and a pop - and now I have no video, no HV, no deflection - nothing.

OK, so what started out as a simple signal problem is now a major (at least cost and pride wise) power supply problem.

Checking the first TO3 transistor I can locate - short - one dead transistor. This is the power supply series chopper.

Checking the horizontal output transistor (HOT) with an ohmmeter - short - second dead transistor.

After removing transistor, I check for rectified line voltage at the input to the chopper - nothing. Tracing this back I soon locate an open fusable resistor.

So, whatever I touched probably caused the HOT to fail (forced on for too great a time can blow the HOT as a single shot event). The shorted HOT probably then took out the chopper transistor.

This is not fun. It is not likely to be inexpensive either. It does seem that no other parts have been sacrificed. Fusable resistors and driver transistors seem ok in so far as my meter is concerned. I still assume that the original problem was caused by a faulty IC400 but this point it is impossible to confirm this since the set id dead-dead.

Damage:

Chopper transistor - $10, horizontal output transistor - $6. IC400 - $15, fusable resistor - $1.

After replacing the components, making sure to use mica insulators and silicone heat sink compound for the transistors, the set comes back alive. Sync is fine. A little touchup of the video background and gain controls (unrelated to the sync problem) and we are done. Ouch.

Comments: The lessons learned here came at a cost - but mostly to my pride. Cascade failures are all too easy to induce through carelessness. Power supply circuits are not forgiving. One would think that probing the sync signal would not be able to kill anything. However, the design of power supply and deflection systems share some common characteristics. One of these is that a single instance of an improper drive waveform can blow the switching transistor as a single shot event - excessive current or excessive flyback voltage. This is a matter of exceeding the safe operating area of the transistor.

What you learn: if possible, make all connections to your test equipment with power off. Insulate all but the last mm of your probe so that any slip cannot cause a short. Work methodically, think things through, don't be over-eager, don't take shortcuts.

- Back to Sam's Repair Briefs Table of Contents.

Repair Brief #13: Dead Microwave Oven

Patient: Microwave oven (don't recall the brand).

Symptoms: Totally dead - no front panel display or anything else.

Testing: Plugged unit into live outlet confirms description of problem.

First step: remove cover.

Second step: confirm that HV capacitor is discharged. Although the unit has been unplugged for several days, it never hurts to be careful. Discharge with high value high wattage resistor (well insulated) and confirm with HV voltmeter.

WARNING WARNING WARNING etc. Microwave ovens are probably the most dangerous piece of consumer electronic equipment in terms of potential for electrocution while being repaired. Much more so than TVs, for example.

- There is up to 5,000 V negative with respect to the chassis while powered and stored in the capacitor when shut down. The energy stored in this capacitor is roughly ten times that stored in the CRT second anode of a TV or monitor. A malfunctioning oven that does not blow a fuse is potentially even more of a hazard since the capacitor cannot discharge into the magnetron load after shutdown.

- The available current exceeds 1 A. Depending on the transformer, this may flow until the fuse blows or circuit breaker trips.

- An isolation transformer (assuming you had one large enough) or GFCI will not protect against HV shock since the HV is already on the secondary side of the HV transformer and, as noted, the HV return is the chassis.

- A circuit breaker or fuse is not sensitive enough and too slow to provide any protection for you.

You might think at first that the possibility of microwave exposure is the principal danger. However, unless the door seal, oven chamber, or waveguide or its seals are damaged, there is no way for microwave radiation to escape. This still means that proper precautions should be taken - don't operate the oven for longer than needed with the cover off and don't stand too close.

Third step: test fuse. Open. Since these have ceramic bodies, it is not easy to determine if the fuse died due to an overload or a short by visual examination.

A microwave oven can blow a fuse for several possible reasons. Some of these are:

1. Shorted Magnetron.

2. Shorted capacitor.

3. Shorted rectifier.

4. Defective door interlock switches.

5. Bad Triac (possibly causes transformer core saturation due to operating as half wave rectifier or SCR).

6. Bad transformer (shorted turns cause overload). Fortunately, all but the last two are generally easy to identify using just an ohmmeter. Sometimes, an intermittent or short that occurs only at full voltage will prove elusive, however.

   Some quick checks reveal that the capacitor is a dead short.

   When replacing a microwave oven capacitor, it is important to get a fairly close match for the capacitance. The uF rating of the capacitor affects the microwave power output. Note that the 'working volts' rating on a microwave oven capacitor is not the same as on common capacitors found in other electronic equipment. It is not the maximum voltage permitted across the capacitor but closer to the VRMS rating of the HV transformer. And of course, before you start pulling wires off (1) mark down where they go and (2) discharge/check for voltage on the cap one more time.

   Replacing the capacitor with one from MCM Electronics brings the oven back to life.

   Comments: It is highly likely that the capacitor failed due to a defect in manufacture rather than some other underlying problem in the circuitry. When one thinks about how a capacitor is constructed - rolled up layers of foil and dielectric - it is amazing that capacitors do not fail that often. Any nick, thin spot, etc. represents a point of excess stress and can fail as in this case after considerable use - resulting in a short circuit, dead oven, and unhappy chef.

   ---

Repair Brief #14: Tandy Color TV/Monitor with Hum Bars

Patient: Tandy color TV/monitor found curbside. Unit appears to be in good physical condition. Remote is missing. Well, you cannot have everything.

Symptoms: When first turned on, TV appears to function normally. Why was it tossed? Well, after 30 seconds or so, a pair of hum bars begins to appear in the picture gradually getting worse until horizontal width and sync are affected.

Testing: Using a Variac, there is a point below normal line voltage where set operates perfectly. OK, so I will keep a Variac attached to the unit!

After removing the cover, the first thing to suspect is the main filter capacitor. If this should dry up and lose some of its value, these would be the exact symptoms. Jumpering (with power off) of a known good capacitor I keep for this purpose doesn't change anything. But what is this? A discolored resistor catches my eye. Maybe it is changing value as it heats and causing these symptoms. I wait a reasonable time for the set to cool and measure the resistor - 360 ohms. OK, replace with new one. Expecting this to cure the problem I am disappointed when there is absolutely no change.

Off to the library for the Sams' Photofact. Darn - Sams' does not have a service folder for this model. Nor for any similar models that I can determine (the librarian was very cooperative).

Well, the problem seems to be heat related. I get out my trusty can of cold spray. After going through nearly the entier can, it would seem that there is only one part that has an effect on the hum bars when it is chilled. It is the SCR that is part of the power supply regulator. Rather than simply obtaining a replacement, I decide to trace the circuit to determine, if possible, the possible cause of the problem figuring at this point that the SCR is simply sensitive to heat.

During normal operation, an IC drives the gate of the SCR but what is this?? Until the secondary supplies kick in and provide power to the IC, the SCR is driven by - you guessed it - the mysterious resistor. The other end of the resistor goes to the raw DC on the main filter capacitor. Now that is odd....Since I do not believe much in coincidences, I now start rethinking the significance of this. Maybe that resistor is not quite what it appears to be.

First, I remove it and see what happens: nothing. Power on, power off, nothing.

Next, I momentarily touch the resistor to the circuit pad - the set comes alive. Then I remove it. The set remains alive. And, after several minutes, no hum bars. Hum....

I then try increasingly larger values of resistance until turn on is not reliable - 15 K seems marginal, so I will go with 8.2 K ohms = that is over 25 times what I measured! No wonder there were hum bars indicating regulation problems - that low value resistor was totally overwhelming the poor IC in driving the SCR.

The set is used daily and has been operating without further problems for over 5 years since reviving it. It works great with a $10 universal remote control.

How did the resistor get damaged in the first place? I have no idea - maybe its wattage was slightly underrated and it just finally decided to poop out. I have no way of knowing what the original value was supposed to be or even, for that matter, the wattage.

Comments: resistors can and do change value, sometimes, as in this case, quite dramatically. Without a schematic, there is no easy way to determine when and if this has happened - and what the original value should have been. However, any discoloration, burn, or scorch marks should arouse suspicion. With 20/20 hindsight, these signs may indicate the presence of carbon - a fairly low resistance substance and thus reduced resistance is likely.

And yet again, a $.02 part brings a complex renders a complex piece of equipment inoperative.

---

8. Back to [Sam's Repair Briefs Table of Contents].

Repair Brief #15: Realistic Portable CD Player Randomly Shuts Off

Patient: Realistic portable CD player, about 4 years old.

Symptoms: Player will shut off at totally random times or sometimes will not recognize the disc. There is a clicking associated with the problem - probably focus search failing.

Testing: Attempting to play various CDs to completion provided no indication that the particular CD or power adapter made the slightest difference. There were some false leads with respect to the latter but these turned out to be strictly coincidence. The lens was inspected and cleaned anyhow with no change.

The first hint of the source of the fault came as a result of an observation that pressing on the cover would sometimes either cause the player to stop in the middle of a disc or allow it to recognize and begin playing a disc when it would not otherwise cooperate.

Perhaps, the interlock switch was not being pressed in far enough. So, rather than open the unit (I really don't like messing with the insides of portable CDs if I can help it - you will see why in a few moments), I glued a bit of plastic to the post that pokes the switch.

This seemed to help. For a few weeks, the problems had for the most part gone away and the owner was a happy camper. Not surprisingly, this fix was only temporary.

Since the quick fix had some effect, it is very likely that I am on the right track. I will have to open it and deal with the switch face-to-face.

This is not too bad except that it is necessary to remove the main circuit board to access the switch which is mounted on a little board of its own. Four screws (large enough to actually see without a microscope) to get the bottom off, another couple to remove the main board. One more and I can remove or at least extend the switch circuit board far enough to inspect its solder connections and get at the switch.

The solder doesn't look too bad but there might still be hairline cracks that are not readily visible. A little reflow and they should be fine. (Problems with solder joints here are not related to heat as in a TV or monitor but rather due to the mechanical stress that is applied to the switch every time the lid is closed.)

Now for the switch. It appears that the cover of the switch can be snapped off relatively easily. The contacts appear somewhat gummy so I clean these and pop the cover back on.

Tests with an ohmmeter now show the switch action to be solid. Wiggling the switch lever and/or the entire switch has no effect.

Great, put it back together and I am done.

After replacing the switch board, main board, and bottom cover - the test.

Fanfare please!

Nothing. The player is dead as a door nail. It now will not even focus and gives up almost immediately.

Off come the screws. Almost immediately, it is obvious what has happened. In replacing the main board, I accidentally squashed one of the printed cables linking the optical pickup and main board, partially severing the cable. In fact, 2 of the 4 conductors are cut. This is the focus and tracking drive cable so it is pretty important. What a pain!

Fortunately, luck is on my side with respect to the location of the break - it is at a non-flexing part of the cable. Therefore, repairing the cable should not be that difficult since once the conductors are connected electrically, they can be coated with a sealer and flexing will not be a problem.

To repair a cable of this type, I have two options: I can attempt to jumper the break with some fine strands of wire or I can go point-to-point from the circuit board to the destination on the optical pickup. However, the latter connections are nearly hidden and would be difficult to solder.

I opt for the first. Using an Xacto knife, I carefully scrape the orange mylar coating from both sides of the break. Then with #30 wire, I carefully solder across the break for each of the conductors. A spring clothespin holds the wire in place during the soldering. The entire affair is then coated with some clear sealer to reinforce it mechanically and provide insulation. It isn't pretty, but it will work fine. For added protection, I add a layer of plastic electrical tape.

Now, finally, reassembling the unit keeping cable routing firmly in mind, there should be no problem.

And, as expected, the player comes back to life and is rock solid with respect to playing and recognizing discs. The oops should have no effect on the expected longevity of the player.

Comments: we all can point to those minor disasters where we have overlooked something where we should have been more careful. Whenever reassembling anything, it is imperative that lead dress (ok, fancy term for how the cables are routed) is kept firmly in the forefront of your mind. It seems that with more and more miniaturization, this is an increasingly important and at times, frustrating consideration. First of all, it is very tempting to say when disassembling the unit 'this is obvious, no need to write it down'. Bad move. Often, it appears much less obvious when putting everything back in its place. I have never quite figured out how they do it during manufacturing - correctly most of the time.

Ignoring cable routing can lead, as in this case, to severed wires. It can also result in shorting between wires or between wires and sharp metal brackets or shields. Broken wires can usually be repaired if they can be located. Shorted signals can result in additional hard-to-locate collateral damage which can really turn your hair gray.

What is even scarier is that with line connected electronics or appliances like vacuum cleaners and even toasters - this can lead to electrically live parts accessible to the user. Sometimes, the plastic insulation on typical internal wiring will not fail immediately but will cold flow and cause problems later. So, one should always make every effort to assure that no wiring is being pinched and for metal cased appliances, check that the case is not electrically live - has a high resistance (usually infinite, but at least a few M ohms to both wires of the AC line with any on/off switches in both positions) after the repair is completed. For non-heating appliances or electronics, a little electrical tape goes a long way. For heating appliances you really need to make sure that bare wires are routed far from any exposed metal of the case taking into account as well any motion that may occur during normal operation or due to being knocked about or dropped.

Repair Brief #16: Sony CDU33A 2X CD ROM Drive Failure

Patient: Sony CDU33A CDROM Drive given to me supposedly brand new but broken.

Symptoms: Drive behaves the same as a similar working drive until it is accessed. Then, there is no response by any DOS or Windows software. No CDs are recognized, always get the message: Abort, Fail, Retry?

Testing: I keep an old (well, what other type are there?) 286 PC clone system around for the primary purpose of testing peripherals. Installing the drive and software confirms the reported behavior. I was given two similar drives. The other one was reported as being intermittent but seems to work fine in my test system. This one was indeed dead.

Since it is impossible to observe the behavior of the pickup and, in particular, the lens with the cover on, the first step is to get at the guts.

Fortunately, the CDU33A is quite simple to disassemble.

There are only two major components: the Printed Wiring Board (PWB) where all the active electronics are located and the Optical Deck including laser, optics, and pickup worm drive mechanism.

The other parts include the upper plastic casting and metal shroud, solenoid latch assembly, right and left guide rails, drawer assembly, and front bezel, two springs, bottom plate, 6 screws.

There are only two electrical connectors inside: one flat printed cable linking the PWB and optical deck and a two pin connector supplying power to the eject solenoid. This is in pleasant contrast to some other CDROM drives I have seen with a half dozen or more small connectors spread all over the PWB making removal and testing very difficult and risky.

After about 10 minutes, I have the drive apart and can now reassemble the major components on the bench outside the case to observe behavior.

I prop up the circuit board and reconnect the flexible cable - noting the orientation marks. I can now run the drive with full visibility of the mechanism and optics. With a CD in place, there is no danger from the laser beam. I make sure the PWB cannot short to anything and that the whole affair cannot tip over.

Having set up this contraption (you would have to see it to appreciate appreciate this terminology), I am ready to continue testing.

Naturally, it now works perfectly.

No amount of abuse seems to phase it - wiggling cables, flexing the circuit board, trying multiple CDs, all fail to reproduce the original problems. Could it be the case? I can think of no reason why it should make a difference? Is there anything else different? I don't think so. Perhaps the sled was jammed somehow and disassembling the drive fixed it. Who knows.

After reassembly, the drive continues to function perfectly.

Comments: How many times has someone brought you a 'broken' device which has magically started working again on your bench. It certainly cannot hurt your reputation. Admittedly, here, I had to actually do an exploratory before rejuvenation to convince it that I meant business.

It has now been almost a year and the drive continues to function. I can only guess that the cable may have been poorly seated or had some dirt stuck in the contacts. Until it fails again, there isn't much more to try. Unfortunately, the saying: "if it ain't broke, don't fix it" now applies. I have no idea if the drive will ever again fail within its normal life expectancy, but in the meantime, where did I put my Win95 CD? (No comments, please, about choice of OS).

---

10. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #17: Panasonic Color TV Shakes and Pulsates

Patient: Late model Panasonic 17" color TV

Symptoms: Width slightly reduced. Slight evidence of 60 Hz hum bar, brightness pulsating, raster shaking, somewhat channel dependent.

Testing: All of these symptoms were easily reproduced on the bench. The 60 Hz hum bar is the giveaway indicating a low voltage power supply problem.

Rather than operating the TV off a Variac to confirm lack of regulation, I decide to just try the most likely solution - a replacement main filter capacitor. With power off and making sure the main filter capacitor is discharged, I use a pair of clip leads to jumper my test cap across its terminals.

The set now works perfectly.

Removing the old capacitor (not easy as the rivlets really do make nice heat sinks), testing with my trusty Radio Shack DMM on its capacitance scale reveals that the value has dropped by over 85% - pretty amazing that the set worked at all!

One highly overpriced replacement filter capacitor (I used a local distributor instead of my favorite mail order sources) and the deed is done.

No disasters on this one!

Comments: This capacitor was mounted next to a large heat sink - possibly the power regulator. When replacing electrolytics, we often ignore one very important specification - the temperature rating. Either the original capacitor was defective or it was not rated for the thermal conditions inside a compact TV. The TV was not that old - maybe 3 or 4 years at most. We all can point to equipment we own that is still working after 20 or 30 years going strong on the original filter capacitors.

---

11. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #18: Dead Zenith Color TV

Patient: Zenith 19" color TV, about 5 years old. This TV is owned by a neighbor of mine who has small kids - more on this later.

Symptoms: Dead as a door nail. Only evidence that it is connected to the line is a momentary flicker of lights when TV is turned on indicating that the main filter capacitor is being charged.

Testing: This set has a pull-type on-off switch. There were no blown fuses. Checking with a voltmeter shows 150 V on the main filter capacitor with the switch in the on position. Ditto for the collector of the HOT.

This would seem to indicate that there is a problem with the startup drive to the Horizontal Output Transistor (HOT).

Off to the library for the SAMs....

Many Zenith TVs use a simple multivibrator to generate a startup signal to the horizontal driver transistor until the flyback can generate the secondary voltages needed to operate the deflection ICs. Once these voltages are present, the startup circuit is disabled. Indeed, such a design is used for this TV.

Checking with a scope (powering the TV through my isolation transformer) at the base of the HOT shows no drive signal.

Tracing back, there is no signal at the driver transistor or from the output of the startup circuit. One of the two transistors in the startup multivibrator is bad.

I do not have a suitable replacement - it is a high voltage low current Zenith part similar to an MPSA43 - 200V. I will need to obtain one, or better yet, two to replace both transistors in the multivibrator.

To confirm that the rest of the TV is operational, I use a common technique to 'jump start' a TV where the startup circuit is defective. This is to inject a signal of around 15-16 kHz directly into the base of the HOT to substitute for the startup circuit.

With the TV turned on, momentarily touching the output of a pulse generator set for 15 kHz and a couple of volts amplitude to the HOT base brings the TV to life. Everything appears normal except that the TV does not start on its own. Somehow, I don't think my neighbor would approve of this solution. (Also, I am not giving up my pulse generator!).

Caution: jump starting a TV like this is risky. In addition to the dangers of mucking with a live TV, injecting a signal with improper characteristics into the HOT can destroy it and possible a lot of other circuitry - instantly. For example, a single cycle with too long an ON time can blow the HOT from overcurrent while driven on or overvoltage during flyback. Use this approach with care.

Replacement of the multivibrator transistors with the exact Zenith parts completes the repair successfully.

Comments: Examining the schematic of the startup circuit reveals that it appears to be designed to fail - especially with kids about. While the transistors are rated at 200 V (they are running on the 150 B+ from the line power supply), the transistor power rating is only .6 W. Even though they are running in a switching mode, I believe that repeated on/off cycles can stress these to the breaking point. Something was mentioned about my neighbor's kids turning the TV on and off repeatedly. I have not duplicated this experiment but suspect that such treatment at least may contribute to premature failure. Fortunately, in this case, it was only in the startup circuit.

Power-on is a stressful time for many types of equipment due to inrush current, transient voltage, so many things changing quickly, etc. In addition, designers may not study and characterize the behavior during startup with the same amount of care that they presumably (we hope) do for steady-state operation.

---

12. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #19: Samsung VCR Caught in Infinite EJECT Loop

Patient: Samsung VCR, Model VR 2610.

Symptoms: Inserting a tape works fine - it plays, it records, it FFs, it REWs. However, attempting to eject a cassette results in an infinite loop - the VCR grabs the tape back just before it pokes out of the slot. Sometimes, the tape can be grabbed in time but usually the cassette does not exit far enough.

Testing: Symptoms confirmed. With the top off, it is easy to catch the tape but I don't suppose this would be an acceptable solution. In addition, the cassette carriages seems king of sloppy - loose for want of a better term. This would indicate a mechanical problem with the cassette basket - the mechanism which moves the cassette into position inside the VCR.

First step: a close examination of the basket mechanism. Nothing obvious - no broken parts visible.

Next step: attempt to remove the basket. With most VCRs, this is a simple matter of 4 screws and perhaps a connector. Not here. There are 4 screws, but once the screws are removed, only one side wants to come loose. The left side, with most of the gears and whatsits, is firmly fixed to the base of the tape deck. No doubt, there are critical timing relationships that might be disturbed once removed. It stays for now.

Perhaps, removing the bottom cover will reveal something. 8 screws later, bottom cover off. What's this? A spring!! So now, we know that something is indeed broken and most likely in the basket somewhere. This sort of spring is not the type to have just popped off - it is a close wound coil spring with hooks at each end. And, guess what, there is also a tiny bit of white nylon which was probably the tab onto which the spring was hooked at one end.

A close examination of the visible portions of the basket above and below deck finally turns up something now that I know generally what I am looking for. Thankfully, it is accessible and I hopefully don't need to pursue removing the basket which almost certainly would not be a fun thing to do.

The spring is supposed to be connecting two gear-type wheels in the EJECT mechanism. With the spring sprung, these were free to rotate when they should not have and their free play was sufficient to cause the EJECT operation to screw up.

So, how to repair? There is no good way to glue nylon and even if there was, the tab is so small that it would be impossible to provide a strong enough bond to withstand the spring force. Replacement of the part with the broken tab is a possibility though again not a pleasent one - it would require removing the basket. Of course, replacing the entire basket is another unpleasent and expensive options. Installing a metal post in place of the tab is also a possibility - one that I do not really want to contemplate.

Well, it appears as though there is nothing particularly critical about the spring placement. Is there an alternative location to connect the end with the broken tab? Yes, it would appear that it will be sufficient to hook it around another large wire spring. However, then it is probably stretched too long, so I make a link out of a piece of a paper clip and this seems to be about right. (Paper clips, bailing wire, scotch tape and chewing gum (well maybe not chewing gum) are among my favorite things). Getting all this in place under spring tension between the edge of the case and the basket plastic frame proves a bit of challenge - requring a dental picks, needlenose pliers, patience, and few carefully chosen four letter words - but I prevail. The EJECT operation now works perfectly.

While not pretty, I believe the newly designed spring attachment will be much more robust than the original. I should write to Samsung!

Comments: This is a another case of poor design - there can be no other way of describing it. The spring is rather large (you can visualize it, can't you?) and the tab much too small. Another .0001 cent of plastic and it would outlast the rest of the VCR. There was absolutely no excuse as there is plenty of space to enlarge and reinforce the tab.

---

13. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #20: Nintendo Game Console Won't Reset

Patient: Nintendo original game system.

Symptoms: Power light blinks indicating that it is not able to run the program contained in the game cartridge.

Testing: Tried multiple cartridges without success.

The most common problem with these units is a worn or dirty system unit game cartridge connector. In this case, the red power/status light will continue to flash even after the RESET button is pressed with a game cartridge in place. Replacements are available for about $9 from the usual sources (MCM Electronics, etc.)

First, I try another game cartridge - the one that is not working may just have dirty contacts or may be defective. This does not work.

So I need to get inside. Fortunately, unlike some other consumer stuff, this is quite easy. Six screws underneath followed by about a dozen to remove the metal shield and circuit board so the connector can be removed and inspected.

Before removing the connector from the circuit board edge, I give the system another chance to redeem itself. With the latching mechanism removed, it is possible to press the cartridge down somewhat lower than normal increasing the chances for good contact. Indeed when this is done, it is possible to occasionally get a good reset and game startup on the TV. This certainly confirms the original suspicion.

Now, can I revive the original connector or must it be replaced? There are three kinds of problems that generally occur with these connectors:

1. Wear of the contacts to the game cartridge. Although full pressure is not applied until the cartridge is latched, there is still wear every time a game is inserted or removed. This take its toll. It is often possible to use a dental pick or a bent paper clip (one of my favorite tools!) to slightly spread the spring contacts so that they grip the edge contacts of the game cartridge more tightly. On a high mileage unit, however, they may be worn through to the point of actually breaking in half resulting in replacement as the only option.

2. Corrosion at the connector to the circuit board. Cleaning with a pencil eraser or at most some very fine sandpaper (600-1000 grit) will usually restore to as-new condition unless some really corrosive agent was at involved.

3. Kid grime on game cartridge edge connector transferred to Nintendo cartridge connector. Favorites: Coke, sugar candy, and ice cream.

So, the first step is cleaning of both sets of connector contacts and the main circuit board edge finger. You may need to use a variety of solvents to completely remove all crud. Water may work better on sugar syrup than normal contact cleaner or alcohol. For the edge finger, a pencil eraser very useful.

Don't neglect the game cartridge connectors. These generally do not wear but may collect all kinds of strange stuff. Rather than fight with the security screws that you may find holding the case together, I usually simply use a Qtip with water, contact cleaner, or alcohol - or one after the other - to clean these contacts. Again, very fine sandpaper may be needed in extreme cases.

Even if these procedures only make a slight improvement - you can press down on the cartridge and the machine will respond to the RESET button - you have confirmed that the connector is indeed the problem. In many cases, just cleaning will result in reliable operation for a long time to come.

In the case of this particular system, all three problems were present. However, for the time being at least, the system has responded well to treatment.

Comments: While the original Nintendo game machine is a couple of generations out of date, many are still in use. And, hey, young kids usually don't care. OK, you don't have to admit to being the one who cannot resist just a couple rounds of 'Super Mario III'!

Old Nintendos can usually be picked up for $5-20 at garage sales sometimes complete with a selection of games, sometimes bare. The games go for $1-$5 depending on the barganing skills of the kid selling the stuff.

However, a bad connector is almost a sure bet with a secondhand system. Consider that most electronic connectors are typically rated in terms of hundreds of insertion/removal cycles. A Nintendo machine must endure thousands of not necessarily gentle cycles over its lifetime. The connector was not designed for that. Furthermore, you are likely to find all kinds of muck inside, mostly unidentified, and often difficult to remove. Nonetheless, these things are remarkably robust, electronic failures are infrequent, and they can usually be revived without much difficulty.

---

14. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #21: Sharp VC7864U VCR Erratic

Patient: Sharp Model VC7864U VCR in generally good condition, garage sale acquisition, $1.

Symptoms: Former owner complained about difficulty in ejecting.

Testing: Tried playing multiple cassettes (not all at once!). For the most part, the VCR behaved normally. Maybe just a bit sluggish loading but no other obvious problems. Why did he dump it?

I did my usual cleaning - rubber parts did not look to bad, leave them for now. Even the idler tire appears to be in decent condition. I will use the VCR and see if any problems appear.

The first sign of trouble appears once when attempting to use REVIEW mode - the VCR abruptly stopped and attempted to unload the tape. The loading motor was spinning but nothing was happening (I think it was turning in the wrong direction and the belt was slipping - I am not sure). Oh boy, time to leave the cover off. Manually giving the motor shaft (fortunately it is accessible from above the deck) a couple of turns convinces the VCR to complete a correct unload cycle.

Well, this sounds like the classic 'if it is an erratic Sharp VCR, the mode switch must be dirty or bad' problem.

(2 years pass as I am in no mood to bother with this repair at the moment.)

OK, now I have a need for a reasonably decent VCR to replace my cousin's Mitsubishi HS328U which is finally dying. So, I dig the Sharp out of the closet and see about its condition. Now, it doesn't even want to play a tape at all. Well, I know I have to deal with the mode switch, so first things first.

The mode switch on this model is sandwiched between the loading gears and a mounting plate - all parts of what I will call the 'loading gear assembly'. To access the mode switch, this entire unit needs to be removed and partially disassembled. The gears operate the roller guide loading mechanism, and a couple of cam operated levers which are conveniently hidden when it is removed or reinstalled. It is driven by the loading motor via a couple of idler gears.

Timing marks: In the unloaded position, there is a hole in one gear that appears to line up with a slot. So, with the roller guides retracted (and the gears which operate this linkage have timing marks which also line up), this hole should be centered in the slot. Fine. This appears to be the only critical relationship with respect to removing the loading gear assembly.

I unsolder the 4 connections to the mode switch, remove 3 screws, and - sproing! What was that? OK, one or both cams still had a lever with spring pressure applied. Hopefully, it will be possible to extend these these when replacement time comes along.

With the loading gear assembly removed, it is still not possible to access the mode switch. Now to disassemble it. There are two fancy cam gears which obviously must be timed correctly - in one position there appear to be an arrow and triangular hole which line up. I add a couple of marks of my own for good measure with a felt tip pen. A simple split washer holds the gear I need to remove onto its shaft. (Note: these split washers are not designed to be reused but with care in removal, they can usually be replaced without any long term problems. Of course, a professional would have an assortment of replacement sizes handy.) Removing the gear carefully, there don't appear to be any flat washers or spacers to worry about.

Once the gear is removed - making a note as to which side is up though this is pretty obvious - the mode switch is exposed. Squeezing the center of the split shaft enables the cover to be popped off and the interior appears. I almost lost the springy wiper as it is not fixed to the plastic cover but popped free when first removed. A frantic search was needed to locate it on the floor. The wiper fingers and encoder contact traces seem to be in good condition but whatever was used as a lubricant is a little gummy and might be the problem. A simple cleaning seems to take care of that. I also bend the wiper fingers a bit to increase the contact force very slightly.

Now, to get everything back together. First, the wiper is replaced and the mode switch cover is snapped back in place. Free rotation is confirmed. Then, the gear that was removed is returned to its shaft along with a cam follower lever that was under it. The split washer is replaced.

To install the entire loading gear assembly means that the original gear timing relationships must be re-established. In addition, care must be taken to make sure those two cam follower levers I mentioned previously are properly positioned. This takes a bit of work but eventually, I am convinced that everything works as it should. The screws are tightened and then free movement of all the parts is confirmed by manually cycling the loading mechanism. The 4 mode switch connections are then resoldered.

Now for the test. Since this was not a hard failure to begin with, there is no guarantee that any problems will be detected.

The tape seems to load correctly but then the VCR unloads and shuts down. What is wrong? It would appear that the takeup reel is not turning. Hum, probably that rubber wasn't as great as I had assumed a couple of years back. I now do a more complete cleaning and, in particular, remove the idler tire and inspect it. It appears to be ok but as a test, I turn it inside-out.

Now, everything works as expected. Testing with a cassette cheater (shell), there appears to be adequate takeup torque. I clean the idler tire again and reinstall it in the normal configuration. All modes appear functional even when testing with a full takeup reel - requiring the most takeup torque. I will order new rubber anyhow and replace it at a convenient time or if problems reappear.

This VCR now appears to operate reliably and consistently. I have seen no evidence of the original erratic behavior. Only time will tell for sure.

Comments: I cannot overemphasize the importance of making careful notes as well as adding timing marks of your own when removing any parts of a VCR which could conceivably have critical timing relationships. Not doing this can really mess up your day. Err on the side of excess - it won't cost you anything.

Sharp VCRs seem to be particularly prone to mode switch problems: Of the 3 Sharp VCRs under my control, 3 of them have developed dirty mode switches resulting in a variety of erratic symptoms including, as noted, going into the wrong mode as well as aborting the tape loading operation for no good reason.

It would seem that a VCR design using an optical mode switch instead of one with sliding contacts would be much more reliable at only modest additional cost. After all, VCRs already use a number of optical sensors and cheap computer mice use optical encoders not very different in design from a mode switch. At least, it would be nice if mode switches were readily accessible. Some are visible as soon as the bottom cover is removed. Others require substantial disassembly with associated risks of incorrect reassembly resulting in mechanical timing problems or even damage when the unit is cycled.

Repair Brief #22: Magnavox Console TV Deflection Problems

Patient: Approximately 10 year old BIG Magnavox color console (when furniture meant something).

Symptoms: Horizontal deflection jittery, possible vertical collapse, arcing flyback - all in one set! This info from Dave whose friend owns the set. Dave is a tech at work who is now doing more software than hardware (not necessarily by choice).

Testing: I did not actually see the original problems, nor did I have access to the entire set as Dave came in one morning with the guts of this set under his arm (more like both arms). We actually attempted to power it without the yoke or CRT but there was absolutely no evidence of anything. Surprise surprise.

Since the original description of the problems is somewhat incomplete, a visual inspection is made and the HOT is tested for shorts just to be sure. There were none. However, the visual inspection did confirm that the flyback had a narrow but rather long (maybe a couple of inches) crack in its housing, There was no conclusive evidence of arcing but this is one area where the original symptoms were fairly definitive as the owner stated that there was arcing around the flyback. (He probably knew just enough to be dangerous, but hopefully has not done anything we will regret.)

This would explain the jittery horizontal but what about the vertical problems? Were there really vertical problems. I never did get a good answer to this question - at least not until later.

While it is likely that the flyback could be patched up at least temporarily, it was decided to order a new one. The owner was willing to spend up to $150 to repair the set - I have no idea why. No match from places like MCM Electronics - must go directly to Magnavox (Philips, actually). $71, ouch. Admittedly, this is one of the spiffiest flybacks I have seen lately (at least since that A-line Zenith with the cool ribbed plastic coil form). It has a detachable CRT anode wire - wire and suction cup sold separately! Well, for $71, you cannot expect everything.

Although we have agreed to order the flyback, I decide to test the old one anyhow, so next day I bring in my flyback testing widget (12 V chopper, see document on flyback testing). This is the first time Dave has seen this tester and Ed (our chief digital design engineer) is also curious but stands at a safe distance, having a great deal of respect for a few puny kV. Ed always stands at a safe distance when anything higher than 5 V is involved!

First step - locate the HV return. In this case, it is obvious because (1) a separate bare wire is brought out to a pin and (2) this wire is connected to no other pins on the flyback. (With a built in HV rectifier, it is not possible to use a normal DMM to locate this wire.)

Next step - wrap a ten turn coil around the core of the flyback and connect this to the chopper.

Apply power - a nice healthy arc can be drawn from the HV lead of the flyback to the return connection, current draw on power supply is low. Flyback is quite functional. This does not test for breakdown at full voltage but does rule out hard shorted turns. (Ed can be overheard mumbling something about sticking with 5 V logic.)

Result is fine by me, owner wants new flyback and this one will make a great HV supply for a plasma globe or something - someday.

So, we pile the chassis and all its attachments onto a table in the corner of the testing lab awaiting our shiny new flyback (minus the red wire, some assembly required). It looks kind of pathetic there but no one else dares go anywhere near let alone touch it after an off-hand comment about charged capacitors!

Approximately 5 days later, our new flyback arrives and is soldered into place.

Next morning: I see Dave pulling up in his Chevy wagon. Guess what is in the back? The entire huge, heavy TV, belly down. Oops. We quickly find a place for it somewhat out of the way in a back room.

Apparently, there is no arcing and the horizontal deflection is stable. But, there is absolutely no vertical at all - flat lined. OK, so the rumors about vertical collapse were not exaggerated.

A little more visual inspection reveals a couple of interesting observations. First, all the deflection circuitry - both horizontal and vertical - is clustered in a small area near the flyback. In addition, the crack in the crack in the original flyback is adjacent to some of the *vertical* output circuitry. So, perhaps, the arcing was making its way to something in the vertical deflection. What kind of output chip is it? Ah, my favorite - a TDA3654. Fortunately, I have a bunch of them to keep one of my tough dogs fed. So, I am well prepared if need be.

A quick measurement of power to the TDA3654 reveals that there is none. Maybe this won't be so bad after all. Tracing back with an ohmmeter and what do I find? An open fusable resistor! And, in exactly the right place to be killing power to the chip. Could it be this easy? Actually - yes in this case. I install a normal 1 ohm 1/4 watt resistor (only for testing). I also use the ohmmeter to confirm that the rectifiers in the vicinity are healthy. We are set!

Power! At first there is nothing on the screen but then snow gradually appears - and it is full screen. There is no antenna. Of course, reception inside our building is nearly non-existent due to all the computer RF interference and steel beam construction. However, we quickly locate a pair of rabbit ears (or maybe it was just a couple of feet of hookup wire) and tune one of the few channels that is viewable at all - which happens to be broadcasting the morning cartoons. But that is just fine. Everything appears normal and I remind Dave to replace that resistor with a proper flameproof variety.

Dave cannot believe it.

Ed is nowhere to be found.

Everyone loves the cartoons.

Comments: The mechanism for the vertical failure still remains obscure. Apparently, the arc caused a momentary but not fatal short circuit in some part in the vertical output circuitry which blew the resistor. We always hear how sensitive ICs are to static - here we have 25 kV of raw power discharging nearby with apparently no permanent damage except to a 25 cent resistor.

Repair Brief #23: Hewlett Packard AN/USM281A

Oscilloscope with Multiple Problems

Patient: Hewlett Packard AN/USM281A Oscilloscope. This is the militarized version of the HP180 lab scope. PL1186 dual channel 50 Mhz vertical plug-in, PL1187 delayed sweep timebase plug-in.

Symptoms: Horizontal position shifted almost off the screen; delayed sweep and B timebase inoperative. Alternate triggering erratic at low intensities(??).

Testing: How does one test a scope? Well, put it through its paces with reasonable input signals - a 10 MHz clock oscillator provides a nice test signal. Maybe another scope would be handy?

Prologue: (You can tell right off that this will be a feature length saga.) I bought this scope at a garage sale. Now, understand, garage and tag sales around the Philadelphia area where I live are usually of the "Aunt Minnie's old silver plate" variety. Electronic equipment is usually limited to comatose VCRs and color TVs that play in B/W (not that I complain about this sort of stuff for the right price - as little as possible). However, one little ad catches my eye: one item amongst all the bric-a-brac is 'test equipment'.

BTW, I never go to flea markets with any serious intention of buying anything. It is clear where their stuff generally originates. All the junk I turn down at garage sales ends up with hugely inflated prices at flea markets!

I get to THE sale relatively early (I am not quite the garage sale addict type who gets up at 5 AM to be first in line). All that is visible are a couple of pathetic old signal generators - one audio, the other RF. Well, $10 for an RF signal generator isn't too bad. I could probably have bargained him down to $5 but first the all important question: Anything else? (Not that I expected any sort of affirmative response given the assortment of hat boxes, deflated basketballs, and old Christmas decorations.) However, surprise surprise! "There is one other item." So he crawls under a table and drags out an HP AN/USM281A - a real oscilloscope! "Well, I have this, um, oscilloscope. It is solid state, dual channel, 50 Mhz, etc." Now, I am paying really close attention (but of course, not wanting to show it). The only oscilloscopes I had seen at garage sales until this time (beside my $3 Tek 321, but that is another story) are usually the really beaten up Eico variety). He is actually doing a pretty fair sell job. So, how much are you asking? "I would like to get $100 for it." Very interesting. Can I try it? "Sure." So, he props 'my' scope on top of a rickety old bar stool (I would have been quite upset if the thing had gone crashing to the floor but still didn't want to act interested enough to suggest he find a more stable spot.) I figure that if it appears to work at all, $100 is a good price even if I have do some repair and calibration. I fiddle with the controls, also noting that it comes with two nice looking 1X/10X probes. Suddenly, the scope really cooperates - it must really want a new home being so lonely stuck in the back of that garage. The trace scoots off to the right of the screen. None of the front panel controls have enough range to bring it back. I mumble: I cannot get the trace back. He says "Oh, um, uh..." Before he can get too far, how about $50. "Sure, ok." I didn't do enough testing to find out that the delayed sweep was also dead. For that matter, even with the 10 turn delay time pot in plain view, the existence of a delayed sweep mode did not register. I only found that out later. No amount of fiddling would produce any difference between the A timebase and Mixed A+B. The B timebase was totally dead.

So, how to go about tackling this? I have no service manual, no schematics, and looking at circuit boards, the semiconductors are HP house numbers. I didn't have an ECG manual. Fortunately, the component side of the circuit boards are readily accessible. However, tracing the wiring is a real treat with HP's love affair with multicolored striped bundled wiring harnesses. I could try to buy a manual (this was somewhat before the days of sci.electronics.repair). Nah, that would be cheating (and probably expensive). I did try our local HP sales rep when we were looking into their logic analyzers but he did the usual salesperson thing and lost interest once we signed on the dotted line.

So, I had to repair it the old fashioned way - ohmmeter, circuit tracing, seat of the pants, etc.

Objective #1: find the horizontal position problem. Even if the delayed sweep remains broken, a dual trace 50 MHz scope is very useful. Fortunately, this problem appears solid now (and not intermittent as was the case previously) so ohmmeter tests of the horizontal sweep board components should be possible. Tracing back from the deflection plate connections to the CRT finally results in a difference between apparently symmetric sections of the output stage. An 11 K ohm power resistor tests open! Well, that wasn't too bad. It doesn't appear as though there is any cause other than age. Replacing the resistor restores full range control of horizontal position. About 1/2 hour to find. Not too shabby.

At this point, I considered the operation a success and put the other problems aside. Partially, this was because what I had was usable and partially because I did not expect the delayed sweep/B timebase problem to be nearly as easy to solve.

(Actual elapsed time: about 2 years. Well you know how I suggest 'sleeping on a problem' when you cannot solve it immediately!).

Objective #2: Fix the B timebase. The only help I have with this is the fact that the A and B timebase circuitry is quite similar so some comparisons of resistance measurements will be possible. However, for some reason, my first pass over the components with an ohmmeter does not turn up anything obvious.

Using another scope (a Tek 564), I poke around the B timebase circuitry a bit to see if I can locate any interesting signals. I suppose my definition of an 'interesting signal' is one that is doing anything - not flatlined.

What's this? A ramp waveform - it must be derived from the A timebase as it maintains a fixed relationship with the A timebase output but goes into the B timebase circuitry. My guess would be that this was be used to provide a gating pulse of variable width controlled by the delayed time (10 turn) pot. Maybe following this signal will lead to something. Sure enough, it goes to what must be a comparator circuit since the pot also connects nearby. And - what is that? A charred resistor! Now, why didn't I see that before? Fortunately, there is another identical circuit across the board and that resistor is readable - 100 ohms. Now we are cooking (hopefully not literally). With great expectations - switch on. Still no action from the Mixed A+B or B timebase. As far as I can tell, not a thing has changed. The B timebase is still as dead as a door nail. The good news is that the resistor is not getting hot, so that is encouraging - probably.

Next, I continue on with my search for shorted or open parts with an ohmmeter. This time, I will be more systematic hopefully not missing anything. Finally, results! Another blown part. This time, it is a transistor. From the remaining good junction I can at least tell it is supposed to be PNP. Measuring the voltages across C-E, it appears as though a 2N2907 will be of adequate ratings (at least voltage wise). Hopefully. Soldering in the new transistor from the top of the board is not fun - but more fun than attempting to remove the board entirely. Power: Darn, still no action.

Continuing with the ohmmeter finally turns up a shorted diode but what type? Again, duplication comes to the rescue. It is a 54 V zener. I use a pair of 25 V or so zeners temporarily to substitute for this unusual diode. Now, finally, the B timebase is responding to treatment! Having done what I always caution against - turning adjustments without marking them - the behavior is a bit - strange, but the two relevant controls (don't ask me at this point what they did) could be set for proper operation of the Mixed A+B as well as B timebase.

How could 3 parts in apparently not directly connected circuits be blown? I have no idea except to suspect that the previous owner may have attempted to repair the B timebase and never stumbled upon the actual cause which was most likely the bad zener but managed to blow other parts in the process.

Objective #3: Determine why turning the intensity way down causes the alternate sweep mode to get stuck on one trace. This one is a minor annoyance only and really doesn't affect the utility of the scope in any way. It is just not quite perfect. I finally locate a couple of adjustments in the vertical plug-in that seem to have an effect on the rise time of the start of the sweep or something - they seem to modify the strange behavior as well as affecting the linearity of the left 1 cm or so of the screen for high sweep speeds. I finally find a compromise position that seems to be satisfactory.

Wow, a whole bunch of simple problems but now it appears to be in pretty good condition. A couple of drops of oil for the delay time control, clean the switches and controls, and a piece of Plexiglas to protect the CRT and it is done.

Comments: What do they say? "Real engineers don't need no f***ing manuals". Or is that programmers? Well, whatever. A service manual would sure have made the task a lot easier. But where is the sport in repairing something with actual accurate documentation?!

The AN/USM281A is still a good solid easy to use oscilloscope for general design and debugging. I don't know if this one ever saw duty in the Navy but I have seen this model going for about $250-300 from test equipment outfits like Tucker. In my tests, the scope will display a viewable waveform and lock at frequencies greater than 80 MHz even though the specs are for 50 MHz vertical bandwidth. The mainframe itself, I think, is rated for 100 MHz. It takes standard HP180 series plug-ins so if I ever come across any of those at another garage sale.... (about the same time pigs learn to fly!)

17. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #24: Sony Servolock Turntable Erratic

Patient: Jeff's Sony turntable. Two speed, quartz locked, nice - if you care about such things anymore.

Symptoms: Platter turns but 'lock' light flickers and speed is slow and uneven (even to the unaided eye and without listening, it is obviously struggling).

Testing: Both speeds (33-1/3 and 45) have similar problems. The selector switches appear to be clean and solid. By gently touching the spinning platter, it is found that there is also essentially no torque - it stops very easily.

It was quite obvious that the servo system was having difficulty reliably locking - as evidenced by the flickering 'lock' indicator and lack of torque. In addition, the platter did not appear to want to start up reliably at some rotational positions.

So, what does it use as a reference? Remove the platter! This requires popping a cosmetic cover and large E-clip. Aha, what is this? A little pickup near the edge that looks sort of like a tape head. However, unlike an audio or digital tape head, it has a series of offset laminations about 1 mm in thickness. Not visible but inferred is a magnetic stripe pattern on the inner surface of the platter which is in close proximity with the pickup when the platter is installed. Better keep magnets far away. That pattern was put on with a special jig at the factory - there would be no way to reconstruct it if some, say, accident were to take place.

As a long shot, I attempt to adjust the pickup closer to the platter surface. Perhaps the magnetic pattern has weakened or something else has drifted. Ouch, now it is rubbing. A little further back. Ah, now it is clear.

Not too surprisingly, there is no change. Symptoms are identical.

Now what? Unfortunately, there is no way to get at the circuitry - under the platter - when the platter is installed. There is no way to excite the magnetic pickup with the platter removed. Not true! After storing the platter at a safe distance, a simple magnet will generate a 20 mV signal out of the pickup. This is probably greater than the normal signal level.

The circuit is pretty simple - couple of transistors and other stuff being fed from the pickup for feedback and hall effect sensors for motor control. The motor is a brushless DC 4 pole type with the commutation control external and on the same board as the servo lock PLL.

Maybe a little signal tracing is in order. Using my magnet, I can see the feedback signal making its way through to what I assume is part of the PLL - probably the phase detector.

In retrospect, even suspecting the PLL's feedback signal was probably not valid. The key is the dependence on rotational position during startup.

So, what about the motor signals? There appear to be two outputs from the motor (in addition to the coil driving signals). What do these look like? The first (from H1 - Hall sensor 1) flips between +5 V or so and ground as the motor rotor is rotated through a complete revolution (Wow, Peter Piper picked a pack of...., sorry, just practicing.) However, H2 seems to be mostly dead - stuck at an intermediate voltage and only varying by a fraction of a volt. Well, that could certainly be a problem.

(If this had not turned up anything, I would have gone on the determine if the driving signals were correct).

Unfortunately, the actual sensors appear to be under the rotor. First the rotor and then the entire motor circuit board has to be removed to access H2. There is a slight risk that removing the powerful rotor magnet from its pole pieces will cause it to lose some magnetization (this can happen when removing the rotors of high energy servo motors, for example, if a dummy rotor core is not slipped in as the rotor is removed). However, I risk it and the rotor magnet seems to be just as strong as ever when replaced. I stick it on a piece of soft steel as a keeper to be sure there no possibility of it weakening while it is off the turntable.

The tricky part is accessing the bottom of the motor circuit board without ripping up the connections to the (fixed) servo board. The actual Hall effect sensor is in a four pin package about 2 mm on a side. There is at least a red dot to indicate pin 1. I use an ohmmeter to double check that the device itself is bad by measuring directly on the package pins. Confirmed, there is are very noticeably different resistance readings across the pins of the good and suspect parts.

I sent Jeff to buy the part (my 'customers' have to do something in return for free repairs and Jeff can convince anybody of anything).

Fortunately, Sony Parts was happy to sell this $4 (wow!) part to someone who is not a licensed Sony repair center. They were very helpful in fact, looking up the part number for H2 in their parts catalog.

Reassembly is straightforward though I had no idea if the alignment of the sensor was adequate until testing.

Now, at least the waveforms from H1 and H2 are of nearly the same shape and about 90 degrees out of phase as they should be. Replacing the platter and the lock light is now solid with decent torque from the motor. The platter will start quickly and reliably from any initial position.

Next day: Jeff comes in complaining that the turntable is vibrating! Indeed, during part of the rotation, there is a distinct vibration that can be felt from the base. What could this be? Best guess is that the pickup needed to repositioned. And, that was the problem. Apparently, my initial adjustment in trying to locate the original problem had resulted in the pickup being positioned further rather than closer from the platter. Some careful incremental movement and the vibrations disappear.

Comments: The elegant simplicity of this turntable is impressive. Too bad that turntables aren't really popular anymore. Well, maybe not bad. I cannot complain about the benefits of CDs though other may disagree. Fortunately, this turned out to be a motor problem and not an actual fault in the PLL which would probably have necessitated a schematic.

I am not sure if Jeff ever used the turntable after it was repaired (about 4 years ago) as I cannot imagine him wanting to deal with vinyl. Maybe that is why there has been no return call!

---

18. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #25: Kenwood KX-55C Cassette Deck with Dead Transport

Patient: Tag sale Kenwood KX-55C cassette deck marked $2-, as-is, 'dead transport'. I paid a whole $1. Otherwise, it seemed in good condition. Well, at least they were honest.

Symptoms: Front panel indicators are alive and the logic seems to repond to the PLAY and STOP as there is the sound of a solenoid but neither the capstan nor takeup reel shows any indication of even attempting to move. There is no sound of a whirring motor.

Testing: With the cover off, nothing appears locked up - everything turns freely and the belts seem to be in reasonable condition. The motor connections are readily found. Voltage to the motor is about 10 V in all modes so in all likelihood, the problem lies inside the motor casing. The only connections to the motor are the two power leads. There is no external tachometer or other apparent feedback used for speed control.

So far, this seems pretty straightforward. The motor bracket is fastened to the transport with 2 screws, a bit awkward to reach but I finally prevail. The motor itself is contained in an second metal case to provide shielding. To get inside requires prying off the cover at the non-shaft end with a screwdriver. So far so good.

Various techniques are used to perform speed regulation in a cassette tape deck. However, for a totally internal regulator, there are usually only two possibilities: mechanical governor and voltage regulator.

In this case, it turned out to be the latter - a little circuit board contained several components including a power device which was shorted. I was not able to identify or cross reference this part so I decided to make my own regulator.

However, first I needed to determine (1) if there was anything else wrong with the deck and (2) the proper voltage for the motor.

The only think I know so far is that the voltage to the motor is less than 10 V.

There is no strobe disk to watch under fluorescent lighting.

Adjusting tape speed:

Make a recording of a single tone on a tape recorder you trust - one with accurate speed.

My Heathkit audio signal generator and Yamaha cassette deck will do. I use a variable DC power supply to drive the motor after soldering wires to the motor terminals and remounting the motor in the deck. Since I will not be attempting to squash my regulator inside the case, I should not need to touch the motor again. I hope.

Apply power. Adjust the voltage to the motor to about 5 V and hit PLAY: It turns! And, there is sound from my amp. Uh Oh, what happened? The transport went into stop mode. In a VCR, I would suspect an idler tire or belt. What was that? Did someone say belt? Right, the belt has popped off of the tape counter. Maybe the tape counter has a contact on it which is used to sense that the takeup reel is turning.

Now, it stays on but the pitch is way low.

Then, I adjust the speed while listening to this same source simultaneously with the tape being played back on the unit to be adjusted. As the speed is adjusted, the pitch changes. As it approaches the correct setting, the tones beat against each other. When it is set correctly, the pitches will be equal and the beat frequency will go to zero.

Even if you are tone deaf, it is easy to adjust the pitch accuracy to better than 1/10 of a semitone using this method.

However, for this initial test, accuracy is not needed as long as the approximate voltage is determined.

The result: A little over 6 V. Excellent, any vanilla flavor IC regulator will do that from a 10 V input. The is quite low.

A scrap of circuit board, an LM317 (on heatsink, though this was probably not essential at the 100 mA or so current required by the motor), a couple of caps and resistors later, and Presto! a regulator. Speed adjust is done with a 50 turn pot. (Well, it was handy.) I do not attempt to stuff this into the motor case but screw it to the power transformer with an insulating standoff.

I now repeat the speed adjustment - more carefully this time.

One thing I do note is that after a few minutes of continuous operation, the motor speed and thus pitch changes by a detectable but not unacceptable amount (still only a fraction of a semitone) and then stabilizes. This is not due to the voltage regulator as the voltage is rock solid. I assume that the windings of the motor heat slightly and increase in resistance. Well, no feedback for speed control, what can be expected?

Regulator running cool, repair completed.

(5 or so years later:)

While listening to a tape, motor grinds to a halt. So what is up now?

Take off the cover. Hard to believe I had all the screws installed!

Checking with a voltmeter, there is only a few tenths of a volt across the motor but normal 10 V at the input to the regulator circuit. With the motor disconnected, the output of the regulator is exactly correct - 6.3 volts. So the regulator is most likely fine. What about the motor. Testing with an ohmmeter reveals that the resistance varies between about .5 and 2 ohms - much less than I would expect. So, there is a problem with the motor.

It is extremely unlikely that the entire motor shorted out.

This is the classic partially shorted Mabuchi-type motor scenario. I am not going to let a little motor get the better of me! I first try spraying it out with some degreaser - no dice, no change. I will just have to take it apart.

The end-plate is held on with a couple of bent metal fingers, pry them out. However, I cannot just pull the end off as it will rip the delicate metal brushes in the process. There are two access holes - I usually call them ventilation holes but I bet their real purpose is to permit a brush spreader tool (pretty impressive name, probably deserves a trademark) to be used to allow the brushes to clear the lip on the commutator. My brush spreader tool(tm) is - as usual - a bent paper clip.

With the end removed, I can now safely pop the entire armature out of the motor case after removing the pulley (plastic, easy press fit).

(Note, this would be risky with precision servo motors using using high strength rare earth magnets as the very act of removing the armature could lead to instant partial demagnetization of the magnets. This is generally not a problem with these cheap PM motors.)

The commutator looks a bit dirty but the real problem seems to be some metal particles bridging the segments - probably dislodged by the continuous rubbing action of the brushes. This is easily cleaned and the gaps between the segments are cleared with a pointy dental pick.

Now, measuring across any pair of segments results in a 20-22 ohm reading, much more reasonable.

Reassembly is uneventful and we are operational once again.

Comments: I can never resist attempting to repair a normally non-repairable part like a motor. Sometimes, they turn out not to be repairable or I loose a critical tiny tiny part to an unexplored corner of may basement but that is the exception. In this case, it was quite easy. The motor did not actually appear worn - the commutator and brushes were relatively smooth and undamaged. Therefore, a replacement would probably not be substantially longer lived than my restored motor.

---

19. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #26: Kenwood CD Changer with Erratic Behavior

Patient: Kenwood carrousel 5 disc CD changer. This is an 'everything in a drawer' type design.

Symptoms: Sometimes, it will recognize the disc and start playing. Most of the time, it will give up and go on to the next slot.

Testing: Several discs were tried without any conclusive differences in behavior. If a disc is successfully recognized, it will play without problems until about the midpoint and then the player will abort and move on to the next. Attempting to manually search forward past track 6 (on one particular disc being used for tests) will result in an abort as well.

Unfortunately, once a disc is rejected, the silly thing remembers that the spot (1 of 5) is empty so without cycling power, it is not possible to even attempt to play the same disc twice in succession.

However, this is a minor irritation.

The first problem was getting the case open. While the screws appeared to be ordinary Philips head screws, it required almost sitting on the screwdriver to persuade them to break free. Hope he never expects to have any warranty work done. The heads are barely recognizable!

Once open, the disc in the play slot is clearly visible. When the player fails to recognize a disc, it doesn't spin at all. Ha! a spindle motor problem. (Rubbing my hands!)

But first, check out startup. With suitable contortions, it is just possible to make out the edge of the lens with no disc in place. Pressing play results in the expected behavior of the lens moving up and down several times before giving up (with no CD present).

There is no chance of being able to see the lens with a disc in place. Forget it.

Well, maybe it is the spindle motor. I put a disc in and press play. Disc moves into position, pause, give up and move on.

I'll show it!

Cycle power. Press play. Disc moves into position. And -- now: give the disc a little twist. Yes! now the CD picks up speed and is recognized and starts playing.

Hummmm.

Sounds more and more like a spindle motor. Perhaps a dead spot or partially shorted winding. Or maybe a weak driver. Is this consistent? For the most part, it is. Sometimes, the disc will be recognized and will play on its own but most of the time, a little help is needed. Once it starts, a dead spot would not matter and the hardest time for a driver is when the motor is starting.

However, what about the problem of not being able to play to the end of a disc once play is successful? I confirm that this is still indeed the case. Yes, it is impossible to play past track 6 on this particular disc. Trying another one, there is a also a time location beyond which play aborts.

What does this mean? It now doesn't sound like the motor as the toughest job for the spindle motor is at the start of a disc.

However, what else could it be?

So, I roll up my sleeves and prepare to do battle with the spindle motor, at least testing it. This is not going to be fun. The spindle motor is located underneath the pullout drawer and there doesn't appear ti be any easy access. Well, every long journey begins with a single step....

As I am removing the bar with the clamper above the optical deck, something catches my eye. What was that? This is the first unobstructed view of the lens. That doesn't look quite right. Normally, the lens of a CD player or other optical drive is shiny with a bluish tinge. This one is fuzzy purple. That can't be right. Well, cleaning is easy enough not believing (but hoping) that a dirty lens could be the problem all along.

One Q-tip later and, yes, all the former problems disappear. Discs are recognized reliably, play flawlessly and to the end, and search works fine for the entire disc.

How could a dirty lens prevent the spindle from starting but then play apparently normally until a certain track? Well, I never actually did confirm that focus was established in the situations where the player gave up. But to have problems with focus but then be able to play substantially free of problems. Well, no one ever said that understanding was always guaranteed.

When discussing the results with the owner, he confirmed that the house was somewhat dusty but I know that no one in his family smokes and the player was not in a kitchen.

Oh well, at least I did not have to take the whole bloody thing (the owner is an Englishman) to pieces.

Comments: Why am I reporting on a simple case of a CD player that required a lens cleaning? Well, to point out that many problems really do have simple solutions even if the initial symptoms may point elsewhere.

In a portable, cleaning the lens would have been done as a matter of course due to the easy access. Cleaning the lens in this changer meant removing the cover as well as the bar holding the clamper. And, some of the symptoms did not really point to lens cleaning.

Repair Brief #27: Panasonic PV 4820 VCR with Multiple Problems

Patient: Panasonic PV-4820 VCR is basically comatose. Owner says her son tried to change the 'fuse' to fix the problem!!???

Symptoms: Front panel display is alive but not much else. There is no response to any buttons or the remote control.

Testing: Tried all the front panel buttons and remote control, unplugging, etc. Nothing.

The fuse in the power supply is fine. What the @#$% is she talking about?

Once the top and bottom covers are removed, a thorough visual inspection is performed. One intersting observation is that the capstan seems to be binding - the rotor of the direct drive capstan motor is rubbing against the bottom support bracket. Surely, this cannot be the cause of all the problems, could it? A little more thought and examination of how the capstan is mounted reveals the likely answer: there is a white plastic 'knob' with a cross-slot poking through the main circuit board on top of the VCR. This knob adjusts the height of the capstan bearing. No doubt the so called 'fuse' that was attempted to be replaced was this white knob which does kind of resemble a 3AG type fuse holder. OK, mumbling something about no user serviceable parts inside, I adjusted the capstan height so that it is clear of the bracket and spins freely. I make a note to check for any problems with the capstan servo after the main problem is found since as expected, there is no change in behavior with the capstan free to spin..

Now, back to the main event. Since there are multiple major system problems - no response to any buttons qualifies - a power supply problem is indicated. This VCR uses the famous (or infamous) Panasonic switching power supply (though I did not know of its fame at the time). I locate the power supply connector and start making measurements. I do not have a pinout or schematic for this particular power supply but there just happens to be a similar model Panasonic in the main conference room. How, I wonder if anyone will miss it for a little while? Any important customers today?

One thing that is fairly obvious: there is no evidence of the typical 5-6 volts that most VCRs use for their logic. The closest voltage is 3.5 V - on a couple of pins. Checking on the power supply connector of the other VCR, these pins correspond to the 5.1 V outputs. The other voltages are a bit high but this is not surprising since there is little load with nothing else working and the regulation is probably faulty.

Rather than working on the power supply in-place I decide to remove it to the comfort of my workbench. This is for three reasons. First, if for some reason, the outputs should skyrocket, I will not have the rest of the VCR to fry. Next, moving the power supply around will probably break the connections due to fatigue anyhow (it is soldered). Finally, it is simply more convenient. Only 9 or so wires are involved, so no big deal.

Five minutes later....

Now, for a switching supply, I probably need a load at least on the regulated output. I locate a 15 ohm power resistor, that should be about right for a +5 V low current (probably under 1 amp) logic supply.

Powering up using a Variac feeding my isolation transformer, the power supply is still outputting +3.5 V on the +5.1 V output. Good, at least it is not an excessive load problem on the +5.1 V outputs (which would indicate a problem elsewhere in the VCR. What about the other outputs? Well, they all test somewhat high (based on the measurements from the other VCR). Thus, an overload on any of those outputs is unlikely as well.

So, what could be wrong? Next step: draw out the circuit. This isn't a complicated power supply, no controller chip, just several transistors, resistors, diodes, an optoisolator, etc.

A half hour or so later, I have a not quite complete schematic. There could still be errors, but it is mostly there and sufficiently detailed to identify potentially bad parts.

Since this power supply is basically working - nothing smoked or blew up - this limits the possible problems considerably.

Testing components in the regulator feedback circuits does not reveal anything.

What about the optocoupler? With power off, I tack a wire across the input terminals (low voltage side). Now, if the optocoupler were leaky, this should make no difference. Bringing up the AC on my Variac, the +5.1 V output quickly reaches +5 - probably at an input of around 50 VAC - and shows no sign of stopping there. This is the expected behavior if the optoisolator were good. Cross that off the list. This also confirms that there is no excess load on the +5.1 V supply holding it down.

What about the filter components for the +5.1 V? Jumping a good electrolytic across the input capacitor (C16) of the Pi filter has no effect. So both the capacitors are likely good as the first should be sufficient to hold regulation. What else is there? What about the zener, D11? No dice, it and its buddy, the only other zener, D15, test good.

What else is there? Hey, what is this capacitor, C21? It seems to be in series between the +5.1 V output and the feedback circuitry? Since it is in series, leakage is important. I need to swap it or test for leakage out-of-circuit. I always opt to swap given a choice.

Ah ha! Success. Replacing with a good 1 uF 50 V capacitor results in precisely 5.1 V. The capacitor, C21, seems to bypass the zener when the output is changing - it in effect limits the rise of the +5.1 V output. Thus, if it turns leaky and passes current, not only will the +5.1 V output rise slower, it will be prevented from reaching its full specified value. The poor regulator does not know the difference between a rising output and a leaky capacitor.

Next day, replacing the power supply in the VCR restores full operation. There appear to be no problems with the capstan. All modes are fully functional. No other none user serviceable parts appear to have been touched.

I write a little note explaining what 'No User Serviceable Parts' really means.

Comments: Knowing what I do now, checking C21 followed by C16 and C17, and then the AC line filter capacitor, C4, would be the first thing to do whenever one of these or similar Panasonic power supplies shows up with incorrect output voltages. What this type of failure indicates is that components like capacitors really are like peas in a pod. When from the same manufacturer and lot number they are all very similar with respect to failure modes like drying up and losing capacitance or turning leaky when used in similar environments.

Most troubleshooting on the professional level is a matter of keeping good notes and/or having a database of previous repair tech tips. While on the subject, how about those solder connections in RCA/GE chassis CTC175/76/77 and all the others for that matter?...

As far as that 'fuse'. I must admit, had I known nothing about VCRs, the white knob does look an awful lot like a fuse holder. To a homeowner, it represents an irresistible temptation. Fortunately, he stopped short of attempting to remove the 'fuse' entirely which would have no doubt resulted in serious damage. And, no adjustment screws had been tightened! Thank you for small miracles.

Repair Brief #28: JVC HR-D860U VCR Mangled Tape

Patient: JVC HR-D860U HiFi VCR, about 2-3 years old.

Symptoms: According to the owner, the VCR gobbled up a tape and her husband 'removed' the cassette but admitted he really wasn't sure of what he was doing(!!).

Testing: In situations like this, a careful inspection of the mechanism should be the first step. For JVCs of this era, parts tend to fall off of the roller guide assemblies. In some cases, attempting to play a tape can cause expensive damage - a loose roller guide can swing up and smash the video heads.

Sure enough, the supply side roller guide assembly was loose on its track and upon removing the bottom cover, the infamous brass pin fell onto the workbench. One drop of Epoxy takes care of the roller guide repair.

So what else is wrong? Was any damage caused by removing the tape or playing a tape with the faulty roller guide assembly?

The VCR appears to be behaving just fine, thank you. At least it played the one test tape fine that I tried.

Return to owner. Try it.

Next day: It's back: Doesn't work on SLP or pause modes. Uh Oh, that sounds like a smashed video head. Sure enough, a close visual inspection reveals that one of the video head chips is broken. Most likely, this resulted from the roller guide flopping around and/or during 'removal' of the stuck cassette. Unfortunately, repair price wise, this is a 6 head VCR. Lowest head price from my source: $71. Ouch. I tell the owner. "That isn't too bad, go ahead". OK, I guess she remembers what it cost new.

One week later: installation is straightforward as the connections are all to a circuit board with no flying leads. Pop the new head on and everything seems to be fine but - what's this - flag waving? Was that there before? I sort of remembered some on my cheapo monitor with the old head (the part that was still good, didn't think much about it at the time).

So, I go and try the VCR on the Panasonic TV in the main conference room. A little better, still some flag waving. However, everything else seems normal - back tension in particular. It could just be my tapes. If recorded on a VCR with significantly different back tension and/or video heads that are not perfectly aligned on the drum (not a user or tech adjustment), flag waving is possible and does not indicate anything is wrong - just different. Many TVs will have a suitable fast vertical sync response or a special channel with this characteristic so not generally a problem.

I returned the VCR, concerned that it would still not be quite right. But, next day, everyone was happy and even with my description, had no idea what I was talking about. Plays just like new. Flag waving, what's that?

Comments: this is one of those situations where the recommendation: "always confirm what does and does not work before touching a piece of equipment" applies fully. Unfortunately, with the broken roller guide, this was not quite possible at the outset. However, I should have paid more attention to the behavior once the roller guide was repaired and before replacing the video head drum.

Interestingly, this was one of my first contacts with the JVC parts shedding VCRs but in the next couple months, came across two more JVCs - one with a dropped brass pin and the other with a loose plastic hinge pin in the roller guide positioning linkage. Then, I 'fixed' a coworker's JVC over the phone (425 miles away) by his description of the **Symptoms**: "Sure, you lost a brass pin. Pull the bottom off....".

VCRs really are like peas in a pod.

Repair Brief #29: Panasonic VCR with Video Noise, Audio Hum, and Erratic Operation

Patient: Panasonic VCR with several problems. Owner's complaint is video noise - sometimes the video disappears to be replaced by noise.

Symptoms: Indeed, video playback is poor. Tracking does not help. At times, the video totally disappears as though the heads are clogged. I also note that there seems to be a hum in the audio at times and there is some erratic operation when switching modes.

Testing: I tested with multiple tapes. Thoroughly cleaned the video heads using a cleaning tape, then cleaning sticks, then my thumb. In no case was clear video totally restored and the heads seemed to get clogged quite quickly. There is definitely hum in the audio. Occasionally, when entering play, the VCR will abort and unload.

This may be a case of multiple independent problems.

The hum leads me to suspect the power supply. This VCR uses a power transformer, rectifier, filter capacitor prior to linear regulators. Fortunately, unlike some Panasonic VCRs, the power supply in this one is easily removed and may be tested easily. Putting a scope on the main filter capacitor reveals that there is quite a lot of ripple - and that it is also somewhat erratic in amplitude. This could indeed account for the hum and erratic behavior. Some simple calculation show that the capacitance must be reduced by 75%. I locate a capacitor that is still perhaps only 2/3 of the labeled value and jerryrig it in place. The ripple is now much much reduced and the hum is gone. Time will tell whether the erratic operations is cured.

The owner was probably not even aware of these problems!

Now for the video problems - which are unchanged.

All symptoms point to a bad head. It is quite likely this machine has seen significant use. The owner is apartment bound and spends a lot of time in front of TV.

Indications of a bad video head include:

- Any visible damage to the ferrite chips.

  No visible damage in this case.

- Excessive video snow which cannot be eliminated by the tracking controls. An image where more or less good video alternates with snow at a 30 Hz rate means that one of the 2 heads in a pair is either dirty or bad.

Definitely present at times.

- Excessive video snow or no picture on some playback speeds (SP, LP, EP, still) since different sets of heads (in 4 head or more) machines are often used for different speeds. If this is due to wear, then it would probably gradually deteriorate and not happen suddenly.

  Yes as described above. This is a two head machine so all speeds are affected.

- Inability of certain internal adjustments such as backtension to eliminate erratic tracking problems may indicate a worn video head. Horizontal bands of video noise may come and go at various places in the picture depending on what speed is being used or the playback location on the tape (beginning, middle, end). These may come and go in a periodic cycle.

  No significant response to backtension. All guideposts seems to be locked solidly in correct position.

- Need to frequently clean the video heads even if you are only using new good quality (name brand) tapes. Video heads are normally self cleaning but very worn heads can tend to collect tape oxide resulting in a noisy, snowy, or totally missing picture.

  Absolutely - even after a manual cleaning (or using the Mark 1 Thumb), bad video seems to return quite quickly.

- You have just been playing a rental, damaged, or spiced tape and you notice any of the above symptoms.

She mostly plays old tapes. However, as noted there is no visible damage. Nonetheless, old worn heads may be more prone to clogging.

Given that most of the qualifications for bad video heads are met, I go and order a new upper cylinder from MCM Electronics. It is about $30.

This does indeed eliminate the video snow.

There is no further evidence of the hum or erratic behavior.

Comments: This VCR gets heavy use. I had cleaned it a few months before the present episode and noted at that time that video playback was not that great. But at the time, it didn't seem poor enough to warrant the expense of head replacement. However, now it was definitely unusable. The gradual and progressive degradation is a classic symptom of worn video heads.

---

23. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #30: JVC 6 Disc CD Changer Gets Stuck

Patient: JVC 6 disc cartridge type CD changer used by Chinese restaurant for background music.

Symptoms: Music gets stuck on outer tracks of some discs. Sections start repeating, stuttering, etc.

Testing: All CDs exhibit the same problems at approximately the same time into the disc.

History: This is the infamous 'Chinese Restaurant' CD player. I believe the problems started when after several years, they decided to change or add a disc. Yes, believe it or not, we had been subjected to the same music for as long as we had been visiting this restaurant - at least a couple of years. We were regulars. On this occasion, we were just getting through the soup (these are the full course lunch specials) when, what was that? The music got stuck for an instant. Being into this stuff, my ears are tuned to typical CD problems. Must have been my imagination. Then, halfway through the main course (Shrimp with Lobster sauce), there it was again. This time, it really got stuck, repeating the same measure for several minutes before anyone noticed and shut it off. Never being able to refuse a challenge, when settling the check, I inquire: so music broken? "Yes, not work." OK, I fix. So we walk out of there with this CD player under my arm and something to do for the afternoon.

Problems of this sort are almost always mechanical with simple causes and easy solutions. Attempting to play a disc - now it was totally incapable of even recognizing the index - resulted in the motor that moves the optical pickup just spinning its wheels. The worm gear was not moving and the pickup remained stuck about 3/4 of the way to the outside of the disc. Giving it a little help, resulted in resetting to the inner track limit and then successfully beginning to play the disc.

The most difficult part about this affair was getting to the worm gear as the optical deck is mounted upside-down and to remove it requires partially disassembling the changer mechanism. However, once this is done, the problem is quite obvious: Chinese grease! The last 1/4 portion of the worm gear is gummed up. As noted, the same 6 discs had been playing for as long as I can remember and none of these ever got to this outer track location. In addition to cleaning and oiling the worm gear, I decide to order a new belt which couples the motor to the worm gear as the slipping has probably weakened it. However, I will return the player to them in the meantime as it should work for a few weeks at least.

Well, that was about 3 years ago. The same new set of discs is still playing and I still have that replacement belt sitting in my desk drawer. We did get a free meal for the 3 of us out of the deal.

Comments: I know that many people are very careful to pamper their equipment. However, unless the various mechanisms are fully exercised to their limits at least occasionally - be it the pickup on a CD player or the suspension on an automobile - dirt, grime, and corrosion can set in and result in expensive repairs later on. At least that is my theory.

Despite my general low opinion of many JVC products, I have to admit that this CD changer has been very reliable. It has probably been running 8-10 hours a day, 6 days a week, for over 5 years requiring only this one minor cleaning and lube job during the entire time. That is not a bad record!

---

24. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #31: Mitsubishi HS-318UR VCR Dropped

Patient: Mitsubishi HS-318UR VCR apparently fell off the TV where it was perched from a height of about 4 feet. Owner had taken it to a repair shop for an estimate - it was recommended he get a new VCR. So, this was basically given to me. Well, loads of thanks! He also had some broken pieces in a little plastic bag - a corner of the front panel and a bit of a circuit board.

Symptoms: Totally dead, no display, no other signs of life. (Yes, I know, you are not supposed to plug in a dropped VCR until a thorough visual inspection is made inside and out.)

Testing: Not applicable.

This is an irresistible challenge. Aside from the chipped corner of the front panel, there doesn't appear to be any exterior damage. But, the piece of circuit board is ominous as it is apparent that there are numerous traces broken - and probably more inside.

Overall, VCRs are quite tough. However, falling in just the wrong way can do substantial and possibly not immediately visible damage. I have heard of someone fighting off a would-be mugger with a VCR but this too is not recommended practice!

In this case, the shop's estimate was way beyond what the VCR was worth and the owner was perfectly happy to upgrade to a newer model. I did make sure to get the remote control from him just in case a miracle happened - or the remote was the only way left to access the major functions.

After removing the top and bottom covers and front panel, the extent of the damage became evident. The good news was that the main board appeared to be intact and the mechanism itself has no obvious damage though this will not be fully confirmed until the electronic problems are addressed. At least, there are no obviously broken or bent parts - and no loose screws or other parts fall out. Nothing has popped loose.

I cycle the cassette loading and tape loading mechanism manually by turning the appropriate motor shafts. Everything appears to be free and seems to operate properly.

Inspecting for broken electronic parts does not reveal anything. At least the display is undamaged. However, the corner of the front panel display board is broken off - this is the piece in the plastic bag - thank you for saving it! In addition, cracks have propagated in a couple of directions cutting even more traces. Yuk. And, these are really, really fine traces. Double yuk. And, this is a double sided board. Triple yuk. Why couldn't the display have cracked in two - put it out of its misery.

There is always a slight risk that the initial impact has already fried electronic parts as a result of a momentary short or from broken circuit traces and there will still be problems even after repairing the visible damage and/or replacing the broken components. Or, for that matter, that my initial power test fried something else. Well, nothing ventured, nothing gained.

Optimistically, at least 25 - possibly considerably more - 10 mil width traces are cut. Some of the breaks are only visible with a strong magnifying glass but as they say, a break is a break is a break.

First, I repair the board physically with some quick setting Epoxy. It almost looks like a circuit board again. There is one little piece that is missing - and some traces go smack through its center. Well, you cannot have everything! Since, this is going to be a feature length restoration, I decide to remove the display board from the VCR - unfortunately, it is soldered in, 40 or 50 pins worth. At least, this is straightforward, just tedious.

With the board removed, it will at least be easier to get at both sides as needed. There is no particularly good place to start - they are all equally bad. Well, every journey begins with a single first step....

Where I can locate suitable end points, I solder fine wire (insulated #30 wirewrap wire) between these terminals. However, in many cases, it is simply not possible to trace far enough to locate the ends. In these cases, I use bare #30 wire directly across the break. A few I take a short cut and just bridge with solder - this will bite me in the end.

I attempt to double check each connection after soldering for correct wiring and that there are no shorts before proceeding to the next.

Unfortunately, one small piece of circuit board is completely missing and traces pass through this piece. I guess as best as possible the routing of these traces and hope. It seems to be part of the tuner memory circuit.

After what seems to be an eternity - it is probably on the order of 5 hours - I am prepared for the smoke test. This requires reattaching the connections to the mainboard and I will thus loose the mobility of having the display board separate. Well, so be it. This isn't even fun!

I plug it in! Well, no smoke at least. The display shows blinking 12:00. Progress! Still, ready to pull the plug, I hit the power button. What do you know - that even works. And there is some sound from the transport initializing.

Now to try the various functions. Let's see, no response from clock set, channel up, tuning controls. It is obvious that there are still a bunch of problems. Other anomalies: the Quick Record indicator is stuck on. What's this? The display just went dark. Oops, there is is back again. Pressing on the board seems to have an effect. There is still an intermittent somewhere.

Well, this is a start. Back to work....

Solder, solder, solder. After finding a half dozen more broken traces that I missed on the first go around, try again. Now, the clock can actually be set (well, except for the minutes). Quick record is still stuck. There goes the display off again. So the intermittent is still intermittent. Ouch! Why is the controller chip so hot? Pull the plug. Checking over the connections, nothing seems amiss but in the rats nest that the back of the board has become, who can say?

Following some traces that run under the display, I locate and repair a couple more that I had missed before. I rewire those few traces that I had just bridged with solder. I never do figure out exactly how the traces running through that missing bit of board should be wired.

This is as good as it will ever get.

For some reason, the Quick Record light is now out, I have no idea why. The display at least seems solid. The controller chip is cool again. Also have no idea why. Now to try a tape....

Success of sorts. The tape will play but the sound is muddy. CUE, REV, FF, and REW even work. It is not possible to reset the tape counter and it is also not possible to set the channel memory. Previously set channels can be tuned so that, at least, is not really a problem. And, who needs the stink'n tape counter anyhow.

It is not possible to adjust the A/C head azimith enough to get truly good sound. Only later, do I discover that the tape I was using for testing had been recorded on a VCR with incorrectly set azimith so this was probably a non-problem.

Just when I thought success was in hand, all of a sudden, after playing for about 10 minutes, the tape suddenly speeds up to about 10X normal with mickey mouse sound and loses sync. This is not CUE mode but yet another problem. The STOP button works but EJECT overshoots the correct stopping position as the main motor is obviously operating at increased speed in all modes. Resetting requires unplugging the VCR for a few minutes and manually rotating the EJECT gear a couple of turns. This is going to be a peculiar way to watch a movie! Something is obviously heating up, possibly causing a failure of one or more of the power supply voltages.

After spending about 15 hours on this VCR, I am in no mood to (1) give up after being so close or (2) do any more serious work. Is there an alternative? Yes, let me cheat. Maybe simply providing a bit more cooling to the power supply will keep it happy. So, I dig up a little blower removed from a defunct ultrasonic humidifier and prop it behind the VCR. Can this possibly work? The answer is - yes. Apparently, the added cooling is just enough to prevent the thermal runaway problem. Now, it is actually possible to play or record a 2 hour movie (first experiment: Star Trek IV). With this setup, the VCR will play or record indefinitely without spontaneously going into warp drive mode.

Comments: If you take a piece of equipment that has been dropped into a repair shop, the estimate you get may make the national debt look like pocket change in comparison. Attempting to repair a VCR or any other complex device that has been dropped is a very uncertain challenge - and since time is money for a professional, spending an unknown amount of time on a single repair is very risky. There is no harm is getting an estimate (though many shops charge for just agreeing that what you are holding is - a VCR!)

I suspect that the final problem - the thermal runaway is not related to the repairs I made on the display board but due, perhaps, to a heatsink that was loosened that I did not notice. Since the small amount of additional cooling provided by my blower was adequate to keep the VCR happy, it could even have been a pre-existing condition that just did not show up in a cooler location.

While a lot of effort was expended on this single restoration, for me it was well worth it. This was my first VCR. Despite the less than total success, the satisfaction was considerable. While the HS-318UR has long since been retired I still hesitate to cannibalize it for parts figuring that it has some historical significance.

---

25. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #32: A Tale of Two Toshiba PA8706 AC Adapters

Patient: Toshiba PA8706 power adapter (Supply #1) for a colleague's T1000XE laptop. I can hear everyone saying "right, one of those really state-of-the-art computers". However, the power adapters for newer models are quite similar so any lessons learned are still valuable.

A second identical power pack will be pressed into service for the loan of some of its organs.

Symptoms: When the bad supply is connected to a laptop with a known good battery pack, the red power LED flashes continuously. No amount of reinserting the battery or plugging/unplugging the adapter's DC plug clears the fault. (These contortions are sometimes needed when starting with a totally dead battery and are sort of normal.)

Testing: A voltmeter reveals that the output, 12 VDC, is cycling at the same rate as the LED. This occurs whether connected to the laptop or not. Comparing this with a good adapter shows that even without a load, the output should be a steady 12 V. The other power pack works fine with this laptop as well. Therefore the fault is definitely in the power pack.

These power packs are actually universal (90-240 VAC or DC) input switching power supplies which makes for a much more exciting adventure than a simple transformer!

The first challenge was getting inside. There were obviously snaps around the sides but it took a bit of detective work (read: the @#$% thing would not split in two) to determine that there was a concealed Torx screw (fortunately not of the security variety) under the manufacturer's label. Once this was removed (by puncturing the decal rather than pealing it back), the case came apart easily. At least it wasn't sealed and potted in Epoxy.

So, what do we have? It looks like a fairly typical small switcher - line filter, bridge rectifier, filter capacitor (big!), switching transistor and rectifier diodes in TO220 cases mounted to a full length heatsink, C-L-C 'pi' output filter. Part types for the power semiconductors cannot be determined immediately because of silicone rubber heat sink boots that entirely conceal the devices.

Uh oh, what's this? A conformal coated hybrid controller. I better hope it isn't bad as there is **no** way of determining what is inside. Obtaining a replacement would no doubt be impossible as well. Naturally, this is the first component that I suspect - wrongly, of course.

Well, what does a cycling output mean? Usually, this is an indication of an overvoltage or overcurrent condition forcing the controller to continuously shut down the supply and restart. A common cause for an overcurrent fault are shorted components on the secondary side of the supply. Overvoltage may result from defective regulator feedback components. The controller may simply be bad and misinterpreting the overcurrent and overvoltage sense inputs.

What does the output look like? On my analog VOM which has a fairly fast response, it appears as though it is cycling between 0 and a full 12 V (not something in between that would indicate a severe overload or short. Running the supply on a Variac reveals that the frequency of the cycle decreases as the input voltage is reduced but that the voltage swing remains the same.

What is likely: the main switchmode transistor is probably good but there may be shorted devices in the secondary side of the supply resulting in overcurrent, a defective regulator resulting in overvoltage, or a faulty sense circuit incorrectly shutting the supply down.

So, as always, I test all of the semiconductors that I can identify with an ohmmeter. Of course, I cannot do this on the hybrid circuit so there is an uncertainty that I might have missed something. However, everything I can test checks out fine.

What is next? Capacitors, resistors. All of these seem fine. I substitute some small electrolytics just to be sure. No change. Removing the output filter capacitors one at a time also results in no meaningful change. (Maybe the cycling rate increased - I did not check.)

At this point, I am temporarily out of ideas and the supply gets shelved for a few months. There is a spare but no one is eager to give it up (or maybe I just don't want to ask) for parts swapping - which is what I really want to do. Guess which part I want to swap?

A garage sale comes to the rescue as I find an identical power pack marked $5 but it is late in the sale (after all, how many people collect these things!) and I get it for $2.50. Whether it works or not, this is a handy source of parts - as long as it does not have the identical problem.

Supply #2: I plug it in and measure its output - nothing. Humm. A dead power pack could mean anything but as with any AC adapter, the first thing to check is the wire. And, sure enough, a little squeezing and bending of the DC plug end results in momentary contact and 12 V out. No doubt, the original owner spent the $60 or so for a replacement - not having read the FAQ on AC adapter repair.

Now, with a little effort, I should have a working power pack - and a source of known good parts as well. It turns out not to be such a simple repair as I have to carefully slit the rubber plug cover and then fish the good wire ends through that to reattach them to the plug itself. As they say, not difficult, just tedious. I have been there before.

Back to Supply #1. Now, I start swapping like crazy. The hybrid controller is first, of course. As you guessed, no change. Next is the transformer, then the switchmode transistor (a MOSFET), capacitors. No change, no change, no change.

Finally, the one part that I should have suspected all along - even if my VOM said it was good - the 12 V rectifier. Swapping this part - a TO220 with a pair of high efficiency (or something) fast recovery diodes did the trick. I know, you are saying: bozo, even in your FAQ, you say to never fully trust an ohmmeter test. Well, it finally did bite me.

Comments: Most of the time, silicon semiconductors stay broken once they fail but not always. In this case, for whatever reason, the diodes would work like - well diodes - for long enough to provide full output voltage but then one or both of them would turn into short circuits or at least develop high leakage. Thus, reducing the input voltage would lengthen this cycle as it would take longer for full reverse voltage to develop on the diodes as a result of the filter capacitors charging.

With switching power supplies it is always tempting to blame the controller, transformer, and switchmode transistor - because they are expensive, difficult to obtain, or both. However, for a supply that shows some signs of life, these components are rarely the cause of the problem.

Swapping parts between a working and dead unit - or between channels of a stereo amplifier or dual channel oscilloscope - is always an ideal way of eliminating selected parts from suspicion. It is a definitive test. There is a slight risk (maybe not so slight with power supplies and power amplifiers) that putting a good part into a circuit with some other fault will blow the good part. But, this risk can generally be minimized by using a series light bulb along with a Variac to limit current to the critical semiconductors.

Repair Brief #33: Mac Plus with no Video

Patient: A colleague's Apple Mac Plus computer. Another state-of-the-art piece of technology. But, hey, these things are still useful.

Symptoms: Power-on results in nothing on the screen and the familiar friendly 'bong' is missing as well. Just some unidentified electrical noise indicating that it is getting power.

Testing: Nothing with the case on. It is obviously not operating as a computer and does not go through the normal boot sequence or even get to the point of asking for a diskette.

This is the 'classic' all-in-one style Mac, physically almost identical to the original MacIntosh computer and the Mac 512K. The much newer Mac Classic is constructed along similar lines. All require the special 'extra long Mac wrench' (1 foot long Torx) to get at the two screws under the 'handle'. Not having one of these (or actually, having lost mine), I make a suitable substitute by grinding down the end of a triangular file handle. It works quite well, thank you.

There are 5 Torx screws: 2 lower rear, one inside the backup battery compartment, and 2 under the handle (they are not all quite identical depending on if they screw into plastic or metal). Once the screws are out, a case splitting tool is supposed to be used but a wide straight blade screwdriver or other metal strip can be used **carefully** to separate the two sections of the case without damage.

With the case removed, I start by examining the large Molex connectors for damage and cold solder joints - there are none apparent (at this time).

How to identify voltages? Well, the floppy is pretty standard, so at least +5 and +12 should be easily found. OK, +5 is low and +12 is very low. Something is probably shorted. How about some ohmmeter checks? Since this is probably a monitor problem, the natural place to start is the horizontal deflection circuit. The small B/W monitor used in the Mac Plus runs off of +12 on the isolated side of the main switchmode power supply so at least this will not be a shocking experience.

Hmmm, HOT (BU406) is a dead short. It also appears to have seriously overheated as the circuit board at its legs is somewhat blackened. The most likely cause of overheating followed by failure is a bad flyback.

Nothing else in the vicinity appears bad based on the ohmmeter tests.

How does one test a flyback transformer?

Three ways:

1. Compare resistance readings of windings with a known good flyback. If these match, substitute it. I really like this one and for a short test, it is low risk - the chance of ruining a good flyback on a low voltage deflection

circuit is quite small. It is also a definitive test.

2. Perform a 'ring test'. Pulse a winding in parallel with a capacitor and see how quickly the oscillations die down. A shorted turn or two will totally kill the Q of the flyback.

3. Drive it with a known good chopper - this is my fun flyback tester - and confirm that it does not load the drive circuit significantly and that it puts out some high voltage.

See the document: [Testing of Flyback (LOPT) Transformers] for further info.

Happily, (1) is an option as I have a good Mac Plus just sitting around doing nothing (you don't act surprised!). There appear to be several variations on the basic flyback model - 157-0042B/B but they appear to be interchangeable. Unfortunately, the ohmmeter comparison is inconclusive and cannot test the HV winding in any case.

So, I decide to swap the flybacks - it is only 8 or 10 solder connections, so quick and painless. I rummage around in my junk box (you probably get the idea that my junk box is as big as a rail car) and locate a BU406D. The built in damper diode should not hurt anything (there is an external one in the Mac already).

Installing the transistor on its heatsink and soldering in the flyback takes all of 5 minutes. Now for the smoke test. There is probably no need (and no easy way anyhow) to use a series light bulb or Variac to limit the current. The Mac switchmode power supply is current limited and unlikely to be able to kill the HOT in the few seconds it will take to verify that the screen comes up. I will know almost immediately if the voltages are more normal as the friendly bong should sound almost as soon as the power switch is flipped.

And, indeed it does. A few seconds later, I am greeted with the inquiring Mac Icon and inserting a boot disk results in the smiling Mac Icon and a proper boot sequence. The picture appears to be bright, well focused, and stable. A few tweaks to position and size, and it is perfect.

Now to order a flyback. $14.99 from MCM Electronics. I leave the BU406D in place permanently.

Three years later: it's back!

New set of **Symptoms**: single vertical line. This is a classic (no pun intended) problem with Mac monitors - bad connections to the deflection yoke. And, sure enough, whacking it brings back the horizontal, though it is somewhat erratic.

The cause is obvious: one pin of the Molex yoke connector has staged a Three Mile Island. It is totally melted and the normally white plastic is blackened and brittle.

Rather than replacing the connector, I elect to just do a bypass and solder a jumper from the remaining wire stump directly to its destination on the monitor circuit board. Who ever removes yoke connectors anyhow? The remaining three pins and sockets (1 horizontal and 2 vertical) appear to be in perfect condition so I leave them alone.

I like easy problems for a change of pace!

Comments: Old Macs, like JVC VCRs that lose parts and Sony TVs with bad tuner shield soldering, have a particular set of problems that are nearly universal. Run a Mac Plus long enough and you **will** see a bad Molex connector or dead flyback.

The flybacks usually fail either by shorted turns in the primary or secondary. Cracked cores or HV rectifier failures are also possible but not common). When it is a primary short, I believe there is a good chance the HOT will blow if not caught immediately. A secondary short may just increase the load enough to cause overheating but not immediate failure. Sometimes, there will still be enough high voltage generated to have some light on the screen but the picture, if any, will be highly distorted. (I have a few Mac flybacks at this point and it seems to be a toss up as to which set of windings failed.

I like it when the primary goes bad because I can then perform a flyback primary windingectomy and have a very nice core and high voltage winding for constructing neat and nifty high voltage invertors. Generating more than 12,000 VDC from 12 VDC is quite easy and reworked Mac flybacks used in this manner seem to be virtually indestructible. See the document: "Various Schematics and Diagrams" for a couple of complete designs using previously owned, low mileage flybacks.

27. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #34: RCA EFR485 (CTC111C) Color TV, Part 1 - Messed up Colors

Patient: My color television - the one I actually bought new (what a concept) at a discount store (after the yoke died on my Zenith B/W 21" tube set from the 1960s). The RCA was about 4 years old at the time of this failure.

Symptoms: At first, I just thought the camera work on the show I was watching was a little strange, maybe the lighting at dusk or something like that. But when the commercials also looked strange, it was obvious that the TV was the problem. There were no yellows or blues! All colors were in shades of red, orange, and cyan. This makes bananas look particularly icky.

Testing: I tried different channels, adjusting the user controls, etc. No change. Black and white programs were normal and turning the color control all the way down resulted in a normal B/W picture.

Therefore, the CRT and its drive are fine, no missing colors. This is a case of messed up colors - and there can be only one small area of the TV's circuitry that can be responsible - the chroma decoder. I suppose, a short between two of the primary color signals - say blue and green - could result in a somewhat similar symptom but it was clear by rotating the tint control that this simple explanation did not hold up.

For a while, I just watched my weird TV since until I could get the Sams' Photofact for it, there would not be much I could do. After a couple days, it didn't seem as strange but nonetheless, I didn't want to have to explain the situation to anyone who visited. So, off to the library. This is a good excuse to copy nearly the complete Sams' folder for the CTC111 chassis even though a relatively small area is involved (in this problem).

A single IC performs all the chroma functions including generation of the 3.58 MHz reference, gating of the color burst, I and Q decoding, and generation of the R, G, and B drive to the CRT socket board. A disconcertingly large number of discrete components surround this chip.

There are basically three signal inputs: luminance (B/W video), chrominance (color information), and a color burst gating pulse.

Since the B/W picture is normal, the luminance input must be fine. There is no likely scenario where a fault in a prior subsystem (i.e., tuner or IF) could mess up the chrominance in any way that would explain the symptoms. The gating pulse matches the Sams' waveform.

What about voltage measurements? These seem to be pretty close though at least one appears to be a misprint in the Sams' (I never do quite figure out if it is or not, it did not have anything to do with the problem but my control settings might not have been the same).

What else is there? The output R, G, and B drives we know are messed up but do they appear funny in any way? Nope, they are all unique and the amplitudes are similar - thus no apparent shorts between them or to anywhere else.

The chip could be bad. Yes, I should have known better but this was over 10 years ago and ICs in TVs were relatively new. Therefore, I obtain a replacement - $15, not too bad considering how many legs it has! I carefully unsolder the old one and install a socket (as I always do in these situations as damage to the cheaply made circuit boards is likely if it needs to be changed again or the replacement is bad).

With great expectations, the new chip is plugged in, the TV is turned on and-

That looks even worse than before! Not only are the colors more messed up but the contrast seems to be off as well. So, either the replacement is bad (yeh, right) or the chip is not the problem. While bad parts are possible, the symptoms looks suspiciously similar, if not quite identical. Therefore, I conclude that it must be something else. $15 wasted? No, I learned a lot: If the chip is good and the signals to it look good, there can only be one set of alternatives - a bad discrete component or solder connection in the vicinity of the chip.

Well, they all look like parts. No smoke has leaked out that I can see.

First, to determine which parts are likely to affect only the color. Based on the controls (color and tint) and identifying parts that would have an effect on phase or frequency response narrows it down quite a bit. There are some resistors, capacitors, and a couple of small inductors.

A methodical test of resistances between pairs of nodes finally turns up something. There is an inductor in what looks like a filter between two pins on the chip which measures open! That would do it. It is marked 6 on the schematic and that is probably the normal resistance - it certainly should not test open. On the parts list, I finally find it - a 39 uH inductor. Just as a quick test, I take a 1 M resistor and wind a very precise random number of turns of #30 magnet wire around it. The 1M is irrelevant but acts as a convenient form for the coil.

Now, finally, a change in the color. Nowhere near correct but this is the first time that anything approaching reasonable colors have appeared since the start of this affair. Still not quite right. I get a another 1M resistor body and wind a whole bunch more turns onto it. Now, that is a lot better. Actually, probably good enough but I have access to an inductance bridge at work so, resistor and #30 wire in hand, I finally manage to come up with a fair approximation to a39 uH inductor. Sure, you are saying, just go buy one. You know that is not my style!

Comments: There is no good excuse for an inductor in a low power circuit to fail. The only explanation can be that one of the connections to the outside leads was not made properly or the fine wire of the coil had been nicked and finally just broke. I attempted to repair it but unfortunately lost the wire inside the potting compound (it was something like #40 wire - very very thin). Just bad quality control, not an induced failure.

Although it cost me $15 to replace the (good) chip, in the end, this was probably well worth it as it definitively (well, almost) eliminated a large unknown from consideration. The TV worked well for the next 12 years and only recently developed the 'No Picture' problem to be dealt with in a subsequent Repair Brief.

---

28. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #35: Panasonic PV1414 Closed Circuit TV Camera with no Video

Patient: A friend's brother's closed circuit TV camera from a building he rented (or something similarly convoluted).

Symptoms: No video. Output will sync the small monitor that came with it but absolutely no signs of any response to light. You could set off a magnesium flare 2 inches in front of it - lens or no lens - and there would be no indication of any change to the video.

Testing: There are no user adjustments beyond focus (there isn't even an iris on the lens). The camera was connected to a working monitor. Nothing, zippo, zilch, nadda.

This is a fairly typical 1/2" vidicon NTSC B/W video camera. 16 mm, f1.6 lens with focus ring, 24 VAC power. Output is baseband (RS170) video from a BNC jack. Apparently, it had been working but then at some point just quit. No one knows if it was a sudden or gradual failure.

First, some vidicon theory:

A vidicon is one of a number of similar camera pickup tubes based on a non- storage photoconductive target. An electron gun, not to dissimilar from the one in a TV or monitor CRT generates a beam of electrons. A number of electrodes shape and accelerate this beam toward the target. A pair of magnetic deflection coils provide horizontal and vertical scanning exactly as in a TV. A focus coil is used rather than focus electrodes (as are common in modern CRTs).

The photoconductive target is high resistance when dark but low resistance when illuminated. When the image from the lens is focused onto the target coating, the light and dark areas of the image results in low and high resistance areas on the target. As the electron beam scans, the target current is a direct analog of the brightness variations of the image. A very high impedance amplifier then boosts this signal to the level required for RS170 video (roughly .7 V p-p into 75 ohms) which is combined with the composite sync from the master timing generator.

Anyway, back to the story...

My friend Bill has quite a decently equipped lab related to his business (special analog integrated circuits) but when it comes to something a bit out of the ordinary, he is less than, shall we say, well prepared. To test this camera on the bench requires a 24 VAC supply for its power. You would think that locating a suitable transformer between a basement and garage full of junk (sorry Bill, that is what a lot of it is!) would be a piece of cake. Nope. We had to jerry-rig a couple of adjustable AC supplies in series to get something approximating 24 V. Oops, phase backwards. Reverse and try again. Finally, 24 VAC, and not too much smoke (though there was some - probably a dead cockroach or something bigger). :-)

From the outset, Bill is insisting that the tube is bad. How? "Oh, the heater will be gone". OK, where is the multimeter?

We use his 25 year old Lafayette VOM with the bent probes (one of which is missing the banana plug at the multimeter end so the wire is just stuffed into the hole). It is probably pins 3 and 4 of the vidicon. Yep, seems low resistance to me. When the camera is powered, in the dark, it is indeed just possible to make out the faint orange glow of the heater inside the tube but this was not obvious at first. The voltage is probably correct, something like 5 or 6 V DC.

Being the more conservative type, I suggest trying to trace out some of the circuit to determine what's what.

Bill, on the other hand wants to start poking around with the scope. OK, fine. At least, many of the connector pins are labeled with signal names. There are even various voltage test points on the circuit boards.

Well, first, let use check the marked voltages. Using the state-of-the-art multimeter, every marked voltage seems to be dead on. (Now, don't get me wrong. I also have an identical VOM which I still use quite a bit. However, it is in somewhat less battle weary.)

Unfortunately, all the marked voltages are power supply outputs - not pins on the vidicon tube which is what is really needed (as you will see later).

OK, what next. "Let's check deflection." Sure, humor him. These are clearly marked on the yoke connector. On the scope, the vertical looks like a decent sawtooth but the horizontal is a really short pulse. I, figuring the inductance of the horizontal coil suggest that this might be normal. Bill doesn't buy into this. I also suggest that even if the horizontal deflection were dead, there would be some light sensitivity - the response is real time with respect to wherever the beam is hitting. As long as it is somewhere on the target, there should be some response to light. The horizontal deflection coils are AC coupled - capacitor is good - so the beam could not be fully off target. Bill is still fixated on a deflection problem. Oh well, humor him some more.

At this point, it is late, I want to do this in my more methodical way, so I bundle the whole thing into a bag and take it home on the back of my 10 speed.

Now, I do not have the nice working setup that Bill does, but I do have parts. You want parts, I have parts. In particular, I have no trouble locating a 24 V transformer and a line cord! So that problem, at least does not exist at my place.

Since Bill won't sleep until this deflection thing can be put to bed also, I decide to trace the circuit to see if the pulsed waveform is entirely consistent with how it would appear to operate. I still believe it is and it is irrelevant anyway.... The circuit is very conventional, not too unlike a horizontal output circuit in any TV or monitor except that there is only an inductor in place of the flyback. Checking the input signal, it is quite clear that the circuit is doing what it should.

Then I get a phone call. Hi Bill. So we are discussing this result someone mentions that it would be easy with a current probe to determine if the deflection waveforms were correct. Current probe! Hello? Did someone mention the words 'current probe' by an chance? Of course. I have a Tek high frequency clamp on current probe - cost me a whole 10 cents at a garage sale. The last time I used it, Bill and I were trying to measure the instantaneous current pulse in an electronic flash unit (about 60-100 A). Why didn't we think of this earlier (Bill has one as well but I bet he paid more for his! Then again, with Bill, you can never quite tell).

This takes all of five minutes - the wires are clearly marked. And, what do you know, a perfect current sawtooth! Hi Bill, guess what? Horizontal current is a perfect sawtooth.

Next, I decide to attempt to figure out what each of the signals connected to the vidicon do. There are 7 pins, the internal electrode arrangement is clearly visible, and the names are printed on the vidicon socket board:

29. Pin 1: G1 ; Grid 1 - sets the beam current (like brightness, 0 to -80V).
30. Pin 2: K ; Cathode - electron emitter. (0 V, 20 V for blanking)
31. Pin 3: H+ ; Filament, around 5-6 V DC.
32. Pin 4: H- ;
33. Pin 5: G2 ; Grid 2 - this is very close to the cathode. (400 V) (1)
34. Pin 6: G3 : Grid 3 - this runs most of the length of the tube. (300 V) (2)
35. Pin 7: G4 : Grid 4 - this is a short ring near the target. (400 V)
    1. This is suspicious as I would expect it to be somewhere in between G1 and G3 in value. However, based on the circuit, this probably is correct as it is fed through a resistor (not voltage divider) directly from the 400 V supply.

    2. This voltage seems to be the feedback for the power supply regulator.

```
     _____  ___________________________
   |                                   \______  _____
```

```
           |
           |                                   ___
           |                                  |  _______K
           |                                    |< H+,H-
           |                                  |_______
           |                            _____  ____      G1
           | ____ _____________________/       G2
           |  G4            G3
           |
        Target
    (Video signal out on external contact ring).  Biased at around +10 V.
```

Touching or even going near the target ring at the front of the vidicon results in a hum signal in the video output. Therefore, the video amplifier chain is almost certainly working correctly.

Taking measurements while adjusting the Beam and Target pots seems to indicate that they have the expected effect. There is just no beam current!

What else? Maybe Bill is right - the tube is shot.

I start rechecking the measurements - probe slips, zap - what was that? Did I see a picture for a second or two? What did I touch? Figuring a cold solder joint, I start prodding in the vicinity. Nothing. OK, recreate the incident. The G2 test point and another pad are very close. If I momentarily touch the two, there is a tiny spark and a faint but recognizable picture appears for a few seconds and then fades out. This is entirely repeatable. What is that other pad? It turns out to be G1 - the beam control grid. Surprise, surprise!

At first I thought that dragging down the G3 voltage or the +300 V rail was having the effect but, of course, it turned out to be pulling up on the G1 voltage - making it more positive with respect to the cathode. In fact, shorting G1 to its buddy next door on the same connector, +H, results in a very nice picture. (Recall that +H is around +5 or +6 V).

For now, I will see if I can get it working consistently and worry about the explanation later. I grab a 1 M resistor and solder it between +300 V and G1. Now, it is possible to adjust Beam (and all the other controls I messed up) to get a quite decent picture. The resistor provides enough positive current into the BEAM pot so that the G1 voltage can easily be brought up to 30 V - well beyond what is needed.

As far as I can tell, the video is fine, the settings are stable. So, we have a case of a device that works in way it should not - which usually means that the 'fix' is masking some other fault. Without schematics with voltage levels or a spec sheet for the vidicon, there is not much more I can do. Bill will no doubt want the thing back anyhow and it will be hard to refuse in the interest of further research.

Comments: There are times when total comprehension is not required. It would be a simple matter to substitute a known good vidicon - if I had one. There is only so much time worth spending on something like a B/W CCTV camera. Based on on my testing, it works reliably. I have had it on for several hours without any change in behavior.

Almost certainly, there is still a fault - perhaps Bill was correct all along and the vidicon is indeed bad in some way - not the way he thought, but bad is bad except when it works! Or, maybe one of the voltages is indeed far enough off to be killing the video. Maybe it will drift further out of spec over time and the 'fix' will now longer be enough. For now, it works, move on. This camera will never be used in any mission-critical application, probably chip inspection, so if it dies, Bill will just have to unpack the Mark-1 magnifying eyeballs from storage.

---

36. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #36: Heathkit IM2202 Digital Multimeter - Dead

Patient: Heathkit 3-1/2 digit bench/portable digital multimeter from garage sale junk box. Apparently, this kit was never entirely completed as the cover was still in its protective plastic wrap.

Symptoms: No display or any other signs of life. No smoke either so at least that is a positive sign.

Testing: Switching through all ranges and modes results in similar behavior as in no signs of life.

Here is a situation that is not quite typical of a repair: a device which is in a totally unknown state. Was it constructed properly? Were all the parts good? Did some prior attempt to make it work blow something out? In many ways it is much better to be working on a device that was functional and then blew its top than to be dealing with something that never worked properly and whose history is not available.

Well, with every long journey, start with a single step...

I don't intend to spend a lot of time on this. If initial tests do not produce any revelations, shelve it. However, I do have the complete instruction manual and schematics so this will not be a totally blind challenge.

Since there is no action of any kind - not even a hint of a display - either the power supply is bad or the controller - an MK6013 - is bad. Hope for the power supply.

This meter is designed to be used on the bench or as a portable. It uses 4 C-size NiCd cells trickle charged when plugged into its detachable power cord. Checking on each of these indicates that they are charging. After a few minutes, there is greater than 5 V across the battery which should be adequate for normal operation. Still nothing. Unplugging, shows that the cells (despite some crystallization around the ends) do hold a charge.

The power supply runs off of the NiCd battery and uses a DC-DC convertor to generate all the voltages required for the circuitry except the +5 which is obtained from the battery through a pass transistor. The neon 7 segment displays require +/- 170 V and the analog circuitry uses +/-12 V. Listening carefully, it is just possible to hear the whine of this DC-DC convertor so at least it is starting up. Are the voltage outputs correct?

Well, the +170 testpoint measures about +70, the -170 V testpoint and +12 are also low and -12. Humm, -12 is nearly non-existent.

Putting a scope on one of the inputs to the convertor transformer shows a highly asymmetric waveform. This is a totally symmetric power oscillator. Therefore, such a skewed waveform probably indicates excess load on one of the outputs - probably on just one diode of the rectifier for that output.

Before I start mucking around in the power supply, I unplug the MK6013 chip and set it aside in conductive foam. I don't really want to blow it out (assuming it is still good) through some power supply screwup. All other parts are common and readily available. I probably would never get around to searching for a replacement for the MK6013, however.

First step: disconnect all windings of the transformer that are not needed to run the convertor oscillator. Fortunately, this is easily accomplished without removing the transformer. Suck the solder, make sure the pins are clear of the pads. Power! OK, now the waveform is a nice squarewave (much higher frequency and no longer audible). This proves that (1) the transformer is likely fine and (2) it is an excessive secondary load problem.

Which output?

First, I reconnect the high voltage (+/-170 V) winding. Still a nice squarewave. The +/- 170 V testpoints measure about 180 V and there is just a hint of a glow from part of the display. Without logic drive, this could be correct.

So, the problem is in the low voltage portion of the power supply or somewhere else powered from the low voltage. Good news and bad news. This narrows down the problem - to most of the circuitry in the entire unit! However, the fault is likely in the power supply.

Next, reconnect the transformer winding for the +/-12. Now, the bad waveform is back. The asymmetry of the input waveform almost certainly points to a bad rectifier as this is the only component that could produce a load current depending on the polarity of the input. Once rectified, excess load should affect both polarities of the input waveform equally and thus not result in the asymmetric waveform.

First, is it the positive or negative 12 V that is the problem? Pulling one transistor easily confirms that the +12 V output is not the problem I then unsolder each of the two rectifiers for the +12 V and nothing changes.

Now for the -12. Unsoldering D212 makes no difference but removing D214 restores the symmetry of the waveform. Even without this diode in place, all output voltages are now well within expected tolerances. A 1N4007 takes the place of its dead buddy.

Now for the acid test: replace the controller chip. And - Yes! - we have a display. It even looks somewhat correct. Obviously, the meter has not been calibrated but it does produce the expected results for DC V and Ohms. The + indicator and a couple of segments are out but some quick jiggling and tapping confirms bad connections. The bad segments are due to loose socket pins and easily remedied with a pair of needlenose pliers. I never do discover the actual cause of the bad + indicator but the problem went away after cycling the AC/DC switch several times.

Some quick calibration shows that it is in pretty good condition. There may possibly still be some minor accuracy problems with a couple of the ranges but in general - the @$#% thing works!

A bad diode! A stupid, 5 cent, bad 1N4002 diode! Can you imagine the frustration of the original owner who, after meticulously constructing the kit - following every instruction to the letter, double checking and triple checking - is unable to make it work because of a simple power supply problem? Keep in mind that this is not a modern DMM where the major parts consist of: case, selector, IC, LCD. This is 1975 technology with many many discrete parts on two 4" x 6" circuit boards. The effort probably represented several dozen hours labor with a hot soldering iron and the extensive use of choice 4 letter words.

Comments: A Heathkit IM2202 Multimeter is nothing to write home about by today's standards but is still useful nontheless. The significance here, if there is any, is in the type of situation in which one is attempting to make a newly constructed unit operational. There are subtle differences in the diagnostic procedures required due to the unknowns involved. In this particular situation, there was no way of knowing how much damage might have been done through prior unsuccessful troubleshooting or whether - as it turned out - some original parts were bad as well. This was obviously not the first electronics kit constructed by this person - there were a number of successful examples at the same sale. Therefore, I did have some confidence that the basic construction was solid and accurate and there would be some minor problem involved - which as it turned out, was correct reasoning.

---

Repair Brief #37: RCA EFR485 (CTC111) Color TV, Part 2 - No Picture

Patient: My color television - the one I actually bought new (what a concept) at a discount store (after the yoke died on my Zenith B/W 21" tube set of many years). This is the second of a 2 part Repair Briefs.

Symptoms: I turned it on and - sound but no picture. No light visible on the screen. That is kind of strange. Except for the color problem 10 years ago, this has been a reliable set. (No tuner shield solder problems, knock on plastic!)

Testing: No user controls have any effect. The screen remains black. There is no flash of light when powering it off either. There is static on the screen however, so I suspect that HV is fine. Nothing is shutting down on its own either.

Since there is sound and HV static, I assume the horizontal deflection is running. As a simple test, I turn up the SCREEN control. This results in a raster. Therefore the power supplies, horizontal, vertical, high voltage, tuner, and sound are all in fine shape. Just no #$%^ picture. Well, that narrows the area of search considerably.

This will require the Sams' and a scope to trace - sure, no problem. I still have the photocopied Sams' from dealing with the previous problem and my scope is just dying to chomp on something interesting.

The only difficulty is that the bottom of the main circuit board is not accessible when mounted in the cabinet. However, maybe RCA thought of this - there are two offset screw holes which (whether by design or not, I do not know) permit the circuit board to be moved about 8 inches to the rear - and the cabling is even long enough. Now, with the TV on its side, everything I need to get to is out in the open.

With my isolation transformer - always a prerequisite - I can conveniently examine various points in the video chain. However, some testpoints are concealed under a shield soldered at multiple points. A slight annoyance - the soldering on this shield is really really good.

Just when I have settled in to try to determine where the video signal is getting lost, the picture pops on. Actually, it kind of dribbles on - first a weak rainbow pattern and then a second later the good picture. Could this be a bad connection? Perhaps, but no amount of wiggling, jiggling, whacking, or cursing, has the slightest effect. Cycling power also does not induce the problem. It is now as though the TV is not broken.

Hmmm. sounds like an electrolytic cap or thermal problem. (BTW, Bill - from Repair Brief 35: "Panasonic PV1414 Closed Circuit TV Camera with no Video is sure that the problem is a bad electrolytic cap and wants to destroy the ozone layer with a can of CFC based freeze spray to locate it.)

Let it cool for an hour.....

One hour later - picture comes on instantly!

Let it cool for a day.......

One day later - picture comes on instantly!

Leave it alone for a week................

Finally - no picture - for about a minute, then rainbow, then solid picture.

So, how does one go about troubleshooting a problem of this sort? Give me a problem that takes a minute or hour to show itself any day but one that is broken for only a minute or two? Not fun.

Well, perhaps even when it is working, there will be some voltage or waveform that isn't quite right. Maybe a visual examination will turn up some potentially bad electrolytic capacitors. Maybe one has lost some of its value and a capacitance check will reveal the culprit. Right, keep dreaming.

First step: narrow down the search area. At this point, I have no idea exactly where the video signal is getting lost - not even which subsystem! I do know that sync is stable - examining the raster shows that the lines are correctly interlaced when a proper channel is tuned. So, this puts it after the sync separator. Since this is fed from the video at the output of the video IF, I know at least that it is functioning to this point. That leaves the entire luminance channel - joy - as well as the chroma/luminance IC (the one I tried replacing in Part 1 of this story, U700).

I spend some time down one blind alley - the chroma input to U700. Suspecting this signal, I confirm that it is indeed always present even when there is no picture. A simple test of shorting this signal to ground at the chip input would have revealed that the most its absence would do is result in a B/W picture. One dead end.

Here is a rough block diagram of the video chain:

```
                                 +--------------+
                         +-------| Lum Peak/Amp |-------+
                         |       +--------------+       |
                         |                            C v      U700
          TP-A  +-----------+    +------------+ B +-----------------+    RGB to
Video IF ---+---| Comb Proc |----| Chroma Buf |---| Lum/Chroma Proc |--- CRT
            |   +-----------+    +------------+   +-----------------+    Drive
       To Sync Sep.                                   D ^
                                 +------------+         |
              From Sync Sep  ----| Burst Gate |---------+
                                 +------------+         |
                                                        |
                               +----------------+       |
 From Vertical Deflection  ----| Vertical Blank |-------+
                               +----------------+
```

I know that the video signal is fine at TP-A at all times. I also know now that TP-B is fine and does not kill the video in any case should it disappear.

Next, I identify the pins on the Lum/Chroma Proc chip (U700) that can possibly kill the picture totally. It appears as though there are only five: 4 of these are controls or power supply voltages (constant DC levels) and the other one is the luminance input, TP-C.

One week, later, preparing for battle I am set to measure the 4 static voltages as soon as power is applied. The scope is hanging on TP-C as well to determine if that signal is present at all times. A signal here would eliminate all the stuff in the 'Lum Peak/Amp' box from consideration (and there is considerable stuff in this box - I have greatly simplified the block diagram).

Charge!, or, err, power!

Voltages: Measure, measure, measure, measure! These all check out within 5 percent or so.

TP-C signal: Yep, it comes up immediately and appears to be valid video and of proper amplitude.

There is no detectable change in any of these when the picture appears 30 seconds later.

That's just great. All five possibilities seem to be fine. Well, when the plausible are eliminated, check the implausible.

First, however, I breakdown and decide to swap U700 with my spare in a week when I apply power again. As expected (but hoped against), the screen remains black for the expected minute. When the picture appears, the color balance is somewhat off (recall, that in our last episode, there were more severe problems with this chip but that was when the actual fault had not been located). However, adjustment of the CRT drives fixes this. For all intents and purposes, the replacement U700 performs identically to the original.

So, there must be some other input to U700 that is messed up.

Well, there is another possible candidate. I had not paid serious attention to it before but it is all that is left - the signal derived from 'Burst Gate' and 'Vertical Blank'. I initially discounted this since there was a signal present even when the picture was blank - but was it the correct signal? Brief checks previously had shown it to healthy - but that was when there was a picture.

One way to find out: short it to ground and see what happens. And - yes - this kills the picture. What is also significant, is that when the short is removed, the picture comes back in a very similar way to when the 'problem' goes away - some initial rainbow effects before it stabilizes.

So, next power cycle (1 week) I am intent on catching this signal in the act! This signal should look like a 2 volt pedestal during horizontal blanking with a narrow 5 volt pulse riding on top. This is called the 'Sandcastle'. I am now thoroughly familiar with what the correct shape should be.

```
                                 ___
             |\                   ^
             ||                   |
          __||_                  7V
________|      |_________       _v_
```

1 Week passes......

Scope, are you ready? "At your service".

Look at that! The pedestal is there but the narrow pulse is missing. Finally a clue. Some quick voltage measurements of the 'Vertical Blank' circuitry shows that it is impossible for it to be at fault as the pedestal would not appear normal. Therefore, it must be the 'Burst Gate'.

This is a fairly simple circuit - a transistor buffer is driven into saturation by the inverse blanking signal. An RC delays its turnoff at which point the positive going pulse at the collector is coupled via a C-L-R network via a diode to U700. The following is somewhat simplified:

```
                             12V
                              |
                              /
                              \ R744
                              /
                              |  C710     CR700      R747
                              +---||---+---|>|---+---/\/\--- TP-D
_____    __       R742       |/        |         |
     |_|     ----/\/\---+---| Q701     C         /
                       _|_  |\         C L703    \ R741
                C709   ---    |        C         /
                       _|_   _|_      _|_       _|_
```

- - - -

Next step: to determine if this transistor is working correctly. This time, scope probes on input and output. The verdict: input and output are both stable instantly at power-on. Having confirmed this, I immediately kill power. Maybe these quick checks will permit whatever is being cured in a minute to remain sick. Now what?

What about the other side of C710. Nothing. How can that be?

Coupling capacitor? Quickly bridging another one doesn't result in any change. Kill power. I cannot afford the bench space, need to get this wrapped up!

On a hunch, I check the resistance across L703. 20 K ohms, Huh? No way, it is marked 21 ohms on the schematic. Not another dud inductor! (Recall that this was the problem in Part I - messed up colors).

I pull L703 - it measures open. How could an open inductor result in a flat-line output? One might think this would increase the output. Well, with the inductor removed or open, the diode charges the capacitor as it would in a power supply and results in the diode output being clamped to zero volts. It actually makes sense.

First I try winding an inductor but even with as many turns of #32 wire as I can fit on a 1/2 watt resistor body, the value must be way too low as the output is still dead.

Rummaging around in my inductor drawer, I locate one that looks kind of similar. Unmarked, but of approximately the right size and construction (I really don't have a great stock of inductors.) The original is marked 471 which I assume to be 470 uH but I didn't photocopy the page of the Sams Photofact with inductor ratings, unfortunately. The results with my unmarked replacement are mixed - the picture is there (well, that really doesn't prove anything) but it seems a little bright. This signal looks fine, maybe the bright picture is my imagination. OK, try a different larger one. This even measures the same on my ohmmeter as the original should (like that means anything). However, the picture now appears normal.

Since the poor lonely inductor sitting on my bench still measures infinity ohms, I am confident that this is indeed the problem. Exactly what mechanism results in a delayed start inductor is not quite clear. It is not heat as there is no time for any thermal effects and the power dissipation in the inductor is about as close to zero as one can imagine. Is it simply the voltage pulses appearing across some kind of marginal semiconductor-like junction formed by corrosion between the coil wire and the leads that eventually results in good contact?

Attempting to 'disassemble' the broken inductor simply results in broken inductor pieces everywhere so I will never really know for sure what happened - until another one of the half dozen or so similar inductors in the TV decides to do its open circuit thing.

Maybe someday I will actually order the correct replacements for both of the dud inductors - this new unmarked one and the homemade inductor that fixed the previous messed up color problem. For now, it seems to be fine and the TV shows won't be any better with the proper replacement parts anyhow.

Comments: No doubt next time (sure, if there is a next time) I will test all the similar inductors first! What could possibly lead to a batch of unreliable inductors is another one of those mysteries of the universe. After all, an inductor is just a coil of wire soldered to a couple of leads. There is no thermal or mechanical shock and the circuit is very low power in any case. The TV is not in a damp location or subject to any other kind of abuse that I know of though based on the appearance of the innards of the inductor, some type of deterioration may have taken place.

How should one diagnose a problem of this type? In hindsight, I guess testing components in the vicinity of the Lum/Chroma Proc after waiting a week and with power off would make sense. But, some of the elapsed time was required to localize the problem to that chip. However, once it was clear that one of the signals to U700 was messed up, the ohmmeter checks would have greatly reduced the additional required debug time. Would freeze spray have worked? Perhaps - if anyone had thought to hit the inductor. There were no electrolytic capacitors anywhere in the circuitry around U700.

---

Repair Brief #38: Sylvania RXX170-WA01 Color TV Clicks - No Picture or Sound

Patient: Garage sale TV. Waited for price to be marked: $5. Paid $3. Then asked if there was remote - they wanted to charge me $30 for that! Just kidding.

Symptoms: Pressing front panel power button results in a click but no indication of deflection or anything else. By listening carefully, it is just possible to determine that the 'on' and 'off' clicks are not quite the same sound. Therefore, the system controller thinks it is cycling power - this is not a shutdown problem. There is no response of any kind to any buttons on the remote control.

Testing: With the cover off, the first check is to determine if the horizontal output transistor (HOT) is shorted - it is not. Applying power (using my isolation transformer), the main filter capacitor shows the expected +150 V from the bridge rectified 115 VAC. Shutting power off causes this voltage to decay over the course of about 10 seconds - therefore, the power relay, its control, and main filter capacitor are probably good. Checking voltage at the HOT shows that it is present (though high - I suspect this is simply due to the fact that there is no substantial load with the set not running). Thus, this is a startup problem and not a catastrophic failure of the HOT, flyback, or some other expensive part. More importantly, startup problems usually have a definite cause and are not likely to reoccur.

The next step is to obtain the Sams' Photofact for this set. A trip to the library is in order. Until then, what about the remote control? Is it bad or is there something else in the TV itself that is not responding to the remote?

A quick check with my IR Tester reveals that the remote is not putting out any IR signal for any button presses. I double-check the batteries - they are good and will operate other remote controls. Opening the remote control is not as bad as some - one screw and some snaps along the sides. Nothing looks immediately amiss - no broken parts. But this is the component side of the circuit board. Depressing some catches around the edge allows it to be removed. Hey, what is this? Along one edge, a trace has been lifted off and broken by one of the catches. Did I do that? I thought I was being careful enough. Well, it needs to be jumpered and soldered in any case. That does it! The remote now puts out a strong IR signal - and operates the TV (to the extent that this is possible - at least it clicks in exactly the same way). I still have no idea of how the trace got broken or if I did it though this would imply an impossible sequence of events as I did not open the remote until *after* it did not work. But it did definitely fix the remote problem. For good measure, I also put a dab of glue on the ceramic resonator which is flapping in the breeze.

Now, back to the main event. Checking the Sams' index is disappointing - this model is not listed in the (1995) manual. However, a model with a very similar number is. Well, asking for the folder doesn't cost anything. Examining the schematics of this folder (for a RXX168-WA01) shows that there are enough similarities to justify copying costs. In fact, it appears to be virtually identical (I cannot actually locate any differences of any consequence). Generally, on the first round, I copy the schematics and any resistance charts and chip descriptions (block diagrams). Later, if I need specific information like part numbers, I will copy the appropriate additional pages.

Since there is voltage on the HOT, there is almost certainly a problem with the startup drive. Checking the base of the HOT shows that there is no drive present when power is turned on.

Checking the base of the horizontal driver transistor shows that there is nothing there either.

How is startup drive derived?

Various models of TVs and monitors use different techniques: multivibrator, deflection chip powered from standby supply, high value resistor supplies current to horizontal driver or HOT directly, etc.

For this TV, a single chip is used for sync and deflection, a TDA8305 - TV Signal Processor. However, after examining every pin on this chip, it is apparent that there is no DC power available until after the set starts up and the flyback supply is running. The supply voltages for the chip are all 13 V - rectified, filtered, and regulated off of a winding on the flyback. This leaves only one possibility - there is a high value resistor between the 130 V B+ and the base of the horizontal driver transistor.

The collector of the horizontal driver transistor has the expected +130 V B+ so the transistor is not turning on or is open (not likely).

First, I unsolder the base of the horizontal driver transistor so I can check the junctions with an ohmmeter - it appears good. Better make sure to reconnect that before applying power or else there will be 130 V on the IC!

Next, I test across R502 - startup resistor. It injects current into the base of the horizontal driver transistor. This applies a pulse to the HOT to initiate the flyback supply. And, what do you know! The resistor tests open! At first I thought I was just using the wrong scale on my VOM. However, it is indeed open - might as well be a pair of disconnected wires. It is a 47 K ohm 1/2 W film resistor. A quick power calculation shows that 130 V across a 47 K ohm resistor is about .3 W - close enough to suspect that simple heat dissipation and thermal cycling over time resulted in an isolated failure. In fact, there is no possible mechanism that would result in a forced failure of this resistor. Even if the 130 V supply was running high, the maximum dissipation is just about 1/2 W.

A replacement - with a 1 W resistor this time - restores normal operation. Not a bad set for $3 (+$2.40 in copying costs and a resistor).

Comments: These are the types of repairs that pay the rent for repair shops. A quickly identified cause with an equally quick and definitive cure. A return problem related to this repair is extremely unlikely. Realistically, a 15 minute repair from start to finish is possible.

This Sylvania TV is also nice to work on. Everything is on one circuit board, components are clearly marked, and it is possible to access everything without disconnecting more than the degauss and speaker connections (not needed for testing in any case). Too bad that a 2 cent resistor was specified with a marginal power rating. All too frequently, startup problems in TVs, monitors, and other switchmode power supplies, are caused by open high value resistors.

Repair Brief #39: Sony Compact Stereo Model HP-179P - FM Dead

Patient: Sony compact stereo system - AM/FM radio, turntable, cassette (at least it is not an 8-track!!!). This is one of my charity repairs. (actually not charity in this case but low income people who would otherwise not get the stuff repaired at all.)

Symptoms: AM works fine but there is only low level static from FM. General whacking and prodding produces no reaction.

Testing: Exercised all buttons and controls, no change. An antenna seems to make little difference.

Getting to the **top** of the tuner circuit board is not too bad - just remove the turntable, uh, record changer (you know what they are, right?). Four screws and disconnect the motor and audio connectors.

However, even before that, I have to vacuum the thing! Why? Apparently, in packing it up (in a pillowcase, no less), some powdered laundry detergent or something similar was spilled into the thing. Yes, the adventures I have! Even my shop vac has difficulty getting every last particle out but for now, it will have to do.

With the turntable removed and set aside, the tuner and preamp board is readily accessible.

The FM tuning capacitor and front end are easily identified. Touching various points in this circuitry results in a large change in output but no selectivity. There appears to be a strong station which peaks around 102 MHz but it is obvious there is no heterodyning action as there is absolutely no selectivity. However, the front end is sensitive to my touch and therefore it is likely that the following stages are good.

I was just about to give up and head for the library and possible Sams when I decided to poke around a little more. My some quirk, I happened to press on a coil in the front end box and instantly good reception returned - as long as I kept my finger on that coil! Another bad connection? A wooden stick worked just as well as my finger (I was sure relieved since I didn't look forward to spending the rest of my existence holding onto that coil). So, probably a bad connection. When operating, reception seems to be absolutely perfect. Most probably the local oscillator was at fault.

Now, the fun begins.

Getting to the bottom of the circuit board is a whole lot more difficult than getting to the top.

First, the back panel needs to be removed. Then several screws holding the circuit board and a ground strap that needs to be unsoldered from a shield. Now it may be moved, but is still attached to the front panel via the dial cord. And you know how much I love to restring dial cords! For a while, I thought the cord would stay put even when pivoting the circuit board up enough to inspect and resolder but no such luck. With a thoroughly disheartening 'pling' the dial cord popped off of its pulleys. Well, at least the board is totally free and the bottom can be accessed.

I resolder all the pads in the vicinity of the coil since may of the connections looked questionable (though there were really none that I could say definitively were bad).

After flipping the board back over, reception now appears to be solid. Pressing, prodding, and pounding have no effect. Will it be permanent? I surely hope so!

Replacing the dial cord turns out to be easier than I had expected (unlike that time where I melted it with my soldering iron!) The only question was how many turns on the tuning knob shaft but there is obviously only one possibility (3) based on the total length.

Checking out the rest of the unit:

The tape deck appears to be functioning, Fortunately, none of the soap powder made its way into the tape mechanism.

The turntable, however, is a sad story. Soap powder everywhere. I remove the platter to find - more soap powder everywhere. It is necessary to disassemble, clean, and regrease the main platter bearing and changer gears.

Only then do I notice that the counterbalance weight for the tone arm is missing and the stylus is bent and would need to be replaced. Checking with the owner, it turns out that she doesn't play records (I can see why) and therefore, as much as it pains me, I will not bother to restore the turntable at this time (and probably never). It would be simple - I would have to come up with a suitable substitute for the weight and order a stylus.

Finally, I check out the dial indicators. One is burned out and another is intermittent (broken filament). The stereo light is burned out as well. These will come from MCM. At first I thought that substituting light bulbs I had in my stock would suffice but the cost of the proper replacements was so low that it wouldn't be worth it and mine would not work as well.

Comments: The world it seems is full of these 25 year old compact stereo systems. While audiophiles and snobs may look down their noses at them, the majority of people are perfectly happy with their performance (or lack thereof). Repairing one of these may not have the glamor of working on a laserdisc or projection TV but this lack may be more than made up for by the flood of enthusiastic appreciation from the owner - especially if they would otherwise not have been able to afford a repair.

Problems with compact stereos are very often low tech - lubrication, dirt, bad connections, dried up capacitors, burnt out light bulbs. A schematic is rarely needed and access to the interior is usually straightforward (though perhaps not as easy as one would expect as in this case).

40. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #40: Mitsubishi HS-U53 - Bad Tracking

Patient: My Mitsubishi HS-U53 HiFi VCR purchased new in 1990 (yes, hard to believe I actually bought something new!). Pampered, used mostly to tape Startrek and NOVA episodes. Not abused at all. How can it do this to me?

Symptoms: Tape is accepted but attempting to play or even display a still results in a garbage picture - tracking is way off. In addition, play results in no tape movement and eject follows as if the VCR finds the content distasteful.

Testing: I tried several tapes but it was obvious that something was very wrong.

I enjoy the challenge of reviving a garage sale acquisition purchased for $1 but I really do not like having to fix something for which I paid real money!

Nonetheless, I have no choice. Actually, this VCR has always been a bit finicky about how a tape is inserted. If pushed into the cassette slot too slowly, it might grab the tape and spit it out. If the tape was accepted, there was a chance that it would not seat correctly and never advance. Therefore, I wasn't entirely surprised by the failure.

Despite all my advise about most problems being simple and mechanical, I was naturally thinking that **my** problem would be something esoteric!

Once the cover is off, the extent of the problem can be seen. This VCR uses a 'rapid access transport' which means that the tape is immediately wrapped around the video heads in the fully loaded position except that the pinch roller may not be fully engaged. Starting from this position is indeed quite fast - less than a second to enter play or any other mode except super fast rewind which unloads the tape back into the cassette. The tape is in very light contact with the spinning drum but with no tension applied - which winds down on its own after a few minutes to conserve motor life (wear of the video heads would be negligible in this state).

Anyhow, back to the story. Checking the tape position after loading reveals that the pinch roller is not moving properly over and down as it should. Further close examination reveals the reason: there should be two wings on a spiral plastic cam gear which guides the pinch roller movement. One of these has apparently broken off allowing it to lose contact with its mate. (I did find the broken-off piece - I really like to account for all parts so they cannot jam something at a later time.)

Fortunately, MCM Electronics has a repair kit for about $12 which includes the entire assembly with a new pinch roller as well as one belt. I guess this is a common problem. Inspecting the pinch roller reveals some fine cracks (somewhat unusual for a pinch roller of this age) so a replacement is worthwhile.

To be safe, I scribe timing marks on the 2 or 3 gears that might be disturbed during the swap. This is always a wise precaution if no service manual is available. As it turned out, this was not needed as the new pinch roller assembly dropped right in without moving anything.

Comments: Why does this sort of thing happen? Originally I thought that Mitsubishi saved 2 cents on the plastic reinforcements and thus timed it to fail after 4 years. Perhaps this is the case. However, the consensus now appears to be that the lubrication of the shaft on which the pinch roller assembly slides gums up or dries out resulting in binding and subsequent breakage.

In either case, the end result is an annoying repair.

I did make sure to liberally lubricate the sliding shaft but fully expect the problem to reoccur in a few years. Now, if I only would do the types of preventive maintenance I recommend to others perhaps this could be avoided!

---

Repair Brief #41: Mitsubishi FA2100-CW FAX Machine Will Not Send

Patient: Mitsubishi FA2100-CW facsimile machine. Old but perfectly usable technology. It should send and receive faxes. What more could you want?

Symptoms: Receive seems to work properly. Attempting to send a fax results in continual redials and the destination phone is never reached.

Testing: Initially, problem was not known. So I had to set up WINFAX on my PC to provide a suitable source/sink at the other end. See below. Once I unjammed the paper roll, receive seems to be fine. Attempting to send a FAX, however, results in repeated attempts to dial without success. Local copy function works correctly.

This fax machine was apparently acquired by my 'customer' as a result of the down-sizing of a local hospital. There is a user's guide but no installation or setup info. Well, better assume all the DIP switches are set correctly. Write them down just in case I should accidentally move one without realizing it (I actually did not do this and was lucky. However, it is a good idea).

At first I thought that the fax machine was never connecting to the phone line and I tried to identify which of the 4 internal relays was supposed to do this. Using a multimeter, the one whose coil was being activated was easily determined but there was nothing measurable across its contacts. Monitoring the phone like with a DMM showed, however, that it was picking up - the 50 V on-hook voltage drops to something like 5 V when dialing.

Further testing by monitoring the phone line both with the fax machine's phone and a separate extension reveals that the dial tone never goes away and the tones seem to be somewhat weak though apparently of the correct DTMF frequencies. The fax machine's built in phone does dial correctly, however. Interesting.

Time for some inspection. Disassembly is actually fairly easy - 2 screws to remove the bottom panel, 5 screws to remove the circuit board and a heat sink. Only complication is the roughly 10 cables that need to be disconnected to free the logic board from its wiring harness.

Oops, what is this? The backup battery is hanging by one lead. Apparently, this had been replaced relatively recently (I really have no way of knowing) and whoever did it was too lazy to access the bottom of the circuit board. Therefore, they attempted to solder in the new pack by heating the leads from the top instead of the pads. It may have worked long enough to close up the unit but was certainly not a long term repair. The other lead is somewhat loose as well.

While I don't expect this to fix the main problem, it is dealt with first. Additional wires need to be solder to the flimsy tabs on the battery pack since they break off as soon as I attempt to reinstall it in the circuit board holes. Some silicone sealer is now used to secure the pack to the board.

I reinstall the board with all 10 of its cables to confirm that **the** problem still exists and that it will now hold its time and other memory settings.

Now the machine is continuously trying to eject the input copy. What is going on? After some minor panic and confirmation that all connectors are indeed installed correctly, I realize that I am trying to run it on its side and there are some interlock switches that are gravity dependent. Setting the unit upright makes it a whole lot happier.

It now appears to hold its settings but as expected, will still not dial for fax transmission.

Out comes the board again.

So, what next? Tracing the circuit might be possible - it is a double sided board - but what about my usual approach - test all the semiconductors and capacitors in the area of the phone line circuitry. This has proven successful on more than one occasion (see Repair Brief #2: USR Data Modem Won't Dial, for example).

And, guess what? I found a little black diode that tested *open*. Now, that is unusual. What type? The part number is not listed in any of my databooks and cross references. Well, if it walks and talks like a 1N400x type, that is what I will try. The symbol on the circuit board is just a diode so I assume it is not something fancy like a zener or Tranzorb surge protector. So I put in one of my lonely looking 1N4007s - I dare you to blow! Hopefully, this wasn't supposed to be some kind of high speed or high efficiency type.

All other components that I can reasonably identify test out at least in-circuit with my DMM.

Reinstalling the logic board with all 10 cables is now pretty quick. I have the technique perfected!

So, now for the test.

Mode: Manual Dial. Telephone number: My PC's modem number.

Uh oh, behavior is the same. I am just about to scream or beat something over the CRT when I pick up my extension phone and hear: "Please touch 1 for sales, touch 2 for service.....". Huh? My PC does not have a voice mail system. It dialed a wrong number!!! Actually, I told it to dial a wrong number. After all, how often would I need to dial *my* PC? I didn't even remember my own phone number correctly.

OK, this will work. After transposing a couple of digits, I get it to dial the correct number but now WINFAX is not picking up. Not surprising as I never configured it for receive.

Finally, I am able to send a fax to my PC.

The customer will need to re-enter the other stored info like rapid dial numbers, their fax number, header and footers, etc., but it would seem that the fax machine is now functional.

Now where did I put the fax number of that pizza place?

Comments: This is yet another example of a simple problem bringing down sophisticated technology. I would have had no chance of successfully troubleshooting anything in the fax logic. However, phone line circuitry problems are quite common - especially after the storms we had the previous week. (I have a VCR coming in which failed during the storm as well). Without the circuit diagram, I have no way of knowing if this was, indeed, storm related damage but the probably is quite high that it was.

Repair Brief #42: Mitsubishi HS3381UR VCR Tracking Bands

Patient: A former colleague's Mitsubishi HS3381UR VCR. (He now works in California and we are near Philadelphia. However, he visits frequently. It worked fine before the move (except for the occasional spasms of B/W only playback but that is another story), he says.

Symptoms: Tape plays but the bottom of the picture is snow and the remainder of the picture has an appearance similar to CUE (forward search) mode - multiple tracking noise bands are visible. However, the tape is clearly playing at normal speed as the audio is is normal.

Testing: Confirmed with several tapes. Same symptoms. CUE and REV result in similarly confused pictures.

The picture is broken up. The top two thirds has the same exact appearance as it would in search mode (CUE or REV) - 3 or 4 bands of noise with good video in between. The bottom third is snow. However, the sound is normal (but no HiFi sound) so the speed is normal and this is strictly a tracking problem. Once you have seen this set of symptoms a couple of times, the diagnosis takes about 3 milliseconds.

We did try to help diagnose the problem long distance. Unfortunately, his description of the picture was not clear enough or the email connection was bad - or something. This turned out to be hopeless. His interest in repairing things usually ends with changing batteries in the remote control anyhow. I am just glad he didn't cause additional problems by using sandpaper on the video heads or attempting to straighten the tilted guideposts with a pair of pliers!

So, next time in town, the VCR is dumped in our hardware lab....

It rattles! And, this is not even a JVC!

Upon removing the cover, the problem is obvious: the right side tilted guidepost has fallen out. It was probably fine as long as the VCR was in an upright position. However, the baboons who packed up his apartment probably had it sitting upside-down for the move so the guidepost worked loose. This is a 5 minute fix using 5 minute Epoxy using just the smallest amount - a dab on either side - then pressed fully into place and rotated if possible to distribute the adhesive (you don't want a continuous coating as trapped air in the cavity may cause the post to pop out before the Epoxy cures.) Tape path alignment should not be needed.

Comments: It seems as though older Mitsubishis are virtually guaranteed to have at least one loose guidepost. I have seen 3 or 4 in rapid succession. These often don't cause problems until the VCR is moved but the symptoms are quite obvious once you have seen a couple (even if you don't shake the VCR!).

Mitsubishis, JVCs, who else?

---

43. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #43: Panasonic PV2812 VCR - no Play or Record

Patient: Panasonic PV2812 VCR used for a lot of time shifting. The owner is apparently quite eager - desperate would be a better term - to have it back.

Symptoms: Play results in snow and shutdown in a few seconds. Record also results in shutdown. FF and REW work normally.

Testing: Multiple tapes result in identical behavior - just snow in play and then shutdown.

This is one of those VCRs with almost no controls on the front panel. Therefore, testing almost anything beyond play, record, and channel selection requires a remote control. I didn't get the remote control so I had to use one from another older Panasonic VCR. Some of the buttons behaved a bit, well, strangely. At least the basic functions seem to be standard.

With the top off, the problem is quickly identified. This model uses a tape transport that loads the tape half-way as soon as a cassette is inserted. A plastic lever called a 'sector gear' drives a metal lever with a vertical post called a 'control arm' which is supposed to pull the tape out of the cassette. (Thanks to Frank Fendley (Studio Sound Service, frank.fendley@datacom.iglou.com) for providing the correct terminology for these parts and for identifying the specific part numbers so I could obtain the necessary replacement).

The first observation is that the tape does not move after play or record are pressed and the microcontroller is shutting down due to lack of takeup reel rotation.

However, the underlying cause is not a common idler or belt but failure of the control arm to pull the tape beyond the pinch roller. Thus, in play, the pinch roller comes down and presses against the capstan but there is no tape there! Without the rotating capstan to pull the tape through, it just sits there. Without control pulses, I guess the blue screen circuitry kicks in and there is no picture. Eventually, the lack of takeup reel rotation results in a shutdown to the stop position.

So, what can prevent the control arm from doing its thing? If this were a late model Sony, it would be dried up lubrication but in this case the arm swings quite freely.

However, it appears to get hung up just short of the pinch roller. How does this work? A spiral multifunction cam gear that looks somewhat like a miniature washing machine agitator (supposedly called a 'Pressure Roller Lift Cam' by Philips who apparently invented the technique) is used to:

1. rotate the mode switch via gear teeth around its bottom edge,

2. move the control arm back and forth using a cam follower lever called a sector gear whose end presses against a cam affair near the bottom.

3. move the pinch roller up and down and press it against the capstan using a stirrup type cam follower which starts at the top and follows the spiral.

The mode switch appears to be fine and properly timed - in the tape half loaded position, the timing marks line up precisely and in the tape-out position, its timing mark lines up with a notch on the plastic case. One can only assume that there was some intelligence at work here!

The pinch roller appears to do exactly what it should coming down and then pressing against the capstan - which does rotate properly during the time it is supposed to be playing.

Therefore, we are left with the control arm itself. This is driven by a cam on the outside of the main gear but not directly - there is another lever - the sector gear - which actually contacts the cam. This drives the control arm via a set of 6 gear teeth. As a result of the way the two levers are pinned, a slight change in cam position results in a large movement of the control arm.

Except that it is getting hung up on something.

Unfortunately, it is almost impossible to view the goings on with everything in place. However, I really don't want to take anything off that (1) might require retiming or (2) have circuit boards hanging by multiple cables (as would be required for this series of Panasonic and clone VCRs).

What appears to be happening is that the actual control arm (which is made of metal) is getting hung up. The sector gear is made of plastic and - guess what! - has a crack!!! It isn't a break and not even much of a crack but will need replacement.

However, is the crack the cause or the result of the current problems?

It is just a small crack so I assume that the overall behavior will not be as grossly affected as it seems to be. Could the crack have been caused by some other problem?

Mechanically, there really isn't much to this. The only way it could not work would be for the control arm to have changed vertical height somehow or bent, or for there to be some obstruction or gummed up lubrication preventing full movement.

It seems as though a projection on the metal control arm itself is supposed to fit into and clear the cam as it pivots. Imagine: Cam moves lever #1 (the sector gear); lever #1 meshes with the gear teeth of lever #2 (the metal one with the control arm post); and a projection on lever #2 then fits into a cavity on the same cam gear. Thus, this cannot be a timing or electronic problem as the mechanics are totally self contained and only depend on the relationships of the two levers. The gear teeth that mesh them are timed properly - the little timing marks align. But the projection just stubbornly keeps hanging against the cam.

I did remove the metal lever completely to check for cracks or bending - there was no evidence of either of these conditions. I also tried raising and lowering it a carefully recorded amount - no change except that when raised, it hit the pinch roller before getting stuck so it was obviously not too low to begin with.

Finally, I decide to remove the pinch roller assembly - this seems pretty harmless as it is fully up and everything should operate fine with my cassette cheater, pinch roller or not. This gives a clearer view of what is going on.

It appears as though there is considerable stress on the plastic lever as the crack widens significantly during part of its travel. However, upon unloading, the pinch roller does move fully as it should. Interesting. Careful observation now reveals that the projection must be entering a cavity in the cam which is not visible and the cause is now likely to be that crack in the plastic lever.

When loading, there is enough stress to deform the lever and due to the mechanical amplification of the lever system, shifts the point of entry of the projection just enough for it to miss the cavity every time.

However, during unload, there is less stress and thus it pops in place for at least part of the way.

With a little less spring torque on the control arm, operation seems to be reliable even with the bad plastic part. Thus, the crack was the cause and not the effect - which is comforting as I was not looking forward to a convoluted failure!

Once the replacement arrived and was installed, I confirmed the timing (I just avoided ruining my whole day as the agitator thing tried to jump up but I calmed it down), and then lubricated some key points as well. The VCR was then whisked back to its expectant owner.

Comments: Once again, a very simple common problem like a cracked plastic part can result in symptoms that are confusing. This would have been a lot easier if there was better access to the mechanism. Unfortunately, this series of Panasonic VCRs puts the main circuit board on top and while not actually covering the cam gear/pinch roller/loading arm certainly gets in the way. I don't like removing it because there are a bunch of cables that never seem to go back just the way they should - at least not without some persuasion.

Unlike the Mitsubishi broken cam follower problem (Repair Brief 40: Mitsubishi HS-U53 - Bad Tracking) which bears some similarity, there doesn't appear to be any real cause for this failure except just normal wear and tear and perhaps too flimsy construction of the plastic sector gear. The design with a projection that must enter a recess seems like some sort of interlock to guarantee that the tape is fully beyond the pinch roller before it comes down and would possible crunch it. In all fairness, there must have been some merit to this design. At no time was there any damage to the tape despite such a fundamental failure of the tape loading mechanism.

However, once a crack develops, it is likely to get worse as the stress is a lot greater on the part when that projection cannot enter its cavity in the cam gear.

Repair Brief #44: JVC HRD-550U VCR - Tracking Problems

Patient: A colleague's JVC HRD-550U 2 head VCR. I was actually expecting this job about 4 months ago but being his third VCR, apparently wasn't an acute emergency case.

Symptoms: Since this is a JVC, I don't even bother to plug it in before taking off the top cover and jigging the guide posts.

Testing: Jiggling the roller guide assemblies reveals that the right hand one is loose. Removing the bottom cover produces the missing brass pin.

I cycle the mechanism half way and pull the plug to gain access to the roller guide assemblies. It is important to take care at this point to prevent the relatively unconstrained roller guide from flopping up and hitting the spinning video heads - a relatively expensive lesson.

So far so good, a drop of Epoxy and that guide post is better than new.

Pop in a tape and...No picture. This was supposed to be straightforward. :-(

Both roller guides are seating properly but - wait - guess what? A missing tilted guide post!

Two dropped parts in one JVC at the same time! Fabulous.

Sure enough, the post is sitting quietly on the workbench minding its own business not caring one wit for being absent from work.

Break out the Epoxy once again. At least this post stays put once pressed into place (unlike the Mitsubishis that have the same problem but the cavity in which the posts are inserted are so closely machined that they trap air and the posts keep wanting to pop back out.)

Try #3: Ouch! The tape is grabbed on the wrong side of the roller guide. After carefully extracting the cassette, it is obvious that the roller guides are not fully retracting into the cassette. Thus, when the cassette drops, sometimes the tape is in front of the one of the posts. How can that be? In addition, sometimes the tape would not load, whirring motors, and it would give up and shut down.

The repairs look fine - brass post snug against the shoulder and nothing to catch on anyhow. What about the other one.

Now some history of this machine. It dropped the plastic pin on the opposite side roller guide linkage a couple of years ago. I replaced this and reinforced it with a tiny screw. The screw is quite secure but it appears to be this roller guide that is getting hung up, but on what?

At first, I thought that a plastic projection on the underside was hitting a sliding widget (great name, huh?) which it seemed to not quite miss as it should. When in the fully unloaded position, the projection on this widget keeps the roller guides in the retracted position. Apparently, it is doing it job too well and preventing it from retracting in the first place!

Carefully bending the plastic which allows the roller guide to pop home results in correct loading but failed retraction the next time EJECT is pushed.

Great! I have a VCR that can be loaded at the factory with one movie and will work fine as long as the cassette is not ejected!

So, is there a timing problem - something off by one tooth - or something else? The only thing unusual about that roller guide assembly is my reinforcing screw. Remove it!

And, sure enough, now loading and unloading is flawless. Apparently, the head of the screw added just enough height above the roller guide assembly to catch on the metal of the cassette basket in the down position. Lesson: when you reinforce the roller guide hinge, use a very thin headed screw.

I have no idea why this didn't show up after the first repair or maybe it has been a problem all along and the owner never realized it. Some careful filing leaving just enough head slot for a jeweler's screwdriver blade and everything appears to be happy.

Comments: This single VCR has has now had 3 of the 6 possible common dropped parts - drop off. In a professional service situation, it would really be prudent to head off the inevitable and reinforce or glue the others. However, they seem as secure as when brand new so I leave them alone. Perhaps, I just need material for a future Repair Brief!

---

45. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #45: SEARS (Goldstar) VCR, Part 1 - Broken Cassette Loader

Patient: Well worn SEARS Model 580.53471750. This is a Goldstar chassis.

Symptoms: Cassette platform is loose indicating a broken part. The owner apparently had someone extract the cassette - cover screws were missing (again - this is not the first such instance).

Testing: Cassette jams as soon as it is inserted. Fortunately, no additional damage is done.

Well, removing the cover is easy at least. Now, is the broken basket assembly the cause or the effect?

To remove the cassette basket assembly requires taking off the front panel (3 screws), video head cover sheetmetal (3 screws), and then 6 screws to actually unfasten the unit itself. The complete assembly can then be unplugged and removed to the convenience of my workbench.

And, hey, what do you know? There is a transverse shaft which keeps the two sides in sync - it drives the left-hand side from a motor and gear reducer on the right-hand side. The little right-hand gear is - missing! Not just fallen off but gone. Apparently, whoever extracted the cassette did a little 'clean-up'. No, it didn't fall off, it is **gone**.

Thus, I need one gear. Better make that two gears - its left-hand mate appears to have a fine crack just waiting to spread.

Frank Fendley of Studio Sound Service identified the part numbers - at first thinking I wanted the large drive gear which has a couple of projections and a spring. This mistake, however, got me to looking at that part and noticed that a plastic post had developed a crack and *was* in the process of breaking, so add one of those to the list.

Hopefully, there is nothing else wrong with the VCR that caused the missing gear to crack in half. However, without the basket in place, it is kind of difficult to be sure. I probably could have nursed it through the cycle even with only the one gear in place but I have confidence that this is indeed the main problem.

The parts arrive 2 days later. The two small gears fit perfectly but the large gear is apparently a slightly different revision and I need to ream out a section of the hole to accommodate a shoulder on the mounting shaft.

I, of course, violate my Rule #1 - mark everything before removal and a couple of email messages back and forth are needed to get the timing adjusted properly.

After a little lubrication with plastic safe grease and reassembly, normal functions appear to be restored.

When I returned the VCR to its owner, she commented: "So, that little plastic piece was the problem?". Thanks. No user serviceable parts....

Comments: The lesson of this story (aside from not messing up the timing) is to always check related components - mechanical as well as electrical - for possible stress or pending failures. This applies equally to capacitors in a power supply and plastic gears in the cassette loader.

---

46. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #46: Beckman Model 310B Digital Multimeter with Random Display

Patient: Beckman portable DMM Model 310B I acquired because - you guessed it - it was broken.

Symptoms: Most ranges result in a random display alternating between large arbitrary positive and negative numbers. There do appear to be differences depending on mode - DC V vs. Ohms but not in any decipherable way.

Testing: Changing battery, applying various inputs, whacking it, using the DMM to hammer nails - no change. Though it might have been my imagination, the character of the screwups may have changed after pounding some 20 penny spikes!

I had taken a look at this multimeter to attempt to repair it a couple of years ago. At that time, I completely (so I thought) disassembled it to locate any standard chips hoping that if I could get pinouts, I could determine what was wrong. There were none except for a couple CMOS CD parts - one in the clock generator and the other in the piezo buzzer circuit.

Everything else was custom and what was worse was that I could not even locate the main A/D and display chip! It had to be there somewhere. since the 2 or 3 custom 16 pin chips I could find were not large enough and not in the proper place to perform these key functions (they turned out to be precision resistor networks - I think).

So, for two years, this thing sat on top of Jim's filing cabinet gathering dust.

Finally, with nothing better to do (right, I can hear you saying: "sure, likely story") I set out to solve the mystery.

After pulling off the LCD panel, cleaning its contacts, and reinstalling - with no change in behavior - I noticed a 'wart' on the backside of the PCB board behind the display. What's that? It has no business being there unless it were hiding something. This 'wart' was a couple of molded plastic pieces that with 20-20 hindsight was obviously clamping something in place.

Prying off the first plastic piece revealed - a second one.

Prying off the second plastic piece revealed - a little circuit card with a blob of Epoxy - chip-on-board - in the center and 40 or so gold pads on the long edges. Ah ha! The A/D and display chip at last. Of course, a lot of help this will be if I need a replacement - no markings of any kind. Connections were via those aligned rubber strips LCD watch manufacturers are so fond of - and which I always suspect for bad connections.

So, I clean the chip-board contacts and reinstall. No significant change.

OK, maybe a little deeper. Next, I remove the chip-board, its mounting, and the two rubber connector strips and clean everything with cotton swabs and alcohol.

Now, finally, a change. The display looks to be half way normal. In fact, at that point I thought it was entirely fixed. Checking with a handy .1 % resistor that just happened to fall out of the sky, the ohms scale seems to be dead-on. Hurray, but premature.

At this point, I go about cleaning up the case thinking that this was pretty easy.

Then, I tried it on a 1.5 V Alkaline battery and got - 3.43 V. Huh? Did I pick up an Lithium by accident? Nope.

My AC line measures around 250 V according to the meter. Since none of my VCRs have melted down, perhaps, there is still a problem.

Well, maybe there are still some bad connections. So I go through the entire exercise of disassembling the chip-board once again and double check all pads. Reassembling results in no change and jiggling, pressing, and other wise fondling the display/IC area doesn't alter anything.

What next? How can ohms be perfect and all other ranges (I also tested DC current and Diode check) be off by more than a factor of 2?

As noted, this thing has a chip-on-board IC - unmarked - for the A/D and display driver and custom Beckman parts for key resistor networks. Thus, it is virtually impossible to determine any circuit details (not to mention the 32 pole rotary selector which cannot be used with the unit disassembled for testing).

There is one pot - full scale adjust - which has about a 10 % range end-to-end and affects everything but resistance. Perhaps, resistance is calculated by performing a comparison with a known resistance. Then, they would both be off by the same amount. Maybe I could bugger this pot to drop it down but I would really like to determine the root cause.

Modifying the adjustment pot circuit turns out to be impossible since it is connected to the above mentioned unidentified resistor networks and any attempt would be a shot in the dark.

So, now it works fine as long as I multiply all my (non-resistance) readings by about .4. I thought I was able to 'fix' DC volts by installing a 1.3 M ohm resistor across a point found by trial and error. However, this did not help AC volts or any of the current scales. And, apparently it messed up the offset as + and - readings seem to differ by an unacceptable amount.

For awhile (like a overnight), I just let the problem bounce around.

Suspecting that the reference voltage was incorrect - low resulting in the higher than correct readings, I searched for anything that might be a voltage reference. There were a bunch of transistor-like things but one stood out since while it had three legs, two of these were shorted together. Jumpering across the unconnected pins with a high value resistor resulted in the readings increasing. Measuring across it with a working multimeter read .54 V. Disconnecting the part entirely resulted in readings that were now **low** by a factor of about 2.5. Since the present part at .54 V makes it read too high by a factor of just over 2, a reference of 1.2 V should be about right. I knew I had saved that bag of 1.2 V zeners for a reason! Sure enough, putting a 1.2 V zener in place of the unidentified part results in nearly perfect accuracy on all ranges I tested - DCV, ACV, DC mA and Diode Check. No doubt it could be tweaked now if I had some voltage reference that I trusted. And, Ohms is still fine (actually probably better since the higher reference will increase resolution).

So, I still need to identify the reference part: HCC 8069 J010? It is a TO-92 but doesn't show up in my ECG or SK databooks.

After posting symptoms to sci.electronics.repair, I did get some useful comments:

(From: Kevin Carney (carneyke@watson.ibm.com).)

> "I've repaired many of the 300 series over the past ten years or so. The problem described sound like one of the finger contacts driven by the cam wheel is staying closed or not making contact. If this meter has these type of contacts it may be your problem. Solving it requires patience taking apart bending contacts putting together and testing. Good luck, Kevin."

As noted, it does not appear to have been bad contacts in this case though this info is certainly worthwhile to keep in mind for the future. The unit had very little use and except for the one contact I bent putting it back together :-((and subsequently had to unbend) the selector switches (all 32 sets of contacts) appear to be in pretty good condition.

Then, one Netter who prefers to remain anonymous replied:

> "I have the part in stock. I will snail mail it to you if you send me your address. The Beckman part number listed in the manual is FG3000-231-102. It is a 1.2 Volt Zener in a TO-92 package. The markings on the part are LT1004 CZ-1.2."

So I guessed correctly. My 1.2 V zener is marked LM305, BZ1-2, K002. I do not know if it is equivalent to the specified part so I accept this generous offer.

Comments: Test equipment is the stuff one depends on to troubleshoot other broken equipment. Therefore, it is disheartening in some ways to have to repair a DMM. To find multiple problems on a lightly used instrument is also disappointing. I suppose it is possible that my prior poking around searching for the random display problem caused the zener to fail but what an unlikely part to damage! I am not entirely sure the bad connections explanation is entirely correct or at least that it is a permanent repair but I will keep my eye on that.

Now all I need is a voltage standard to set its calibration.

---

47. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #47: Quasar TT4259WW Color TV - Dead

Patient: Bill's brother-in-law's 17 inch color TV.

Symptoms: Only the channel numbers work. In all other respects, it is a paper weight - and a big one at that.

Testing: No change when run up on a Variac. It remains dead.

So, Bill gives me a call at 7:30 in the evening: "I have this TV, about 13 inches. Only the channel numbers work, nothing else. Can I drop it off?" No, Bill, if you want to come and help to troubleshoot it, that is fine, pick a time. Otherwise, hold on to it. You can clutter up your basement. "OK, I will see if I can get dad to watch Bobby". Any excuse to get away from the kid. Five minutes later: "How about a half hour?" Sure, fine.

About 45 minutes later (30 minutes of Bill time), he comes lugging this huge TV down the basement stairs. At first, I thought it was at least 19 inches but measuring the CRT, 17 is about right. Well, at least it *should* be easy to work on - lots of empty space.

Plug it in and just as expected, only the channel numbers work. No picture, no sound, no static, no deflection whine. The thing has push button controls so I guess the standby power is ok. Time to check the power supply and HOT.

Eight screws later, the back comes off cleanly. There is a nice 3" x 4" parts layout diagram, still legible, so that is a help.

Check the fuses. One is black. Bill, which is the fuse closest to the back?

"Uh, looks like the B+".

Check the horizontal output transistor (HOT) with my trusty 25 year old Lafayette VOM. Case (collector) to other pins: 0 ohms. OK, bad HOT. What else?

Unfortunately, they saved a couple cents and soldered the transistor rather than using a socket. Bill, write this down: The yellow wire is on the right. "Done."

Removing the bad transistor is easy though we manage to lose one of the lockwashers. Well, as long as it is not on the circuit board somewhere.

I go into my HOT drawer and pull out a 2SD871. Nah, that is too good a part for testing *this* set, how about a BU208A? I won't be too unhappy if one of these blows. (Note: I have no intention of leaving either in place once the set works. I will order the proper replacement, a 2SD950.)

Installation is equally smooth with the yellow wire on the right. These is also a little insulating sleeve which I swear went on the yellow wire pin but Bill thinks went on the other. Oh well, I will put an insulator on both later on. Replace the fuse.

I go get the Variac and series light bulb widget and plug these in to my isolation transformer rig.

Starting with a 100 W light bulb.

Bring up the voltage until about 100 V - channel indicator lit - push ON button. Light bulb flashes brightly and set shuts off.

OK, Bill, unplug the degauss coil from the mainboard.

"What? Huh? Where is it?"

Locate the coil and work backwards. Here, this connector....

Try again. Similar result. Up voltage to 120. Now, it stays on, not to full brightness but more than I would expect if the set were working properly.

There is still no picture, no sound, no static on the screen. I think I can hear the deflection whine, however. The HOT is holding.

Try a larger light bulb!

I put in a 150 W outdoor flood. Try again. Turn Variac to 130 V (or whatever its maximum is).

There is still no picture, no sound, no static on the screen. I definitely can hear the deflection whine. The HOT is still holding.

Then, Bill says: "Shut it off. Shut if off. I see smoke...."

Sure enough, there is a wisp of smoke coming from the vicinity of the flyback. It stops too quickly to determine the source. There is a small electrolytic there as well and the smoke could be originating elsewhere. The odor could be burning plastic or burning electrolytic.

Now for the real smoke test! I go get a foot square piece of Plexiglas that was once part of a homemade HV capacitor to use as a shield if something should decide to blow up.

Power it up again. After about 20 seconds, the smoke appears but it is still not possible to determine if it is the cap, flyback, or something else.

Well, change the cap. It is a 1 uF, 160 V electrolytic. I will show it! I put in a .8 uF, 200 V polyester type. No change - still smokes. This eliminates the capacitor. Bill is sure it is coming from the flyback at this point anyhow.

Bill is getting ichy as he knows his dad won't be able to take much more of Bobby. So I suggest that we pull the flyback and I will test it later. The big pins are a pain but attempting to discharge the CRT HV under the suction cup thing yields nothing as expected.

Bill is about to leave. Hey, how about buttoning this baby up so it is not cluttering up my workbench. "OK," Just a couple of screws, put the other stuff in a plastic bag. "I think the flyback is bad."

Next day:

I get out my flyback tester widget - the 12 V chopper - and hook it up. Ten turns of wire around the core connected to its output. If the flyback is good, this should excite it to produce 8 or 10 kV with only a small load on the power supply.

I locate the HV return on the flyback by turning up the juice just enough so it is oscillating - barely. Measuring on the 5000 V scale of my Simpson 260 shows a couple kV between the CRT HV connector and only one pin on the base of the flyback. That must be it. The others show zero volts.

Now, turning up the input power to my normal 'full' results in a nice 1/4 inch arc between the HV output and the return. Is the flyback good? Just then, an arc develops between the return pin and its neighbor. What is this? Kill power. Did I pick the wrong return pin?

I drag out the TV chassis to confirm that the pin I selected was indeed the HV return. It was. The other pin is a winding for one of the auxiliary outputs of the flyback.

So, what is going on? A quick check with the multimeter solves the mystery: All resistance measurements are reasonable except one - and a fundamental one at that. I measure 1.76 K ohms between the CRT HV connector and three pins on the base of the flyback - and one of those is the pin that arced.

Therefore, this flyback is history. Apparently, internal breakdown between the output of the HV rectifier or multiplier and the low voltage windings resulted in destruction of the original HOT and blown fuse. This is a pretty spectacular failure mode!

I call Bill on the phone: flyback is bad as expected. Short, CRT HV to pins on base. "I already told him it probably wasn't worth fixing".

The flyback is definitely bad but could it have damaged other circuitry in the TV? After all, until the HOT popped, that HV was arcing internally to the low voltage windings. I suspect that it did not cause any damage, however. Despite the fact that the HV output is on the CRT capacitance and could really zap something, it is likely that the short didn't develop suddenly but over at least enough time for the capacitor to discharge harmlessly. The actually current available from the flyback HV output is quite small and the low voltage flyback windings have almost no resistance to ground.

We will probably never know since Bill talked the 'customer' out of spending the money for the expected repair parts. The HOT would probably be around $5 and the flyback is $26 from Dalbani. Add shipping and this will likely come to over $35 for a 13 year old TV. And, there would still be a chance that it would not work at all without additional parts or have long term reliability problems.

So, if anyone has a good TLF14617F flyback they want to sell cheap....

Otherwise, the set goes to the great TV spare parts graveyard in the sky (or actually in the attic of my garage).

Comments: I promised that not all these stories would have entirely happy endings. This is a case where determining the extent of the damage and cutting losses made the most sense. If I come across a replacement flyback (sure, like they are all standardized!) then it will be worth the effort to see if that is all that is needed.

Repair Brief #48: SEARS (Goldstar) VCR, Part 2 - Shutdown in Play and Record

Patient: Well worn SEARS Model 580.53471750. This is the continuing saga of the VCR described in Repair Brief #45: "SEARS (Goldstar) VCR, Part 1 - Broken Cassette Loader.

Symptoms: VCR will enter Play and Record successfully but then shut down in anywhere from 10 seconds to 10 minutes.

Testing: I was able to confirm these symptoms and it didn't take long, about 2 minutes the first time, 10 seconds the next. I tried several tapes without any apparent change.

It was only two weeks since returning this unit to the 'customer' after repairing the cassette loader. These are classic symptoms of dead rubber but I knew the rubber parts were fine having replaced them not so long ago. And, observing the behavior as it shut down, there was never a problem with spilled tape or a weak takeup reel. This is confirmed by testing the takeup reel torque using a cassette cheater (shell).

The reel rotation sensors would be the next natural suspects. What about them? Well, there is only one, for the takeup reel. The tape counter does increment but on closer examination, there does appear to be some weirdness. Instead of counting 0000, 0001, 0002, 0003, etc. It occasionally skips counts. So the sequence might be: 0000, 0001, 0003, 0005, 0006.... I don't know how the microcontroller determines that the tape is moving but it might just test the least significant bit periodically. If the counter is skipping counts - say only doing odd numbers for a while - this could end up not changing for too long.

So, now I start playing with the takeup reel with the VCR in STOP mode. Fortunately, the counter is active and I can simply twirl the takeup spindle to my heart's content. It doesn't take long to realize that IT is behaving strangely. If I go very slowly, there will be times when the counter display will free-run, counting rapidly and continuously. This is, in fact, most likely what is happening - the reel is turning slowly enough that as it passes through these 'bad' areas, the counter skips a count or two. Why?

Putting a scope on the sensor signal doesn't reveal anything amiss - it changes smoothly from low to high and back again. However, when it is approximately in the middle of its range, the counter does its free-run thing.

I trace the circuit to a buffer on a little circuit board tucked in a very inconvenient spot needing to extricate it from several connectors. Examining this circuit shows that it is, well, just a buffer. No hysteresis or debounce. Its output is changing as expected. Tracing the output reveals that it is going to a large multilegged creature - the main system controller chip. So, if that does the debounce, I am kind of out of luck as I am not going to invest in a new microcontroller.

Well, I will show it! I build a little widget board with a single transistor (2N3904) and a couple resistors as an additional buffer and put this in series with the original signal. I then add a feedback resistor from the output of both buffers to the input of the first one. This adds just enough hysteresis to prevent the circuit from even likely lingering in the bad area.

At first, this works like a champ but then the sensor seemed to be losing sensitivity and its output refused to go low! Could a dying sensor be the entire problem? No, I don't think so. That free-running count problem would still exist even if the transitions were sharper - it might be unlikely during normal tape movement but could still happen if the tape stopped at a just the wrong spot.

Removing the sensor under the takeup reel requires popping the split washer and pulling the spindle - taking care not to lose the washers under the spindle. It could be worse.

The sensor is a roughly 3/16 inch diameter affair with an LED and photodiode pointing at a four quadrant aluminum reflecting pattern on the bottom of the spindle. Everything is clean and undamaged so perhaps the LED or photodiode is in the process of failing. It doesn't really matter which is bad as failure of either would render the device useless.

What to do? My usual places like MCM Electronics do not list a replacement and I really wouldn't have a minimum order anyhow. I check with Frank Fendley - he has it - but I cannot justify the $5 S&H for a $2 part.

I will make one from the guts of an optoisolator! I at least want to do this to further test my theory (though at this point I am nearly certain that the sensor is the **final** problem).

I totally destroy 2 optoisolators in the process but finally extract both an LED and photodiode intact. Fortunately, my friend Bill has bags of these left over from his switchmode power supply design days.

The circuit board is marked so it is easy determine which leads are the LED and which are the photodiode. It isn't pretty but with a bit of filing and other manipulation, using the correct chants, etc., it finally is positioned to have enough sensitivity to activate the counter. Unfortunately, the top of the LED rubs on the bottom of the spindle during rewind slightly scraping the reflecting pattern but not enough to affect anything. A bit more filing and a key incantation and it seems to be solid. The response does not quite seem to be as sensitive as I would like but operation appears to be consistent, reliable, and repeatable from one end of a T120 tape to the other.

In fact, I ran the VCR for about 20 hours in Play and Rec, end-to-end of tape, and at SP and EP speeds without any apparent problems. I know I can obtain the replacement part but for now my kludge is just fine, thank you. The @#$% VCR will probably now die in a couple months in some other interesting and creative manner.

Comments: This is my VCR from hell. It seems to have problems with multiple unrelated failures at nearly the same time. I have already had to replace the video heads (due probably to just plain wear and tear) and also suspect a bad connection in the video circuitry as well. Sometimes, I have simply needed to clean the video heads. In addition, the 'customer' insists on using old, worn, and damaged tapes.

Assuming that the cause of the aborted Play and Record was a weakening sensor and/or bad debounce circuit inside the microcontroller, there is no way of tying these in with the prior failure of the gear on the tape loader mechanism. If it were just out of warranty I would credit Goldstar with timing multiple parts to fail simultaneously but it is at least 8 years old at this point.

Repair Brief #49: HP DeskJet Professional Printer, Part 1 -

Dead

Patient: Garage sale HP DeskJet Professional ink jet printer in pretty good physical condition except see below. $5*.

Symptoms: Switching power on results in absolutely no indication of life either from the front panel LEDs or motor movement.

Testing: The output of the power brick is marked and I was able to verify that it was approximately correct - 20 VAC. Since it is a simple transformer, it is probably good. Attempts to evoke a response from the printer without opening the case were all dismal failures.

You probably know me better than to believe I paid a whole $5 for a broken printer. Well, I did get a PC power supply and a bunch of old hard drives and controllers as well. As of this writing, the power supply and at least one of the hard drives are known good.

Unfortunately, I neglected to ask what the original problem was. But from his attitude, the printer must have died totally. Otherwise, he would have likely mentioned that it was probably a minor problem (and attempted to charge more than $5).

Anyhow, the printer is in a box sitting on the ground and somewhat waterlogged. I don't know if the stuff was out all night and it rained or what.

First test, as noted, was of the AC adapter which is apparently just a transformer. Its output read a bit higher than the listed value that is typical of an unloaded wall transformer.

After drying the case off, I plugged the printer in and turned it on.

Nothing. No sign of movement from any of the motors, no lights on the display, and no response to any buttons.

OK, time to get inside. Some HP engineer probably won an award for the mechanical design of this thing. (I seem to recall reading about this product line in a past HP report.) Indeed, it is easy to get apart and the subsystems are readily accessible. The top of the case is held in place with 4 snaps. There are only 5 modules inside: power supply, logic board, print head driver board, printer mechanism, button and display panel. Except for the fact that HP seems to used weird size philips head screws, the entire thing can be disassembled to the module level in about 10 minutes. However, I would have preferred screws to hold the top of the case in place rather than snaps as it is necessary to deal with the snaps every time the top is removed - which during troubleshooting is quite frequently as the paper tray is part of the top cover.

Back to the story. All I have done to this point is remove the top of the case. However, the next time I switch it on, the print head whomps to the left end of its travel and seems to be trying to fling itself off into space.

Power off. Let's try that once again. Power on: Whomp-whir! Power off.

Then, I notice the puddle of water on the logic board!

First, I try to deal with in-place by mopping up what I can get to. Then, I start up the old air compressor and use that to blow and dry the water. Well, it isn't really up to the job so I start up the 3 horse shop vac on blow. However, I cannot get under the print mechanism where the bulk of the logic board is located.

Removing the print mechanism requires only disconnecting of 3 connectors and a ground strap (one of those darn HP philips head screws!).

Now, it is easy to get to all parts of the logic board. I also remove the EPROM and dry out under it to be sure.

I replace the print mechanism.

Ready? Power on: Nothing. OK, we try that once again. I said power on: some lights on the display. There is no response from the buttons and no motor movement. Several more power cycles results in somewhat random lights but no other action.

OK, I will take out the logic board so I can inspect the underside for water. This requires removing 7 or 8 screws and the power connector. The board is fine. I also reseat the power connectors.

Reassembling - ready? Power on: Now, I get lights AND the print head seems to be doing something reasonable, like the reset sequence. Back and forth, prime, and then the On-Line light comes on. Its pitiful brain thinks that everything is fine and ready to print. Is it?

Along with the printer came about 15 sheets of somewhat water damaged (but now dry) paper. This should be good enough to test it even if every third sheet jams and tears.

Now, how to do a self test? Fortunately, the complete HP users' manual was part of the deal. "Hold the FONT button while turning on power". OK, no problem.

Now, the printer goes through all the expected motions of initialization and then proceeds to load a sheet of paper and....

Nothing. Actually, as far as it is concerned, the self test worked fine. But, there is no ink on the paper! Well, the cartridge could be empty but it doesn't feel that way. Based on my past experience, it is nearly full. The nozzles could be clogged but sucking on the business end of the print head (yuck) results in some ink drops appearing.

At this point since I do not have another cartridge to try, I decide to strip it down completely once again and do a thorough inspection. Somehow, I don't think the water was the cause of the original problem. All connectors are reseated (including those to the print head which are the flexible printed variety).

Everything looks fine except for the solder around the DC power connector output pins of the power supply. There may be a hint of cracks around several of them. Well, my soldering iron makes short work of those!

Put it all back together once again. No change. There is always a chance that operating the printer with the waterlogged logic board may have damaged something - always fear the worst, right? Therefore, I decide to do a little exploratory probing of the print head driver board since everything seems to be fine except there is no action from the ink jet nozzles.

A bit of ink jet theory: There are something like 50 thin film heating elements inside the micromachined chamber at the business end of the print head. These heaters are pulsed at precisely the right time by the logic to vaporize the ink in direct contact with them and expel a drop of ink toward the paper. If a heater is bad or a nozzle is clogged, there will be a missing line (out of the 50 possible lines) on the paper. Priming is supposed to assure that the nozzles are clear, loaded, and ready to go.

First I test for power - there is both +5 V and +20 V. I assume the +5 is for the logic and +20 for the print head nozzle heater elements. There are something like 50 nozzles and I have no intention of testing them all but it is fairly easy to determine that the print head receives +20 for power and the nozzle driver pull low to turn them on. Probing with a scope while the printer is supposed to be doing the self test confirms that there are pulses at a representative sample of the nozzle wires.

The only thing left to do is try a new cartridge. But, that has to wait until I can 'borrow' one from the office.

Two days later.

None of the cartridges we use at the office are exactly the same part number but they do have the same array of gold pads and the same size print head itself. I take one of each of the two types we have (one is the super-high capacity type - all right!.

I first try the cartridge that looks exactly the same as the one that came with the printer (though the part number is different).

And, what do you know! The self test is nearly perfect. There is one missing line. This could be a bad driver (hope not) or defective cartridge (yeh, right!).

Next, I try the PaintJet 'high capacity' cartridge and this also works but now there are 2 missing lines. :-(

Going back and forth, they are consistent. I am not sure if one of the two missing lines are the same on both cartridges. Could something be marginal or is the priming not working? However, all other nozzles seem to be rock solid. Reseating the connectors to the print head makes no difference. If I knew which drivers were involved I could look at the signals but it will be difficult to trace the circuitry from the driver board to the actual nozzle.

Comments: I suspect the original problem resulting in the dead printer to have been a cold solder joint on the DC power connector which I repaired. I don't really think that the nozzle problem was caused by the water since the print head driver board was never wet. Since the data connection to the print head driver board is a 20 pin cable, this must be a common bus and thus it is unlikely that any failure on the main logic board could manifest itself as a single or pair of bad nozzles. Stay tuned.

---

Repair Brief #50: Panasonic PV1545 HiFi VCR - Eats Tapes

Patient: Garage sale oldie but goodie. Asked $10, paid $5 ("Sure, I just want it out of here"). I did suggest to the owner that he could probably fix it himself for under $3 but I guess he hadn't read the FAQ, or it didn't match his decor, or something. I did ask about the remote but that had long since walked.

Symptoms: I was told by the owner that he had to open the VCR to extract the tape. I asked: "You didn't do anything that I will be cursing you out for, did you?". The answer was 'no' but he did not sound all that convincing....

Testing: No take-up reel movement in FF, CUE, or Play modes even with a cassette cheater and no load on the take-up reel. Not that I am terribly surprised.

If this had not been a HiFi VCR, I would probably have passed as I have enough Panasonics of that era. However, I also know that those machines can be kept going with minimal effort and investment almost indefinitely.

The first step is virtually automatic: replace the idler tire.

Removing the idler on this VCR can be accomplished without any disassembly beyond taking off the top cover - but this was easily done as the owner never replaced the @#$% screws. Grrrr.

Pop off the split washer (careful - don't loose it. Yes, I know, you are not supposed to reuse these....).

Since I don't happen to have the proper size tire in my inventory, I first try to turn the old one inside-out but this little bugger refuses to cooperate. I finally find one that can be stretched to fit until I obtain a replacement (actually get one from my secondary inventory at work).

FF and REW now work fine. Play, however, results in a picture which is nearly total snow with a distorted picture showing through and no HiFi sound. I use my Mark 1 thumb on the heads - no change. I then clean the video heads using cleaning sticks and alcohol - no change. Then, I realize that I have not tried to adjust the tracking control and on some machines, if tracking is way off, the picture will not just have noise but will be totally unwatchable. Sure enough, the picture and HiFi sound now come in clearly.

CUE (forward search) works fine. REV (reverse search) results in snow and then shutdown. Then, I realize that I have not replaced the split washer on the idler. I don't know if this was the cause, but replacing that washer results in REV working fine after this. Maybe, the idler assembly was creeping up on its shaft.

For good measure, I also check the two belts under the deck. They are in good condition. Therefore, I just clean the belts and pulleys. I also give the top side a general cleaning - capstan, pinch roller, roller guides, fixed guide posts, full erase head, and A/C head stack. The only detectable oxide/dirt buildup was on the capstan and pinch roller and even this wasn't that significant.

Recording seems to work as well. I leave it recording for several hours to be sure that there are no thermal problems.

Comments: This VCR is about 11 years old but in excellent condition. Older Panasonic VCRs were built very solidly with a lot of metal in the transport and reliable electronics. As noted, little tends to go wrong - rubber parts, power supply capacitors. Thus, keeping them going requires minimal effort. While these machines don't have spectacular features by today's standards, they will outlast a bucket load of the cheaply constructed junk that passes for many modern VCRs.

---

51. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #51: HP DeskJet Professional Printer, Part 2 - Missing Lines

Patient: Garage sale HP DeskJet Professional ink-jet printer in pretty good physical condition. Original problem was described in Repair Brief #49: HP DeskJet Professional Printer, Part 1 - Dead.

Symptoms: Ink-jet nozzles #45 and #47 do not work resulting in a pair of white lines every 1/8" or so on the printout.

Testing: A variety of new and used print cartridges produce similar results except that in some cases, only 1 line is missing (??).

As you will recall, this printer was dead (and somewhat waterlogged) when I picked it up for $5 at a garage sale. Drying it out and soldering a few suspicious connections resulted in everything working except for 2 nozzles on the print head - #45 and #47. Well, 24/25ths of it works, what do you want for $5?? :-)

Interestingly, when using a new PaintJet cartridge, only 1 nozzle appeared to be bad...

The electronics for the DeskJet is divided between two circuit boards - the main logic board and a smaller print head driver board. Due to this way of partitioning I did not think that the water I found on the logic board could result in damage in such a way that only 1 or 2 nozzles were affected.

(From: Paul Grohe (grohe@galaxy.nsc.com) in reply to Repair Brief #49: HP DeskJet Professional Printer, Part 1 - Dead.

> "I concur. If just *one* jet is not firing, then it is on the driver/flex-cable/connector/cartridge side. All the nozzle decoding is done on the driver board, so the 20 pin interconnect cable is okay. The DC (well..really 20VAC) power connector does take some abuse in normal service, this could have aggravated the cold joint."

Given this behavior, there are several possibilities:

1. Bad driver(s) - stuck off resulting in no heating and no ink.
2. Bad driver(s) - stuck on burning out print head heater(s).
3. Bad connections to print head - flex cable, connector, or contacts.

(From: Paul Grohe (grohe@galaxy.nsc.com).)

> "I assume you have cleaned the contacts (with a Q-tip, on both cartridge and socket). Use a magnifying glass and check *each* of the gold 'bump' contacts. Repeated cartridge swapping, or improper insertion, can cause a crack to form around the base of the 'bump' and the pad (or the pad and the trace). The 'bumps' can also be 'flattened' by cartridges that were forced in at too much of an angle. There should also be some 'give' or 'sponginess' to the contact area to assure even contact with the cartridge."

I have done this inspection - everything looked ok (at least as best I can without removing the flex cable).

I removed the driver board and gave it a thorough visual inspection. As expected, the soldering was perfect. Leave it to HP.

(1) would be difficult to find until I had a complete wiring diagram of the driver board, flex cable, and print head. Therefore, I defer on this until I have exhausted other possibilities.

(2) would be rather disappointing as this would mean that I have already blown two new print cartridges ($20+ each) in testing (and that the problem was probably in one of the 40 pin HP ASICs). At first I was *sure* this was the case (of course, always fear the worst!) as testing between certain contacts on the print cartridges resulted in unexpected readings. Most of the resistances were around 32 ohms except for 1 which was open (blah) and another which was high (51 ohms).

Then I examined the pads under a magnifying lens and found that the open contact was indeed - open and not even connected to anything by design. The 51 ohm reading was too consistent - all 3 of my cartridges (including the original that came with the printer) measured nearly the same value. If this were due to a partial burnout, it would be an amazing coincidence.

The shorted driver theory was finally put to rest when I took one of the cartridges into the office and confirmed that it functioned properly in a working printer.

(From: Paul Grohe (grohe@galaxy.nsc.com).)

> "Check for broken/bad traces in the flex-cable that goes from the driver board to the cartridge. Ohm out the cable between the supply commons and the individual driver lines (at the PCB) with the cartridge in place. I think the jet resistance was about 50 ohms (It's been a while). There were four separate jet sections (commons). All four commons were tied to the +20V supply through four separate (12 ohm?)

series current limiting resistors. The driver outputs seemed to be grounded emitter, open collector (w/clamp diode?). The jets themselves are driven individually and are not multiplexed."

This (3) seemed like the next step. I drew a diagram of the two 28 pin connectors on the driver board. Then I identified the 4 common lines (1 for each 12 or 13 nozzle heaters). These went to some common 10 ohm resistors to the +20 V power supply. I then measured between the nearest common and each pin to the print head. When I was on a heater fed by that common, the resistance would be about 32 ohms. When to one fed from a different common, it would be around 52 ohms (32 + 2 * 10). In every case but 3, these made sense:

- One of these measured high even though it seemed to be no different than the others. I finally concluded (or rationalized) that this was the funny high resistance element in the cartridge.

- The other two tested open on the cartridge that had 2 defective nozzles but one of these was the proper 32 ohms on the PaintJet cartridge that had only one bad nozzle. Interesting.

Time to disassemble the flex cable connecting the driver board to the print head.

The retainers on the flex cable at the connector-end just snap into the open position and the cable comes free. Four screws release the print head cover and the cable then pops free of its indexing posts.

Under the contact area is a rubber pad with a little bump for each contact. All the bumps seem to be in good condition and minding their own business.

A careful inspection of the flex cable shows that it is in virtually perfect condition as well with no cracks or wear at any locations including the 56 contact points.

However, the indexing holes seem to be a bit deformed. Could the cable have worked out of position slightly resulting in poor contact to a couple of pads? Wishful thinking, maybe....

While it is it out, I confirm connections between the two open pins and the corresponding contact pads - finally correctly locating them. Following the many fine traces is a bit tricky to say the least.

Reassembly is equally straightforward. I take care to center the flex cable on its indexing posts. Is it my imagination or are the contact pads now sitting flatter and more uniformly than before?

On a hunch - I really did not expect anything to change - I check the two open pins. And, what do you know? They now measure 32 ohms. At this point, I am now, of course, absolutely confident that the printer will work!

The first few lines out of the self test are disappointing as it appears as though there are now many marginal nozzles. However, guess what? The top line of text which previously listed the numbers of the bad nozzles is the normal printout - ID E. Before it was: 45 47 ID E. The printer's pathetic brain thinks all the nozzles are working fine. Then, half way into the second page, the print died out totally. OK, maybe that cartridge needs to be cleaned and primed. It has been bounced around, turned upside-down, and otherwise abused. A little blowing into the vent hole (drip, drip - love that dreaded black finger disease) and a wipe - and we try again. Now it is perfect - no missing lines, no smudges, run, drips, or errors. I have a working printer!

Comments: Once again, that actual problems turn out to be exceedingly simple: bad connections in both cases. As noted previously, the HP DeskJet series in general is a well engineered design with only a half dozen basic components. While my printer is one of the oldest, the fundamental design has not really changed dramatically in the last several years as evidenced by the fact that print cartridges for some much more modern printers work just fine in this old machine. The print quality with a new cartridge is nearly laser-quality. Yes, HP seems to come out with a new, faster, cheaper, color, etc., printer every few weeks. But, looking inside newer printers shows that their basic design and construction is quite similar.

52. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #52: Aztech CDA-268-01A CDROM Drive - Drawer Continuously Closing

Patient: Aztech CDA-268-01A double speed CDROM drive in excellent physical condition.

Symptoms: Drawer is constantly trying to close. Shutting off power and pulling the drawer out half-way results in drawer closing and motor spinning its wheels.

Testing: A universal CDROM interface card (Panasonic, Sony, Mitsumi) was used to confirm that this was not a case of there just not being an interface card present. See the text below.

This drive was sent to me as non-working having been removed from a PC after it failed with the symptoms described above. An IDE CDROM was purchased to replace it so it was not known whether the interface (probably a sound card) was at fault.

I first began testing drive simply connected to a spare PC power supply (with an auto headlight to provide the required minimum load for the supply).

It's behavior was consistent - the poor little drawer motor just continuously tried to close the drawer regardless of pushing the any buttons. The Busy light remained solidly on. The motor was getting quite toasty in the process.

Note: this drive has two front panel buttons that serve multiple functions. to open and close the drawer and start and advance tracks for audio play without software. While I was not sure of their exact function at this time, neither button evoked a response of any kind.

So, I wonder if my magic spit will have any effect? Some careful trials on the interface connector revealed a pair of pins where pressing with exactly the *correct* concentration of magic spit(tm) would cause the motor to quit and the Busy light to go out momentarily.

Hmmm. Maybe the interface card is required after all. There might be nothing wrong with the drive. The original interface may have been bad. Since the replacement used IDE, this would have gone undetermined.

What type of interface is it? Originally, I thought I was actually told IDE but a close examination of the pin configuration showed this to be impossible as the grounds were in the wrong place. It is a 40 pin connector, so SCSI is ruled out. Therefore, it must be one of the proprietary interfaces: Panasonic, Sony, or Mitsumi.

Since I am not willing to cannibalize one of my working PCs to obtain an interface, this waits until the next time I am in the office. A co-worker (OK, actually, the boss management weeny) who insisted on having a PC built for him but rarely uses it and never has to the best of my knowledge used the CDROM won't notice if the card disappears for a few days: "What, your CDROM drive doesn't respond anymore? it must have gone bad from too much loneliness.... I will get to it as soon as possible." HeHeHe. :-)

The interface card is a universal type - a jumper will select between the three types. It is obvious from the pin configuration that the Mitsumi interface is the only one that makes any sense with one complete row of ground pins.

With the interface installed on my state-of-the-art DTK 286 mainboard, the behavior is unchanged. The drawer still insists on attempting to close forever.... With the cable installed, the magic spit no longer has any effect so the pins involved are probably being driven from the interface.

Thus, the drive is really and truly bad. I assume that what was happening was that my magic spit(tm) was triggering a master reset and thus disabling all operations. This is encouraging in some ways - the drive is not completely hosed.

What next? Checking the drawer switch is fairly easy and it is definitely good - zero resistance at either end of its travel.

To get at most of the circuitry on the board requires removing a sheet metal shield - 3 solder connections, no big deal.

I expect that if the drawer switch signal goes directly to an LSI chip or ASIC, this drive becomes spare parts as such a multilegged creature is not likely to be easily obtained, inexpensive, or replaced without a great deal of cursing even with proper soldering equipment.

However, on this drive, the drawer switch signal goes to a 74LS244 octal buffer in a surface mount package (joy!) and a pullup resistor. Checking at the buffer input, the signal swings very nicely between 0 and 5 V.

Checking at the output we have - stuck around 2 V. Is the buffer bad? That is what I thought at first but then I realized that:

- The enable to the buffer is not simply tied to ground (on) but is driven from another chip.
- The output is connected to a data bus and not a dedicated chip input. Therefore, I am seeing the average bus activity of that bit and not a solid level.

Using a fine soldering iron and dental pick to lift the leg, I disconnect the output pin of the 'LS244. Now, this output tests low regardless of the drawer switch signal level - either it is bad and open or it is tri-stated. However, momentarily grounding the enable pin to the 'LS244 allows the output to swing the full 5 V following the drawer switch signal and this confirms that the the chip is actually good.

The enable signal looks sick - it is floating at around 1.5 V. How is it generated? Would you believe, a surface mount 74LS00??? Most of the circuitry on this board is in a few large custom chips and yet there are still a few jelly beans as well! Grumpf, there is no accounting for designers' tastes. Better for my chances of repair. Interestingly, there are absolutely no adjustments of any kind on the mainboard - probably a digital servo system.

Checking the LS00 shows that the gate in question has its inputs on pins 13 and 12 and its output on pin 11. Pin 13 has a nice periodic pulse on it but pin 12 looks as dead as pin 11 - not a solid logic low but close enough to ground that the output (it is a NAND after all) should be high and it is not. Lifting the output pin makes no difference so it is not being loaded down. Power and ground connections to the chip seem solid. Checking the other 3 gates of the chip show that they are equally screwed up with outputs that are in never-never land and do not change significantly (though there is some slight response) when the inputs switch. My suspicion is an internal power problem with the chip, not that this helps us.

```
                                             _  1/8 74LS244
                                            | \
                Door Switch o----------------|   >o----X-------o Data bus
                                            |_/         (Break at X and
                              13 _____       o Enable    pulse data bus)
         ___|___|___|__ o---------|     \ 11  |
                              12| NAND |o---+ Dead - about 1.5 V
                1 _____        +---|_____/
            +---|     \ 3     |                NANDs are sections of
            |  2| NAND |o----+                 74LS00 in SMT package
   Ground o--+---|_____/  Dead - about 1 V
```

To see if the relevant output of the 'LS244 (the bus line) actually has an effect, I connect a fine insulated wire to it while it is still disconnected from the 'LS244 and power the drive. Now, momentarily touching this to ground will sometimes get the drawer to stop and even sometimes the CD will try to spin up (accelerating past Warp 10 and never actually succeeding in reading the directory (I presume since it never stabilized). I expect this is due to the fact that I am overriding whatever else is supposed to be on that bus line and it is getting really confused. Poor thing. :-(

At first I thought a neighboring 74LS04 (hard to believe, huh?) was also bad but the designer morons at Aztech or Mitsumi or whoever actually did this board did not tie many of the unused inputs to valid levels so they were just floating. (With LS TTL, unused gates should be forced to a constant output by tying their inputs to ground or through a pullup to Vcc, whichever is appropriate for the logic.) So that was a false alarm.

In fact, only 2 of the gates on the LS00 are used (1 of these as an inverter, see the diagram!). Only *1* inverter on the LS04 even connected to anything. What a waste!

My initial thought was to wire up the unused LS00 gates to substitute for the bad ones but these, too, were deader than the proverbial dodo. I thought about wiring some unused sections of other jellybean chips (there was a mostly unused 74LS08 across country) to create the needed logic. But sanity prevailed and I decided to try to locate a replacement. I finally found an old PC I/O card (that might even have been bad) with a 74LS00 in the same SMT package.

Fortunately, at the office, we have a PACE rework station so removing the old LS00 and its replacement goes smoothly using a tip that heats all of the pins simultaneously. After cleaning up the pads, I use a super-fine tip soldering iron to tack pins 11 and 4 and then solder the rest of them without too much difficulty.

Now for the test: Although I did not take the rest of the drive, I should be able to cause the Busy light to go out if I can convince the drive that the drawer is actually opened. And, sure enough, momentarily grounding the drawer switch signal results in the Busy light going out. Furthermore, the behavior is slightly different on every other push of the Open/Close button indicating that it is actually trying to read the disc when it thinks the drawer is closed. Of course, with no optical pickup attached, this might be rather difficult!

The initial functional test will be made with an audio CD since that should be good enough to confirm basic operation. Apply power: drawer closes and stops, Busy light goes out. OK, we are cooking (no smoke!). Insert disc, press the button. Drawer closes, discs starts spinning, sort of. Well, actually it starts spinning in the wrong direction (counterclockwise). Then, apparently it thinks better of it and accelerates clockwise. While it does not go ballistic, it is certainly spinning faster than the 1X speed. Of course, I really don't know what it should be doing not having an instruction manual! A little experimentation with the buttons and then it seems to be spinning more slowly. Maybe I hit the combination to play the audio CD. Time for the headphones.

And, sure enough, track 1 is playing, a bit scratchy, but nonetheless, there is music! A little more experimentation with the buttons reveals that the left hand button advances the tracks and will cycle back to the beginning once the last track is played. The right button pauses the play with one push and ejects with a second push. Of course, if I could interpret the icons on on the bezel, I might have been able to figure this out without trial and error!

The scratchy sound is a little disconcerting knowing that data readout is more critical. Furthermore, it seems to have problems accessing the outer tracks. Stopping the CD results in similar strange rotation before it finally decides to open the drawer.

Well, the CD I am using has seen better days, being a casualty of a couple other Repair Brief CD experiences. So, I get a good CD. Unfortunately, now my Vivaldi is not even recognized! Grrrrr.

I clean the lens.... No change.

There is one other possibility that doesn't involve thousands of lives and millions of dollars - I have not yet replaced that sheet metal shield. Perhaps there is some interference between the electronics and the pickup.

Sure enough, after soldering the shield into place, *all** detectable problems vanish - even the peculiar wrong-way rotation.

Now for the computer. Rather than putting together my state-of-art DTK 286 system again, I will install the CDROM in a real PC (OK, well a real PC from about 5 years ago).

Hardware installation is a snap. What about a driver? Since it has a Mitsumi interface, I assumed it would work with a Mitsumi driver. Wrong. After finally finding the correct I/O address (as my interface card is not marked well - just jumpers for Bits 1-4 but what position is Bit 1 and is a jumper a 1 or a 0?), it will still not initialize properly though it does find the card - the light on the drive flashes. No combination of IRQ or DMA makes any difference.

Internet to the rescue! A Lycos search turns out to be totally worthless not even being able to quickly locate the Aztech homepage. Did you know that there are 4 or 5 companies with Aztech in their name?

However, using Yahoo, an entry of "Aztech CDROM" results in the third or forth entry being a link to the Aztech Utility/Driver FTP Directory. Sure enough, there is an entry for my CDA268-01A, ATCD268.ZIP, Install Disk V1.35, 53,561 KB.

Download, unzip, pop into the PC's A drive and 5 minutes later I have a working CDROM. No runs, no drips, and no errors. I was tempted to install Win95 but I figured that wouldn't work really well on a 4 MB 386!

Comments: Despite what I had to say about the Aztech engineers, this drive seems to be a very clean design. There are virtually no discrete parts and no adjustments of any kind on the mainboard. The layout is fairly wide open on a double sided printed circuit board. There is also an LSI chip on the optical pickup itself - perhaps the focus/tracking servos and front-end decoding.

I expected this CDROM to either have a trivial problem like a bad connection or bad drawer switch or a fried custom irreplaceable chip. I would never have anticipated that a jelly bean 74LS00 would up and die. But that it is what it did as there is no evidence of any kind of trauma, spike, or spill. One assumes that 20 year old technology will be reliable. This is yet another example where the initial expectations and fears can be totally unfounded.

Repair Brief #53: Craftsman Electric Drill - Worn Motor Bearing

Patient: Garage sale electric drills. I picked up two of these (similar models) at different times).

Symptoms: Running the drill at anything near full speed results in a spine tingling squeal.

Testing: Putting a drop of oil in the rear bearing will quiet it down for a few minutes but this is not a long term cure.

This is a classic case of cost cutting (or how much the Marketing department controls the Company) resulting in early failure. Simple bronze bushings are used at both ends of the motor shaft. At the gear-box end, this is acceptable as this is enclosed and shielded against contaminants. However, at the handle end, all kinds of stuff can find its way into the motor and bearing. In particular, when using the drill with a sanding disk, fine powder easily infiltrates the motor absorbing lubrication. (Please, no comments about using the proper tool for the job. The fact of the matter is that electric drills do get used in this type of service.) The result is a dry bearing which rapidly wears if not attended to. It is hard to ignore as the result is a spine tingling squeal whenever the drill is running.

How to deal with it? I could probably have purchased a replacement bronze bushing from Sears Parts or used the good one from the other end of one of the drills to fix the other. However, what is really needed is a double sealed ball bearing instead. The seal is the important part though at the speed at which the motor runs, a ball bearing isn't a bad idea in any case.

I have upgraded a couple of these drills to ball bearings. The substitution is straightforward requiring disassembly of the drill - removing of the front gear reducer and then one side of the case. At this point, the old sleeve bearing is easily freed from its mounting (just the plastic of the case) and pulled from the shaft. The shaft is likely undamaged unless you attempted to continue running the drill even after going deaf.

The drills I upgraded had bearings that were 7/8" OD, 5/16" thick, and with a 5/16" ID center hole. The old ones were worn by almost 1/32" oversize for the center hole but the motor shaft was undamaged. I found suitable replacement double sealed ball bearings in my junk box but I would assume that they are fairly standard - possibly even available from Sears Parts as I bet they are used in the next model up.

If the gear reducer needs to come apart to access the motor, take note of any spacer washers or other small parts so you can get them back in exactly the correct locations. Work in a clean area to avoid contaminating the grease packing.

The bearing should be a press fit onto the shaft. Very light sanding of the shaft with 600 grit sandpaper may be needed - just enough so that the new bearing can be pressed on. Or, gently tap the center race with hammer (protected with a block of wood). Make sure that the bearing is snug when mounted so that the outer race cannot rotate - use layers of thin heat resistant plastic if needed to assure a tight fit (the old sleeve bearing was keyed but your new ball bearing probably won't have this feature).

These drills now run as smoothly as Sears much more expensive models. Of course, the chuck will probably fall off at any moment...

Comments: I had to do a similar upgrade to a cheap shop vac which had basically the same problem - the top bronze bushing had lost its lubrication resulting in accelerated wear and failure. Unfortunately, access to this was quite a bit more difficult requiring almost total disassembly of the motor/blower unit. These sorts of failures are common with inexpensive hand-vacs as well.

This isn't rocket science but a simple modification like this can significantly extend the life of a tool that would otherwise be discarded. Of course, if it were designed properly in the first place, such upgrades would not be needed.

Repair Brief #54: NEC CDR-260 Double Speed CDROM Drive - Intermittent

Patient: A friend of a coworker's CDROM Drive inherited from his company when it broke (of course). Got that?

Symptoms: The thing was sitting on the edge of Dave's desk when I showed up in the morning. All the pieces were there, some assembly required. I could not really get a coherent description of the problem - I thought it had something to do with the drawer opening... Sound familiar? (Recall Repair Brief #52: Aztech CDA-268-01A CDROM Drive - Drawer Continuously Closing).

Testing: I had to reassemble it first! Then I suggested I take it home since I really didn't have time to deal with it at work.

First, I give it a careful examination but find nothing. I then reassembled it to the point where power can be safely applied. I did not bother with the interface, just the power. For these occasions, I have an old switching supply conveniently mounted under my PC desk - and one that doesn't even require one of those quaint headlamp minimum loads! At first the drive appeared hesitant to spin the CD but then after a couple of minutes, seems to be fine - the 2X and Busy lights flash on momentarily as the disc spins at what I assume to be 2X speed. It seemed to behave all night as I would every so often push the Eject button to open and close the drawer.

At this point, I figured the problem had gone away or was solved or something. Suspecting bad connections at the flex cable connector, I disassembled the unit once again and cleaned and reseated these. I cleaned the lens as well while it was accessible Testing showed it to still be fine at least in so far as the basic reading of the disc identification was concerned.

Email to Dave: The CDROM seems to work, I will try it when I come in next.

Next time at the office, I installed the drive in a PC that we had been using for various CDROM and CDR projects which was conveniently in pieces.... It was running Win95, so I assumed that the CD would be found automatically. You know, Plug 'n Pray!

The drive has what I assumed to be an IDE interface - the missing pin was in the correct location. I finally found the info on jumper setting where one might actually expect to find it - on the label!

However, trying all reasonable combinations of jumpers (Slave, 8/16 bit) with the harddisk set for Master on a single IDE controller did not result in any recognition by the New Hardware Wizard. The first time I tried it - with no jumpers resulting in the CDROM being set for Master - I did see harddisk errors and the Busy light on the CDROM drive flashed as the harddisk was being accessed.

Then, I noticed that it did not seem to be initializing properly, again - the red and orange LEDs did not flash on when I inserted a disc. Hurrrumph.

"Hey Dave, well I thought it was fixed but now it is dead again."

Back home and with the top cover off, I watch as it is supposed to be spinning up. Now the disc will not turn at all! However, if I give the spindle help, it will seem to try for a little while but never get to the proper speed. Ah ha! Can we spell - are you ready: Spindle Motor?

Disassembling the drive further to access the bottom of the optical deck reveals a cheap brush type permanent magnet motor - essentially the same as those used on our favorite Pioneer CD players and changers. We know what a joy they are!

Testing with an ohmmeter results in readings between 12 ohms and 0 as the motor shaft is slowly rotated. This is one sick motor.

First, I tried spraying it with tuner and control cleaner through the ventilation/brush access holes in the rear. This did not seem to make any noticeable change.

I can use a power supply to attempt to clear the short. First, I unsoldered the red wire so that there is no chance of blowing any of the circuitry when external power is applied.

First, I got my genuine Heath variable power supply but this proved incapable of spinning it as the current limit kicked in at 700 mA. Into a dead short, this was not enough and the voltage stubbornly remained near zero.

So, I got my trusty "destructo-proof give it all you can take" variable power supply. Now we are in business!

Turning it up to about 10 V allows the motor to spin at high speed hopefully flinging the metal whiskers or other crud off of the commutator.

That did it! Now, the reading varies between about 15 and 20 ohms which seems much more reasonable. I resolder the red wire.

This will work now!

Sure enough, spinup is once again consistent. At least now, I am sure it will remain that way for a little while at least.

So what about trying it on a PC at home. Now, which PC to use.... Paul Grohe suggested the 'blue one' when I asked him if he knew of a proper software driver for the NEC. OK, where is the blue paint? :-)

After giving up on my version of Netscape trying to download a .EXE file, I finally used ftp to get NEC-IDE.EXE, a self extracting .ZIP file containing README.TXT and NEC_IDE.SYS which is a universal driver for NEC IDE CDROM drives under DOS/WIN31. (Win95 has these drivers built in but my newly painted 'blue' PC is only a 4 MB 33 MHz 386.)

After following the instructions on modifications to the CONFIG.SYS and AUTOEXEC.BAT files, I am ready. The jumpers are set for Slave and 8 bit.

Long pause.... "No drives found - initialization aborted". Boot completes

Grrrr, maybe it is 16 bit...

Long pause.... "No drives found - initialization aborted". Boot completes.

Double Grrrr, let me remove the Slave jumper, at least that will confirm if the drive is recognizing IDE commands as it should conflict with the harddisk and cause harddisk errors or cause the boot to hang with "HDD Controller Failure".

Long pause.... "No drives found - initialization aborted". Boot completes.

Wait, that messed things up when I tried it at work (before I figured out that the Slave jumper was needed at all). What else could be wrong....??

Maybe, power needs to be cycled to reset the drive.

Slave, 8 bit:

Long pause.... "No drives found - initialization aborted".

One more time - Slave, 16 bit:

Short pause, Busy light flashes, "One drive found....." Success! The drive is now accessible under DOS and Windows.

Semi-documented software is soooo much fun! :-)

Email to Dave: The drive works, same spindle motor problem as Pioneer changer. I cleared it for now but changing motor will be a slight pain....

I never did notice any problem with the drawer.

Comments: It somewhat amazes me that many CDROM drives still use the same cheap brush type permanent magnet motors as Pioneer and many other CD players. When driven at more than 1X speeds especially, these are prone to metal particle migration or metal whisker formation or whatever - more commonly known as crud buildup. Thus, the same problems that are so common with many brands of CD players are destined to appear on CDROM drives - and the same, at least temporary - cures are effective. The use of a brushless spindle motor - even common in some basic CD players - would totally eliminate the possibility of this failure mode. Even some cheap Walkmen tape players use brushless drive motors. Perhaps, these drives are *not supposed* to last that long by design, good excuse to upgrade.

55. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #55: RCA FPR560ER Color TV - Erratic Behavior

Patient: RCA FPR560ER (CTC130C chassis) 19 inch color television. This is a nice TV but it has been driving Bill up a wall.... (You will recall my friend Bill from Repair Briefs #35 and #47.)

Symptoms: The TV will power itself on/off and/or lose channel lock for random amounts of times at random times.

Testing: Whacking did not seem to have any definitive effect - but this TV is quite solidly constructed so it is not clear that the whacking reached the relevant components.

I got involved with this after Bill had initially attempted to repair the TV for what he thought was a simple case of a blown horizontal output transistor (HOT). He had replaced it with something from Radio Shack that they called an HOT. :-) The transistor ran extremely hot and lasted about an hour. Now we know why Radio Shack called it a HOT! (I don't even think Radio Shack lists higher power transistors in its current catalog - I wonder why!). Next, he replaced it with a TIP552 which has decent specs. An additional heat sink was added as well (although we know this should not be needed with a properly functioning deflection circuit). Nonetheless, this seems to be holding up.

However, Bill then noticed the onset of the erratic behavior and believed that the blown HOT somehow caused the set to start acting weird.

I suspected that the erratic power cycling caused the original HOT to fail. Thus, this was a symptom of another problem, not the cause.

The behavior took on a variety of forms. Among them were the following:

- Sometimes the screen would go black for a few seconds with or without the channel numbers incrementing at random and then come back as though nothing happened.
- Sometimes the TV would actually appear to click off for a few seconds or longer.

- Sometimes in the middle of the night the TV would just decide to turn itself on at full volume.

Needless to say, this is no way for a self respecting TV to act!

Bill and I decide to spend a little time on it. Bill drags out a rickety typewriter (you remember them, right?) table to put it on. Will this hold, I ask? "Sure. If it collapses, we won't need to repair it." OK, keeping my distance. It holds. However, the TV operates fine for the few minutes we have allocated.

Bill (who used to design switching power supplies) is attempting to come up with some explanation involving a problem with the power supply or control logic.

We, of course, know better. From early on, I was working on the hypothesis that bad connections were involved but where were they? No amount of wacking seemed to evoke a response. And, the TV never would perform on demand. We even dragged it over to my place and I would run it whenever I was around but it never screwed up - until s couple of weeks after it was lugged back to Bill's house. I kept telling him that it wasn't fixed. But, Bill is the kind of guy who figures if it doesn't screw up immediately, the problem probably went away. Yeh, right.

For about a year, he was using the TV on a switched outlet. He would shut it off totally when not in use and live with the erratic behavior when it was on. During the course of an evening, it probably would only misbehave once or twice.

At least the HOT seems to be surviving.....

Finally, it became too much and it was relegated a corner of the basement where it sat for another 6 months or so. Every so often he would mention the TV but I wasn't really that eager to deal with it.

Then, while on a cleanup crusade, "Sam, take this thing. If you cannot fix it, trash it. I will go get a 27 inch set on sale."

So, we lug it back to my work bench. Even though it is only a 19 inch set, it is quite heavy and somewhat bulky. Since the only way I can get it off my bench will be to fix it, I start the search....

Unlike some more modern sets that can best be described as a CRT with a wart (the main board), this has one circuit board for deflection and video, one for the tuner, another for the A/V inputs, power supply, etc.

Checking each in turn (I didn't start with the tuner hoping - more like wishful thinking - that the problem would be elsewhere since the tuner required more disassembly):

- Power supply - all soldering looks good.

- Deflection and video - removing this requires disconnecting some cables but once this is done, it comes out enough to examine in detail. Everything looks fine.

- A/V - this is unlikely to be the cause so I do not attempt to get to the underside which would be a pain.

- Tuner - to get at the bottom of the board requires unsoldering a metal cover at several points. My Weller soldering iron is not up to this but a 140 W soldering gun comes to the rescue.

  Almost immediately, some suspect pins come into view. However, they are not obviously bad. First, I try to measure for resistance changes as I flex the board and/or press on each pin. This turns out to be impossible as there is no convenient place to hang clip leads and my DMM's response is too slow anyhow. The only way to find out is to now prod each one with power on.

There are three main blocks of large pins. Viewed in the normal orientation, these are at the upper left, middle top, and upper right. Starting at the upper left results in immediate gratification: tapping lightly with my solder sucker causes the set to power on and off in a manner very similar to the original symptoms. There is definitely a hairline crack around at least one of these pins. Well, there is only one way of knowing for sure. I resolder all five of the pins on this connector. Now, it is rock solid. Hitting it with a (insulated) hammer has no effect.

I also solder all the other similar size connector pins on the board.
Now, to come up with suitable substitutes for half the cabinet screws which Bill lost....

Comments: While this is not the infamous CTC175/176/177 tuner solder problem, these older RCAs seem to have a less severe case of the same disease. I have seen others with cracked solder connections often in similar locations. Unfortunately, the only way to be sure of the repair is to let Bill start using it again. One can never be quite sure of a repair to an intermittent problem that happens so infrequently.

---

56. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #56: Toshiba M4200 VCR - Weak Intermittent Audio

Patient: Garage sale Toshiba M4200, $13. Owner mentioned audio problems suggesting that it needed a new audio head. I love it when the owner offers a diagnosis - they are almost invariably wrong.

Symptoms: Indeed, audio is somewhat weak but not as bad as I was led to believe. I expected nothing. When pressing START, the audio seems to fade in rather than coming on at correct volume every time.

Testing: Playing various tapes at multiple speeds exhibit similar symptoms to a greater or lesser extent.

First, I tried cleaning the tape path. This seemed to make a slight improvement but not much. Adjusting the azimuth setting on the A/C helped a bit more (but I found out later that it was the VCR on which the recordings were made that was misaligned.)

As a more extensive test, I let it record for a couple of hours. The beginning of this tape played back somewhat weak but was otherwise quite listenable. However, about halfway through, the audio dropped out totally over a span of a few seconds. After this, only silence.

As another test, I play a tape (Battle of the Bulge, if you care) and after about an hour and a half, the audio starts fading out to be replaced first by silence and then a sort of whine/buzz.

Interestingly, the video is rock solid and perfect under all conditions.

Could this be an electronic problem? Perhaps, the audio driver/preamp chip or its power supply is failing due to heat? We always tend to suspect the hard-to-locate or expensive problems first.

A careful examination of the tape path reveals the problem but at first not the cause: the tape is moving up on the A/C head so that the audio track is no longer aligned with the record/play head. The control track is wide enough that enough overlap is still present and there are no servo problems. I can only surmise that alignment is such that a combination of the audio and its guard band are in contact with the audio head. Very gently pressing on the edge of the tape restores full audio volume but eventually it wanders off again.

The tape movement is also not mirror smooth - it is rippling between the A/C head and right roller guide. However, no tape edge damage seems to result.

So, what is the cause?

At first, I thought that there was some actual mechanical alignment problem. It could not be with the roller guides as the video is perfect (this is a non-HiFi VCR so there is no issue of HiFi head alignment). Roller guide tilt, fixed guide post vertical height or alignment, even A/C head tilt, can affect this.

Careful experimentation with the adjustment of the A/C head doesn't result in any noticeable improvement.

Could one of the fixed guide posts have shifted? Not likely, they are screwed down tight and locked.

What about the capstan and pinch roller? I had cleaned them but could the capstan have shifted position changing it angle or something like that? Again, not likely - the 3 screws are secure and this VCR did not fall off of a 10 story building as far as I know.

This leaves the pinch roller.

The pinch roller seems to be in reasonable condition but not perfect. So, as a test, I will grind off the outer deteriorated (oxidized) layer which is hard and shiny instead of resilient, dull, and rubbery. Removing the pinch roller is very easy - just pull up on the plastic cap and the pinch roller is freed.

I used a #8, 2 inch machine screw and nut to mount it in my drill press. Then, a file and fine sandpaper were used to remove the outer somewhat hardened (oxidized) rubber layer. Care must be taken not to upset the perfectly flat cylindrical shape of the rubber surface.

This appears to result in a substantial improvement. The audio is still a little weak but much more consistent. It is now possible to play a long tape to completion without audio problems.

Although resurfacing the pinch roller is generally considered a temporary fix I have used the VCR this way (though only occasionally) for several years.

I recently obtained the correct replacement from Frank Fendley since he was able to identify the exact part number.

In addition to replacing the pinch roller, I had to construct a battery compartment cover for the remote control since this was missing. Can you believe it? I really expected more for $13! :-)

Comments: When I got this VCR, I wasn't as aware as I am now that old rubber parts - even if they look good - can result in these sorts of symptoms. Of course, we all know that erratic audio, random speed changes, and crinkled tapes edges can result from a hard worn pinch roller. Therefore, the usual cleaning, inspection, and replacement of dead rubber parts should be performed first before contemplating exotic mechanical or electronic problems.

Repair Brief #57: HP DeskJet Professional Printer, Part 3 - Print Fades Out

Patient: Garage sale HP DeskJet Professional ink-jet printer in pretty good physical condition. Original problem was described in [Repair Brief #49: HP DeskJet Professional Printer, Part 1 - Dead] and [Repair Brief #51: HP DeskJet Professional Printer, Part 2 - Missing Lines].

Symptoms: The printer will be happily going its merry way when within the space of one line of text, the ink will fade out across the page. After this, only blowing into the vent hole (with resultant possible mess) will result in any ink on the paper. This may occur after only a few lines or several pages.

Testing: A number of cartridges and text files were tried with similar results.

As you will recall, this printer was dead (and somewhat waterlogged) when I picked it up for $5 at a garage sale. Drying it out and soldering a few suspicious connections resulted in everything working except for 2 nozzles on the print head - #45 and #47. Well, 24/25ths of it works, what do you want for $5?? :-) This problem turned out to be bad connections to the cartridge due to the flex cable with the 56 contact points shifting position.

Just when I thought the printer was fully functional, what do you know? Halfway down a page of text, the type dies out over the course of a couple of lines. Now, keep in mind that I had been using the printer without incident since finding the bad connections in the print head.

My first thought was that something electronic was changing - perhaps a power supply or pulse width - resulting in too much to too little juice to the nozzle heaters. This would be a @#$% to find unless it were one of the power supply rails. Even then, a few seconds shift in level would be all that was needed to mess up the carefully orchestrated operation of the nozzles.

I went to far as to monitor the +20 V while printing without seeing anything out of the ordinary - just a few mV change in value depending on the load (number of firing nozzles/amount of black ink on the line). I removed the print head driver board and examined it for cold solder joint. There were of course none as is typical of HP's quality manufacturing. I wiggled anything I could think of but nothing correlated with the drop-outs.

(BTW, never stick anything into the vent hole. I found out the hard way that this may result in failure of the vent valve and ink all over the place since it depends on the cartridge being sealed above at normal operating pressure to keep the ink in place. I salvaged the cartridge (maybe) with a blob of silicone sealer over the vent hole. I do not really know what the long term implications of this might be.)

At this point, I even sent an email message to Paul Grohe asking if he had seen the symptoms described above since from his postings and email it is obvious that he is knowledgeable on the subject of DeskJet printer repair.

The problem in detecting this was that as noted, whatever was happening would only need to occur for a second or two to then require manual (by blowing into the vent hole) priming.

Come to think of it 1, why didn't normal priming work?

Come to think of it 2, did normal priming ever work?

Although it never quite registered until now, normal priming cycles never seemed to accomplish much of anything. I always had to blow to get anything to print if a cartridge had lost it 'charge'.

OK, so how does priming work? Very cleverly actually.

There is a kind of 'service station' where the print head is positioned for priming. When in position, a rubber cup seals against the face of the print head and connects with a drain tube below. In the base of the printer is a positive displacement roller and tube pump - a set of rollers (I assume they are rollers as I did not entirely disassemble the unit) rotates against a compliant plastic tube (like the blood pump in a heart-lung or dialysis machine if you have ever seen one of those). The direction of flow is determined by the direction of rotation of the rollers. This is controlled by the position of a spring loaded 'feeler' which enables one of three 'shift levers' to be lifted to engage the sucking pump (Maybe, one of them blows - I didn't entirely figure out what they all did). The position of the 'feeler' is determined by print head location which is under control of the print head servo system. Thus no additional electronics is needed. Slick.

The priming action, which operates off of the paper advance motor takes place between pages - when there is no paper being fed. With my printer and the drivers being used, it appeared as though it should prime between every page.

Was it working?

I removed the print mechanism and found a drive gear I could rotate by hand. With the number one shifter lifted, the pump should have been sucking. Was it? Using some of my Magic Spit(tm) in the drain tube, I could see it being pushed out of the tube - away from the print head. Darn, it is working. But then, when I let up, it appeared to get sucked back in. Huh? Maybe something was blocked.....

After removing the cartridge, I got a syringe with some water and loaded up the little cup so the water was even with the top.

Shift, rotate, rotate, rotate. Nothing! It should have sucked that water away in the first pass.

I got a toothpick and attempted to insert it into the bottom of the cup and locate the hole for the tube. At first, it would not go anywhere but eventually, I found the hole. Still nothing. I then rounded off the end of a resistor lead to use as a probe. With this, I was able to push it (gently!) down and into the semi-transparent tube so that I could see it. A little manipulation (sort of like root canal if you have been unfortunate enough to be familiar with that) cleared out the channel. Well, at least, any dentists reading this will know what I am talking about.

Finally, rotating the pump by hand resulted in obvious movement of the water (now mixed with ink). Enough rotation and I was able to clear the cup of liquid and dispose of it via the drain. Obviously, dried up caked on ink was blocking the hole and tube connected to the cup. Priming could not possibly have worked.

Now for the test.

I installed my original old cartridge which had never worked properly under any circumstances. And, what do you know?! I get quite a nice printout on the first try without doing any of the manual blow priming I had needed previously.

I sent another email to Paul Grohe starting something like:

"By now you are probably saying "what a moron". I cleaned out the priming tube which was totally blocked with dried ink. So far so good."

The next day I received a lengthy reply outlining some other problems of a similar nature that are common with DeskJets. These will be added to the FAQ.

So, the priming had not worked for as long as I have been mucking with this printer!

Now, hopefully, this is the last Repair Brief on this printer!

Comments: This is probably monotonous by now but once again, this was a simple mechanical problem. Not an expensive chip. Not a power supply. Not even a bad connection. Just dried up caked on ink. What is amazing is that it worked at all. Perhaps, the filled cartridge had enough pressure from the weight of the ink to not be as finicky but when it got used up somewhat began to cause problems.

Repair Brief #58: Magnavox FD2000-SL01 CD Player - Dead

Patient: Garage sale Magnavox FD2000-SL01 CD player. This is a classic top loader. It is as big and heavy as a typical full size VCR. I paid $2 but also got the service manual as part of the deal - slightly waterlogged but quite legible.

Symptoms: Power is alive - the front panel LEDs come on but discs are not recognized though they do spin.

Testing: Tried various CDs, whacking, cursing. Nothing changed.

First, a description of the FD2000-SL01:

While we have become used to CD players of all shapes and sizes with various levels of feature-mania, let us not forget their roots. The Magnavox Model FD2000-SL01 is probably one of the earliest consumer CD players. It is a design more reminiscent of a linear tracking servo locked turntable - which is probably one of its close ancestors. The engineer was probably told: "We need a consumer CD player - yesterday. You have designed linear tracking turntables. Make it operate like one of those."

The service manual (included in the $2 price) has a date of 1983. The manual was ordered in 1988 (I have the invoice for that as well).

The front panel buttons include the usual PLAY, STOP, PAUSE, >>, <<, and REPEAT. There are even STORE and CANCEL buttons. However, there is no time display, only two rows of 15 LEDs.

The top row LEDs are illuminated to show the complement of tracks on the disc while the bottom row LEDs indicate the current track that is playing and/or the next track to which it is seeking. The top row LEDs go dark to show which tracks have been played so this is similar to the traditional calander or linear displays of modern CD players - but in LEDs instead.

Pressing PLAY while playing serves as a track forward (>>|) button. There is no track reverse (|<<) seek.

As noted, it is a top loader, about as large and heavy as a full size VCR. The see-through double action lid permits one to watch the CD spinning - what a concept! The interior is pretty much packed with electronics - as opposed to any modern CD player or compact stereo you might encounter!

Internally, the FD2000-SL01 consists of the following modules:

- Optical deck with its own front-end circuit board. It uses a radial voice coil type actuator.
- Servo board (about 8 x 8 inches).
- Demodulator/audio board (about 8 x 8 inches) with the actual EFM decoder on a separate mezzanine card. These two boards are enclosed by perforated metal shields.

- Display/button board mounted behind front panel.

- Power supply board (about 4 x 6 inches) and power transformer.

The pickup uses the Philips rotary actuator technology - little different from modern Philips CD players or CD ROM drives except that it is much more solidly constructed with individual parts - the laser and photodiode array - designed to be field replaceable assemblies. However, while you would think this design results in rapid access, think again. As you will see below, this player has by far the slowest seek time I have ever encountered.

We now return you to the present:

With the bottom cover removed, the optical deck comes into view. Pressing PLAY does result in some action - the pickup bounces to the far end, then back to the home position - perhaps a couple of times - before giving up. During this time, one can hear some high pitched whining as the servos attempt to locate the disc directory.

After a few minutes of wiggling and prodding, I am successful at getting the disc directory to apparently be read - the number of LEDs corresponding to the number of tracks on the disc are illuminated. Expectantly, I connect the audio outputs of the player to my handy-dandy Heathkit compact stereo. However, the speakers remain disappointingly silent. :-(

At this point, the servo systems appear to be working - if a bit erratically. I assume there were/are some bad/dirty connections in the cabling or socketed chips. In fact, in the end, there is still at least one bad connection I have yet to locate.

Seeking to the next track reminds me of an inch-worm moving along: zeek, zeek, zeek, zeek, zeek,....., zeek (though inch-worms don't, I suppose, make these sorts of sounds). I assume what I am actually hearing (the 'zeeks') are the sounds of track ('track' here referring to the spiral groove or line of pits on the CD) crossings. If the positioner is moved by hand, you can hear the same track crossing sound - almost like dragging the stylus across an old LP - but much more closely spaced of course. With a practiced ear, it is even possible to count the tracks. Let's see... This CD has exactly 17,243, or was that 17,244? :-)

It takes about 20 seconds (and 40 to 50 zeeks) to seek from track 1 to the last track on a typical CD using a coarse-fine search strategy. So while the rotary actuator should result in a very short seek time, the designers had not taken advantage of their superior technology. Audible search (>>, <<, at least I think it should be audible), makes a more conventional dit, dit, dit, dit... sound.

Some careful tweaking of the focus and tracking adjustments shows that these are probably optimally set already. Since seeks work and the disc directory can apparently be read, it is likely that the optical components including the laserdiode and photodiode array are fine. As a double-check, I put my scope on the RF test point. The 'eye' pattern is stable and free of noise.

All power supply voltages check out.

To go further, I need to get to the top of the circuit boards. The cover comes off easily enough - the owner had been in there already and lost most of the screws. Grrrr. The only connection to the cover is the interlock switch which is easily bypassed. In order to get the CD to spin properly, I remove the clamper magnet from the lid and set it on top of the CD. The laser beam is safely blocked by the CD so there is no danger.

Getting to the demodulator/audio board requires removing the metal shield by prying it out with a screwdriver. The servo board is underneath this (the foil side is accessible from the bottom after its shield is removed but since the servo systems seem to be working for the moment, I should not need to get to it).

Since I have the schematics, I first go for the audio signals out of the left and right channel (separate) D/A converters - nothing.

Working backwards from the D/As indicates that there is no activity on the digital lines into the D/As. This confirms a digital problem in the readout or decoding logic. The audio circuitry is likely in good condition. Woopie!

There is a mezzanine card mounted in the lower right corner of the servo/logic board which does the EFM decoding. It includes some sort of controller, static memory, and some logic and I/O buffers. There is no activity on the outputs of this board - or on its local bus. In fact, although the clock is running, nothing else seems to show any signs of activity. The main chip is a CX7934. I have been unable to identify its internal functional block diagram or even a pin description. So, while all power and as best I can determine, all inputs are correct including the EFM input (buffered squared up eye pattern), audio muting, clocks, and power. I do not know for sure if this chip is dead but it sure appears that way. I believe it is also is running somewhat hot...

Thus, for now, I am shelving the unit. I may return to it in the future. In the meantime, the only sound produced by *this* CD player is the zeek, zeek, zeek of the rotary actuator.

Comments: This was an entertaining experience since many interesting signals are actually accessible with the level of integration used in this design. Modern CD players use 2 or 3 chips to do all of the processing with serial data running between them. Here, there are actual bits you can hold in your hand!

I would still like to get this machine operational. It is a wonderful example of early CD player design. I would be interested if anyone has one of these complete CD players or individual components that are likely to be functional sitting in an attic, basement, or junk pile. I am pretty sure I need the mezzanine card (possibly designated 30-892-C16) at the very least.

---

59. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #59: GE 13AC1504W Color TV - Dead (With Other Problems)

Patient: Garage sale 13" GE color TV. Sitting by itself on the lawn near end of sale. I think I paid about $5 for it - which was probably about $10 too much!

Symptoms: Initially, the TV appeared totally lifeless.

Testing: External whacking had no effect. However, some prodding of the mainboard would occasionally get it going. Once running, it might continue to work but with erratic messed up color and occasional vertical jitter.

This is one of those GE chassis affectionately described as 'bad solder connections held together by copper traces'. I, however, wasn't familiar with these at the time, so the troubleshooting took some time - make that lots of time!

Among the problems were:

- Erratic startup.
- Incorrect and washed out color.
- Jittery vertical deflection.
- Dirty tuner and controls (trivial in comparison with the others).

Since prodding had an effect, bad connections were indicated. But where? Careful examination of the soldering didn't reveal anything. Suspect joints that were touched up made no difference.

Most connectors seemed to be firmly seated and without detectable problems.

A couple of power transistors in the vertical deflection hanging out in midair (by design) were connected via 3 pin plugs. These seemed to have some weak contacts so I extracted each pin and bent the contact to increase the spring force. This helped some with the vertical jitter but the erratic startup and color problems remained.

Prodding also had an effect on the color problem but it was not possible to localize it.

Off to the library to copy the Sams' Photofact for the set. Silly me. I thought that would actually help!

It took me more time than I care to admit before realizing that this was a double sided circuit board and those stupid rivet things where not just test points or wire connections. I had not checked the top side wiring!

Now more about this disaster called a TV:

The wiring on the circuit board uses what are called 'rivlets' - poor man's through-holes or vias. For each connection through the circuit board or to a wire, a metal rivet is first set in the board and clinched. Then, the wave soldering machine is supposed to complete the electrical connection by soldering the rivlet to the circuit board traces. This has to be done on the top as well as the bottom but with solder from the bottom. The only problem is that the temperature probably wasn't high enough or not enough or improper flux was used. Initially, the connections were fine and the TV worked reliably for anywhere from a few milliseconds to several years.

However, repeated thermal cycles finally resulted in numerous intermittent connections.

Removing the mainboard requires unplugged 8 or 10 connectors. Fortunately, most were keyed and labeled so I got away (by accident) with not drawing a picture of how they were arranged. I had copied the Sams' Photofact schematic for the set but not the entire folder with the parts and connector placement. The mainboard may be removed without disconnecting the CRT anode as the flyback is mounted to the frame.

What I finally did to more-or-less fix the set was to use a soldering gun with fresh solder and flux to rework every rivlet I could find on both the top and bottom (basically going over it twice) of the board. In some cases, components had to be temporarily removed as some rivlets lurked underneath.

This did cure all three of the major problems.....

Until I buttoned it up. A couple days later, the picture faded to black over a period of 15 seconds - and then came back over the same amount of time. Oops, forgot to rework the CRT driver board. Sure enough, I found an obvious bad connection to the CRT filament - this one I could actually touch.

A couple of years later, the convergence deteriorated suddenly. You guessed it. I hadn't reworked the little convergence board.

A while later, the poor color problem returned intermittently. On initial power-on, the color would be fine but would then drop out and shift toward blue/green. It was sometimes possible to obtain correct color by turning the COLOR control all the way up and the TINT control to one end.

I finally bit the bullet and resoldered the entire mainboard yet again.

Now it is working again (crossed fingers). Anyone need a great TV?

Comments: The 'proper' way to reliably repair this chassis would probably be to remove all the solder from each rivlet, scrape the solder mask from the traces in the vicinity, and add bare wires through the rivet hole and to the traces to complete the through-hole connection. Then, fresh solder and flux with a hot iron. One could spend their waking life on one such set! There are probably only a half dozen actual rivlets that are the problem children. However, there is often no visible evidence of the bad connections. Even with the schematic, locating them based on would be difficult and there would be no way of knowing where the next one would crop up.

---

60. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #60: Canon FaxPhone 80 - More or Less Dead

Patient: Garage sale Canon FaxPhone 80 really big and old fax machine. Hey, it was only $2. (They gave away the supposedly dead microwave oven free - I still am not quite sure if there is anything wrong with it other than the missing temperature probe. Maybe the Fax was dead and they should have charged $2 for the Microwave!)

Symptoms: Buttons and LCD display do seem to work but there is no paper movement, it keeps insisting on paper problems 'Check Paper' when attempting to copy. It was also flashing 'Load Ink Sheet'.

Testing: I only have about 2 feet of the semi-special paper this machine uses. It is a thermal wax transfer type print mechanism with a full width ribbon. I try copy mode but there is no action. Even paper advance complains (once I located the correct button with no manual and those 'universal' icons).

You might call this a plain paper fax - but one using a special ribbon, a wax transfer type. The ribbon seems to be mostly used. The 'Load Ink Sheet' message was caused by the marking on the last few feet sensed by an LED/photodiode sensor. Hopefully, there is enough left to at least test the machine while troubleshooting. Better yet, I just rewind it a few feet. So what If I get the previous owner's faxes in negative (like a used carbon ribbon from a typewriter or impact printer) superimposed on my test! Actually this could be interesting. :-) I don't even know if one can buy this type of ribbon anymore.

The paper seems ordinary - perhaps a roll of shelf paper would work just as well as the kind Canon no doubt sold for this unit.

In all fairness, it does seem to want to cooperate - just that the paper is not moving. So, what operates the paper advance (and the cutter, for that matter - it makes a horrible grinding noise and seems sick as well - there is likely a common problem).

In order to access the electronics, I need to remove the cover. This turns out to be relatively straightforward - 2 screws in the front and 2 on top. The phone itself unplugs but is not needed anyhow as the keypad remains with the main chassis.

Now, I can see the gears. My first observation is that one gear is just twitching when the paper should presumably be doing something. Sound familiar? Try Repair Brief #1: Daisy Wheel Printer - Carriage Gets Stuck.

It seems that getting to the electronics takes a little more work - two more screws in front and removing the rear panel. Then, the entire mechanical assembly swings up enough to get at... the driver board for the paper advance motor. It is a small separate board, easily detached from the frame. Very convenient.

Of course, pressing paper advance with the machine in this state results in the paper actually advancing - what a concept!

Prod, prod, flex, flex. Oops, there it goes into spaz mode again. So, how about those bad connections? I reseat the connectors - no change. A visual inspection of the back of the board shows a number of solder pads that may be suspect but no smoking gun. Running my finger over individual pins has no effect other than to draw blood. However, flexing the heatsink/board combination does seem to make the problem come and go. Well, there is only one way to find out.

About 10 minutes and a hundred or so solder connections later (just to be sure, did nearly every one), the paper advance function is now stable. Flexing and prodding the board has no effect. Hurrah!

OK, so do I have a working fax? With my precious 2 feet of paper, I set out to copy a page - seems like some old assembly language program. Well, as they say, a page is a page is a page.

Sure enough, copy mode seems to work and the quality isn't half bad.

Will it work with a phone line. Simplest is to transmit a fax to my PC but that would involve disconnecting from the Net! No way.

I send a one page fax to work - "To sam - Fax Test #1". I am in no hurry.

Next time at the office, sure enough, the fax was sitting in my (physical) mailbox.

This fax will prove convenient for sending though I will have to find a not exorbitantly priced source for the roll paper. For now, I rewound the ribbon about halfway to provide more than enough for any of my needs. Let's, wasn't that a wedding invitation that just went by? :-)

Comments: The motor driver circuit board does not appear to plated vias (I cannot even recall now if it is double sided). In any case, there was clearly inadequate support for the leads of the larger component - just a thin film of solder. The holes were grossly oversized and with no plating, did not provide adequate mechanical support for even slight thermal expansion and contraction cycles. As soon as touched with a hot iron, the solder pulled away from most of the pin - I had to add a fair amount of fresh solder to produce a decent bond.

---

61. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #61: Sony D14 Portable Compact Disc Player - Smoked

Patient: Player given to me to look at. I was told that it didn't work and smelled really bad...

Symptoms: Even unpowered, it did smell really bad. :-) I had to borrow a Sony AC adapter to test it. The unit was totally dead. Applying power didn't help the aroma either.

Testing: Using the proper Sony 9V adapter results in no action, not even the display does anything other than all segments being black.

So Sharon (not her real name), our purchasing person (before being laid off), hands me this Sony portable CD player. "A friend of mine, Larry, would like to know if there is any hope". Sharon appeared kind of embarrassed to ask me to deal with this dead fish. :-)

Even with the cover closed, it is obvious that something unfortunate happened. I don't believe I was actually told that an improper power adapter was used but this would become obvious pretty quickly. The sorts of catastrophic failures I found do not generally occur spontaneously.

This is one of the early Sony portables - solid metal construction. The bottom comes off easily revealing a scorched surface mount part. Hmmm, maybe this won't be so bad after all. Wishful thinking. A little tracing reveals that the crater where the part used to live is basically across the 9 V DC input. Protection diode. I scrape its remains off of the board clean with alcohol, and replace with a 1N4007.

No change - surprise, surprise.

Furthermore, it still smells really bad.... It might even be a little worse.

So, how do manufacturers of portable devices protect against accidents or stupidity?

There is often some kind of protection in the form of one or more of the following:

1. Diode across the power input with reverse polarity so that it normally does not conduct. It will short circuit a reverse polarity supply and hopefully fail shorted with excess reverse current.

2. Diode in series with power, again for reverse polarity protection. It will simply not conduct if the polarity is wrong.

3. Maybe a fuse or two in disguise. There are things called "IC protectors" which look like little black transistors but with only two legs. Hard to identify on surface mount, though.

4. Overvoltage crowbar - zener triggering an SCR at substantially higher than normal input voltage. This shorts across the supply and (hopefully) blows an internal fuse if the resulting current is excessive before the SCR and circuit traces vaporize.

In this case, only (1) was present - at least I could not locate any fuses, fusable resistors, or IC protectors.

What next? I still need to locate the source of that really bad smell.

Nothing else on the readily accessible solder side of the mainboard seems to be in distress. Unfortunately, getting to the top side components requires unsoldering a bunch of skinny wires (labeling them) and a flat printed cable (the focus and tracking drive, which I managed to eventually rip from repeated assembly and disassembly).

This done, I still don't see anything smelly on the top of the board. Then, I notice *the box*. It is a sealed metal enclosure about 1" x 1/2" by 2" housing the DC-DC converter which powers most of the player's circuitry. Although, there is no visible charring (how can metal char?), this is the only possibility. Fortunately, only 4 or 5 pins anchor this module to the circuit board. Once removed, it is obviously the source of the aroma. Yum!

I use an Xacto knife and soldering iron to remove the cover - soldered along the edge. Then the damage becomes clear: the largest transistor is totally melted, split in two, and unidentifiable. Traces on the little circuit board are also destroyed. The insulating cardboard *is* nearly charred. However, other small transistors and discrete components appear to test fine using my multimeter.

I try a generic NPN power transistor - no output from the DC-DC converter. It appears not to be enabled as the on-off switch is a logic level going to the main microcontroller which appeared to be dead. I even tried to substitute external power supplies for the voltages provided by the DC-DC converter. Again, no change.

Tracing the input power connections show that they go directly to a large multilegged chip. Generally, reversing power on integrated circuits is not a good thing to do as they rarely survive.

Obviously, something more powerful than a typical AC adapter had been used Usually, such damage is the result of something like attempting to use an auto cigarette lighter adapter to power the device.

Nothing I have received so far in my quest for dead optical pickups, portable CD players, CDROM or optical drives, has been in anywhere near the sad state of this poor Sony. :-(

I sent Sharon email:

> "Larry probably tried to power this thing from his cigarette lighter, huh?
>
> It would probably have survived for a while on the 12 to 15 V of the auto battery instead of 9 V from the adapter. But, he probably got the polarity reversed. With the virtually unlimited current capacity of an auto battery, the microcontroller was toast before it knew what hit it. Any fuse would have been too slow to prevent terminal damage even if the circuit traces didn't vaporize first.
>
> If Larry wants it back, no problem. It still looks like a CD player. If he takes it in for repair, the technician (while holding their nose) will even probably agree that it was a CD player at one time."

Actually, with the blown up parts removed and the circuit boards cleaned with alcohol, the odor has mostly disappeared. I still have it as a reminder that AC adapter connections and ratings are not the same as data cables which can often be reversed without damage. But not always - like those 44 pin min-IDE connectors used on laptop harddrives - they smoke really expensive parts if plugged in backwards because power is also on the connector at one end. :-(

Sharon forwarded my email to Larry who confirmed my suspicion. He was attempting to use the player in his car.

I did remove the optical pickup and tested it. The laserdiode, focus and tracking coils, and motors were fine (I have not tested the photodiode array but expect it to be undamaged as well).

The DC-DC converter isolated most of the circuitry from damage. Unfortunately, at least that one large IC, presumably the main system controller, ran on the wall adapter DC voltage directly and appeared to be toast.

I also have a bag of smoked digital clocks, a smoked clock radio, and a smoked cordless phone (which I have since repaired) from Larry (now Sharon's former friend)..... I will discuss those in a future Repair Brief. Stay tuned for: "Clocks, Clock Radio, and Cordless Phone - Smoked." Till then, you can attempt to guess what happened. :-)

Comments: those voltage, current, and polarity ratings marked on portable equipment are there for a reason. The voltage rating should not be exceeded. Using a slightly lower voltage adapter will probably cause no harm though performance may suffer. The current rating of the adapter should be at least equal to the printed rating. The polarity, of course, must be correct. If connected backwards with a current limited adapter, there may be no immediate damage depending on the design of the protective circuits. But don't take chances - double check that the polarities match - with a voltmeter if necessary - before you plug it in! Note that even some identically marked adapters put out widely different open circuit voltages. If the unloaded voltage reading is more than 25-30% higher than the marked value, I would be cautious about using the adapter without confirmation that it is acceptable for your equipment. Needless to say, if you experience any strange or unexpected behavior with a new adapter, if any part gets unusually warm, or if there is any unusual odor, unplug it immediately and attempt to identify the cause of the problem.

Some devices are designed in such a way that they will survive almost anything. A series diode would protect against reverse polarity. Alternatively, a large parallel diode with upstream current limiting resistor or PTC thermistor, and fuses, fusable resistors, or IC protectors would cut off current before the parallel diode or circuit board traces have time to vaporize. A crowbar circuit (zener to trigger an SCR) could be used to protect against reasonable overvoltage.

Not this one, unfortunately. All the smoke has been released....

Repair Brief #62: Zenith System 3 Color TV - Intermittent Blue Fog

Patient: Trash-picked 25" Zenith System 3 Model SC2569W in pretty good physical condition.

Symptoms: Occasionally, mostly during the first few minutes but possible other times as well, picture is replaced will solid blue screen with retrace lines.

Testing: Running the set resulted in occasional blue flashes. Tapping the cabinet did not have any effect.

My cousin (the one with the 3 kids, 2 dogs, and 13 goldfish), was walking the LARGE poodle when she came across this TV sitting on the curb. The owner was about (or perhaps she knocked - that wouldn't be out of character - so the symptoms were available. "Screen occasionally turns all blue".

Upon my return from garage sale-ing, I get this call. "Are you interested in a Zenith TV"? How big? "Big". OK, I will check it out. My usual rules are that (1) I don't tend to bother with consoles, (2) TVs with knob tuners unless they fall into my lap, (3) those that are excessively abused, or (4) those that are really old but not old enough for antique status.

This one turned out to fit the requirements - a table model only slightly larger than the CRT. No remote - darn. Have to send her back for that! Fortunately, I have a half broken remote from one of Bill's dead TVs (you know, the one that had a totally white picture that I may talk about in a future Repair Brief, then again, maybe not, it isn't pretty) It is (was) a Zenith A-line chassis TV but fortunately the remote seems to work. Of course, Bill lost the battery compartment cover - typical. :-(

Getting it home wasn't too bad - only half a block away, fit the back seat of my car.

At first, the supposed symptoms didn't show up. Great! Maybe the ride home has cured it!

Then, after screwing around with a broken CD player for a while, came back and turned it on - and - what do you know? Picture came up all blue and flashed to normal.

Removing the cover is easier than some - 8 screws, back slides off and set is fairly stable though I wouldn't want to sit on it.

Now, of course, no amount of tapping or prodding can make the picture turn blue. Turn it off and wait.

A few minutes later, powering on results in a few flashes of blue - and - more importantly, tapping on the CRT neck seems to affect it. Prodding the CRT driver (neck) board or anywhere else has no effect.

The detailed symptoms appear to be:

1. Blue gun turns full on but with Red and Green still visible under the fog.
2. A second or so later, red and green disappear and only blue remains.
3. Tapping or waiting results in screen flashing to black (presumably as some capacitors charge or something)

and then normal picture appears.

This is almost certainly a heater-cathode (H-K) short in the picture tube. Since it is intermittent, I cannot simply measure the resistance but must check it while running.

I fabricate a temporary isolated filament (heater) winding by wrapping 3 turns of insulated bell wire around the flyback core. Carefully, I unsolder the picture tube filament connections to the CRT driver board and jumper the temporary winding to this. My multimeter is connected between the filament and signal ground.

Now, applying power should result in the blue gun video drive voltage appearing on the filament when the short occurs.

Sure enough, after a few on-off cycles with no problems, the meter jumps to a reading greater than 100 V. With the heater isolated, no apparent change takes place to the picture.

To do a permanent repair, I first determine that 3 turns is satisfactory: Reducing it to 2 turns results in a dull orange glow from the filaments and slightly fuzzy slightly dim picture. 3 turns was correct - the glow is bright orange. (I could also have compared it with the original.)

I locate a couple of feet of well insulated wire and make a more permanent winding, routing the wires well away from the high voltage connector and any hot components. I carefully cut the traces on the CRT driver board right at the filament socket - maintaining the spark gaps to a couple of other socket pins. Then, the new winding is soldered directly to the filament pins.

I could also have probably reused the winding on the flyback and just isolated it from the ground on the CRT driver board but this would result in more stress on the flyback - probably irrelevant but the homemade winding was easy enough.

While the set is open, I adjust the position of the CRT as well - for whatever reason, perhaps since new, it is tilted and off center on the bezel. If I hadn't removed so much dust, I would have suspected it to be a replacement CRT but probably not.

I call my cousin: Do you want the TV? It is fixed. "No kidding, how?". So I told her: There was a short in the picture tube but I rewired the set. "It won't blow up or anything?" Nope, just not something every TV repair shop would do. "Sure, I can give the one in the living room (Repair Brief #12: Sylvania TV with no Horizontal Sync) to the nanny and this one will be fine for use with the VCR (Repair Brief #21 - Sharp VC7864U VCR Erratic). The kids will like a bigger screen." This is also convenient as there is already a universal remote at that location being used with the VCR which will be fine with this set.

Comments: The owner probably called a TV repair shop (or perhaps lugged it in) and was told that with these symptoms the CRT was shot and fixing it would not be worth the time and money. However, there is really nothing wrong with the isolated filament. In fact, the stress on the red and green guns is actually less as the difference in voltages between the cathodes and heaters is on the average smaller and the maximum voltage difference is less as well. As long as an H-K short does not occur with the red or green, there should be no problem.

---

63. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #63: Sony Boombox CD Player - Erratic Shutoff

Patient: Ralph's Sony boombox AM/FM/CD/Cassette.

Symptoms: CD player erratic - sometimes won't recognize discs, sometimes shuts off and resets in the middle of a disc.

Testing: Tried multiple discs (classic to rock) just to make sure it isn't just a matter of the player not liking Ralph's tastes in music (which most other humans don't like either.

Ralph was our 'Nedrie' type (from the movie 'Jurassic Park'). Visualize a Sun workstation with Coke stains all over the keyboard, empty Coke cans and half eaten week old pizza, manuals and other stuff cluttering his desk and the immediate area. He is, however, an excellent software engineer which is why all this is tolerated.

Anyhow, Ralph treats his boombox about like the two vicious dogs he keeps locked in his basement at home - firmly. :-) Perhaps, I will discuss the ruggedness of old Realistic portable CD players at some point in the future. One of his (previous) dogs thought it was a bone. The CD player looked pretty beaten but continued to run. I don't know about the dog.

He used to have a pet iguana as well.

Anyhow, Ralph keeps a typical small Sony boombox in his office (2 doors from mine). Thankfully, the volume is turned down and/or he uses headphones. Otherwise, I *would* be very creative about seeing to it that the CD never worked quite right. Oh, your CD is acting up - again? That is really a shame.... ;-)

I had taken a look at this boombox once before, even partially disassembling it, but then the problem went away. This time, the top is squashed in about 1/2 inch due to Ralph's constant beating in an effort to get it to cooperate.

The main problem is gaining access to anything. In order to remove the CD player assembly, one must remove the front cover (six recessed screws - at least the locations are more-or-less marked), LCD display/LED/button card, cassette deck, power supply, and part of the audio/radio section. The CD player including the optical deck and electronics board can then be extracted but actually running it in this condition is difficult or impossible. However, I did manage to set everything carefully propped up and run the player sitting on the table. It, of course, ran fine all day in this configuration. Well, maybe Ralph would not notice the additional disarray......

At first, I thought the erratic problem was due to marginal power as the display LEDs fluctuated slightly in brightness while the CD was seeking. However, the line transformer is built into the boombox rather than being an external adapter so at least there is no way to use an improper adapter. Testing voltages internally seemed to indicate that power was fine.

Next, I removed the CD player completely and went over the solder side of the electronics board carefully looking for bad solder connections. On one connector, there was a suspect joint or two which I repaired. These were probably the source of the erratic shutoff problem. I also tested the interlock switch for intermittents - it was fine. I then ran it for another few hours without incident which, of course, proved little.

Reassembly required another 15 minutes or so but was straightforward. The interior is relatively open so cable routing, at least, was not a problem. I installed only two cabinet screws and left the cassette deck in my desk drawer for a few weeks so access would be easier should the problems return.

Ralph never noticed.

It has been a couple of years now and I have not heard of any complaints. One time I thought there was a problem when I went into his office and attempted to play a CD but it must have been a bad CD because he has seemed happy (at least with respect to the boombox). Ralph has recently left for greener pastures though I am sure I will hear from him if the CD fails again!

Comments: One wonders why product engineers cannot take a few more minutes to design an enclosure that is easily serviceable. I suppose the quick answer is that these are deliberately designed to be throwaway products in any case. There is no way that anyone can justify the cost in time to gain access to fix a miserable cold solder joint. The whole thing probably cost $100 retail. Of course, one wonders further why cold solder joints are still so common even on ordinary (not large pins) components. Then again, Sony's manufacturing engineers haven't met Ralph!

Now I see that an AM/FM/cassette/CD boombox is on sale for $60. I wonder what kind of construction it uses....

---

64. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #64: Book Tape Player - Missing Channels 3 and 4

Patient: This is one of those portable tape players often used by the severely visually impaired to listen to 'books-on-tape'. It has oversize buttons with tactile function impressions, a wide range speed control, and the ability to play any of the 4 channels on a standard cassette.

Symptoms: I was told that the player would not finish the tape. In fact, what was happening was that it would not play channels 3 and 4 resulting in a high noise level but no proper audio.

Testing: I tried the tape provided as well as a regular stereo audio cassette. Only 2 of the 4 channels worked properly.

This 'customer' has provided me with quite a lot of 'business' in the past (keep in mind, I don't charge for anything beyond parts in these cases). Mostly, previous problems were due to unintentional abuse. These have included bad solder connections on a classic as well as more modern Radio Shack multiband radio and a sprung reel clutch on a cheap boombox.

This tape player is a nice well designed unit with large rugged controls. There is no sign of external damage but that may not mean much.

Since I at first thought that this was a case of the tape not finishing rather than not playing properly, I first checked for takeup reel and capstan motion and torque. Both were fine and thus I rather doubted that it simply stopped playing a tape. Then I tried the tape channel selector.

Recall that a standard stereo cassette has 4 channels of audio - L+R forward and L+R in reverse. Book tapes use all 4 channels individually. A switch selects between the L (1 or 2) and R (3 or 4) channel is being played. (OK, it might be the other way around.) Flipping the tape over selects 1,3, or 2,4.

Anyhow, after a little testing, it was obvious that channels 1 and 2 were loud and clear but 3 and 4 resulted in some background noise - greater than the tape hiss of channels 1 and 2 but not hum or oscillation.

What could it be?

Keeping in mind that there is only one channel of amplification in this unit and the switching is done mechanically, not much.

One might suspect the electronics - but this is probably impossible as the same electronics is used for both channels.

One might suspect the tape head - easy to check.

One might suspect the wiring - quite likely given a well used possibly abuse tape deck.

To test for output from each tape head channel, all that is needed is a small pointed tool like an awl or jeweler's screwdriver. Touching each of the 4 terminals on the tape head should result in hum or buzz on at least one of them - depending on the channel selector setting. (This also works for normal stereo cassettes - you should get a hum or buzz out of the appropriate channel when its tape head terminal is touched.)

I didn't even need to go that far as the cause came immediately into view once I was able to access the tape head terminals.

The designers of this tape player did a good job. Unlike many similar devices, there is a pop out plastic piece which covers the tape head - presumably to allow access to the azimuth adjustment screw. As soon as this was removed, the broken wire came into view. Since the entire tape head assembly moves, some slight flexing must take place at the point of soldering. It should not be much as the cable is clamped to the moving part but there may still be some flexing so over time, the wire simply broke off.

Someone searching for an electronic fault would have had the guts of this thing strewn all over the workbench and shop floor before finding the true cause! It was tight, but just barely possible to strip and solder the wire back in place. I probably should have put a drop of semi-flexible sealer over the connection to stabilize it but did not. Well, in another 10 years I will know what to do!

Comments: This is not one of those 'cast of thousands' repairs. Nonetheless, for those who depend on talking books for their education and Pleasure, a working tape player may be more important than a high tech entertainment system.

---

65. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #65: Aiwa CSD-707 Boombox CD Player - Doesn't Recognize CDs

Patient: Aiwa 'Compact Disc Stereo Radio Cassette Recorder CSD-707'. Wow, what a mouthful! Don't the designers of these things give people credit for at least minimal powers of observation? It's a boobbox, for goodness sake. Geez!

Symptoms: Everything works fine except for the CD player. Insert a CD and close the door. The disc starts spinning clockwise (correct), then changes its mind, reverses direction, and goes into warp drive in the incorrect (counterclockwise) direction. Eventually, it shuts down with a 0:00:00 display.

Testing: Multiple discs behave in a basically similar way. None succeed in reading the TOC.

Jeff brought this beauty to work. "Sam, I have something to keep you busy". Not the printer...? (The previous week, he showed me this Apple LaserWriter NT that was making a horrendous noise. Since I concluded it was from the fan in the power supply underneath, I really did not want to deal with it. It would require half the day just to get at it Apparently, the printer was behaving - Jeff now only turned it on when needed. "No, my dad's boombox."

This boombox appears to be in excellent physical condition (unlike the one described in Repair Brief #63: Sony Boombox CD Player - Erratic Operation which was slightly crunched. Indications are that it just stopped playing CDs without an provocation. No scratches or dents.

Well, since it is not even possible to view the lens without some disassembly, I warm up my screwdrivers...

It requires removal of 8 long screws to separate the front portion with the all the CD player components, speakers, and cassette door (yes, just the door) and the rear half with the rest of the electronics. Four cables link these two sections: speakers, CD power, CD control, CD display/button panel. Four more screws and it is possible to separate the optical deck from the CD electronics board. It is just possible to arrange everything such that the unit can be run with access to solder side of the CD electronics board. This is definitely much easier than that Sony boombox which required removal of almost everything to gain access to the CD player.

With the system disassembled, it is possible to observe the following as it attempts to read the TOC of a disc:

- Sled moves about 1/4 of the distance along the track and then resets to the inner stop. Sled motor stops. This indicates that the limit switch is working.

- Disc starts spinning clockwise, hesitates, then reverses direction. Sled motor spins attempting to move the pickup *past* the inner stop. This continues until shutdown takes place. The limit switch is being ignored.

- It is possible to hear the 'gritty' focus/tracking noise which indicates that the optical pickup is at least partially working - focus must be nearly correct. Tracking may be messed up. Only a scope will determine this.

With such behavior, my first reaction is that something must be really really screwed up since the disc spins at warp speed in the wrong direction and the sled isn't bothering to recognize the inner limit switch when it gets into this state. However, I have come to realize that small problems can result in bizarre behavior from CD players!

So, first I clean the lens -- no change.

Next, I disconnect the optical deck from its intermediate circuit board and go over all the solder connection on it -- no change.

OK, bring in the heaving equipment - I drag a scope into my office.

There are marked test points including RF, TE, FE.

The RF test point is - well - strange. When power is applied, it jumps, then momentarily is of high amplitude but then decays to a much lower amplitude signal with somewhat random characteristics. In fact, I cannot make any sense of it.

At this point, I decide that other tasks are of more immediate concern (like lunch) and will button it up and take it home to work on at my leisure. I tell Jeff. "So what are you going to do." Oh, probably stare at it some more, a little cursing, then give up. Jeff knows better but just laughs.

Next day, I start by disassembling it once again (of course, I had only installed 2 of the 8 cabinet screws) but going further this time:

- Remove the front panel as well (in hindsight, this wasn't needed).

- The clamper disk with the magnet so that I can have access to the disc itself.

- Stuff a wad of paper into the interlock to keep the switch closed.

- Solder wires to the RF test point and a convenient ground for my scope.

Now I can work without having to juggle the front panel, electronics board, optical deck, and scope probe all at once.

The connections to the optical deck look to be the same as for some of the optical pickups I have been accumulating but no cigar - nothing that I would risk swapping until I get desperate. I could easily blow the laserdiode or electronics if they are not quite the same and I don't even know for sure that those other pickups work. After all, they were guaranteed to be dead. :-) I will postpone that decision.

Confirming that nothing has changed - nothing has. The RF test point which should have the eye pattern is still strange. With easy access to the disc to stop it from spinning by hand, the 'gritty' sound is unmistakable - the focus servo, at least, appears healthy.

My test disc is one of those zillions of AOL free 15 hours CDs. While I don't expect to be able to listen to the data, most CD players will recognize the TOC of a CDROM - though the resulting display will be meaningless. Thus, I don't need to worry about damage to the disc - there are a semi-infinite supply of these! Of course, should I succeed reading the TOC, I will need to use a music CD for audio tests and adjustments.

OK, well, Mr. AOL CD behaves the same as the others.....

Now, do I dare tweak anything? There are three readily accessible adjustments: Laser Power, Focus Offset, Tracking Offset. (There is also a Tracking Gain pot which I noticed later. However, the gain controls are usually of secondary importance so I never do bother touching it.)

I generally do not touch laser power adjustments until I am sure there are no other options.

What about focus or tracking?

This smells like a tracking problem. However, the fact that the eye pattern's amplitude doesn't remain fairly constant suggests that there may be some sort of focus problems. Toss a coin.

Normally, this is the point at which I would insist anyone doing any adjustments mark the positions of all controls. Yep, you guessed it, I violate rule #1. What the heck...

Starting with T.OFS, just a hair in each direction - and what a change!! The RF signal remains at high amplitude for much longer AND the disc now tries to spin clockwise for a much longer period of time. My goals now are twofold: (1) to get the disc to spin in the correct direction at roughly the correct speed of 500 rpm and (2) to maximize the amplitude/length of time that the RF test point signal remains at high amplitude.

Then I realize something else that is in the FAQ: I really should use a non-metallic screwdriver as the slot seems to be electrically connected to high impedance circuitry and the behavior is changing when I touch it with my cheapo jeweler's screwdriver. A quick remedy which seems to be adequate is to wrap electrical tape around the handle.

A few minutes of going back and forth between F.OFS and T.OFS finally - I see the display change to what is obviously it pathetic attempt to interpret the time/tracks of the AOL CD. Of course, not thinking, I press PLAY and am greeted with a loud hum/buzz - the 80X86 object code of the AOL SETUP program or something. Hit STOP.

OK, so how about a proper music disc.

I have an 'I don't really care much about this disc' disc for just this purpose. One of those 'Intro to the ballet' or something. You know, it sounds like the Salvation Army orchestra on a bad day. But serves my purposes....

Although the TOC is read with a bit of hesitation, the player seems unable to locate track one. OK, so the current settings may not be entirely satisfactory.

A little more tweaking. Still just some whining and clicking sounds once I hit PLAY. Well, maybe it will like an outer track better. (I have no idea why it had no problem starting to 'play' the AOL disc.)

This seems to do it. It is finally successful at locating track 5 or 6 and starts playing - a bit scratchy. Now that it is stable, I can carefully adjust both F.OFS and T.OFS for maximum amplitude of the eye pattern. After a couple of false starts where it got confused and shut down, I have both set optimally and the player now seems to work normally.

I also note that touching the metal frame seems to cause some static but I assume this is due to the poor ground through the cable - normally the electronics board is screwed directly to the frame of the optical deck.

I finally did risk tweaking the laser power to obtain a 1 V p-p eye pattern at the RF test point. Without service information to know what the proper setting is, this can be risky (even a dirty pot could conceivably blow the diode). I just adjusted it up from about .9 V to 1 V p-p. It was clear from the response to my screwdriver - I could have increased it much further, probably to the point of burning it out - that the laserdiode was not weak. If the laser was dying, the power would have topped out about where it had been set as the feedback would be doing all that it could to maintain constant power.

After fine tuning the focus and tracking adjustments yet again, the behavior seems relatively normal. I rather suspect that there may still be some kind of problem as the tracking adjustment did not have as distinct a peak as I would expect, but who knows?

I will have to embellish the repair description for Jeff. I cannot just tell him I adjusted something. Maybe: "Well, I transplanted the laserdiode from an extra 25X CDROM drive - I figured you would consider the boombox more important than such antiquated technology" or something juicy like that. :-)

Comments: Would Aiwa Service have replaced the optical pickup? Perhaps. I have no idea why adjustments were so far off as to render the CD player useless or why this happened suddenly (as far as I know) without any warning. Perhaps it was dropped and there was indeed a change in the optical alignment. Perhaps a bit of dirt caused one of the controls to change value and my twiddling really just cleaned the track on that pot. Perhaps the original adjustments were marginal. Whatever the cause, It now works and appears stable. The eye pattern looks fine. The music sounds fine.

---

66. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #66: Sony KV-13TR-20 Color TV - Erratic Reception

Patient: A Sony 13" color TV model KV-13TR-20 in excellent physical condition.

Symptoms: Initially, all channels resulted in a white screen. After some warmup, overdriven video (AGC bad) appeared on one channel. After some more warmup, a couple of channels were fine.

Testing: Let it run for a while. Whacking on the cabinet didn't seem to have much effect.

A little tag came with this TV: "Tuner/IF Block, $99". I assume the owner took it in for an estimate (or maybe just called someplace on the phone). Obviously, $100 to repair a $150 TV is a bit steep. Now my usual rates, on the other hand....

These are classic symptoms of the Sony bad solder joint problem afflicting many models of middle aged TVs - not to be confused with the GE/RCA tuner bad solder/EEPROM problems which are similar. :-) See the document: "Sony TV Tuner and IF Solder Connection Problems".

Fortunately, on this set, getting to the tuner and IF boxes is pretty easy once opening the case is overcome - snaps are used in four spots rather than screws. Give me screws any day! On the other had, you cannot lose snaps. Note that on some larger screen Sonys, the engineers in their infinite wisdom placed reinforcing plastic at exactly the wrong place to block access to the pins on the solder side of the mainboard. :-(

The tuner module has about 8 thick pins and 5 shield connections to the mainboard. The IF module has about 11 thin pins and 4 shield connections. Both come off easily (no bad connections visible on the mainboard pads.)

I resolder all the edge pins (though most did look fine), all shield connections, and anything else that appeared marginal. I wasn't convinced that I had located the cause of the problem. There was no smoking gun...

Indeed, the symptoms are essentially unchanged.

Now, I start prodding each of the metal boxes. The tuner box is rock solid but I can get the problem to come and go by pushing gently on the IF box.

Out it comes again. Now I get out the heavy artillery - bright light and magnifier. Then I spot *it* - one lone pin not particularly noteworthy in any respect except that there is clearly a broken solder connection and the pin even moves visibly. This is apparently a common location for these problems - one pin of a coil. I check over everything else once again but I am confident that this is *the* cause of the erratic behavior.

Indeed, once reinstalled, reception is flawless - even playing bongo on the TV has no effect.

Comments: As I have noted before, you would think that after several decades of manufacturing consumer electronics, soldering would not be an issue. But, this certainly seems not to be the case. The demands of the bottom line as well as manufacturing issues of mixed through-hole and surface-mount technology combine to make reliable assembly quite a balancing act. At least the Sony and RCA/GE bad solder problems are well documented and straightforward to repair.

---

67. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #67: Magnavox Phonograph - Record Changer Problems

Patient: This is a Magnavox 'Stereophonic Phonograph Model 3P2515', age unknown but likely at least 25 years old. I bet the feature length name sounded really impressive at the time.

Symptoms: Record changer load and eject functions totally inoperative.

Testing: Cycling mechanism results in no change. It does play records if the tone arm is positioned manually. The stylus also wants to eat the vinyl.....

Since the changer did not respond, I directed my attack to this mechanism. Unfortunately, the owner was not available to explain if this was the main problem - it could possibly be something else.

On an older mechanical device, be it a dinosaur such as this or reel-to-reel tape deck, lubrication, deteriorated rubber parts, or broken parts, are the prime suspects.

But how is this one supposed to operate?

A large metal cam gear actually moves and raises and lowers the tone arm. This is engaged by a smaller nylon idler gear which is moved into position by the OFF/ON/EJECT knob or the movement of the tone arm to the end of the record.

In this case, the idler was failing to engage most likely due to gummed up grease. Once it was freed, the large cam gear was so tight that either the motor slowed and stopped or the gears teeth were skipping - thankfully without lasting damage.

To free up the large cam gear, required removing a bracket and using some WD40 to loosen the dried grease. Once this was accomplished it was worked free. The shaft and bearing surfaces were cleaned. That seems much better.

Darn, the eject is now ignored.

Oops, not the correct timing - there are two possible positions for the relative relationships of the cam and idler. Try the other one.

Well, although it now cycling correctly, the record does not drop. The spindle mechanism is - what? Totally frozen!

Upon closer examination, it would appear that the load/eject mechanism had been glued into a fixed position - the parts of the spindle that normally drop the record were immovable. At first I thought this was simply dried up grease but I am quite sure it is really some adhesive - possibly Epoxy.

Disassembly requires removing the entire platter bearing assembly from the changer, clamping it in a vise, and twisting and pulling to free the spindle. It would appear that this, too, was glued in place!

At first, I try freeing it up with WD40 but this proved inadequate so I use a punch to remove the roll pin. The assembly now comes apart easily - and I promptly forget how it goes back together! One would think that something so simple would not be a problem but it took another 10 minutes or so to come up with a logical arrangement of all 6 parts and several more minutes on the floor searching for a 1/16" shaft that popped free.

However, once cleaned, lubed, and back together, it does appear to be much happier.

Replacing the platter bearing assembly goes smoothly except for accidentally stripping the hole of one of the 3 mounting screws - replaced with machine screw and nut.

At first, everything appeared to work correctly but then the motor shut off before cycling. In fact, it will only stay on erratically, sometimes only when the control knob is held in the EJECT position. While I was tempted to suspect that I didn't get something back together correctly, sanity prevailed and I examined the motor switch. It seemed that the lever that operated it did not quite push far enough and the contact was marginal. After disassembling the switch and cleaning the contacts - and bending one slightly - operation is reliable.

Perhaps, this was the actual complaint since there is no way the changer could have ever worked in modern times!

Another quirk seems to be that when cold, the motor takes a few seconds to come up to speed. At first I thought this was an idler rubber problem but then discovered that the motor seemed to be running at half speed even with no load.

There is no starting or running capacitor to go bad, it is simply a shaded pole motor. Interestingly, it acts as the power transformer for the amplifier with an isolated center tapped low voltage output. I cleaned and lubricated the motor but

I do not believe this is the problem. The speed does seem to recover so I am not going to lose much sleep over it.

One final adjustment: The tone arm tracking force was set so high that I was afraid the stylus would dig a trench entirely through the record on the second or third playing. It took a minute or two but I located the tracking force screw and set it to a more reasonable value - high by audiophile standards but a 3000% improvement.

Comments: There are still many people who depend on this sort of ancient technology for their listening pleasure and are probably better off than many of us who worry about signal-to-noise ratio, dynamic range, and whether Shannon and Nyquist really knew what they were talking about. They are much happier to have their old record player restored to health than to have to learn or afford new-fangled technology like compact discs and (gasp!) DVDs.

Repairing this equipment is generally going to be a seat-of-the-pants affair due to lack of easy or convenient availability of documentation - which is generally not needed in any case if a few brain cells are assigned to the task. Causes are nearly always simple in principle - dried up grease, deteriorated rubber parts, broken parts (hope you can fabricate replacements!), or previous attempts at repair.

---

68. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #68: Clocks, Clock Radio, and Cordless Phone - Smoked

Patients: Two LED clocks, 1 clock radio, and 1 cordless phone, all really and truly dead.

Symptoms: Dead. What more can one say?

Testing: Plugging into the wall outlet results in no action of any kind. No display and no sound.

So Sharon walks in with this bag of stuff. "I have some presents for you. Larry was working on the wiring in his house."

Is Larry the same guy who toasted the CD player? (See: Repair Brief #61: Sony D14 Portable Compact Disc Player - Smoked). "Yep, he accidentally connected the 220 to the 110...."

Geez, you really have to work at screwing up to achieve such a spectacular disaster. Then again, Larry does have a track record. :-)

What happens when 110 V devices are connected to a 220 V line?

Actually, it is quite predictable as I found out. The transformer primary melts and opens. That is it. Period.

I tested each device by providing my own low voltage AC from a Variac feeding a 24 V center tapped transformer substituting for the original smoked power transformer.

In all cases, there was absolutely no damage to the electronics despite the application of an input voltage twice what was specified. In the case of the clocks and the clock radio, there are is no internal voltage regulation. I can only assume that either the components were able to withstand the excess voltage - which must have lasted long enough to burn out the transformer primary - or that the transformer core saturated and limited the output voltage to something much less than double.

The cordless phone was too good to pass up. Instead of attempting to locate a UL approved transformer to install inside like the original, I located a 9 VAC wall adapter of suitable current capacity and wired this into the phone circuit board. It has been operating this way for several years now.

I didn't bother actually repairing the clocks and clock radio. All I did was confirm that they worked with my jerry-rigged power. The clocks I keep as reminders. I cannot easily use the wall-wart trick on them as a center tapped transformer is required. The clock radio required at least two separate center tapped power inputs.

Comments: I, at least, would have expected more damage from such an overvoltage. However, it would seem that just-good-enough design has its merits if indeed core saturation saved the electronics.

Obviously, this should be a lesson to anyone doing major rewiring: don't do it live - both for your own safety and the risks to your appliances! Have the main power disconnected (by a licensed electrician or the utility company if necessary). Turn all the breakers to the 'off' position or remove the fuses. Before applying power, double check the wiring. With main power restored, check the voltages on the circuit feeds and subpanels. Then energize the branch circuits one at a time and check for proper operation.

I can only guess that one of the power line Hot cables touched the Neutral bus feeding the branch circuits. It wouldn't need to be there very long.

Interestingly, at least one VCR survived with only a blown fuse - similar to an incident where a lightning strike totally obliterated a TV but only blew the fuse in a Panasonic VCR.

Repair Brief #69: GE Portable Color TV - Dropped

Patient: GE Model 13GP235 color TV in generally good physical condition but Susan explains that it fell off of a bookcase.... I don't ask.

Symptoms: Dead. Normally, I would not plug a piece of dropped equipment in until I had inspected it but apparently, this had already been done. What the heck. In any case, nothing.

Testing: NA. Inspection comes next.

Indeed, it was not necessary to go very far to locate the problems, many problems....

First, one of the case fastening tabs was broken off. Otherwise, there is no visible external damage. At least it doesn't rattle!

Next, the mainboard was visibly bent around the area of the flyback transformer which of course is the heaviest component. Depressing a lock lever allows the mainboard to be slid about half way back and out of the chassis before stopped by some cabling. But that is quite enough! The major damage comes into view - a crack clear through the board running about 3 inches from the rear near the center. It is obvious that numerous traces have been severed.

At this point I drag Susan in to see the extent of the damage. I explain that even if I can repair all the traces - which I expect would take several hours - there is no assurance that the CRT has not suffered some trauma which would result in the color purity being messed up (popped or deformed slot mask). She says "keep it". Lest you think I am taking advantage of her, Dave and I have just repaired a nice 19" Sony of hers with the classic bad tuner solder connections problem. Now, if she would only get it off our lab bench....

Of course, you know, I am not going to let it go to the dumpster (actually my parts bins/boxes/cabinets/piles without a fight!

About 6 months later, I finally manage to drag it home. I remove the back and them turn it upside-down with a cardboard box under the rear to prevent a, shall we say, unfortunate accident. To get at the full extent of the damage, I only need to pull off the degauss connector and the mainboard slides out far enough for my soldering iron.

Where through-hole pads connected to the broken trace are conveniently located on either side of the crack, I run a short length of #24 tinned wire to the pads. Where there is any chance of shorts, I use insulated wire.

If this is not possible because the pads are nowhere to be found - too far away - I scrape off about 1/2" of soldermask (the green coating) on either side of the break and use a 1" length of tinned wire to bridge the gap. This isn't as hard as it might sound since the surface tension of the molten solder tends to align the wire on the bare copper. These should be quite strong. Since the board is actually supported from the rear edge by the plastic cover (at lest under normal conditions), I believe no additional reinforcement is needed.

Where there is a convenient pad close to one side of the break, I wrap the wire around that but still remove the soldermask and solder to the copper on both sides of the break.

I think I have found everything. One last inspection. No shorts. Time for the smoke test. In order for the front panel power button work, the mainboard must be pushed all the way back into the cabinet. Grrrr.

And - yes! We have snow. With the addition of a pair of rabbit ears, we even have a - totally messed up picture. :-(The colors are all wrong and not uniform across the screen. Could the CRT be ruined? Well, not to give up yet. It is still sitting upside-down (though I did remember to plug the degauss coil back in). There are no field adjustable ring magnets for purity and static convergence. Better hope these are not messed up! Waving a speaker magnet around the screen seems to help some. OK, turn it over. That seems to be much better. Some more waving (I am too lazy to drag out a degaussing coil) and the picture is not half bad.

Is the repair solid? I start pressing on the circuit board and - oops - the set goes off. Then comes back on when I release it. I must have missed at least one.

Out comes the mainboard.

Oh, the crack passes under a surface mount resistor apparently lifting one side loose resulting in a bad connection. To fix this, I add a bit of wire looping over the resistor end cap and connect it to a nearby through-hole pad.

Lights! Camera! No change. Pressing on the mainboard results in exactly the same behavior, maybe a little worse. @#$%@

Out comes the mainboard once again.

Now, how could I have missed that?! A second crack, nearly as long as the first, runs from the edge of the board near the flyback under the flyback severing a half dozen more traces. For that matter, how did it work at all?

A half hour later, I am sure it is finished.

Sure enough, pressing and prodding now have no effect. The edge of the board even seems straight enough to not require reinforcement. The plastic back of the TV has prongs which will support the board. I am confident that the repaired traces will resist anything short of another 5 foot fall - and perhaps even that (but I don't intend to find out).

When testing the next day, I thought a new problem had developed - I was getting 2 bands of snow drifting up the screen mostly on VHF channels. What is this? A power supply problem? After poking, prodding, and cursing, I went to plug it into my isolation transformer to do some probing and guess what? The snow disappeared! It didn't return even when plugged directly into the wall. Flakey EEPROM? No, it turned out to be interference from a power massager being using elsewhere in the house! That device must use a non-RFI protected interrupter.

Comments: You have probably seen the TV advertisements - I don't recall what they were for, an insurance company, perhaps - where a late model TV is dropped out a many story window on a bunjie cord. The set rebounds once undamaged and without hitting a baby in a stroller passing under the window but then smashes to smithereens on the sidewalk once the stroller had moved on. Needless to say, this is generally not a recommended way to treat a TV set!

Ok, so your set survived in slightly better condition.....

If you take it in for service, the estimate you get may make the national debt look like pocket change in comparison. Attempting to repair anything that has been dropped is a very uncertain challenge - and since time is money for a professional, spending an unknown amount of time on a single repair is very risky. There is no harm is getting an estimate (though many shops charge for just agreeing that what you are holding was once - say - a TV, or was it a fishtank?)

When making repairs on printed circuit boards that have been cracked or broken, do not be tempted to just bridge the breaks with solder even if the board has been glued and reinforced. Solder is not compliant, bad connections will develop over time and you *will* be returning to your handywork many times in the future. In the case of this set, the total time to repair was about 3 hours - time well spent to assure reliability.

Stay tuned for "Magnavox 31 Inch TV - Fell on its Face". :-(

70. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #70: Nutone RF Wireless Chime - No Response to Button

Patient: Nutone RF Wireless Chime model LA-99N - otherwise known as a wireless doorbell.

Symptoms: No response to button. Owner claims new batteries installed in both button unit and base station.

Testing: No amount of fiddling with the buttons has any effect. The battery contacts seem springy, clean, and free of corrosion.

This unit is similar in many ways to a garage door opener Tx/Rx pair. The button unit has a five position DIP switch, presumably to set codes (and as I discovered later, to select between chime sounds for front and back door use). A 9 V battery powers the code generator (a single chip Motorola SC41343) and the RF transmitter (all contained in a little shielded box) except for a trimmer capacitor (which I don't dare touch).

After checking to make sure the batteries were indeed fresh and checking that the button was indeed operating its contacts, the next step is to determine whether the problem is in the button unit or base station.

How to do this?

The operating frequency is not marked and I don't really have anything to conveniently detect a low level RF signal at no doubt hundreds of MHz anyhow.

Therefore, I punt and go on the the base station!

This is powered by 4 D cells and a single AA - what this is for, I have no idea. There is no backup memory as far as I can tell! Removing 4 screws from the bottom allows the cover to be removed exposing the solder side of a 2-1/2" x 7" circuit board. The antenna is connected to a point at one end.

Running my finger along some pins near the other end results in some faint clicks from the speaker. OK, it is not totally dead.

Time for Magic Spit(tm).... Moistening my Mark 1 thumb and using this as a probe evokes some more clicks. Placing it on suspect transistors finally results in triggering the chimes. Therefore, I expect that this transistor is the gate from the RF/decoder circuitry. I can fairly repeatably trigger the chimes in this manner. A 56 K resistor from the base to collector will also do this. Thus, I know the chimes are working.

Now for the front end. There are several ICs on the non-chimes side of the circuit board. The two that seem to be interesting are an MC1776 which is an op-amp and a Motorola SC41342 which appears to be the decoder mate to the IC in the transmitter. It is connected to a four position DIP switch.

That op-amp looks promising. Even with just a DMM on pin 6, the output clearly jumps when the remote button is pressed. Time for the scope.

The waveform at pin 6 is clean and stable when the button is pressed. It is 9 low pulses followed by 7 high pulses repeating. How does this change when the DIP switches settings are altered?

Answer: Not much. At least, not every switch setting produces a unique bit pattern. In fact, most of them are the same as this one which probably isn't really even valid.

The op-amp signal goes into pin 8 of the SC41342. Pin 10 goes via a resistor to the base of that 'trigger' transistor. As expected, there is nothing on this pin.

Next, I decide to try all combinations of the four common DIP switches on both transmitter and receiver as well that lone fifth switch on the transmitter. The majority produce the same waveform. However, 3 other combinations of the 4 switches prove interesting:

- Two settings result in codes being transmitted only when the button is released. The bit rate of this code is lower as well.
- Several settings produce 9 low and 3 high pulses.
- One and only one setting produces an alternating pattern of long and short pulses - AND a response from the chimes!

It is erratic, however. As is apparent from the scope display, the bits are not stable for this one 'useful' pattern. However, a good percentage of the time, the chimes will trigger. It is at this point that I discovered the effect of the 5th DIP switch - to change the pitch of the chimes presumably to distinguish between the front and back doors. There are only 6 components in the code generator - the SC41343, 3 resistors, 1 capacitor, the pushbutton, and the DIP switch. Three of these parts obviously determine the bit rate - jumpering them with similar valued components affects only this. I check them all anyhow. Nothing seems amiss. The soldering is perfect.

I decide to check the battery once again - it is a little low, perhaps 8.5 V. The owner did mention something about putting in a new battery but the button being stuck in the depressed position. So, maybe the battery isn't so fresh after all. This really should not matter but what the heck. However, a new battery seems to clean up the erratic pulses.

So, in all likelihood, the SC41343 is bad resulting in a whole wad of missing codes - only one pair seems to work - and marginal operation with a slightly weak battery. Can a chip wear out from being on for too long? :-)

Unfortunately, an initial check shows that my usual haunts don't seem to carry this chip. Then I email Paul Grohe: I was just wondering if you had any datasheets for either of the following Motorola chips: SC41342 and SC41343?

> "AH! Never blindly trust Motorola's search engine! (Ya gotta know where to dig!). Here ya' go:
> - MC14502 Product Summary
>
> This datasheet contains the RC Tx/Rx parts. The 'SC' #s are low-power versions of the 'MC' parts."

Sure enough, the pinouts match perfectly and Dalbani and Allied list the MC145026 transmitter chip. With an actual datasheet in-hand, I go back and scope all the pins but this only confirms that the chip is almost certainly bad.

It is likely that these chips are used in a number of garage door openers as well. With a total of 9 possible input bits, each of which may be set to any one of 3 states (low, high, open), this results in 19,683 possible codes. That number of combinations seems to ring a bell (no pun...) with ads I have seen.

Comments: This is not the first time I have come across a situation of this type. My cousin's Sears garage door opener decided to ignore at least one of the 8 DIP switches. It would work fine as long as that switch in the transmitters and receiver was set to a 1. In the case of this doorbell, it would appear that a much more drastic failure has occurred.

For now, I will return it to its owner but will order the replacement part. The only problem with selecting the only working code would be if a neighbor has the same model set to the same code! At least, it is not the default.

---

Repair Brief #71: Tandy Color TV/Monitor - Intermittent Shutdown

Patient: Tandy color TV/monitor model #16-232. This unit was described in Repair Brief #14: Tandy Color TV/Monitor with Hum Bars. Since that initial repair after being rescued from curb-side, it has been in daily use for about 5 years.

Symptoms: The set will randomly shut off and then come back on after a few seconds. There appears to be some correlation with high temperature or high humidity but not much.

Testing: The appearance of symptoms is so infrequent that I do not do anything until it seems to quit for good....

Finally, it goes off and stays off. Oh well, something finally died....

So I unplug it and take it down to the workbench.

Plug it in - still dead.

Whack it once, whack it twice - and - it springs to life! Ok, where are the bad connections on this one?

The previous problem had to do with startup drive to an SCR based power supply. Once started, however, the circuitry involved was not active so the new problem must be, well, new.

I remove the back and start the hunt.....

Soldering is pretty good except for a few spots - one is a just visible crack around the base pin of the horizontal output transistor. Hey, that looks promising....

Unfortunately, I am unable to confirm that soldering this pin is *the* solution since it is so erratic. Although I was able to restore operation with my special whack(tm), I have never been able to make it go off in this manner. While I am in there, I also resolder a few other power components and the video source select switch because it had such an ugly soldering job. :-(

I also replace my startup resistor since the one I was using seemed to have a power rating just a tad too small.

However, the cause of the erratic behavior was almost certainly the crack at the HOT.

Operation *is* now solid but only time will tell if the problem returns. FWIW, the TV has been running for several months without incident.

Comments: This isn't a standard bad tuner solder shield problem but similar nonetheless. Large components heat and cool stressing the solder connections ever so slightly each thermal cycle. After awhile it is just enough to break the solder bond to the single sided circuit board. Then, this expansion and contraction cause the two parts to shift ever so slightly sometimes breaking the connection. With some kind of stress relief or reinforcement, this would not happen. But that might cost a few cents....

I was initially prepared for a long troubleshooting adventure with this set. There is no Sams' Photofact for this model - none even close. I just checked the Tandy info at http://support.tandy.com/video.html and a model that might be this one (the number is slightly different - 160-232A - but everything else checks out) is there. However, only a parts list seems to be available. I was thinking at first: HV shutdown or heat or humidity sensitive component and was not at all disappointed when it turned out to be something simple.

---

72. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #72: Braun Quartz Clock - No Movement

Patient: Braun table-top quartz clock (don't they manufacture coffee makers)?

Symptoms: Clock does not run even with fresh battery. No audible signs of life either. These don't go 'tick-tock' but there is usually some faint click each second.

Testing: Battery is fresh and contacts are springy and clean. Gently whacking and twisting will not start it going.

I know, most people would toss a clock of this type when it started acting up. This one is important to the person who owns it. Some people have rabbit feet; she has a favorite clock!

The problem with these things is that everything is small, made of plastic, and fragile.

Anyhow, To get at the guts requires removing the back (2 screws) and popping out the plastic 'crystal'. This done, the hands can be removed and set aside, Now, the solder side of the circuit board is accessible.

First test: check the solenoid for continuity. I had one where the fine wire broke - thankfully at the terminal and it was repairable. This solenoid is fine.

Without it mounted in the case, I need to locate a substitute battery holder to apply power.

Next, I look for pulses on the solenoid. I have already noted that the alarm works by moving the hands to set it off. This confirms that the quartz crystal is oscillating and the huge 8 pin chip is working, at least to some extent.

Putting a scope across the solenoid terminals reveals alternating positive and negative nearly 1.5 V (the battery voltage) pulses at what I presume to be a 2 second rate for an entire cycle. This would seem to indicate that it should be working.

Therefore, the problem must be mechanical. In fact, gently rotating the second hand shaft seems to point to a problem with the gears.....

I have to go deeper! Popping the gear cover finally reveals the problem: the rotor of the motor is a teeny tiny cylindrical magnet glued to a plastic pinion gear. The glue has failed. Can you believe it wasn't constructed to military standards! A 1/4 drop of household cement and it should be as good - no - better than new.

It is interesting that while this is a 2 pole single phase motor, the starting direction is not ambiguous. How? It seems that there is a little plastic tab on one side of the rotor. When the clock is mounted in the normal upright direction, this is just enough unbalance to force the rotor into a known orientation when unpowered and between pulses (it will be settle with this tab at the bottom or perhaps just balanced at the top but not on one side). From this, the N-S pole relationship is guaranteed to force the proper clockwise rotation of the hands (at least in this part of the universe). Clever and simple.

Reassembly is not as difficult as I feared - the gear shafts are guided to the holes by conical bevels on the cover.

And - it works! I even got that little plastic tab oriented correctly.

Comments: OK, so you are saying "Why bother?". Maybe it is the challenge. Maybe it is not being able to say no. Maybe I have too much junk already and I would never throw it away if I couldn't fix it. The owner will be happy. And, I (and perhaps, you as well) have learned something about quartz clock movements. Not a bad deal for 1/2 hour's work.

---

73. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #73: Sony D88 Portable CD Player, Part 1 - Does Not Recognize Discs

Patient: Sony D88 'Dual Size' portable CD player. This really cute miniature CD player was designed mostly for CD 'singles' and is only slightly larger than a 3-1/2" disc. Normal CDs hang out on 3 sides.

This is the first of the "Request for (dead) optical pickup series" of Repair Briefs. This classic Sony was donated by Zev Berkovich (ah392@freenet.toronto.on.ca).

Note: I am still looking for additional samples of this model and other portable CD players, CDROM drives, optical pickup assemblies, and other optical disc technology technojunk. I will pay slug mail shipping (e.g., UPS Ground Commercial).

Symptoms: Inserting a disc and pressing PLAY results in the pickup moving toward the center but the disc directory is never read and the player gives up after 10 seconds or so.

Testing: The behavior is the same with several discs. It doesn't appear as though it is even focusing correctly....

First some history - here is the dialog between Zev and myself:

From Sam: Original posting (summary):

Newsgroup: sci.electronics.repair Subject: Request for (dead) optical pickup assemblies.

I am interested in complete or partial optical pickups or optical decks, portable CD players, CD ROM or optical drives for parts. I will be slightly disappointed if they are fully operational. :-(Obviously, I do not want to pay much so no offers of new Sony pickups at retail prices please! Since I do not not make money on most of my repair activities (family, friends, charity, the Internet, personal amusement), I am only willing to pay for slug mail shipping and perhaps a wee bit more if there is enough fascination value in it. In return, you *will* get priority replies to your repair problem postings! :-)

From Zev:

> "I have a non-working Sony portable CD player (it is designed for 3" CD's, but will also play 5" CDs with part of the disc sticking out of it). I have the complete service manual with schematics.
>
> Since this unit would be of little use to me even if it worked, I have not really put too much time into it. However, I have used it to play around with and try different things on my scope. The laser, BTW, is fully operational and is drawing exactly the right amount of current. I am pretty sure with some time put into it the thing will work perfectly, I just have no use for it, and I would be happy to let you have it.
>
> The laser unit is not compatible with later sony discman models."

From Sam:

Thanks, that sounds perfect - it satisfies my criteria for optical pickups and would appear to be a really interesting item. What is its current status?

From Zev:

> "Originally I had very carefully adjusted the focus and gain settings, and I did manage to get it to work. After it played for a few hours though, it just quit on me. I may have gone a little wild after that tweaking the dials, so it's possible that they are all out of adjustment."

After I received the package...

From Sam:

When one compares the newer models to these, it is amazing how far the manufacturing has come - a couple of ribbon cables/connectors and the entire optical deck pops out - none of this flying lead stuff! BTW, that pickup looks to be similar to those used in a number of quite new non-Sony model portables and boomboxes including Emerson (whoever makes them -- Mitsumi?), Aiwa, etc.

The other portables I have received based on my request for dead optics have all had good optics! :-(They have seemed to have power problems - one was smoked by too much voltage, another has an overheating problem.

From Zev:

> "Hmmm. I never thought about comparing the optics to other brand names. I just compared it to the newer Discman models (D121 and up), which use a totally different connector (one ribbon cable and a couple of two prong snap on connectors) which I can pop in and out in a matter of seconds.
>
> What is also quite amazing is that when you look at the evolution of Discmen even over the past 5 years, they have gone from multiple circuit boards that take up all available internal space, down to a tiny board which only inhabits a fraction of the interior."

Initial testing confirmed that it failed to access the disc's directory (TOC). An internal inspection, revealed that the unit was still set to test mode but was behaving more like normal mode. Interesting....

Since Zev sent along the original Sony service manual along with supplements, I at least have a starting point. Given that it seems to not want to go into test mode now, I figure I will check some basics from the service manual.

Resetting the test mode jumpers was a royal pain! This was just the start of pain. The jumpers are itty bitty solder pads, already slightly abused from Zev's previous efforts through no fault of his. I proceeded in further damaging one trace and had to add a jumper wire to bypass it.

Changing the jumpers made absolutely no difference! I double checked the soldering... Everything appeared correct.

It didn't take long to identify an anomaly: One of the adjustments is for +5.4 V. Once I located the test point, it measured only 4.1 to 4.2 V and the adjustment had no effect. Hmmmm.

From Sam:

I started to measure some test points and found that the 5.4 V was not being generated and the 5.4 V Adj. has no effect. This is produced by a charge pump running off of the servo chip - it seems that the servo chip thinks the voltage is enough but it is only 4.1 V. Reducing the input voltage results in the DC-DC converter running but never getting up to any reasonable voltage. Unfortunately, since it will not now go into test mode, operation is only for a few seconds at a time.

I checked the jumpers. You left it in service mode but I guess with the inadequate +5.4 V it behaved as though in normal mode and putting it into normal mode made no difference.

BTW, don't you love how much pain it is to go back and forth resulting in lifted pads etc. after awhile? Why couldn't Sony put in a switch or at least a single jumper?!

From Zev:

> "I did have it in test mode to repair it. When I got it running again, I put it back in normal mode. Then when it stopped playing, I remember trying to achieve test mode again, but it was stuck in normal.
>
> How about providing an external +5.4 V supply to see if that helps?

I guess you can see now why I got rid of it. I've repaired quite a few of the newer Sony Discmen, but those older ones are a real pain."

I considered the idea of testing with an external power supply but decided to use this as a last resort - I have no idea what would happen if main power were removed with the external supply still on. There could be, shall we say, unfortunate consequences with sneak paths through the chip protection diodes.

How are the various voltages generated in this thing? Quite cleverly in fact: After some careful examination of the schematics (that is, once I located the set that corresponded to the PCB revisions for this model), it appeared as though a little circuit boosted the 4.4 V source to 5.4 V. This simplified circuit is shown below:

```
                   +4.4 V in
                        o                          +---o +5.4 V out
                        |                          |
                        C                  +-------+        +----||----+
                        C L703             |       |        |          |
                        C          L704    |       \ R708   +---/\/\---+
                        |  D701    ::::    |       / 62 K   |          |
               2SD1048  +--|>|--+---^^^^---+       \        |  |\      |
                  Q704  |       |          |       | +5.4 V +--|- \    |
      |\      R706    |/ C     _|_ C705   _|_ C706 \  Adj.  |  |    >--+---o P
D o---|  >o--/\/\--+--| X-6    --- 10 uF  --- 4.7  /<----------|+ /
      |/       1K  |  |\ E      |          |  uF   \        |  |/
       IC701       /    |       |          |       | R701   /
      TC7S04  R707 \    +-------+----------+-------+ 22 K   \  (The amp is
              10 K /    |                  |       |        /   part of IC504)
                   |    |                 _|_      |        |
                   +----+                  -       +--------+
```

One of the large chips is the controller for this switching DC to DC converter. Of course, I at first suspected this many legged surface mount chip! However, I should have known better. The voltages associated with the converter were way off and the drive output to the boost circuit appeared mostly dead. This came directly from the large chip, IC504.

The regulator includes a difference amp (reference-fraction of output voltage), pulse width modulator (sawtooth clock and comparator), and a driver. I finally was able to convince myself that the amp was working since it output and feedback components are external and I could see the output change when the relative values of the two inputs were adjusted.

The leaky integrator provides the control voltage to the pulse width modulator that drives the DC-DC converter. The op amp circuit is internal to the motor driver chip, IC504). The output, P, is compared with a sawtooth derived from a clock signal. The result is the charge pump drive.

Then, I thought the driver was dead. However, upon close examination, there appeared to be an occasional burst of activity - but no corresponding change in output voltage. The inverter was the complement of the driver output. So, maybe that boost transistor circuit is not working.

Unfortunately, Q704, R706, R707, and C704 are all mounted on the underside of the circuit board - all surface mount and inaccessible from the top. Getting to the bottom is a real treat mainly because two printed cables and numerous thin wires interconnect the main logic board with the optical deck and microprocessor board (the control panel in the hinged top of the case). However, after undoing a bunch of black tape and pulling one of the printed cables, I can *just* get to the required components without needing to unsolder anything.

Tests with DMM: Resistors - A-OK, Capacitor - Not shorted.

Transistor - What have we here??? Finally something that is a bit strange: The B-C junction has a normal .682 V drop on my DMM but the B-E junction is 1.29 V? I double check. Yes, indeed, the junction seems to be bad. Joy! It is an SO23 surface mount part, barely visible let along replaceable.

Now, where can I find a replacement? It is probably just a vanilla flavored transistor - a 2N3904 would probably be fine. (In fact, I checked while writing up this Repair Brief and the 2SD1048 is a general purpose switching transistor). However, I would rather use an exact match to be sure.

Now, where can I find one? Hey, remember that smoked Sony D14 (Repair Brief #61 - Sony D14 Portable Compact Disc Player - Smoked)? I bet it has some usable body parts that were not damaged. After all, most of its circuitry was on the output side of its DC-DC converter module (but not the controller, unfortunately.

Sure enough, there are numerous similar transistors - type X-6.

I manage to mangle one of them because they are glued in addition to being soldered to the board. Finally, using a combination of my soldering iron, SoldaPullit, jeweler's screwdriver, Xacto knife, and needlenose pliers, one comes free in good condition. Confirming this with a multimeter is fun as well since it is barely possible to even hold the thing without it popping out of existence.

The broken transistor is removed more easily since it is not glued - heating the solder while prying on one side frees it.

I use a set of tweezers to position the replacement and a wooden clothes pin to hold it in place while soldering. You would have to see this setup to believe it. :-)

Now for power!

At first I thought there was no change. Did the new part blow already? But then I realized that I had been playing with the +5.4 V Adj. pot and left it where the two inputs to the op amp were just about equal - which would yield around 4.1 V even with the DC-DC converter operating properly.

And, indeed, now the +5.4 V adjustment has an effect. I would have been surprised if the player had actually started working as you will recall that the internal adjustments are probably way off. In fact, the behavior doesn't appear much changed at all. :-(

However, now, I can try some experimenting with the adjustments. I solder a wire to the RF test point for my scope.

Nothing. OK, let's see if Focus Bias (offset) does anything. Nothing. What about Focus Gain? Nothing. How about back and forth? Oops, what was that? Is that an eye pattern? Well, of sorts. Can I persuade it to stick around.

Adjust. Adjust. Adjust. Adjust. Adjust. Tweak. Tweak. Tweak. Tweak. Tweak.

Finally, it seems to be fairly stable though not the prettiest eye pattern I have ever seen. Will it play? I have been using my trusty AOL CD which really leaves something to be desired in the audio department... Of course, it isn't much use for getting on-line these day either. :-)

Sure enough, my 'Strauss Greatest Hits' disc does play - a bit noisy but recognizable. It seems to have some trouble locating and playing outer tracks so a little more tweaking is in order. A slight shift to the PLL free run frequency and it now is somewhat happier.

Someday, I will perform the proper servo alignment though I do not think any of the adjustments are far off. Nonetheless, I might as well take advantage of the luxury of having an actual service manual!

Unfortunately, another disc played with a lot of noise and it seemed to be touchy about my even going near the player! I checked to make sure the +5.4 V had not died again - nope, exactly correct. Oh, well, enough for now. Stay tuned for: "Sony D88 Portable CD Player, Part 2 - Erratic Audio Noise".

Since I did not attempt any adjustments prior to replacing the transistor, I really don't even know if the correct voltage on that +5.4 V bus really made any difference but I am not complaining. I also do not know what caused the original transistor to blow - it might fail if the drive were on for more than a few microseconds as the inductor is the only thing limiting collector current. I left if playing on repeat mode to see how robust it is.

Comments: This is a really cute CD player - not really very practical but probably one of the neater examples of solidly built Sony technology which still contains some metal in its structure!. I would be very interested in obtaining other samples of this or similar vintage CD Sony players.

Would a repair shop ever have taken the time I did to analyze the circuit and locate and replace a surface mount part? No way. Only a Sony service depot would likely get that deep into anything of this sort and then again, probably not even there.

Repair Brief #74: Sony D88 Portable CD Player, Part 2 - Erratic Audio Noise

Patient: Sony D88 'Dual Size' portable CD players. This really cute miniature CD player was designed mostly for CD 'singles' and is only slightly larger than a 3-1/2" disc. Normal CDs hang out on 3 sides.

This is the second of the "Request for (dead) optical pickup series" of Repair Briefs and is the continuing saga of this classic Sony CD player donated by Zev Berkovich (ah392@freenet.toronto.on.ca).

Symptoms: After locating and replacing a bad SMT transistor and retweaking the servo adjustments, the player works but playback with some discs in particular is noisy at times - sometimes very noisy. Seek times are sometimes excessive. Moving near the player seems to have a significant effect as well - often to the point of killing tracking and playback entirely.

Testing: I substituted another AC adapter just to make sure it wasn't at fault. Tweaking the servo adjustments has minimal effect.

As you will recall in Repair Brief #73: Sony D88 Portable CD Player, Part 1 - Does Not Recognize Discs, this player was totally dead when given to me. Zev, the original owner, said that he had tweaked the servo adjustments and it worked for a few hours and then died. He then did some more tweaking without success.

After a feature length troubleshooting session, I was able to locate a bad surface mount transistor - part of the +5.4 V boost DC-DC converter - and replaced it. I was then able to get the player to work somewhat even if it does appear to have an attitude problem......

A few days after the initial success I decided to try another disc and was greeted with terrible noise which seemed to correlate with the disc rotation rate. What's up? The eye pattern didn't look great. In fact, come to think of it, the eye pattern looked terrible. Therefore I decided to do a little more investigation. (As it turned out, a lot more investigation - an entire afternoon's worth!).

With service manual in-hand, I checked the laser current and eye-pattern amplitude;

- Laser current was 50 mA - the sticker said 47 mA - well within the acceptable range of +5,-11 mA).

- Eye pattern amplitude was .7 V - just a tad short of the lower limit of .75 V but probably acceptable.

Since there doesn't appear to be anything wrong with the optical deck or pickup, there is no point in pursuing it. The laser power is at its correct setting (there is no adjustment in any case) based on the current measurements. The lens and its suspension appears well within normal limits. I did test the spindle motor which seems fine with no evidence of shorts or dead spots (the symptoms do not really apply to a bad spindle motor anyhow).

However, on closer examination of the eye-pattern with a better scope (350 Mhz bandwidth), its ugliness became even more apparent. In fact, there seemed to be a 100 MHz oscillation superimposed on the signal. Is this an artifact of my scope probe? I do not think so. Could the laserdiode actually be oscillating at 100 Mhz? Oh come on, that is grasping at straws.

Another interesting behavioral quirk was that the disc didn't like me! Recall that this is a strange player - 5-1/4 inch normal CDs hang over the side. If I moved my finger *near* the spinning disc, the audio becomes noisier and will cutoff entirely when close enough. This did not appear to be mechanical - I could be 1/2" away from the disc and still detect a significant change in the audio. At first I thought this was a problem with a component in the player but it was the disc - placing a strip of aluminum I was holding near the disc produced the same result! Well, after some thought, the only conclusion could be that my finger was capacitively coupling to the aluminum of the disc's information layer and *that* was capacitively coupling to the metal parts of the optical deck. Shouldn't these be connected to an analog reference point or analog ground? Of course - and there was even a hint staring me in the face - a taped unconnected wire. However, there is no mention of this in the service manual or schematic!

There is a shield which is part of the printed flex cable which carries the laserdiode power/feedback and photodiode signals and this is soldered to the metal cover plate of the optical deck. However, it wasn't connected anywhere else! At first I ignored that dangling wire and soldered it to what I thought was a suitable ground.

Wrong! That connection didn't work at all - it must have been a noisy digital or power ground. In fact, I wasted another hour tweaking the servo adjustments and then ripping the player apart once again suspecting (incorrectly) that my efforts to attach the ground wire and clean the optics while I had the unit disassembled had damaged something else! All was not well (at least as well as it was before) until I removed my original ground wire completely. The player came back to life but as expected was just as noisy and tempermental.

If I had followed Rule #45123 - never change or fix more than one thing at a time without testing, I could have saved a lot to time and aggravation.

Finally, I came to my senses and connected a wire to the proper solder pad and - presto! - the audio noise completely disappeared and the RF test point now looked like a much more respectable eye pattern - quite nice in fact.

Obviously, the sheet metal of the optical deck cover was picking up all kinds of crosstalk from the electronics - perhaps even forming a feedback loop of sorts - and totally corrupting the RF signal (and who knows what else).

A little more tweaking to optimize the amplitude and appearance of the eye pattern (With the player in the upright position and the controls accessed from underneath - joy!) as well as adjustment of the PLL free-run frequency (according to the service manual, no less!) and I do believe the player is in pretty good operating condition. Since even the service manual doesn't provide procedures for adjusting focus and tracking gain, I left these at their midpoints. This may not be optimal but seems to be quite acceptable for all the discs I tried. (Gain of these servos affect mostly the performance with dirty, scratched, and/or warped discs.)

Comments: I still do not know if the original problem with the +5.4 V would result in a totally dead player. It seems to mostly feed the audio circuits and somehow also is involved in the selection of TEST mode. Maybe someday I will tweak it back down to 4.1 V and see what happens (yeh, sure). Perhaps it would totally kill audio or simply result in screwball behavior.

This is a case where the previous attempted repair probably resulted in this entire problem - no fault of Zev's). Without a mention in the service manual or schematic, it required a visual inspection to finally identify the missing shield connection. However, this does underscore the nature of possible difficulties in servicing equipment that has been worked on by others.

I have seen erratic behavior caused be a missing shield in CDROM drives (see Repair Brief #52: Aztech CDA-268-01A CDROM Drive - Drawer Continuously Closing.) In that unit, even audio play was noisy until a circuit board metal shield cover was replaced. Thus, whenever you repair a CD player, CDROM or similar device, pay attention to the ground strap, jumper, or spring clip when you remove the optical deck!

Repair Brief #75: Panasonic CT-714 Color TV - Dead

Patient: Old but solid state at least - Panasonic 19 inch color TV model CT-714.

Symptoms: Totally dead.

Testing: Tried different outlets, nothing.

I didn't locate the circuit breaker until much later - probably just as well. Other components may have let out their smoke if I had pushed the button.

First, I searched for any fuses. I only found one on the mainboard and it tested good.

Then, I tested resistance to ground at HOT - dead short.

Removed HOT - tests good. Still dead short at socket.

Removed red wire (whatever that it) - still shorted at socket.

In order to get at the components on the HOT socket requires removing the HV multiplier/focus block (4 screws, 3 push-on connectors - better remember where they go!) and popping the socket from the heat sink where it snaps in place.

Once this is done, I unsoldered damper and snubber - these are shorted.

Removing the capacitor shows that the damper is shorted.

I tested other power semiconductors - a transistor near the main filter capacitor tests good. A T03 package device which turned out to be an SCR (probably part of power supply regulator) tests strange G-K low in both directions; A-K, high impedance in both directions. Maybe it is good. Perhaps, there is an internal resistor that is confusing my meter.

Before proceeding, I go get the Sams' Photofact from the library.

Unfortunately, this set is at least 20 years old and the Sams' folder is on microfilm - an actual spool! (Or so I was led to believe. A later visit resulted in the hard copy magically appearing from a back room. Grrr.) This was actually not too bad as the microfilm reader had variable zoom and pan so with the assistance of the person in charge, I could get exactly what I wanted (after waiting for all those other people to copy old newspaper and other articles). The bad part was that the copies were only marginally legible but probably good enough though some identifying numbers could only be guessed.

I decide to replace the HOT and damper with a transistor that has a built in damper diode. I keep some in stock for general replacement in TVs (though I would not do this for an SVGA monitor). One nice one is a 2SD871D. The advantage of this is that if there is still a problem, I don't have to take out the tripler and socket - just pop the transistor.

I will power it using a Variac AND series light bulb and check the HOT for excess temperature rise periodically.

However, first I will leave the HOT out entirely just to make sure the front-end of the power supply works.

I connect the the Variac to the output of my isolation transformer in series with the light bulb.

At first - nothing. Series light bulb remains dark.

Then, I found the circuit breaker and pushed the reset button. There was a satisfying click. :-)

Now, my series light bulb (100 W) glows brightly (degaussing) and then nearly goes out. This is the correct behavior with almost no load (horizontal deflection not running).

Checking voltage at the regulator with my multimeter - it doesn't come on at all until the Variac is 2/3 of the way up but then stabilizes close enough to what it should be - 110 V - that I feel confident in proceeding.

I pull the plug and set about installing my replacement HOT/damper combo.

At least the main filter capacitor bleeds off in only a few seconds. Just double check - no need to discharge it.

It is somewhat difficult to get at the pins to solder in the cramped quarters between the CRT yoke/convergence board. This is one of those TVs where there are zillions of convergence adjustments which I have no intention of touching!

Finally, it is done (so I think). Snap the socket back in place, install the HOT and tighten the screws securely. No heat sink compound was apparently used - perhaps before I button it up, I will add some if it seems to be needed.

Replace the HV multiplier/focus block. Oops, where did THAT lead go. Oh, but there are two pins, now who added that second pin? :-) I was just able to make out scrape marks on one and stuck the wire there. (It seems there are two possible locations for the focus wire, for whatever reason.)

All set?

Power - slowly ramp up the Variac. Light bulb glows brightly and then settles back to still glowing somewhat brightly though not full on (which would have indicated a short). The voltage on the power supply now reads 60 V.

I am not ready to try a larger light bulb - 100 W should work.

I try disconnecting that red wire - still don't know what it is - but that makes no difference. Removing the HV multiplier/focus block also makes no difference. Could the flyback be shorted?

There is one thing - my combination of the Variac powering the isolation transformer is not what I usually use so I put the isolation transformer first.

Now, for whatever reason, at nearly full voltage, I suddenly get a burst of static and a few seconds later, just a hit of a raster and picture - about 1/2 size and rolling.

I power down and check the HOT - cool as a cucumber.

OK, what about a larger light bulb?

I find a 150 W PAR floodlight bulb.

Now, I get something much closer to normal. A little squashed top and bottom but nearly or totally full width.

Go for it!

Leaving out the light bulb but still using the Variac, a not too terrible picture appears at about 90 V or so and is fairly independent of input voltage. An antenna helps quite a bit but the picture is still pretty ugly. The vertical is squashed top and bottom and pulsating apparently along with some hum bars rolling up the screen.

I let it run for a few minutes and pull the plug.

HOT is still cool. OK, so it, at least, is happy. What about that ugly picture.

Adjusting V-height and V-linearity are not able to get it full screen top and bottom simultaneously and there is still that pulsing behavior.

Well, probably a bad capacitor.. There are only about a half dozen electrolytics in the vertical output stage. Locating part numbers is a bit of a pain with the poor quality copies but the forth one I test reads way low on my capacitor checker (part of one of my cheap Radio Shack DMMs). It is a bypass cap on the collector of the vertical output pair (yes, discrete transistors).

Jumpering a good capacitor across this returns the vertical deflection to something respectible and the adjustments now are able to completely restore normal operation of the vertical.

Then, I notice a slight double wiggle moving up the screen. No obvious hum bars but just a 1/8" or so wiggle. I check the obvious - main filter capacitor (actually after the SCR regulator) and a couple of other bypass caps in the power supply but jumpering across them with good capacitors has no noticeable effect.

There is a linear regulator (called Automatic Picture Stabilizer - APS - or something like that) after the SCR regulator. The output of the SCR regulator according to the Sams' should have about 6 V of ripple. I check it and indeed, there is about 5 V of ripple. However, there is exactly the same ripple on the *output* of the linear regulator. As a matter of fact, the output of the linear regulator measures exactly the same as the input! I thought I checked that transistor.....

Testing on the circuit board, B and C are shorted. So, either it is now bad or some other component is shorted. It didn't take long to locate the problem. A zener diode apparently there to protect against too high a voltage drop on the transistor was a dead short. At first, I was not able to identify the part from its markings but a 5.1 V 1 W zener seems to work fine and ran cool. The wiggle is gone. Ripple on the 110 V output is almost undetectable on the scope. (Later, I went back to the library and confirmed that it was supposed to be a 15 V 1 W zener - which fortunately, Radio

Shack stocks - and even a genuine Motorola part!

I was all set to return it to its owner when the next morning I noticed what could only be called an instability - for the first couple of minutes after power-on, the raster would tend to jiggle or perhaps change size and brightness erratically. After it warmed up, everything would be fine as though the TV was taunting me - "You think I am repaired. HeHeHe". I hate those sorts of problems! Not enough time to probe anything.

One reason I did not notice it before was perhaps that I had been switching power to the TV rather than using its on/off switch. This is one of those 'instant-on' TVs. The picture really does appear within 2 seconds of pulling its power knob as it keeps the CRT filaments hot at all times. Using an external power switch, of course, killed power to the filaments as well and thus the worst of the jiggling was probably gone before the picture appeared.

Only when I put the set on a Variac was I able to actually see the supply going into a low frequency oscillation (about 10 Hz) at high line voltage even after it warmed up (though it was less susceptible after warmup). And, I had actually seen some hint of it before on the scope but it went away quickly and there were no operational symptoms. Only when this added ripple really became large was there any evidence of it in the picture.

Assuming it was a bad capacitor, I systematically removed and tested each and every electrolytic in the power supply regulator. Well, it wasn't so bad - there are only half a dozen or so - except that since my photocopies of the Sams' sheets are almost illegible, it takes a little creative parts identification to find each one. Of course, it was the last one! A 1 uF, 150 V capacitor was reading between .01 and .3 uF depending on what capacitor range my meter was on. An organ donation of another dead set took care of that. Regulation stabilized throughout the relevant range of my Variac.

There is still a little bit of video noise - a slight pattern of vertical undulations - at the left side of the screen on some channels but I could spend the rest of my life checking capacitors in this thing. I suspect more are on their way out......

Comments: It could be that these four problems were totally unrelated though the zener probably failed at the time the damper shorted. Certainly, the bad capacitor in the vertical deflection just died of old age and the owner probably never noticed. If there was a cause for the failed damper diode in the first place, it could have been the bad capacitor in the power supply totally messing up the main B+ output. Perhaps, it really got out of control if the set were off for an extended period of time. In fact, the TV had not been used for about a month prior to its failure though I do not know if it died the first time it was turned on after its vacation.

---

76. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #76: Emerson VGA Monitor - Dead Doggy

Patient: Emerson 14" VGA Color Monitor. This was Ed's PC monitor until he was forced to 'upgrade' to a NEC 3D. It then was used on the PAL burning PC which meant that it was often forgotten and left on all day and all night.....

Symptoms: While on and unattended, this monitor started making a high pitched whine with loss of picture.

Testing: Connections to the PC were verified and a substitute monitor worked fine on the PC. This is standard DOS boot and VGA on a nothing-to-write-home-about video card so there is no issue of incompatible scan rates.

Most often, a dead monitor emitting a high pitched whine indicates a short circuit in the secondary of the power supply, horizontal output transistor, flyback transformer, or one of its secondary loads. In many cases, this would also result in failure of the SMPS chopper and/or horizontal output transistor but not always.

This monitor has a separate switching power supply connected to the mainboard via a removable cable. Although no schematics were available, measurements were made of the voltages on this connector both with the mainboard connected and removed. On average, the values were about half the unloaded values when attached to the mainboard. The whine disappeared when the mainboard was unplugged.

While this most likely indicates a fault on the main board, it could also indicate a power supply that has (very) poor regulation.

A quick check was made of all the visible semiconductors on the mainboard including the horizontal output transistor (HOT), I did not locate any shorts. One diode that was initially suspect turned out to be in parallel with a 4.7 ohm resistor as part of the HOT base drive circuit.

Without schematics, there was no way of knowing the correct voltage values. I decided to do a little reverse engineering of the primary output of the switching supply - the one connected to the feedback optoisolator. This took roughly 10 minutes and revealed that the open circuit voltages were correct. The reference was supplied by a 6.2 V zener diode and a simple transistor controlling the optoisolator - turning it on when the output voltage exceeded 120 V. While the supply could still be bad, the probability of this is small based on this new information.

Next, the flyback transformer was removed from the circuit (after verifying that the CRT anode was discharged). Using my chopper based flyback tester, no faults were found. However, since this device does not test at full voltage so a breakdown failure was still possible.

Next, the flyback was connected via a pair of wires to only the HOT collector and B+ source to guarantee that no secondary loads were the source of the failure. Behavior in this case was unchanged.

Probing the collector of the HOT with a scope showed a grossly abnormal waveform. (Note that probing of the collector of the HOT is usually to be avoided in a working monitor or TV since the flyback spikes can exceed 1 kV. However, with the reduced power supply voltages due to the fault condition, this was considered safe). The 'on' portion of the waveform starts out near ground (correct) but starts ramping up toward the end of the sweep. The 'off' time shows a great deal of ringing. It was thought that this now pointed back to a bad flyback.

The base drive signal looked fine in terms of shape and levels. With normal drive signals, the ramped up 'on' portion of the waveform indicates a flyback of greatly reduced inductance and Q permitting excessive current to flow toward the end of the sweep - no doubt due to a short or internal arc.

Although the possibility of a bad HOT is small, it was an easy thing to substitute a similar transistor. There was no change.

At this point by the process of elimination, it was thought that the flyback transformer was the only other possibility. A closer inspection - actually a closer listening - revealed that in the instant that power is applied, there is a brief snap as though something is arcing internally following by a very faint sizzle indicating a continuous internal arc. Perhaps it was wishful thinking....

On the basis of this, a new flyback transformer was ordered. With great expectations, the new flyback is installed but what is this - no change. Same low voltage, same screwy waveform - darn. :-(

What next? Well, we have not tried substituting parts around the HOT. So, one by one, the caps and damper diode are removed. Using the Variac should be safe as an indication of a major improvement should be obvious before the HOT can be destroyed by lack of the snubber caps or damper diode. There, however, does not change in behavior in the least.

Give up for a while....

OK, there is only one more major item that has not been checked - the deflection yoke. A shorted yoke is always a possibility. How to test? Well, it is on a plug - remove it, no interlocks.

Running the voltage up on the Variac - poof. Oops, too late realizing that the parts around the HOT have not been replaced. However, this is progress. If there was no problem with the yoke circuitry, there should not have been a major change in pulling the yoke. Now, there was enough flyback kick on the HOT to have blown it.

OK, rummage around for a replacement. A BU508A should be an acceptable replacement for a BU508V at least for testing.

Replace all components and solder in new HOT. Monitor B+ while running up line voltage. B+ climbs nicely through the 60 V barrier and stabilizes at 120 V. While watching both front and back of CRT - after all there is no deflection and the screen can get a permanent navel quite quickly - there is now filament power with normal brightness of the filaments. This indicates that the flyback is probably running at a normal power level. Nothing on the screen yet. Maybe the monitor has a shutdown circuit that prevents anything from showing up without a video signal. Connect PC. Still nothing. Try user brightness and contrast. Still nothing. Finally, try the flyback screen knob. Now I can get a spot indicating that there is HV. Quickly turn it back down to protect CRT.

Next: deflection yoke testing. (Actually, about a year passed.)

So, how does one test a deflection yoke?

Here is a brief tutorial:

The deflection yoke consists of the horizontal coils and vertical coils (wound on a ferrite core), and mounting structure. There may also be some additional windings on the same assembly in some designs for various functions like pincushion correction and raster rotation. The following deals only with the actual deflection coils - the others can be tested in a similar manner.

If possible, compare all measurements with a known good identical deflection yoke. Of course, if you have one, swapping is the fastest surest test of all! Note: it doesn't have to be mounted on the CRT which would disturb purity and convergence adjustments but see the caution above about drilling holes in the CRT face plate!

- Horizontal - the horizontal section consists of an even number of windings hooked up in parallel with half of the windings on each of the two ferrite core pieces. In rare instances there may be other components (like the S-correction capacitor) on the same assembly.

  The horizontal windings will be oriented with the coil's axis vertical and mounted on the inside of the yoke (against the CRT neck/funnel). It may be wound with thicker wire than that used for the vertical windings.

  - Resistance check - This may be possible without removing the yoke from the CRT if the terminal block is accessible. Disconnect the individual windings from each another and determine if the resistances are nearly equal. Check for shorts between windings and between the horizontal and vertical windings as well.

    Typical resistance of the intact windings (at the yoke connector assuming no other components): TV or NTSC/PAL monitor - a few ohms (3 ohms typical), SVGA monitor - less than an ohm (.5 ohms typical).

  - Inspection - Look for charring or other evidence of insulation breakdown due to arcing or overheating. For the horizontal windings, this will require removing the yoke from the CRT since little if any of the windings are visible from the outside. However, even then, most of the windings are hidden under layers of wire or behind the ferrite core.

  - Ring test. See the document "Testing of Flyback (LOPT) Transformers". This deals with flyback transformers but the principles are the same. Disconnecting the windings may help isolate the location of a fault. However, for windings wound on the same core, the inductive coupling will result in a short anywhere on that core reducing the Q.

- Vertical - The vertical section is usually manufactured as a pair of windings wired in parallel (or maybe in series).

  The vertical windings will be oriented with the coil's axis horizontal and wound on the outside of the yoke. The wire used for the vertical winding may be thinner than that used for the horizontal windings.

  - Resistance check - This may be possible without removing the yoke from the CRT if the terminal block is accessible. Disconnect the individual windings from each other and determine if the resistances are nearly equal. Check for shorts between windings and between the horizontal and vertical windings as well.

    Typical resistance of the intact windings (at the yoke connector assuming no other components): TV or NTSC/PAL monitor - more than 10 ohms (15 ohms typical), SVGA monitor - at least a few ohms (5 ohms typical).

  - Inspection - Look for charring or other evidence of insulation breakdown due to arcing or overheating. The accessible portions of the vertical windings are mostly visible without removing the yoke from the CRT. However, most of the windings are hidden under layers of wire or behind the ferrite core.

  - Ring test - Since the Q of the typical vertical winding is very low, a ring test may not yield much useful information.

End of Deflection Yoke Testing 101.

In the case of this Emerson, the horizontal winding is actually 4 pairs of windings in parallel. It measures about .6 ohms. I use the first approach and unsolder the individual windings at one end to measure resistance. This is easy since the terminal block is at the top of the yoke under a plastic cover which snaps off.

Almost immediately, there is indication of a major anomaly: 4 of the windings measure about 4.7 ohms but the other 4 vary from 3.3 to 3.7 ohms. OK, so there ARE some shorted turns somewhere. Now, this is progress!

Since nothing is visibly charred on the outside, I draw a diagram of the precise position and orientation of the yoke and purity/static convergence magnet assembly and remove the yoke.

Wow! That is surely the problem. In one corner, where the windings are possibly near the tube DAG coating, there is a black charred spot. It seems to involve a number of individual wires.

Can I repair it? Possibly. With a pointy jeweler's screwdriver, I was able to separate approximately 8 or 10 wires from the windings that appear to have their insulation burned off. Oops! One broke - possibly due to excess force, possibly due to prior damage. Oh well, I will have to jumper that one.

Once they were all separate, I used a Q-tip and alcohol to thoroughly clean everything in the vicinity. There did not appear to be any other damaged wires. Then, I wrapped each one with a layer of plastic electrical tape. I repaired the broken wire with a piece of bare wire and then wrapped it with electrical tape. The repair is now well insulated though I do not know how well the plastic tape will hold up to heat, if any. I may go back and replace the tape in the future if this repair turns out to be successful.

Getting the yoke and magnet assembly back in place is no problem - there was some glue originally holding the yoke to the convergence wedges and the break in this showed exactly how it should be positioned. The magnet assembly is probably close enough. In any case, these can be adjusted later.

Ready? Power!

Guess what? No whine and big bright screen - way out of focus - appears almost immediately. Well, I don't know what it should do without a signal, so I move the whole affair over to the PC on which it was on originally.

Boot the PC, then power the monitor! Same behavior. Then, it occurs to me that the focus and screen (G2) pots on the flyback were never really adjusted after the initial test of the flyback because there had never been a raster with the replacement flyback.

Sure enough, a little twiddling and there is a picture. Then some fiddling with the yoke orientation to get it straight and the convergence magnets to eliminate fringing. Ouch! What was that? A stray wire bit me... It looks like one of those windings was never reconnected. (Maybe the picture was a bit narrow..) I will fix that and try to be more careful.

For the first time in a couple of years, this monitor is working - better than new.

Comments: Had a substitute flyback transformer been available, this process could have been shortened considerably. In this case the tester should have been believed.

One nice feature of the design of this monitor (whose specs are really nothing to write home about) is that the switching supply is fairly well short circuit protected and current limited. Therefore, it is probably virtually impossible for any fault to destroy the HOT through overcurrent (though apparently not through overvoltage) or other power components on the mainboard. Even with the shorted HOT, the power supply just whined a bit but was perfectly content despite that fact that the B+ line was dragged down to 3 V.

What caused the yoke to arc? There is no way of knowing but the location at a corner suggests damaged insulation. Magnet wire insulation is very fragile to begin with so any kind of scuffing during manufacturing is a failure waiting to happen. Perhaps it was bent too far at some point and then straightened out or scraped against something. Perhaps, expansion and contraction from thermal cycling caused it to rub against the CRT. Given the characteristics of magnet wire, it is quite amazing that these types of failures are not more common.

Repair Brief #77: Sony KV-2675R Color TV - Will Not Power Up

Patient: Really BIG fairly old 25 inch Sony console.

Symptoms: Pressing the power button results in a relay click and some evidence of high voltage (a bit of static on the screen) but no picture and only a slight hum from the speaker. Releasing the power button results in it shutting off. The standby LED is flickering.

Testing: No additional tests possible without getting inside.

When Frank asked me if I would take a look at a TV for him, I had no idea it was such a BIG TV. How will we put it up on the bench? And, for that matter, how will be hide it in the lab when those VIP types come around? After all, TV repair is not supposed to be our main occupation. (The latter problem was easily solved at least - it ended up in my office!)

Than I find out that it is Frank's landlord's TV....

This is most likely a problem in the standby power supply. Best to go get the Sams' Photofact before poking around. Checking the Sams' Technical Publishing (formerly Howard Sams') web site (http://www.samswebsite.com/, of course everything is done on the Internet nowadays even if checking the hard copy Sams' index is easier) reveals that there is no Folder for the KV-2675R. The closest is the KV-2670R. Well, that will have to do. Hopefully, the Sony engineers didn't get carried away with 'improvements' between those two models. I only photocopied the AC input/standby power supply and microcontroller pages assuming that since there were indications of HV, the deflection and signal circuits are probably fine. Hopefully.

First problem: how to get at the circuit board? Well, it isn't finding it or even the available free space around it - the cabinet is *mostly* empty space. Rather, working on the floor is just not convenient! So, Dave and I clear some bench space and man-handle this console up onto a regulation lab bench. I put some blocks underneath to prevent it from rolling off (it is on wheels). Now, it looks kind of strange but access is perfect. At least no VIPs are expected that day!

A couple of snaps, release a few cables, and the solder side of the mainboard is accessible. The components are even labeled.

Hey Dave, check the voltage on C114. "Uh, I don't see a C114". How about C115? "No, wait, yes. Around 1.5 V". It should be +5.1 V. OK, how about across C609? "Wait...... 47 V." Are you sure you are on C609? It should be 129 V. "Yep, 47 V." What is connected to it? "Just a sec.... From the plus side, D603 bar, C608, C114 plus,..." What about the minus side? "Let's see, L604, C114 minus,.." OK, that checks out. Here, I brought some caps just in case... Put this in place of C609. 10 uF, 150 V.

A couple minutes later. Ready, plug it in.

At once, there is lots of static on the screen and few seconds later, snow appears. As usual, reception even with our rabbit ears is terrible in the lab. We finally find a UHF channel that has a signal-to-noise ratio greater than about .1. A broken VCR (at least the blue screen wasn't broken) worked fine. Later, we would leave it on Channel 57 or something playing the usual afternoon cartoons.

I later tested the original C609 and found it to be totally open. Its rating was 10 uF, 250 V. A dead TV contributed one that was 10 uF, 200 V. That will have to do since Frank is leaving the country in a week (I wonder why!) to return home and there is no time for an MCM order. The maximum voltage on it should be less than about 160 V under any conditions so this should be fine.

At this point, the only remaining problem is that the TV seems to be finicky about powering on and off. Not due to any power supply problem but rather it appears to interpret the button press erratically. Suspecting contact bounce due to a dirty pushbutton switch, I had Dave swap two of the switches but this made no difference. Once it comes on, it is solid and once it goes off it is solid. Just, sometimes it will decide not to cooperate. This seems to be worse when it has been on for a while. Another capacitor?

I asked Dave to bring in a Sony remote control to see if it behaved the same way with that. I wasn't around when he did so but claimed that "it 'worked well enough for me' so I left it at that and told Frank to get the BIG TV out of the lab"! Well, at least Dave knows when to quit.

Comments: The flickering standby LED kind of guaranteed that it would be a problem with the standby power supply. Since there was some power, it had to be a simple problem like a dried up capacitor. Fortunately, this Sony was close enough to the model for which I has service data - most of the part numbers seemed to match - that finding the culprit was very easy. However, even if it had not been the case, some quick checks of the parts in the vicinity of the AC line input would have found the bad cap in short order.

---

78. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #78: Magnavox 31 Inch TV - Dropped and Fried

Patient: Magnavox 31" TV. This is what one would call one unlucky set. :-(First, it was used for a jungle gym by a colleague's 2 year old and fell off a low platform smack on its face (fortunately, no one was injured). About 6 months later, a truck hit a substation transformer resulting in excessive voltage on the 110 VAC lines. The resulting county wide power surge blew electronic equipment in dozens if not hundreds of residences. I am sure the insurance companies just loved it! (No claim was filed on this set, however, because it was already in bad shape - there are still some honest people in the world.)

Symptoms: Originally, colors were messed up across the screen resulting in areas of colors shifted between red, green, and blue. After the power surge, it was totally dead... I am not sure which was really the worse situation.

Testing: The front bezel was slightly cracked and there was an ominous rattle from inside. After the power surge, well....

When I first saw this disaster - the first time - the complaint was that all the colors were messed up. Once I was told the story, it was nearly certain that the cause was something mechanical - unfortunately likely to be in an inaccessible location inside the CRT.

First step: Remove back. Actually, let Tom remove the back. :-)

The only visible damage appears to be that the mainboard broke loose and is just sitting on the bottom of the cabinet. No real damage to the board itself or the circuitry.

Powering the TV reveals serious purity problems. A roughly vertical band in the middle has the correct colors which then transition in a rainbow pattern toward the upper left corner (red-green-blue). Similarly, toward the right edge, the colors transition once or twice. Not promising.

Manual degaussing does absolutely no good.

External degauss was attempted with power on to confirm that it was not a magnetization problem. Similarly, this does absolutely no good.

The yoke and purity magnet assembly seem to still be solidly locked in place and adjustment of the purity magnets has no useful effect.

The only conclusion can be that the shadow (slot) mask inside the CRT either deformed or popped loose due to the impact.

At this point, the TV was pronounced incurable and sent home to be used for video games hoping the kids wouldn't notice the weird colors or think that they were abnormal.

Six months later, a large truck hit a substation transformer. This apparently resulted in a 12,000 V feed falling across a low voltage line sending mucho excessive voltage to an unsuspecting neighborhood. It made the news in a big way.

Many many houses were affected with lots of blown stuff. Geez, if I could have driven around there for the next few weeks on trash days, I could probably have collected all sorts of late model electronics - much of it (as you will see) having easily corrected problems (as opposed to this TV).

Tom comes in one morning mentioning the power surge and I volunteer as usual. Sure, bring the stuff in (not really knowing what to expect).

So, this unlucky TV shows up again. This was a couple weeks after his toasted Panasonic VCR was brought in only requiring a new fuse.

In the case of the TV, it turned out that a fusable resistor sacrificed its life to protect the fuse. For testing, a jumper was used in its place but a proper replacement was ordered for the permanent repair. Sure enough, the set comes back to life. Unfortunately, the colors are still messed up...

There is one other possibility to at least reduce the severity of the color problem: refrigerator magnets. If a compensating magnetic field can be created, the beams might be convinced to hit the proper phosphor dots! The next day, Tom shows up with a bag of all sorts of small magnets and by the time I take a look, there are numerous warts pasted around the perimeter (as well as further back) of the CRT.

"Hey Sam, why do these magnets vibrate when they are brought near this thing on the tube"? This of course is due to the 60 Hz field current being pumped through the vertical deflection coils. The effect is very noticeable up to several inches from the yoke.

"Hey Tom, did I mention that the fat red wire here has about 25,000 V, this thing with the coils (the yoke) has 1,200 V pulses on it while the set is on, and that you probably don't want to let the TV fall over again with the picture tube all exposed like that?"

Well, Tom survived somehow.

However, poor Tom was only using a VCR's blue screen to position the magnets for a pure blue screen. What he didn't realize (and I forgot to mention) was that the geometry was being quite thoroughly messed up while the purity was being repaired. Thus, when we played an actual tape, the colors were now more or less correct but shapes were distorted. Oh well, you can't have everything. Tom will have to decide which will keep him (or his kids) happier.

Comments: On a 31 inch CRT, the shadow mask is a thin sheet of metal 2 feet across. Drop the tube on its face and it is likely to distort or pop free. This wasn't a slight bump as the bezel was cracked and the mainboard broke free. It has been suggested that in this case one should then drop the TV on its back to reverse the effects of the original fall. I don't think Tom is quite willing to try this....

79. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #79: ConairPhone Desk Phone - Almost Dead

Patient: Basic Tone/Pulse dialing 'Princess' phone clone made by Conair, Model SW-204. Don't they make blow dryers and back massagers?

Symptoms: One can just barely make out a dial tone - very faint. Buttons do seem to produce tones or pulses depending on the switch setting but these do not make it to the phone line. Side-tone does work.

Testing: Tried different cords (both base and handset), whacked and pounded it - no change.

Rich brought in both a Fisher VCR that eats tapes (boring - bad idler tire) and this cheapo phone. Well, it takes all types.... He said he was trying to determine why the phones in his house went dead and tried in the 'test' jack, wherever and whatever that might be. Then this phone stopped working everywhere else.

Indeed, plugging it into a known good phone line results in just barely being able to make out the dial-tone. Nothing else works.

I figure it is probably not worth spending a lot of time on this thing. After all, it is not what you would call valuable in any sense of the word. Check for bad connections, test semiconductors for shorts, clean the keypad. That is about it. Maybe I will get lucky. It has happened in the past.

First, the base unit. One screw to remove the cover. Not much in here. Just the bell (a real genuine gong, none of this piezo buzzer stuff). There is nothing here that is the least bit suspicious - the on-hook switch seems to be in good condition and does function even though you cannot really hear it too well.

The handset is more interesting. A bunch of transistors, diodes and rectifiers, other stuff, and a single chip.

Prodding the circuit board has no effect. Even my Magic Spit(tm) is utterly worthless - can you believe it?! No change except a couple of pops from the earpiece.

I check all transistors and diodes for shorts - none.

I remove the keypad rubber pad and check for stuck keys - none.

I was about ready to pronounce it dead-dead when a lone part on the bottom of the circuit board caught my eye. What is this? A blue diode? What sort of diode would dress up in *blue*. Checking across it reads about 50 ohms on my VOM. That doesn't sound right so I unsolder one end. Still 50 ohms. I can just make out the part number - ITT ZPD120. My ECG Guide shows this to be a 120 V 1 W zener diode.

For testing, I just leave it out since I don't expect any phone calls that might produce a ringing voltage (which is the only situation where there could be anything approaching 120 V outside of a lightning strike).

Sure enough, the phone now works perfectly.

I don't have anything like a 120 V zener in my junk box. However, a neon lamp would probably work in a pinch to protect against the ringing voltage or voltage spikes. An NE2 would have a breakdown voltage of about 90 V (and sustaining voltage of about 60 V) - close enough for now.

Later on I had second thoughts. Was that really a 120 V zener and not a 12 V zener? Unfortunately, I misplaced the bad diode on the basement floor and by the time I located it, the printing had been obliterated. Therefore, I did a little circuit tracing.

The zener was across the output of the bridge rectifier connected to the phone line. From the types of transistor (HV - 300 Vcbo sort of things) and high value resistors (100s of K ohms) I conclude that indeed the 120 V is probably correct. In fact, it would appear that a voltage divider is set up (100K/2K) such that one of the transistors would just turn on in response to the ringing voltage.

Just to be sure (well, for peace of mind - other parts would have blown if my conclusions had been incorrect), I dialed the phone from my computer line a couple of times to check that it rang correctly and didn't explode.

Comments: There is no way of knowing what caused the zener to go bad. Maybe ESD (Electro Static Discharge), maybe Rich's electrifying personality. Nah, forget that option! More likely he somehow managed to plug it into a power outlet.

The diode actually looks like an afterthought - mounted on the bottom of the circuit board across two pads with no component marking of any kind. The designers probably found out the hard way that such protection was needed!

Repair Brief #80: Sharp 13KM15 Color TV - Dead

Patient: Nice little older 13 inch color TV. Nothing fancy but probably worth some time, effort, and (someone elses) money.

Symptoms: Dead-dead-dead.

Testing: Not a cord or outlet problem.

Actually, Dave had been talking about buying a bunch of horizontal output transistors (as in 3 just in case) from MCM Electronics for several weeks. Seems this TV blew the HOT and a fusable resistor before I saw it. Finally, we placed the order....

The day after the parts arrive, he comes in. "Well, the flyback is arcing". So I asked him if he had tried taping over the location of the arc.

One week later. "Well, I put a bunch of layers of electrical tape over the cracked area of the flyback and then it started smoking".

OK, bring it in. Without knowing whether anything else has been fried by the bad flyback, it is probably not worth investing in a flyback. If the arc got into the signal circuits, anything could be fried.

The following week, the TV shows up. Without powering it up, I open it and then connect my series light bulb AND Variac gizmo. I really was just doing this for the entertainment value (not the shows) rather than seriously fixing the set. The friend of a friend of Dave who was our 'customer' had already decided at that point not to pursue a repair since there was no assurance that a new flyback would not be just the first of a long line of replacement parts.

My plan was to confirm that the flyback was beyond redemption and strip the carcass for parts (like the still surviving replacement HOT).

Now for the action! As the voltage is brought up, the light bulb glows brightly (from the degauss circuit) and then goes dim as it should but sure enough, the set starts smoking. Some closer examination shows that the smoke is not coming from the flyback but from somewhere *under* the mainboard. What do you know!? There are a couple 1/4 watt resistors tack-soldered in place. It looks like the location where a fusable resistor would live. What the heck. I remove the resistors and put in a jumper wire. As long as I use my series light bulb, it should not be a problem. And this is just for fun anyhow!

Now, no smoke, but there is indeed arcing under the bandage (electrical tape) Dave has installed on the flyback.

Now I cannot resist the challenge. I would really like to be able to get it working well enough to confirm that the rest of the set is undamaged. Well, first step is to rip off the tape and see what is actually there. Now, when power is reapplied, it appears as though the arcing is from within the area of the focus and screen pots.

I then unsolder the flyback from the set and pull off the jerry-rigged focus connection (no solder of course!).

So, I get out my hacksaw and Vise-Grips (OK, no Vise-Grips but a rather large screwdriver used as a pry-bar. You guessed it. I cut around the periphery of the focus/screen pot cover and pry it off. Interesting low cost design. The 'pots' are just screened on resistor material. The knobs just seem to have a sort of conductive plastic or rubber for wipers. Probably good enough.

After a little cleanup, I give it another try. Now, no arcing but of course, no picture either as the CRT screen (G2) is not connected. I can solve that! Some careful positioning of the focus and screen wire ends (hanging off of the CRT neck board) in contact with the resistor material on what is left of the flyback! This should work. However, adjustments will be really tricky. :-)

Sure enough, it is now possible to power up the TV and even tune in our favorite channel 57 broadcasting the afternoon cartoons.

I must have guessed pretty close - the focus isn't too bad and the brightness is about right.

Hey Dave, the TV is working... "Uh, yeh, sure." Really. Adjustments are touchy.... BTW, what was the value of that fusable resistor. "Probably 2 or 3 ohms." Why were there a couple of 22 ohm resistors installed? No wonder they smoked! "I noticed that.....a little too high, huh?"

Of course, Ed came over to watch all of the clowns at play (but from his usual safe distance, being a 5 volt TTL type).

As it turns out, the 'customer' reconsidered and has now decided that it would be worth springing for a new flyback now that we knew nothing else is broken.

Comments: No, I would not recommend this as a permanent repair. Even taping or insulating a flyback is somewhat risky if a new breakdown path develops. Had I known exactly where the arc was located, I probably could have done less of a hatchet job on the flyback retaining use of the focus and screen pots - knobs and all. The actual path of the arc seemed to be from a corner of the cover via the surface of the rest of the flyback to the core.

It was important to confirm that nothing else had been blown by the arcing (the original HOT and missing fusable resistor had been the first casualties). Having done this, one can confidently order parts knowing what to expect.

---

81. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #81: Sony KV-19TR20 Color TV - No Reception

Patient: Ravi's Sony color TV.

Symptoms: No reception. A/V input works fine.

Testing: Tried with antenna and output from VCR.

There apparently was a history to this set....

Ravi came in and said "I have a Sony TV that doesn't work."

Right, so what else is new? This isn't the same one Dave and I repaired before, is it?

"No, a friend had borrowed the TV and it broke about six months ago. He attempted to repair it by replacing the IF box, whatever that is."

How did he know to do that? Did he see it on the Net?

"Uh, perhaps. Now it doesn't work at all."

OK, bring it to the lab.

Sure enough, there is nothing when using the RF input. Connecting it to a VCR's RCA jacks results in a perfect picture. So, maybe the problem wasn't the IF box or maybe the repair wasn't done correctly. I, of course, expect that the original cause were the infamous bad solder connections Sonys are known for.

It didn't take long to determine the problem - nearly every pad to the IF box had been ripped off of the circuit board!

Hey Ravi, what did he use to repair this thing? A blow torch? I have never seen a worse soldering job. It took a minute or two, but Ravi finally realized what I was talking about. Hey Dave, you have to see this....

Hopefully, the new IF box wasn't actually damaged by the attempt or by being only partially connected (mostly not connected).

It required about 20 minutes to install jumper wires to the nearest component pins on each trace. Even where there was some sort of pad remaining, I added jumpers to be sure there would be no problems in the future. I just hope this IF box doesn't develop internal bad solder connections. Whoever ends up working on it will be in for a real treat. Guess who that might be? :-)

And, presto! Reception is now perfect - at least to the extent that can be tested in our lab which is to say, at least there is now snow and the VCR's channel 3 and 4 output works fine. Ravi later told me everything else was fine as well.

Comments: One assumes that those reading the repair guides have some minimal desoldering equipment. However, this episode prompted me to add a section on the need for proper tools to both the GE/RCA and Sony FAQs.

In this case, I am sure Ravi's friend didn't get his advice from the Net as there was a problem report form from "Tom and Joe's TV Repair" or some such place (hope not anyone reading this). So, the set was probably taken in for an estimate but Ravi's friend figured he could save some money..... Too bad I don't charge for this stuff - I could have cleaned up!

---

82. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #82: Emerson CGA Color Monitor - Dead

Patient: Andy's friend's cast-off Emerson Model 1400EMA RGB as in CGA monitor.

Symptoms: Dead as a brick.

Testing: Tried with and without a source of video. Of course, coming up with a CGA output was a bit of a challenge but a classic Toshiba laptop came to the rescue.

So I found this thing sitting in the middle of my office floor one morning. As usual, I just stepped over it and went on with my business until the donor came around to say something.

So Andy, what is this thing??? "A friend of mine was cleaning up and was going to throw it out. Of course, I said I knew someone who would probably take it. He thought it could be fixed." How? "I don't know and I haven't tried it."

Of course, Andy is a MAC person so the last comment, at least, is not at all surprising. :-)

The monitor is indeed very dead. Getting at the mainboard proves to be quite a challenge. There are many shields. Even just being able to probe the bottom of the mainboard requires 20 minutes to remove countless screws.

No fuses blown.

B+ appears to be present on the output of something that looks like a linear regulator. It is also present at the collector of the horizontal output transistor (HOT). Nothing appears overheated. Since there is absolutely no response of any kind - no initial static or even a tweet - it is not likely in HV shutdown.

Checking at the base of the HOT, there is no drive of any kind at any time.

To determine how base drive is obtained requires tracing back from the base of the HOT. This goes to the usual driver transformer. The primary side of the driver transformer appears to go to a multilegged chip - likely a combined H/V deflection processor.

There is nothing on the pin of this chip that goes to the driver transformer but there is apparently power to the chip. The output appears stuck low. Wait... There is just a hint of a pulse at the horizontal frequency (around 15.7 kHz) free running. What about on the supply side of the driver transformer. Is the chip shorted? I unsolder the pin. Still almost nothing on either the isolated pin or the transformer. That cannot be right - that transformer pin should now be pulled high. Double check - yes, there is power to the other side of the winding.

We have an open transformer primary!

Unsoldering the transformer (4 pins) and testing out of circuit confirms an open winding. So, how could that happen? It really could only be a case of a manufacturing defect. There are no signs of overheating or other stress.

Now for the repair.....

This is a simple straight core ferrite design so it is easy to get at the windings, at least.

The primary of the transformer is wound *under* the secondary. First, I peel off the mylar insulating tape and unsolder the start of the secondary. After noting the direction of the winding, I remove the wire saving it as I will just replace it when the primary is fixed. It is only about 20 turns.

I then peel off the mylar insulating tape between the two windings.

Fortunately, the break is just about at the terminal so that it is not necessary to unwind the entire primary (which has many more turns - the ration is probably at least 4:1, perhaps much higher.)

I inspect the other connection as well but it seems fine.

After unwinding one turn (no one will ever know) I carefully resolder the wire making sure not to nick or damage it.

Then, I replace the mylar tape, secondary winding, and outer insulation.

That should be as good as new.

Sure enough, the monitor comes back to life.

Just when I thought I was done and about to button up the case, I try is once more. What is this? No vertical sweep. OK, must be a service switch inside somewhere that got knocked to the service position. Yep, after a couple of minutes of panic, I find it toward the front of the mainboard. I probably bumped it when replacing the transformer from the top of the board. No, I really did not want to disassemble this thing again.

Comments: The only possible explanation for this sort of failure is that the wire was nicked during assembly and eventually, the small but persistent vibration of the transformer at the horizontal frequency and/or thermal cycling finally caused it to break free. Considering the wire size (probably #34 at least), such damage could happen quite easily. At first I was concerned about some cause like a shorted chip resulting in overcurrent but I do not believe this was such a problem.

Although this monitor is much much simpler than modern SVGA monitors, this sort of problem could occur with either.

---

83. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #83: Tatung CM1495 Multisync Color Monitor - Dead

Patient: My cousin's VGA monitor. OK, actually my cousin's 3 kids' VGA monitor. OK, actually my Tatung CM1495 on loan to my cousin's 3 kids.

Symptoms: Dead-dead. Not much info. "The computer doesn't work" is about as much as was forthcoming.

Testing: No response of any kind when plugged into computer or wall outlet.

I had put this state-of-the-art 386-20MHz system together from spare parts for my cousin Kathy's three kids (ages 8, 8, 9) to use. Kathy knows next to nothing about computers though she does somehow manage to use a Mac Plus for letters and rumor has it that she has even logged onto AOL at least once from the PC.

I originally found the Tatung monitor along the curb with some cast off Atari PCs and an EGA monitor. I grabbed the monitors, too bad about the computers! Both monitors worked fine - no Repair Briefs material at that time.

About 3 months after giving them the system, I get a frantic call from the oldest: "The computer doesn't work. The screen is dark but it makes some noises like it wants to work." Did you see what happened? "No, it just wouldn't come on." OK, I will be over. Just in case (actually a sure thing), I take a spare NEC Multisync II to be used in place of the likely dead monitor.

Sure enough, not even the power light is lit. Swapping the monitors makes the kids happy and Kathy as well since she doesn't need to keep hearing their whining.... I have offered repeatedly to give them another pair of computers but there really is no room......

Getting inside this monitor isn't too bad and the power supply is a separate unit which is easily removed - 4 screws or so and 4 or 5 connectors. It will also be possible to test the supply outside of the chassis which will be convenient.

One problem appears immediately - a blown fuse on the AC input to the power supply. Testing shows a dead short. The posistor is on a separate fuse and it is fine - darn, that at least would have been easy. :-(

It takes a few minutes of unsoldering various components to discover the problem - the main switching transistor of an STK7406 switching regulator is shorted. Unsoldering that single pin restores resistance to normal.

There are actually two virtually identical sections to the power supply board. Both use similar STK parts and have their own apparently independent feedback for regulation. However, only one of these is controllable via a signal from the mainboard - this is likely the deflection B+ which must vary based on scan rate. I considered swapping the STK7406 for its mate but decided that not only was that risky but I really would be sure of what I was seeing with only one side active.

So, I at least need to order a new STK7406 but what caused it to go bad?

This is where not knowing the actual events that led to failure will always leave a lingering doubt. There are no other obvious problems. Was it left on overnight? Perhaps, without video input? Would this matter? Did it overheat? Were the kids screwing around with Windows or switching screen resolutions? (The last one I rather doubt as they have strict instructions which appear every time the PC boots not to mess with it!)

I test nearly every electrolytic capacitor on the power supply board with an ESR meter - all appear fine. No bad solder connections are in evidence. There are no other shorted semiconductors.

OK, I will order the parts and just be very careful in the initial testing.

Three weeks later......

The new STK7406 and fuse are installed. I am going to start with a Variac and 100 W light bulb to be safe. The power supply board is propped up next to the monitor with suitable insulators to prevent shorts.

Power! The light bulb comes on brightly and then dims out as it should. There are some erratic flashes on the screen at around 100 V - jumpy vertical as the scan seems to start up and die. Well, that could just be too small a light bulb.

Next, I try a 150 W PAR floodlight. Not much different. At low line voltage, bulb glows quite brightly as though there is a bad region of input voltage where excessive stress may exist. It doesn't seem to recover at normal line voltage.

I will give it one more chance before declaring there to be other problems. Now, with a 300 W light bulb, there should be no excuses! Hear that?

Sure enough, bringing up the voltage slowing results in the bulb glowing brightly at lower voltage but it recovers when full line voltage is applied and a normal raster appears. Watching the glow of the bulb is instructive as my test PC boots - it increases in brightness just a bit. Then, when switching into Windows at 800x600, the brightness increases another notch. Still just barely glowing.

I put a clip-on AC ammeter in the line circuit but this really doesn't show anything more than the light bulb. Current is well within specifications. Only a comparison with an identical monitor could truly show up any difference.

Removing the Variac and using the power switch results in no sudden increase in bulb brightness except due to the degauss coil (the first time after having been off for a while). Thus, it really doesn't like low line voltage. Could a brownout have been the original cause of the failure? How about flipping the power switch quickly off and on again?

Comments: This is a case where the failure is obvious but the cause may never be known. I am tempted to leave the light bulb in place all the time when it is used. Whether that would save the STK7406 from subsequent failure should the same conditions arise again I do not know. In the meantime, the kids are using the NEC which interestingly appears to use a very similar design as I found out when swapping a mainboard on one of these for my friend Bill. The external controls and internal construction are too alike to just be a coincidence. The Tatung is probably a reduced cost knockoff of the NEC MSII.

Repair Brief #84: Sony Portable CD Player - Dead

Patient: Arnold's portable CD player (I don't recall the exact model but it is one of those that still would set off a metal detector). The optional battery pack is missing.

Symptoms: No response of any kind - not even the display - using the AC adapter.

Testing: The AC adapter tests fine. I even tried another one without any better success.

The first real test is to determine if the CD player will work from the battery input rather than the AC adapter. The normal battery pack is a 4 V rectangular lead-acid type.

Four volts is close enough to 5 V minus a diode drop so I connect the battery contacts to a logic supply in series with a handy diode I found sunning itself on the floor...

Sure enough, all functions are normal. Hey Arnold, it works fine with this nice 100 A power supply but it may be just a bit too heavy to carry around. :-)

So, the problem is in the power circuitry. I suspect that the AC adapter output is supposed to be converted to 4 V from which all the CD players circuits operate.

The bottom comes off after removing just a few micro-screws but this is one of the all metal super thin Sony Discmen - and impossible to access for repair.

The power input/regulator/converter is all crammed on a 1/2" x 3/4" circuit board with lots of very very tiny surface mount parts. Only the solder side is visible. Thus, the surface mount parts cannot be probed without additional disassembly. There are no obvious cold solder joints or other evidence of bad connections. The DC jack seems in good condition and checking voltages with a multimeter reveals that power is making its way onto the board. Something is faulty in the power conversion circuitry.

So, I have two choices:

1. Spend a semi-infinite amount of time riping the player apart and attempting to check microscopic surface mount components, reverse engineer the circuit, or attempt to locate a service manual or, :-)

2. Hey Arnold: do you care if the battery pack can be used at all - ever??? "No, It died after a few weeks and I

never bothered with it again. Why?" I can rig a regulator to fake out the thing into thinking it is running off battery power when it is actually running from the wall adapter. "Sure that would be fine. Whatever works."

So, I added the following regulator circuit and mounted it inside the battery compartment.

```
                D1           I +-------+ O          D2
    Vin (+) o----|>|---+-------| 7805  |-------+----|>|----o Vout (+)
              1N4007   |       +-------+       |  1N4007
                       |           | C         |
   Sony 9 V          +_|_ C1       |          _|_ C2      Battery
   adapter            --- 10       |          --- 1 uF    terminals
                     - |  uF       |           |
                       |           |           |
    Vin(-) o-----------+-----------+-----------+-----------o Vout (-)
```

An aluminum plate (a piece of roof flashing) was attached to the regulator to serve as a heat sink. D1 provides reverse polarity protection. D2 reduces the output of the 7805 by one diode drop. This produces about 4.3 V under load which is close enough to the output of a fully charged batter pack.

Wires were soldered directly to the DC jack and routed into the battery compartment. The original connections to the internal voltage converter were cut.

OK Arnold, it seems to work fine. "What do I owe you?" Only charge is that if you ever decide to dump it, send it to me. It is a nice example of Sony equipment when the Sony name meant something. "Sure."

Comments: I could have made this into a major time consuming repair or opted for a short cut. Since the battery was never used, why spend a lot of effort when a simple regulator could replace the functionality of the defective circuitry? In principle, the original wiring could be restored - and then the original problem could be remedied. For now, it works fine as far as I am aware.

Somehow I don't think I will ever see this player again as Arnold has since moved to Japan. :-)

Repair Brief #85: Lambda LUS-8-12 Switching Supply - Fried

Patient: Surplus Lambda LUS-8-12 12 V 1 A switcher - a cute little supply that I was using to test an automotive radio/cassette when something went horribly wrong. :-((There was nothing wrong with this unit that a new belt didn't cure - boring.)

Symptoms: Fuse blew. Of course, what did I do? Put in a larger fuse! Then other stuff blew.... I just figured it blew due to the overload, not to its parts shorting out. Right. :-(

Testing: It doesn't take a series light bulb, Variac, or rocket science to now see that this is a very blown power supply with a dead short on the power line!

OK, so this was from my younger days and was the first switchmode power supply I had ever attempted to repair other than bad connections and the like. It was also the first (and hopefully, last) such supply that I blew so completely and in such a spectacular manner! (I won't mention that other one that billowed smoke from its main filter/doubler caps after blowing the switchmode power transistor due the slip of a scope probe....).

The original problem was a result of miswiring of the power inputs to the radio/cassette: a clip lead was shorting +12 to ground. No problem - these supplies are short circuit protected, right? WRONG! Or, at least, not entirely. I may have been operating it on a Variac and increasing the voltage gradually without realizing that there was no voltage across the power inputs to the radio/cassette. At some point - POW, the fuse blew with a bright flash. It was all down hill from there!

This is a really cute little cased switcher which is the only reason I spent several hours and $10 or so for parts to repair it. It was more a challenge than anything else. I may never use this supply for anything again before the Sun becomes a red giant. :-)

Known casualties in the parts department:

- Line fuse.
- Switchmode power transistor.
- Fusable resistor.
- HA17339 (LM339) quad comparator.
- 5.6 V zener diode.
- 1N4148 signal diode.
- 2SD467 transistor.

There may have been others - I lost count.

I suspect that only a couple of parts blew at first but the rest of the components let out their smoke when powering up for the second time. There is no way to know for sure at this point and I am not about to recreate the disaster!

All the fried discrete semiconductors were dead shorts so it just was a matter of checking each with a multimeter. The HA17339 wasn't totally shorted but had a low resistance on its power-ground pins so I guessed that it, too, was bad.

I traced out the entire circuit which wasn't fun or quick. It took a while to determine that the HA17339 was just a common LM339 clone - Internet search engines didn't exist back then.

I replaced the HA17339 with an LM339 in a socket. Removing the original part wasn't easy even with my SoldaPullit - I damaged a couple of pads which needed to be jumpered.

For testing, I substituted a BU406 which I had handy from a long stripped video display terminal.

Using a Variac (no light bulb at that time), the supply came up properly and ran without smoking. I then installed the proper transistor. Next power-up it worked fine but when I removed the Variac and plugged it directly into the wall, it was lifeless again. I feared the worst but as it turned out, only an underrated resistor had opened (the fusable resistor I had temporarily replaced with a 1/4 watt film type). After installed the proper resistor, it seemed happy as before. I just will now know not to attempt to drive short circuits!

Comments: This was my first exposure to SMPS repair and also to 2S part numbers. When I first ordered the 2SD467 it was a guess - that the part in the MCM catalog was really what I wanted. Well, everything has to have a first time. If this weren't such a cute little supply - and I wasn't to angry at myself for blowing it up, the time and effort would not have been justified. In fact, it was relegated to the scrap bin until I saw the light with respect to parts identification.

Many SMPS designs are robust only near full line voltage. At lower voltage, the pulse width modulator struggles to achieve regulation and succeeds or kills everything unless the designers specifically took these conditions into account and provided appropriate current limiting. Just claiming that a supply is short circuit or overload protected is not enough. This is one reason brown-outs can be hard on equipment.

Repair Brief #86: Fisher Power Amp with Blown Channel

Patient: Derek's friend's Fisher component 80 W/channel power amp. It looked kind of nice with those LED power meters. No comments about Fisher quality, please. :-)

Symptoms: The right channel is stone dead. No hum, no noise - not a thing.

Testing: Double checked inputs and tried several, whacked it (to wake up any speaker relay) or bad connections, switched input selector back and forth. No effect of any kind.

With absolutely no hum or noise on the dead channel, the problem is probably not in the input circuitry or preamps. There would be some evidence of life in those cases - some low level hiss at least.

The nice thing about stereo equipment is that there are two of nearly everything. Thus, comparing signals, voltages, and resistances can be effective even without a schematic.

Unfortunately, these assumptions led me astray......

Big audio amps are often designed along the lines of power operational amplifiers. They have several voltage gain stages and a final power/current gain output driver - with negative feedback around the entire thing. One implication of such a design is that intermediate signals may look strange even when the unit is operating properly.

In this case, the intermediate signals on the good channel looked like hum and noise while the similar signals on the dead channel appeared to be normal audio.

Among the problems found were bad solder connections on the pre-driver transistors due to their running hot (no heat sinks) but repairing these had no effect on the original problem.

Fuses were all good. Checks of major power rails showed them to be healthy.

Finally, I was convinced that the most expedient approach would be to swap the finals - STK0080 hybrids. There is always a slight chance that swapping power components can blow the previously good part but since everything else appeared normal, what the heck. They are only 10 pin devices and less than $20 in any case.

Five minutes later, sure enough, the right channel seemed to be working normally and the left channel - was, well, missing a hybrid!

However, now there appeared to be some noise and erratic behavior when powering up. One or both channels would not come on as soon as the speaker protection relay clicked but at some random time later. The input signal source selectors did not appear to have any effect on the noise but tapping the relay revealed that it was at fault. Fortunately, the top poped off easily and some contact cleaner and burnishing restored it to health at least temporarily.

Comments: As noted, most stereo equipment has a distinct advantage when troubleshooting in having duplicates of nearly everything but the power supplies. Therefore, it is pretty easy to locate obvious shorted discrete parts by simple comparison measurements. Even testing of the hybrid modules may have been possible in this way though I did not think to try. However, with a design depending on a closed high gain feedback loop around nearly the entire system, actually looking at signals can be misleading unless you are aware of the possible implications of what is being observed. In this case, the power supply rails had substantial hum (normal) and signal points did not have anything resembling a signal on the working channel - rather it was just low level noise and hum. Buried in there somewhere was the actual signal. The similar test points on the bad channel had a reasonable audio waveform because without proper feedback they were operating at a much higher level than was normal. It was probably highly distorted but was more recognizable as an audio signal.

Repair Brief #87: Mac Plus and Original Apple 20 MB Hard Drive - Multiple Problems

Patient: Garage sale Mac Plus with original Apple HD20 (non-SCSI). It was marked $50 but before I could make an offer, the price somehow dropped to $25. OK. No keyboard or mouse, however. Well, can't have everything. At least with a Mac, basic functionality can be determined without any user input devices!

Symptoms: Powering without keyboard or mouse seems to result in attempt to boot from diskette which is stuck in the internal drive. However, without a keyboard or mouse, it is not possible to attempt to eject from software. The paper clip in the eject hole doesn't work either - it is jammed. The hard drive does not spin up.

Testing: I borrow a mouse and determine that the computer itself seems ok except for the uncooperative diskette drive. The hard drive remains dead.

This poor little Mac was sitting by itself along the side of the driveway at this garage sale that also had other interesting items but the Mac seemed almost useful. I probably would have gone higher than $25 but wasn't about to argue. (Recently I picked up a Mac Classic at a flea market for $5 but that is another Repair Brief!) They did say the hard drive probably didn't work either....

In fact, it came in handy when my cousin was given a Mac Plus system with a dead flyback. A flyback transplant confirmed that nothing else was broken and got her up and running nearly instantly. :-)

First step is to see what is wrong with the diskette drive.

Of course, opening any of the single piece Macs is always a joy unless you have the proper foot-long Torx (or hex) wrench to get at the two screws under the handle. I did not and so was forced to improvise. I ground down the end of a triangular metal file to a shape approximately a Torx. As they say "If it works, use it." And, no, you don't need an Apple approved 'case splitting tool' to get the back off. With care, a pair of wide flat blade screwdrivers work fine without damaging anything.

With the cover removed, it is a simple matter to remove the diskette drive. A close examination reveals that a little bracket that is part of the eject mechanism was somehow bent out of shape - short work for my needlenose. The grease - a common problem with older Mac diskette drives - appears to be in as good as new.

It doesn't appear to be defective or weakened in any way. My guess is that someone attempted to pull a diskette out of the slot by using a pair of pliers rather than the paper clip or software. I cycle it a few times using the slightly abused but still serviceable diskette and a paper clip - as good as new!

After replacing the diskette drive I confirm that it will boot with a known good system disk. It even ejects on command. What more can you ask?

Next, the hard drive. There seems to be no sign of life from this. The power switch does nothing as far as I can tell. Possibly the ready light flashes on momentarily, but that is about it. No spinup sounds at all.

After removing the cover it is necessary to blow out several years worth of accumulated dust before checking anything electronic. The controller and drive itself do appear to be receiving power - the chips get warm at least. :-)

Could it be sticktion? This system probably has not been used in a quite some time. Fortunately, this is one of those drives ('some user serviceable parts") where the spindle motor flywheel/magnet is readily accessible once the drive is removed from its mounting.

The flywheel is quite stiff. Actually, this is probably not actual sticktion where the heads glue themselves to the platters but just dried hardened grease. I spin the flywheel back and forth a few times by hand. This seems to loosen it up considerably. I then reinstall the drive on its mounts.

Sure enough, it now spins right up and the Mac even boots - slowly but what do you expect? - revealing some useful word processing programs, tons of games, and a database of horticultural information. Not bad for an hour's work.

I can hear you all saying: "Joy, a computer with the power of my digital watch and the features of a boat anchor!".

Sure, but (1) this was a few years ago and (2) this became the one of the Macs for my cousin's three kids (who now have a state-of-the-art 386-20 as well)! I still have the hard drive but really don't know the location of the system unit as we have played musical chairs with the Macs several times at this point (but I would have heard if it stopped working).

Comments: Whether you like Macs or not, one cannot deny that the Mac Plus was a cute little computer that could do useful work and had a user interface that surpassed anything from Bill Gates at the time - perhaps even today. Most of the time, problems with these computers were easily diagnosed and easily repaired - burnt Molex connector pins and blown flybacks are two popular failures.

I have not had a reoccurrence of either the diskette or hard drive problem despite it not being used all that much but I guess 'not all that much' beats 'not at all' by a wide margin.

---

88. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #88: HP DeskJet 500C Color Ink-Jet printer - No Printing

Patient: Color version of my HP DeskJet Professional. This is an older but nice little printer. The separate black and color cartridges make it much more convenient than some of the newer models.

Symptoms: Goes through all the motions but nothing appears on the paper. Cleaning/priming doesn't help. Both cartridges are not likely empty!

Testing: I use the built-in test initiated by holding down the FONT button while powering up. Nothing on the paper.

So Joe comes by and mentions that this printer has been acting up for several months now. This is on his son's computer so I imagine Joe is not that eager to have it working properly - considering the high cost of color cartridges.

He did tell me that he called some place and got a flat quote of $140 to repair it excluding any needed cartridges.

"OK, drop it off but I don't know when I will get to it."

The printer shows up a few days later - no scrap paper to test it with. At least he provided the power pack!

Fresh from my experience with my DeskJet, it takes about 30 milliseconds to locate one problem: the rubber boot that seals the priming station is nowhere to be found. I am not at all surprised that printing is erratic without this. Priming would be useless without the suction seal. Now, I wonder where it went.....

As with the original DeskJet, the top pops off after releasing 4 catches near the corners. Ah ha! There it is... Shading itself on the mainboard! Did some overzealous manual cleaning cause it to pop free? Nah, I doubt anyone in that house would realize that such things need cleaning. It may have just popped off from one of the automatic cleaning cycles - it does seem a bit lose. However, in all my subsequent activities, it stays put just fine.

I clean the contacts on the cartridges and the ribbon cable as well.

Since this hasn't worked for a few months, I clean the cartridges by hand just to be sure - some warm water, patted dry with lint free paper towels. A little blowing in the vent hole on top of the black cartridge, no vent holes visible on the color cartridge.

Ready?

Sure enough, the basic test patterns come right up. Only a couple of nozzles not firing. More cleaning, blowing, priming. OK, now B/W seems to be fine but there is only a hint of color - maybe yellow.

Even when executing the ALIGN command, almost no color (magenta) shows up.

I try more washing of the color cartridge. Now, there is a hint of the magenta alignment marks but they are spread from here to kingdom-come. In other words, a vertical line prints as a scatter diagram of dots!

I try some cleaning cycles. These prime the cartridge and then should print stripes of each color. At first, only yellow shows up. After 4 or 5 attempts, there is some evidence of cyan (blue) and magenta (red) appearing at the start of each line but they then tend to die away.

OK, that could just be an empty cartridge. Yellow seems to be fine and there really isn't anything different about it. (This is not surprising as yellow is the least used color.)

So I call Joe: "You know how they were going to charge you $140 to service the printer (hint hint - never works with him! Maybe if I didn't make it sound so easy....), well it appears to just be that a rubber part popped loose and the color cartridge appears dead." You mean it prints in black? "Yep, as good as new."

Two hours later, a new color cartridge shows up.

And, sure enough, this works just fine out of the box.

I recommend that he obtain replacements for the two rubber boots, at least, as they do seem to be on their way out.

Comments: Once again, a simple cause with dramatic consequences. I am still amazed that ink-jet technology works at all given the simplicity of these printers. Of course, that simplicity masks some very sophisticated and precision technology that goes into the cartridge/nozzle construction and controlling firmware.

Nothing serious ever seems to go wrong with these older DeskJets. Now all I need to do is locate a parts source for the plastic guide bar that broke in the DJ855C at the office!

---

89. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #89: Craftsman Eager 1 Lawn Mower - Rod Disaster

Patient: Garage sale Craftsman Eager 1 - 4 HP, 22 inch, self propelled, electric start. $10. Seems to have had some hard use but not bad, I was thinking.

Symptoms: Although there is plenty of gas in the fuel tank, it will not start and shows no signs of even wanting to start.

Testing: Doesn't start at all - no way, no how. There is no sign of even a weak attempt at turning over.

The seller mentioned that all it needed was to have the carburetor cleaned. This made sense though I wouldn't have trusted him as far as I could throw him. :-)

After yanking on the starter cord for a while, I removed the spark plug - dry as a bone. Squirting a couple teaspoons of gas in through the spark plug hole, replace the plug, then crank - and it will sputter to life and run for a couple of seconds. So, the carburetor is a good bet.

Removing the float carburetor on a Craftsman engine is a simple matter - two screws, the fuel hose, and the throttle/governor linkage.

Before taking it inside, I unscrew the bolt at the bottom and drain the remaining gas in the float bowl.

On the bench (actually, on top of a wad of newspapers on top of the washing machine), I disassemble the carb. What a mess! This must be 10 seasons of neglect - icky disgusting green caked on muck. After removing the rubber gasket (as it may be damaged by harsh solvents), liberal use of carburetor cleaner and a roll of paper towels are able to remove most of the build-up. I recall that there are critical holes - orifices - in that bolt. Using some wooden tooth picks, I am able to clear it down to the shiny brass.

There, that should do it.

Reassembly is straightforward - or should be. Now, which hole did that throttle governor wire go into???? Well, that one looks correct but I wonder...

Tighten the screws, replace the fuel hose. Ready?

Wow, that started right up. Might it be running a little fast?

A quick check of the oil. Maybe a bit low. Let me test the mower a bit. Then I can change the oil and check out the air filter, spark plug, etc.

So I mow the back yard. This is a self propelled but the drive engage-lever doesn't seem to stay in the selected slot. Well, something else to take care of later.

Is it running fast??? Even on slow speed, it sounds more like my other mowers on fast. Try fast. That isn't right - sounds more like a 2-stroke. Back to slow.

Bang! Ding! Clunk! Arggggg! Ever get that sinking feeling? Well, I got it.

Something bad happened. Or, as Luke Skywalker liked to say in Star Wars "I have a really bad feeling about this." Or was it C3PO. Well, no matter.

After checking for something under the deck (I didn't really expect to find anything), I had to come to the conclusion that there was a major mechanical failure inside. :-(

That is when I took a closer look at the oil level. Dang - it was much worse than I thought at first. In fact, one could say that all that was left really was the sludge! Geez, what a disaster.

Without even moving it from the spot on the lawn where it died, I start to do the disassembly (or perhaps, autopsy would a more accurate term).

Off comes the cylinder head. Rotating the blade or flywheel no results in no movement of the piston and it is not possible turn it through a complete revolution. I never did find one of the head bolts amongst the weeds....

Unbolting the engine and taking it into the basement:

Off comes the blade. As expected, the blade shear key is broken. Later I discovered that the flywheel shear key was also - sheared.

To remove the front wheel drive pulley requires some careful filing of the burrs on the keyway slot. This will also prevent damage the main bearings when the crankcase (sump) cover is removed. At least I as thinking rationally enough to take these precautions.

Unbolting the cover and a little tapping - darn, the gasket tore. Oh well, it probably would need to be replaced anyhow.

The extent of the damage is now clearly evident (amid the icky disgusting dripping black sludge). Maybe more newspapers would be nice.

The connecting rod is partially broken off from the cap. One bolt is still hanging loosely but the other bolt is laying in the bottom of the crankcase. There is a chunk of the rod laying there as well and a big ding has been taken out of the soft aluminum of the crankcase when the broken end impacted (but that is just cosmetic damage).

Arggggg. This won't be cheap.

Was it lack of oil? Was it the apparent overspeeding? Was it both?

Close examination of the broken parts reveals:

- There was some overheating - there are brown deposits on the rod and cap in the vicinity of the crank bearing.
- The bolt that was sitting by itself had backed out on its own and just dropped off - the threads and hole where it mounted were undamaged. It was not ripped out.
- Without the second bolt, the constant pounding of crankshaft/piston actually distorted the cap until it mashed

into the crankcase and broke into three pieces.

- There is scoring on the crank pin but it does not appear to have been caused by the current problems but would seem to be a result of normal wear and neglect. There is no evidence of overheating (blue tinge, etc.).

So, I tried Sears for a replacement. Unfortunately (or perhaps, fortunately, as we will see), I didn't have the 27 digit engine number so I couldn't get the time of day let alone an estimate of what a new rod and cap would cost.

Probably about $25 was the closest they would come. Though, I wasn't exactly sure they even knew what a connecting rod was! Fan belts was more their speed.

Well, I am not going to spend $25 on a $10 lawn mower.

I also tried a lawn mower repair shop. They were even worse (still would't give me the time of day) but quoted $45 anyhow.

That evening I emailed to a fellow Netter among other things that I was thinking of writing a lawn mower FAQ (not actually describing the disaster of the afternoon).

> "Speak of the devil.... I swapped cranks in an 'Eager-1' (Craftsman) mower this weekend for a friend. His wife ran into the curb and, well, the shaft was about 9 degrees bent. :-/ He picked up another mower that was 'stripped' but the crank was there... So, it was pretty simple actually. Started the first pull too. :-)"

Hey, where did you get the replacement? What did you do with the rest of the carcass? You wouldn't happen to have a connecting rod by any chance???

> "I'll check. Does it have a slant gate or a perpendicular to rod? I ask because there are two types, the straight and the slant type."

Thanks. It is the slanty type. Here are the dimensions....

> "I got the piston+rod for you. The part # is 25-0-25 (rod), 30-0-?4 (cap), 5-0-66 (piston, includes shaft but not clips, sue me. :-) It's the slant-gate one. Let me know if the numbers jive..."

Perfect. The '?' in the 30-0-?4 even matches. The piston isn't the same but my piston is fine (send the piston along anyhow, though, you never know when these things will come in handy.

Well, that wasn't so bad. The price was right - just shipping.

The parts that arrived were in perfect condition!

Hey, how many hours on that mower?

> "Only about 25 hours before the incident with the curb. :-("

I did some rough measurements of clearances using the new rod+cap on my beat up old crankshaft. The crank pin clearance is marginal (large) but no way I am going to hunt down a new crankshaft. It will have to do.

In order to assure that no metal chips are hanging around anywhere, I completely strip my engine, wipe down the inside of the crankcase, and blow out the oil passages, etc.

Everything goes smoothly until I realize that I didn't make note of which way the piston goes (there is a right way and a wrong way) but the Chilten small engine manual comes to the rescue. (Pistons are not symmetric - the piston pin is slightly off-center to account for the direction of crankshaft rotation and the direction and center of force. If it is installed the wrong way, at the very least, there will be excessive piston slap; at worst, parts will just bind outright.

Tightening the rod bolts - the most critical as far as proper torque is concerned - is always fun. It is just possible to get my torque wrench with a 3/8" to 1/4" adapter and a 1/4" socket in place into the confines of the crankcase with the crankshaft in one particular position and alternately tighten the bolts to specification.

All the other parts go together easily. I obtained new gaskets (actually bought them at that lawn mower repair shop) but reuse the old head gasket until I am sure everything inside is fine. Later, I will install a new one.

Timing is obvious since there are marks on both the crankshaft and cam gear.

To assure that the oil pump passages are clear and the pump is working before total reassembly, I add a little oil to the sump, remove the test port screw, and frantically crank the engine with no spark plug installed. After what seemed like the 199th or 200th pull, I realized the darn thing had electric start. Plug it in, push the button, oil starts trickling out of the hole almost immediately. I then replace the screw and then tighten the sump bolts.

I also repair the front wheel drive shifter while I am at it - mostly some careful rebending of the sheet metal but getting to it meant drilling out some rivets and that was not fun.

I replace the carburetor now actually comparing it to one of my other mowers (what a concept) to determine which hole the governor linkage goes in. What do you know, it was the OTHER hole. :-(

Total damage: Broken rod and cap, broken blade shear key, broken flywheel shear key, gasket set, bruised ego.

Finally, I top off the oil.

Now for the test: Not too shabby. It started on the second pull. It seems to run fine (now at a more normal speed) without any excessive vibration or noise. Only time will tell.

Comments: Whether it is a lawn mower or an automobile engine, oil is its life blood. That is why even if you don't do any sort of maintenance on your car, at least you should check the oil periodically and head the oil idiot light should it even come on - pull over, stop the engine, get a tow. Running without oil for a couple of minutes can ruin the engine. Ever seen that TV ad where they drain the oil and then run a bunch of engines till they seize? And, no, synthetic super-duper oil won't save you.

This whole episode was likely preventable if I had actually taken the time to check the oil and had realized that the overspeeding was a danger sign.

How long will it run? I don't know. If it weren't for that clearance on the crank pin, it would be as good as new.

In the end, there was some benefit to this whole affair. It was the stimulus to write Notes on the Troubleshooting and Repair of Small Gasoline Engines and Rotary Lawn Mowers.

Repair Brief #90: Harman-Kardon Model 520 Stereo Receiver - Multiple Problems

Patient: Our first stereo receiver - Harman Kardon model 520.

Symptoms: Burnt out Stereo Beacon(tm), noisy left channel, weak right channel, tuner stuck on one station, intermittent stereo reception, erratic controls (not all at the same time).

Testing: Where applicable, checked multiple audio sources or stations.

This receiver is from the days when one could buy stereo equipment at record stores (yes, records, vinyl, remember those?). Yes, it is solid state. :-)

Fortunately, Harman Kardon 25 years ago was willing to sell service manuals. I do not know what their policy is today. And, even in 1970 dollars, it was cheap - $3 including postage!

This series of problems occurred over the course of 25 years or so - it isn't as though the whole thing turned to you-know-what one day. :-)

Problem 1: Stereo Beacon(tm) doesn't work.

This one is easy - the usual underrated incandescent lamp has bit the dust. Rather than replacing it with (1) an overpriced part from Harmen Karden that will (2) burn out in a couple of years, I locate a bright LED and 220 ohm resistor. Since this actually runs on DC of about 5 volts from the stereo detection logic, no additional components are needed. The LED will last well into the next century.

Problem 2: Noise on FM only, left channel.

This took a bit little more work. Since only one channel is affected but no other audio sources, this limits the possibilities greatly. It cannot be in the tuner itself nor in anything common to Aux/Phono/Tape inputs. However, it appears as though there is a clump of circuitry unique to FM mode just beyond the tuner. It is apparently an amplifier between the tuner and the source select switch. Why would they need an additional amp? I have no idea but in any case, it is only 4 or 5 components for each channel. The active element, a transistor marked with an HK house number, seems to be sensitive to vibration. At that time, I was more conservative than I am today (and didn't have an ECG cross reference book either) so I actually ordered the exact replacement. Can you believe it? Problem solved.

Several years later, a similar problem developed with the other channel (or maybe it was the same channel - faulty replacement) and guess what? I just threw in a 2N4401 or something like that. Indeed, it sounds every bit as good!

Problem 3: Weak right channel.

This one developed over the course of several months and affected all audio sources but not the Tape Out suggesting a fault in the power amp. The fact that it didn't happen suddenly meant it was probably something like a dried up electrolytic capacitor. Since there were only a few of these in each channel, I simply jumpered across each with a known good cap until the problem went away. (Actually, I picked the big ugly one first - which happened to be the culprit!)

Problem 4: Tuner stuck on unknown station.

While just about to settle into the Evening Concert, what happens? Reception of my classical station is lost and some rock station replaced it. In fact, the tuning knob had no effect whatsoever.

My initial thought was that the tuner was hosed which would be bad news since I really don't like troubleshooting tuners! The service manual does include actual tuner schematics. Since other audio sources work just fine, this would point to the FM tuner.

However, first things first: check power supply voltages. It turns out there is one that is unique to the FM tuner. And sure enough, what should be 10 V reads 0 V!

Well, this isn't anything fancy: resistor->10 V zener->capacitor filter. The zener is a dead short. The resistor doesn't look so healthy either. In fact, while it tests within tolerance, it would appear to have seen better days being somewhat discolored. There are signs of long term overheating on the circuit board as well.

Since nothing else really seems faulty, I replace the zener and resistor with ones rated at twice the power just to be safe. Like the Stereo Beacon(tm) light bulb, these appear to be somewhat underrated as well. I wonder how many cents they saved!

Problem 5: Intermittent stereo.

At first I thought the station I was listening to was not broadcasting in stereo for some reason but after checking a few others dial locations, it would seem that the stereo selection circuitry in the receiver wasn't working. However, prodding and pressing of components on the MPX circuit board resulted in the stereo coming back and staying there. As best as I can determine, this turned out to be a polystyrene capacitor with an intermittent internal connection. Pulling on this component only resulted in restoring correct operation the next time the stereo dropped out.

Problem 6: Erratic volume, mode, speaker select, etc.

Another easy one: contact/control cleaner in the various pots and switches.

Comments: If you get the idea, this receiver has been a problem, you would actually be wrong. It dates to 1965 and has been in continuous daily use since then with no plans for early retirement. While not trouble free, name something you could buy today that would have a 30+ year service life with so few problems and no major failures? My total cost of maintenance over the years has totaled less than $10.

Yes, new audio equipment tends to have control panels that would look more at home in the cockpit of a 777 but that really doesn't make the music sound any better. This receiver is a case study in simplicity and I would be happy to have something modern which is as easy to use and maintain. Speaking of which, my Yamaha R8 now has a case of amnesia - forgetting its settings when powered off. Probably a bad SuperCap but that is for another Repair Brief!

Repair Brief #91: Multifunction Desk Phone - Erratic Operation

Patient: ExecuFone(tm) multifunction desk phone - 20 button memory, clock with alarm and timer, speaker phone, etc.

Symptoms: Pickup of handset results in static rather than a dial tone. Repeated attempts may result in dial tone eventually.

Testing: Tried replacing cords and using different phone jack - no change.

This rather nice full featured phone was given to me by the original owner in working condition - this wasn't a problem originally. (The owner, a typical CEO type, isn't happy if his toys are more than 6 months old. OK, he probably didn't actually pay for it either). However, the erratic behavior developed over a period of a few months (a couple of years later) to the point of the phone not being usable.

No doubt a bad connections problem somewhere but where?

Internally, there are several small relays as well as leaf/microswitches for on/off hook. It didn't take long to determine that one of these microswitches was at fault.

Under the lever operated by the handset is a bank of 3 separate microswitches. Two of them seem to be fine but the other would appear to have burnt contacts.

In an ideal world, I would hunt up a replacement - and of course there would be a service bulletin on a modification to prevent the same problem from reoccurring - but this was not to be.

Instead, I carefully unsoldered a pair of the microswitches from the circuit board and popped the top off of the bad one. After cleaning the contacts as best as I could, I replaced the original switches swapped in position. (Unfortunately, I also ripped a couple of pads off with the switches so this complicated the reassembly slightly.)

This did restore operation for a couple of years. I knew I shouldn't have passed up the same model phone at that garage sale! It would have yielded two good microswitches - no doubt the reason it was being sold was this same problem.

I still use the phone for its autodialer and clock but have another (ATT) phone on the same line to grab the dial tone! :-)

On a separate note, interestingly, the phone's instruction manual recommends replacing the NiCd battery pack used for memory and clock backup every two years. That same battery pack has been just fine for the last 13 years!

Comments: This isn't rocket science but how many phones are cluttering up land fills due to just these sort of simple problems? In this case, it is almost certainly a design fault - there is nothing funny about my phone lines. Since the problem didn't occur suddenly, it is also not due to a lightning strike or other one time event. Just, gradual deterioration of an underrated set of switch contacts.

---

92. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #92: Aiwa Boombox - Dropped

Patient: Slightly battle worn Aiwa Sports AM/FM/Cassette boombox. Well, it doesn't appear very 'sporty' but I suppose styles change...

Symptoms: The cat did it! Fell off window sill. The cassette works fine but there is absolutely no sign of life from either band of the radio.

Testing: Sure enough, not even a peep (or meow) out of the radio on AM or FM.

Jeff comes by my office: "Wanna fix a boombox." This isn't that Aiwa disaster is it? (Repair Brief #65: Aiwa CSD-707 Boombox CD Player - Doesn't Recognize CDs). "No, this is mine. Fell off a window sill. The radio doesn't work." OK, sure bring it by.....

So, a couple weeks later, Jeff walks in with this vintage boombox. You really want to fix that thing? It is also an Aiwa, but probably at least 15 years old. "Yep, I opened it up but didn't see anything wrong." Sure Jeff, open it up again. "A couple of the screws are missing and one of the plastic post thingies broke off in the fall." Right.....

At first, there didn't appear to be anything obviously broken so I decide to power it up (after all, Jeff had already done this so the additional risk is minimal). Fortunately, it can be powered easily with the two halves of the case separated.

Sure enough, the radio is dead as a brick. Pressing and prodding produces absolutely no change.

Then I notice something... Uh oh, it looks like the corner of this circuit board is cracked off. OK Jeff, you will have to remove it and it doesn't look like fun as the dial cord seems to run from the main case to the variable capacitor pulley on the circuit board. Better make a detailed diagram of exactly the way this is run so that we can replace the string if it pops loose. "Yeh, sure."

I come back 5 minutes later to find the board removed. "No problem, the dial cord didn't need to be disturbed." Chalk one up for Aiwa - intelligent design. It turns out that the pulley engages a keyed shaft so the string and all the other dial cord stuff remains in place.

With the board removed, the extent of the damage is evident - not really that bad, just two traces that run around the corner of the board. These are easily jumpered from wider expanses of copper near their destinations.

Then, Jeff notices that the other corner is also broken - another pair of traces, possibly extensions of the same ones.

Inspecting the remaining two corners indicates that these survived intact.

Power! Sure enough, the radio now appears to work fine.

Jeff, close it up.

"Sure boss. :-)"

Five minutes later: "I even managed to anchor one of those corners with a the broken piece so that at least 3 of the corners are attached AND I won't let the cat near it again!"

Comments: It could have been much worse - many fine traces run really close to the corners but they were spared. A better mounting arrangement to reduce stress on the circuit board could have been designed (either by Aiwa or for the repair) but these things are only supposed to be subject to reasonable bumps - not total abuse.

I don't know about Jeff. A while ago, there was another boombox - or maybe a clock radio - that had been dropped with similar consequences.....

---

93. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #93: Kenmore Microwave - No Heat and Dead Buttons on Touchpad

Patient: Mid size Kenmore microwave. 'Customer' just said it doesn't work and is willing to pay 'whatever it takes'. Really must like it - nothing special.

Symptoms: About half the buttons on the touchpad are dead and even when it is started, there are normal sounds but no heat.

Testing: Not much more can be done without removing the cover.

As usual, the cover comes off easily. It is somewhat gunked up from lack of cleaning but not excessively so. There is a schematic of the microwave generator but as expected, not of the controller.

Since the unit is not totally dead, the main fuse must be ok.

A quick examination of the power circuitry reveals the likely cause of the no-heat problem: a deteriorated lug and terminal on the filament of the magnetron. This likely occurred over time as a slight resistance due to corrosion or the lug just being a little loose resulted in heating and eventual failure.

Rather than attempting to install another FastOn(tm) type lug, I elect to drill a hole in the tab on the magnetron itself and then use a ring lug, nut, and bolt, to attach the wire. There is ample metal for this and once filed clean, it results in a secure connection to a magnetron that would otherwise require replacement.

I inspect the other connections to the magnetron and high voltage transformer (secondary and primary sides) but they appear to be fine.

A quick test with a cup of water shows that the microwave generator is now functional.

To prevent accidental operation of the HV circuits while testing the touchpad and controller, I unplug the connector for the AC input to the HV transformer from the controller board.

Now, for the touchpad. This is not going to be nearly as easy. In order to determine if the problem is in the touchpad (as expected) or the controller (which would be bad news), I need to reverse engineer the touchpad matrix.

For some unfathomable reason, manufacturers never seem to like to use a nice orthogonal logical layout. Each 'row' or 'column' line snakes its way all over from here to yonder. Of course, there is also printing or other opaque paint in random locations to further stymie this activity.

However, there do appear to be two distinct sets of buttons with different behavior when pressed:

- The working buttons result in a dramatic drop in resistance.

- The dead buttons result in erratic or no change in resistance.

Eventually, it would appear that one of the row wires is damaged somewhere in an inaccessible location inside the touchpad. In fact, careful examination of the front of the touchpad reveals a very tiny dent - possibly a break - in the plastic cover. Perhaps, a knife was thrown at the panel? While it doesn't seem to account for the problem, this is the only evidence of damage.

To confirm the diagnosis (though I am pretty sure at this point), I go back to the ribbon connector and use a 10K resistor to manually jumper a row and column pin that correspond to one of the bad buttons. Sure enough, that function now responds.

The touchpad is only available from Sears parts at a cost of about $30 but the 'customer' is quite happy to pay this even when informed that the magnetron may be on its way out of this world in the not too distant future. (As it turns out, I have not heard of any problems with this oven and it has been a couple of years now.)

Comments: I have not really figured out the sequence of events accounting for these failures. Perhaps, the no-heat symptom occurred first and the user attempted to convince the oven to cooperate by whacking at the touchpad. If the touchpad problem happened first, the entire oven would have been virtually useless as some of the numbers and other functions were affected.

94. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #94: Hoover Vacuum Cleaner Doesn't Pick Up

Patient: Paula's vacuum cleaner. One of those newer 'mostly plastic' things. This is not like the good old days where a vacuum was so heavy that a fork lift was needed to carry it up the stairs. OK, so maybe they weren't such 'good old days' after all. :-)

Symptoms: No air flow at all. This vacuum really doesn't suck.

Testing: The official Corn Flake test is not required to evaluate this one!

"Sam, do you want to look at a vacuum cleaner.". Sure, what is wrong? "It doesn't seem to pick up the way it used to." OK, maybe it is just a belt or clog. "OK, it is in my car. I will get it later."

Trying the vacuum on Paula's office floor, it indeed really doesn't do much of anything. The brush does spin - so the belt is good. The bag is not full. In fact it has nothing in it. The air passages appear clear. So much for those theories.

This will require some disassembly.....

Removing the bottom (or was it top?) cover doesn't reveal anything new. For all intents and purposes, it would appear that while the motor makes the normal very impressive 'mega horsepower' sound, there is no airflow - zero, zappo, nadda.

Naturally, Hoover uses Torx screws for all internal parts. At least it is modular and easily disassembled - two screws to remove the entire motor unit and four more to remove the blower cover.

Ah Ha! Paula, Paula, where are you? Look at at this: The blower wheel has come loose from the motor shaft and indeed is not spinning at all despite the motor noise.

"Can you fix it?"

I can attempt to reattach the blower to the motor but eventually, a new blower will probably be needed - I have no idea how much that would cost.

So, I pile the remains of the vacuum in a corner of Paula's office and will take the motor/blower unit home to work on it. Unfortunately, since the Hoover isn't in any condition to do its thing, the pile of dirt and dust dislodged during disassembly will have to be cleaned up the old fashioned way. Is there a broom in this place? :-)

Well, I thought it was just the plastic blower. Wrong! After some additional disassembly of the motor itself, it would appear that the bearing at the blower end of the motor has entirely disintegrated - balls, race, covers, everything. This was likely the actual cause of the blower failure causing it to rub and then bind resulting in its loosening and becoming detached from the shaft.

Well, I don't keep a collection of ball bearings for nothing!

Rumage..rumage..rumage.... Ah, here is one that has the correct ID and OD but it is sealed on only one side. Oh, well, cannot have everything. I locate a metal washer and file out its hole so it will fit the shaft and protect the bearing - somewhat. I orient it so that this improvised shield in toward the inside of the motor - hopefully, a less hostile environment. I check end play (because of the additional washer) to be sure that there is adequate clearance - there is.

Now for the blower. Due to the effects of the shaft spinning inside the stuck blower, the mounting hole is totally distorted. Therefore, I use a reamer to enlarge it symmetrically and then make a bushing out of some roof flashing to center the blower on the shaft. It was mounted by a nut and this will still work but for good measure, I drip some windshield sealer (similar to Duco Cement) into the assembly to prevent the assembly from working free and then tighten the nut securely. Then some more adhesive to seal the nut.

After allowing this affair to dry overnight, I am ready for the big test!

Using a Variac, I can run the speed up from 0 through normal line voltage to the 140 VAC limit of the Variac with no obvious problem and no excessive noise (well, in a relative sort of way) or vibration. The air flow is really quite impressive!

A few days later when I return to reinstall the motor: Paula, I think it will work for a while - have no idea for how long. If it dies again, we will need to order the proper part. "Great! Now I can clean my apartment."

After putting everything back together, I then proceeded to vacuum up the new pile of dirt and dust dislodged during reassembly as well as my office which was in much worse condition! :-)

This vacuum really sucks now!

Comments: At first, I was going to blame the excessive use of plastic for this problem. However, it would actually appear that the cause was the failure of the blower-end ball bearing. This, then caused the blower to bind and be literally ripped from the motor shaft.

How could a ball bearing fail? This isn't subjected to excessive loads of any kind and I doubt that the vacuum had seen that much use - it just isn't that old (no reflection on Paula's housekeeping). I have a 45+ year old Filter Queen (well, they haven't existed for decades - built 'em to last!) that still runs fine. Ball bearings do not fail that often! Thus, one can only assume that either the bearing was defective or its seals permitted dust to enter.

The much greater use of plastic in modern appliances has indeed reduced weight and cost (or boosted profit margins depending on your point of view). In this case, flimsy plastic probably wasn't a factor but one can point to many instances of parts being under designed for the application resulting in premature failure.

---

95. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #95: Subaru Auto AM/FM/cassette - Intermittent Reception

Patient: Paul's wife's car stereo. Subaru stock in-dash AM/FM/cassette.

Symptoms: Reception would come in and out. Paul noted that BIG bumps seemed to affect the radio. Also problems with rear speakers.

Testing: No BIG bumps handy. Tapping it didn't seem to do much.

Paul had been bugging me for several weeks to look at this problem. In general, I don't like dealing with car stereos as removal is a pain, powering on the bench is a pain, and reinstalling is a pain. The key work here is 'pain'. :-)

However, I reluctantly agree to at least take a look at this one.

The first step is to figure out how to remove the radio (I tend to call anything in a car dash a radio even if it will mix drinks and is DVD-ready). Fortunately, the 'radio' is held in by four Philips head screws. On the first go-around, that is far as I got. For whatever reason (I don't recall exactly), I was unable or unwilling to take it to the lab (perhaps, the connectors weren't obvious or there were no connectors).

At the same time I took a look at the rear speakers which Paul had also been complaining about. The right speaker was kind of mushed with a damaged cone. I asked Paul if he wanted to repair or replace it. "No, as long as it makes some sound." (He wanted to sell the car eventually.) I kind of unmushed it but don't expect any crystalline highs. The left speaker seemed to have become detached. Paul, exactly what kinds of bumps have you been going over lately? Pushing the connectors back in place restored its sound.

This doesn't cure the main erratic problems so inspection of the interior of the radio is next on the agenda.

The next week, we are prepared for action. I have Paul park the car near our rear exit for convenience if tools or parts are needed. Then, I remove the radio again from the dash and pull off the top cover. Nothing is immediately visible but touching some vertically mounted daughter boards results in the sound coming in and out.

Sure enough, a careful inspection of the solder side of the main board from the bottom reveals some hairline cracks in the connections between one daughter board and the main board. How the manufacturer expected something like this to survive road bumps and potholes escapes me. However, it would seem that this sort of construction is used in many types of equipment subject to mechanical shock. (I will tell you about the Tandy multi-band radio with the erratic volume control someday.)

OK, so I go back into the office, fetch our Weller soldering station and a pair of 50 foot extension cords...... It doesn't take long to touch up the two rows of pads.

That did it. The reception is now solid and totally immune to as much whacking and wiggling as I could provide. This was actually a lot less traumatic than I had expected.

The clock in this car developed a bad connection problem several months later but that, alone, would not qualify for a Repair Brief though it did take a couple of attempts before the actual problem was found - a corroded cold solder joint that required removal of the old solder, scraping of the pin and pad, and new solder to repair.

And, yes, Paul did unload the car, mushed left rear speaker and all!

Comments: As noted, car radios are not my favorite repair activity. Perhaps they just don't have that entertainment value in addition to being difficult to service - did I mention how everything about them is a pain? :-)

Aside from road bumps and potholes, the electrical system in an automobile is prone to dips and spikes - some quite spectacular. The environmental conditions may be horrible - from arctic to tropical temperatures. There can be condensing humidity and tobacco smoke as well.

Thus it comes as no surprise that many common failures with car radios relate to mechanical problems and to a lesser extent, electrical abuse. In some cases, locating the cause is easy. In others, it can be very frustrating as Dave is currently finding out with a friend's car radio. Stay tuned (perhaps) for a report on that one in the future.

---

96. Back to Sam's Repair Briefs Table of Contents.

Repair Brief #96: GE Frost-Free Refrigerator - Reduced Cooling

Patient: GE top freezer 21 cu. ft. refrigerator.

Symptoms: Rising temperature in fresh food compartment. Frozen food may be softening up also but this is not as obvious.

Testing: Checked that compressor was running (continuously). Condenser coils (underneath) have been cleaned. They are moderately warm.

Some possibilities for inadequate cooling:

- The door is not properly closing for some reason.
- Someone messed with the controls accidentally.
- Something is blocking the passageway between the evaporator and the fresh food compartment.
- The defrost cycle is not working and ice has built up in the evaporator coils. This could be due to a bad defrost timer (most likely), bad defrost heater, or bad defrost thermostat.
- The interior light is not going out when the door is closed - that small amount of heat can really mess up the temperature (remove the bulb(s) as a test if you are not sure.
- Low Freon can result in problems of this type but that is a lot less likely. (These refrigeration systems are hermetically sealed (welded). Slow leaks are unlikely.)

Although various convoluted (and expensive) faults are possible, the most likely problems have to do with the defrost system - defrost timer, heater, and defrost thermostat. Door seals are intact and the interior light is out when the door is closed. Controls are set for lowest fresh food temperature.

With the compressor running and clean condenser coils, there isn't much else that is external to the sealed system.

The most common type of defrost system on a no-frost refrigerator or freezer usually consists of:

- Defrost timer - motor driven (typically) switch which selects between the compressor and its associated devices (like the evaporator fan) and the defrost heater (located adjacent to the evaporator coils). The timer motor likely only runs when the main thermostat calls for cooling.
- Defrost heater - resistance element located in the evaporator compartment to melt ice built up on the coils
- Defrost thermostat - closed when the temperature is below about 32 degrees F to allow current to flow to the defrost heater. Shuts off once the ice melts as indicated by the temperature rising above 32 degrees F.

The terminal numbering and wire color code for the defrost timer in a typical GE refrigerator is shown below:

```
                      Black (4)
```

```
    Gray (3)      /o---------o Normal position - Compressor, evaporator fan.
H* o-----+------/
         |        o---o Blue (2)
       Timer          |         Defrost heater  Defrost Thermostat
       Motor (3180    o------------/\/\/\------------o/o----------+
         |    ohms)                31 ohms          32 F          |
         |                                                        |
         | Orange (1)                                             |
         o--------------------------------------------------------+--o Common
```

```
   * H is the Hot wire after passing through the main thermostat (cold control)
     in the fresh food compartment.
```

The entire timer unit is readily accessible once the kick plate is pulled off.

By turning the finger access shaft in the defrost timer, I was able to get the reassuring click indicating the start of the defrost cycle. Sure enough, this was followed a couple minutes later by a variety of melting and sizzling sounds. These are normal as the ice melts and parts expand. Then, a steady trickle of water could be found dripping into the pan below.

I also noted that the timer motor did not seem even moderately warm as it would normally be - running as it should about 90 percent of the time. Could the motor be bad?

Two screws and the timer assembly comes free. After writing down the positions of each of the colored wires, I disconnect them and take the timer to a more convenient location for inspection. The motor is stone cold....

The timer assembly consists of two parts: A synchronous gear motor and a plastic housing with the cam and contacts. Two more screws and the cover to this part comes free. Initially, nothing looks amiss but then I notice a wire just hanging in mid-air. And, it is one of the two wires powering the motor!

Apparently, the wires were tack-welded to the metal strips with the contacts on their end. And, guess what happens when something flexes even a small amount a few thousand times? It breaks!

A quick soldering job and we are back in business.

Once reassembled, I force several consecutive defrost cycles (until no more water comes down into the drip pan) to assure that all the built up ice is gone.

Five years later:

Guess what? Same symptoms. Now, the diagnosis is even quicker. This time the wire broke near my soldered connection. To make sure this doesn't happen in another five years, I solder the wire to a location just behind the outside terminal - a place where there is no movement of any kind!

(The built up ice did a number on the styrofoam insulation between the bottom of the freezer and evaporator compartment but there is no way I am going to pay GE $75 for a 50 cent sheet of styrofoam! A little universal mending material, a. k. a. duct tape, takes care of that!

About 5 years later, 1 week after an extended power failure (1-1/2 days! At least it was the dead of winter).

Same symptoms. However, this time the motor is warm so my previous repair is still intact. :-) The motor is receiving power but nothing visible is turning as confirmed by rotating the cam by hand to the defrost position - where it would happily remain indefinitely.

Upon removing the cover of the gear reducer, the cause is obvious - a split plastic gear hub most likely due to gummed up grease (it hardened after cooling off while power was off) caused excessive stress when restarting.

Well, bite the bullet. Calling in a serviceman would result in a $135 bill. Our local appliance store had the timer assembly for about $30. Just after this episode, MCM Electronics started carrying universal defrost timers for about $12.

Comments: A properly designed and manufactured refrigerator or freezer is a very reliable appliance. The hermetically sealed compressor and coils can last virtually indefinitely as long as they are not abused (like using a sharp instrument to pick ice off of the soft evaporator coils!). There have been instances of early failures (and possible recalls) of some models but in general, several decades is not an unusual life span for the refrigeration components.

The defrost system is another matter. Its parts are exposed to the elements and get a workout several times a day. However, diagnosis and replacement is usually straightforward (except, that is, for finding a place for a freezer full of thawing food!). With luck (of sorts), the timer is the problem and this is a 5 minute repair if you are willing to just replace it.

Repair Brief #97: Panasonic VCR Power Supply - Comedy of Errors

Patient: Panasonic VCR model PV4820.

Symptoms: Just blinking --:--. No response to any front panel buttons or remote control.

Testing: Nothing much without going inside.

This should have been a 15 minute repair (if you don't count gaining access to the power supply):

- If I had been able to read my ESR meter correctly. :-((No fault of the ESR meter.)
- If I had simply installed a power supply rebuild kit.
- If I had elected to use my scope to check a signal or two sooner instead of later.

As it turns out, it was more like a two hour repair at the cost of a pair of smoked zener diodes.

The blinking --:-- with no response to any buttons is a classic symptom of a power supply problem. In the case of Panasonic PV48xx and other models using similar power supplies, the culprit is usually C21 or C16 (though not all may use the same numbering), or some other electrolytic capacitor in the secondary side of the switchmode power supply. In fact, this turned out to be the case: C16 showed high ESR and I should have found that in about 2 minutes but did not and was led on a wild goose chase.....

Anyhow, back to the story.

With the cover off, the power supply connector is readily accessible. Although there are a number of variations on the power supplies used in the various models, all should show a couple of pins with a voltage of around +5 VDC.

Probing carefully reveals a bunch of much higher voltages (which are expected) but two pins have something around +3.6 to +4 VDC. Checking my reverse engineered Panasonic power supply schematic, these pins should have the +5 V.

No problem I say, remove the power supply, check C21. It should test with high ESR or low uF, replace, and be done. (Actually, the common failure with C21 is to have excessive leakage but no matter, I would just try replacing it anyhow.)

Removing the power supply module in these VCRs isn't too bad (as opposed to some older Panasonics which have apparently been designed specifically to make this difficult). A bunch of well marked screws holding the main board, lift free, unbend and unsolder a couple of tabs. Then unbend a couple of tabs on the sheet metal cover and - presto - access to both sides of the power supply circuit board.

To fully appreciate what is going on in the discussion below, it is recommended that you refer to the typical Panasonic VCR power supply schematic which may be found at Various Schematics and Diagrams.

Here is the important part:

```

-V source o---+--------------+
```

Note: Measured voltages shown in ().

C21 does show slightly high ESR, so I find one in my stock and replace it.

No change. In fact, if anything, the output voltage has *decreased* slightly. (It turns out that the replacement cap had lower ESR and actually would be expected to make the problem worse given the actual cause.)

Next, I check all caps in the vicinity with the ESR meter. I even specifically checked C16 which would result in excess ripple and this would feed through C21 if C16 had high ESR. Apparently, I missed it - probably ignoring the absence of the huge decimal point thinking it read .20 ohms when in fact it actually was 20 ohms.

Next, I figured, "Well, maybe my replacement C21 was bad as it wasn't a new cap". So, I removed it entirely for testing.....

Now, C21 serves at least one function I know of and that is to limit the rise in voltages as the power supply is powered up. It couples any AC component of the +5 line back to the regulator to reduce output if there is excess ripple or if the voltage is increasing rapidly. With C21 removed, this protective function is not present......

But I realize this and put the supply on a Variac so I can increase the input slowly and avoid any problems. Right. :-(

Guess what? As I am increasing the input, I hear that high pitched whine indicating an excessive current fault somewhere in the power supply.

Well, maybe it is just the absence of the cap (not really thinking it through). Replace it.

No change.

OK, what happened? Is the supply now badly fried? Could the VCR have been affected as well? Well, at least the latter is unlikely.

It would appear as though something has shorted. Not the main switchmode power transistor as that would blow the main fuse and really mess up my day.

Well, I got lucky - at least in the time to locate the problem. Measuring across the first part I tested - a big fat diode - showed 0 ohms. Unsoldering it made no change but unsoldering a nearby zener diode (D15) showed that it was shorted. D15 is on the +15 V output and protects (by sacrificing itself apparently) against overvoltage since it does not really conduct during normal operation. (It is an 18 V, 1 W zener as I found out later).

Fortunately, I had a replacement known to be good which was removed from a similar supply when I installed a rebuild kit.

After the zener is installed, we are back to square one - 3.6 V on the 5 V line.

With the caps supposedly eliminated, that leaves the feedback network.

A bit of analysis shows that regulation is accomplished by feedback from the +5 line through a 5 V (approximately) zener (D11) to the base of a transistor (Q3). When the output exceeds 5 V, this transistor turns on which turns on another transistor (Q4) which supplies current to the LED of the optoisolator. Its photodiode then conducts and reduces the pulse width of the switchmode power transistor. Got that?!

Checking at the base of Q3: -1.5 V which is nicely .7 V more negative than the emitter. Q3 should be solidly off. However, its collector reads about .8 V less than its supply... Hmmmmm. I replace Q3.

No change. In fact, I replaced Q4, the optoisolator, AND D15 for a second time after I experimentally shorted the input to the optoisolator to confirm that it was capable of increasing the output - it was :-(and D15 blew again.

Not knowing the rating of D15, I replaced it with a 1N4742A, 12 V zener. However, this caused the +5 to read +4.1. At first I thought this was a clue but then realized that it simply was allowing more drive by sucking some of the power by conducting. Installing a 15 V zener remedied that. Back to square one again. (18 V is the correct value but at least the 15 V zener isn't loading the circuit.)

Finally, I do what I should have done early on - turn on the scope! Looking at the base of Q3 it is now obvious that I must have missed something in checking the caps. As the input voltage is increased, a very significant pulse waveform can be seen riding on top of the +5 V (now +3.6 V) output. This is coupling enough signal to the feedback circuit to reduce the output voltage. Since C21 has been eliminated as a possible suspect, the only other possibility is C16. Sure enough, a quick test with the ESR meter and - what do you know - 20 ohms. That is over 100 times what it should be!

Installing a replacement and all is well - only a couple hours more than it should have required!

Frank Fendley identified the correct value for D15 - 1N4746A, 18 V, 1 W but to top it all off, our local electronics distributor is out of zener diodes! Some prototyping house bought up their entire stock or so the story goes. And, Radio Shack only goes up to 15 V! I will obtain an exact replacement rather than cobbling something together from two lower voltage zener diodes since D15 does serve as protection and I don't want to affect that.

Comments: This repair should have taken about 15 minutes. I have no idea now I missed the ESR reading on C16 as I specifically went to that cap as it is one of the two most likely causes of this problem. I guess we all have bad days. On the plus side, the confusing situation forced me to analyze the operation of the power supply in more detail. I even found a couple of errors in polarity on the schematic. (It has only been available for the entire world to see at the Sci.Electronics.Repair FAQ site for about 3 years now. You would think someone else might have noticed!)

In the end, the only damage was about 40 cents worth of blown zener diodes and my ego in return for a little knowledge gained.

Repair Brief #98: Kenmore Window Fan - No Breeze

Patient: Kenmore 26" window fan - two speed bidirectional with thermostat.

Symptoms: Does not spin in either direction on either speed.

Testing: Spinning the blades gets it going a bit but it never reaches anything approaching normal speed and makes a clicking sound.

This is my cousin's fan and has been in use during the summer months for the past 15 years. I had lubricated it once before but never really properly disassembled it entirely. (That was after the floors had been refinished - the sanding dust didn't help matters any.)

Everything structural in this fan is made of plastic except for the motor, and speed and thermostat trim plate.

Eight screws must be removed to take off the rear grill.

Ah - now that is a problem.... It seems that the blades in this are molded as a single unit with a section on the shaft for the clamp. Well, that section is totally broken off so even if the motor wanted to get up to speed, there is nothing holding the blades to the shaft! The clicking sound was probably the result of the shaft slipping inside the hole.

However, first the motor must cleaned and lubricated (at least) as it seems tight. Disassembly requires the removal of a front cover plate with the controls (speed and temp.) and then 4 nuts holding the motor itself. Then, 4 long bolts which clamp the motor halves together.

The closed-end seems fine - adequate lubrication and no damage.

However, the open-end is dry. It appears to be in basically good condition so a thorough cleaning and then some electric motor oil on the bronze bushing and the felt oil reservoir would appear to do the trick. I add a few drops to the other end as well just to be safe. Testing shows that the motor works as well as the day it was built.

Now for the broken blade problem.....

Repair with adhesive is not possible as the broken pieces could never be reliably reattached. Sears doesn't stock a replacement blade for this model (can you believe it?) and it would probably cost more than the entire fan if they did. So, I will have to improvise.

At first I figure on finding something in my junk boxes that would fit the shaft and screw or clamp to the hub portion of the blades. However, nothing seems to fit or lend itself to modification.

Therefore, I decide to fabricate a mounting assembly from some sheet aluminum and a hose clamp.

This consists of 3 strips of aluminum stock about 3/8" x 2" x .050, bent over 3/8" at almost a right angle at one end. Holes are drilled near the opposite end which will be used to screw these to the hub of the blades.

The source of this material was a long ago cannibalized HDS video terminal keyboard cover plate. You probably already know that I don't throw away much - somewhat less than gets wasted from a typical cow - never mind. :-)

The right angle portions were then attached to the shaft with the hose clamp and while in position, holes were drilled through the hub of the blades (a roughly flat portion about 5 inches in diameter. Screws, nuts, and washers made from the same material were then added and the entire affair was tightened in position.

Since only the clamp portion of the blade hub was missing, there was still a reasonably tight hole for centering and a layer of tape removed any sign of movement. However, a bit of adjustment was needed to correct a slight wobble. Translation: I rotated the blades and noted the high side - and then pressed down on it!

Now, the fan runs smoothly at both speeds in both directions though I will recommend using low as much as possible.

Comments: This represents yet another case of an appliance snatched from the jaws of the dumpster and land fill. There is nothing high tech about either the problem or the repair but these projects are much more satisfying than simply going and buying a new fan. Cheaper as well - $0 in parts at least. How long will it last? The motor is as good as new. The blade mount seems at least as sturdy as the original - only time will tell.

Where the nights are cool, an exhaust fan is a much more energy efficient solution than either window air conditioners or central air conditioning. The fan sucks out stale house air which is replaced by outside air through any open windows.

We still use an all metal window exhaust fan - it is just about 45 years old at this point and runs fine. A few drops of oil every so often (though I must admit to being negligent in this department of late) and it keeps chugging along.

Repair Brief 99: JVC 20 Inch Color TV - Flat Line

Patient: Dave's neighbor's JVC Model AV20TP3 20 inch color TV.

Symptoms: Single horizontal line - video appears to be present.

Testing: External whacking has no effect, no service switch. Flexing the mainboard, however.....

Dave had been talking about this TV for a couple of weeks. So, finally, I found it with the back off on the bench in the lab. I wander over. Of course, there is just a dim horizontal line (Dave DID turn down the brightness). Naturally, I cannot resist a little exploring...

I flip a switch on the edge of the board that could have been a service switch but it had no effect (I later found out it was the CATV/TV/ANT/etc. switch).

Tapping and whacking don't do anything.

However, pulling up on the mainboard in the vicinity of the flyback transformer results in momentarily restoring a full raster.

DAVE??? Do you know that flexing the board has an effect?

"Um, yes, I think."

OK, let's put the board up on its side - can you do that so it doesn't short out?

"Sure."

So, I rummage around for something insulating - a flux removal brush would seem to be appropriate.

Dave, you watch the screen while I run this over the pins. Oh, I see you have touched up a few joints, huh?

"Just a few."

OK, here goes....

First, I attack the area of the flyback on the chance that the bad connection is for the power to the vertical circuits which probably are scan-derived.

No change.

Next, the area of other power semiconductors - hopefully one of these is the vertical driver.

Still no change.

Finally, just systematically over the entire board.

"STOP - there was something".

Backup, slower this time.

"Ooooo - you had it. Gone now".

This? "No." This? "No." This? "No." This? "No." This? "Wait, yes. Good. Bad... Bad... Good.. Bad... Good."

It is an IC. Let me try each pin....

"Bad. Good. Bad. Bad. No effect."

Pin 2 of this chip. Let me try to locate the crack. Is there a magnifying glass in this place? It took very close inspection but there was a definite crack that would widen as the pin was pressed to one side.

Dave, on Pin 2, jumper a wire to another pin on the same trace. Also, touch up all the other pins on this IC.

"I guess I wasn't forceful enough."

Five minutes later:

"They were all somewhat short of solder - what was there kind of disappeared when I touched them with a soldering iron but I think they will be fine now."

What is the chip ID? 'Uh, IC421, LA7838.' LA7838 is a vertical deflection processor. Pin 2 is 'Vertical trigger in'. Yes, that would explain a lot!

Sure enough, the TV is now solid.

Comments: There was no evidence of heating or other damage. With the meager amount of solder present, just the very slight effects of thermal cycling were likely enough to cause this failure in set which is something like 2 years old.

Dave's neighbor was about to toss the set because someone else had told him it was likely a bad picture tube! Simply amazing. :-)

Repair Brief 100: Minox ME1 Electronic Flash for Minox B Camera - Dead

Patient: Three-part unit for one of those teeny-tiny Minox spy cameras. :-)

Symptoms: Dead on both AC and rechargeable battery power.

Testing: Not applicable - done via email. :-)

I was contacted about this rig via email and attempted to walk Stan through the diagnostic and repair process. With such an old device, any rechargeable battery was almost certainly dead and any electrolytic capacitors would also be highly suspect.

Since the unit acts totally dead both from its battery as well as the AC adapter, I first suggested replacing the NiCd cells. Having accomplished this, and letting it charge overnight, there is now at least some quite whining to indicate that the inverter is running. However, the ready light still does not come on even after several minutes (cycle time should be under 10 seconds).

I next suggested that Stan should attempt to measure the voltage on the battery as well as the energy storage capacitor to determine how far - if at all - it is charging. I warn Stan to take extreme care around the cap - those can be lethal!

The report isn't promising. On battery alone, the battery voltage is stable at 2.45 VDC and the cap only charges to 48 VDC or so; on AC to 170 VDC. Even the latter is much less than the expected minimum of 300 VDC. What is going on?

Since Stan noted that the capacitors retain their charge for hours, it is unlikely that they are bad - leaky - but just in case, I suggest just replacing them with any sort of capacitor with similar uF rating and at least equal voltage rating (for testing only) - those from disposable cameras would be most appropriate and FREE if you know where to ask!

No change at all. At this point, Stan suggests that he is over his head on this one and is about to give up. So, I volunteer to look at the unit if he pays shipping both ways.

A few days later.....

The flash head itself is about as big as the entire camera with the power supply and charging adapter being somewhat larger. Actually, the power supply is a lot larger. I don't suppose spies generally like to use electronic flash in covert operations too often anyhow!

My first step is to reverse engineer the circuit. I don't expect anything particularly unusual but this will make any troubleshooting a lot easier (also available in GIF format as [Minox ME1 Inverter and Energy Storage Capacitors]()):

CCAC o------------------------------------------+
```

Note: The BAY90 rectifiers cross to 1000 V, 2.5 A general purpose diodes.

The Flash Intensity switch, S2, selects between 12 W-s and 24 W-s. There are actually three positions. Apparently, you are supposed to pause in the middle one called "Hold 1 Sec" when switching between power levels for at least 1 second (surprise, surprise!) to allow the capacitor voltages to equalize! I would assume that the reason for this is to prevent damage to the switch contacts.

The flash head is separate from the power supply and appears to be very much like any of the other strobes. However, note the adjustment for the ready light!

I was not willing to completely disassemble this unit so some of the actual components and wiring were guessed (also available in GIF format as [Minox ME1 Ready and Trigger Circuits]()).

```

HV- o---+--------------------------+------+--------+------+
```

The wall adapter/charger provides both the current to charge the 2 cell NiCd battery and a high voltage AC output (CCAC) to power the flash when plugged into an outlet regardless of the state of the batteries. When operating from the wall adapter, D1 and D2 in the power supply unit in conjunction with C4 form a voltage doubler that takes the 130 VAC (>80 V peak) output of the adapter and produces over 300 VDC to charge the energy storage capacitors (also available in GIF format as [Minox ME1 AC Line Circuitry]()).

```
                      T3     C5   J1-3

```

Some interesting features I was not aware of previously - which might have helped to narrow down the problem (and possibly give up - as you will see):

- It is a dual energy flash - a switch selects between low and high power modes. There are two energy storage capacitors. This really doesn't affect anything but at least explains why Stan was referring to two large capacitors....

- The AC adapter generates the high voltage directly via a clever little voltage doubler in the power supply and its own isolated 130 VAC transformer winding. This is significant.... Having two basically independent means of powering the unit both be messed up implies a problem on the secondary side of the inverter since there is nothing else in common.

Since the capacitors (and other sources of leakage) have been eliminated, on a wild guess, I decide to replace the high voltage rectifiers. The are marked "BAY90" which crosses to 1000 V, 2.5 A (probably less but that is what my ECG book says). Replacing with suitable diodes and.... No change at all.

There is only one other thing that can prevent the capacitors from charging from the AC adapter - an open inverter transformer secondary. This would not be fun. Indeed, all efforts check its resistance failed. The transformer is bad. Can it be repaired? I don't think so - not unless the break is at the end of the winding on the outside. No such luck. In fact, after unwinding all 1,950 turns of #46 wire, I never did find it - probably one of the 50 or so times I thought I broke this super fine wire in the process, it was already broken. :-(No way to get that back together anyhow and the ferrite core was in several pieces as well....

So, go to plan B....

I tell Stan to see if he can locate another similar unit at auction or elsewhere to use for parts - even if it doesn't work. Within a half hour, he replies that an eBay on-line auction lists an identical model - with the identical symptoms - and it was still available at $37. No way I said, it may have the same problem as well and thus not be repairable! (That unit finally sold for $83 - Yikes! - and it could be a dud.)

So, I volunteer to perform a transplant......

There is nothing particularly unusual about the requirements - charge some large caps to around 300 VDC. Any vanilla flavored pocket camera needs to basically do this. However, just any unit would not necessarily work:

- It runs on a pair of NiCd cells totaling 2.4 V so the circuitry out of a disposable camera is not appropriate, being designed for 1.5 V operation.

- The inverter may need to run continuously. For this reason as well, the disposable camera solution is unacceptable since they usually are activated by a push button and may only be designed for short duty cycle operation.

- AC operation must not be affected.

- The circuitry must fit in the case.

Checking the schematics for each of the other battery powered flash units in the document: "Notes on the Troubleshooting and Repair of Electronic Flash Units and Strobe Lights and Design Guidelines, Useful Circuits, and Schematics", it seemed that the one described in the section: "Photoflash circuit from Keystone pocket camera" might work if it could accommodate the 2.4 V NiCd rather than 3.0 V Alkaline battery it expects. This is often the case since Alkaline voltage is not really constant at 3.0 V but drops gradually as they are used up (NiCd voltage is nearly constant until the charge is exhausted). Therefore, it probably should work down to about 2.0 V (but with longer cycle time). And, the lower effective series resistance of NiCds would partially offset the lower initial voltage. I have a couple of the Keystone units so it is easy to try.

A simple test jumpering 4 wires confirmed functionality. The actual inverter portion of the Keystone flash occupies a volume of about 1" x 1-1/4" x 3/4" or just slightly more than that of the original dead inverter transformer! Some quick action with a hacksaw and nibbling tool resulted in a cute little circuit board that could be tucked into the available space. Some electrical tape assured that there would be no nasty short circuits. The chopper transistor was left exposed so any heat from it would have somewhere to go.

The excised circuit was attached to the positive terminal of the battery, the negative (center) at the switch, and the two secondary leads of the inverter transformer, taking care to get the polarities correct (the waveform out of the inverter is asymmetric and it would not work well if reversed). Except for T1 (dead) and C2 which I removed, all other components were left in place since they shouldn't affect anything.

It seems to work fine on both power settings and on battery or AC. The voltage on the energy storage capacitors stabilizes at about 315 to 325 VDC in all cases. The battery charges fine. What more can you ask? :-)

At first, I thought there was one slight problem: When plugged into an AC outlet with the power switch in the 'on' position (meaning the inverter is also running - the flash operates from AC with this switch off), I was afraid the voltage will eventually climb beyond the safe limits of the capacitors. Then, about 3 AM the next morning I realized there was a missing plastic piece that Stan had not sent me to prevent the switch from being moved into the 'on' position with the adapter plugged in (or vice-versa).

Comments: There is no doubt this unit would have hit the land-fill had it not been for my curiosity in determining what exactly was wrong - since the behavior didn't make sense given my (initially incorrect) understanding of the basic design. Once the nature of the AC adapter was revealed, everything fell into place. Had stand tested the transformer and found it to be open, I would have probably just suggested a nice funeral. :-(

Fortunately, the original inverter was so huge compared with the replacement that space was not a problem. I also believe that the cycle time is now about half of what it was originally so that is an added bonus. I bet the unit will produce more shots on a single charge as well.

Virtually all small battery powered electronic flash units use circuit designs that are very similar. Over the years, parts - particularly the chopper transistor and transformer - have improved greatly, thus the decreased size and increased efficiency.

Introduction

Scope of Thie Document

Capacitors may not be considered the superstars of electronic equipment (except perhaps in devices like xenon flash units and pulsed lasers), but more like the helpers and extras. However, they play a vital role in virtually everything that uses electrons in some way. A defective 2 cent capacitor in a TV or monitor can render it useless.

This document describes techniques for the testing of capacitors using a multimeter without a capacitance test mode. Information on safe discharging of high value or high voltage capacitors and a discharge circuit with visual indication of charge and polarity is also included.

There is also general information on capacitors, capacitance and ESR meters, and other related topics.

- Back to Capacitor Testing Table of Contents.

Safety Considerations

Basic Capacitor Safety

While accidental contact with capacitors on a 3.3 V logic board isn't going to result in a shocking experience, this is not true of many common types of equipment including TVs, computer and other monitors, microwave ovens; the switchmode power supplies in some VCRs, laptop computers, camcorder battery chargers; electronic flash and other xenon strobes; laser power supplies, and many other consumer and industrial devices.

Where equipment is AC line connected or uses high voltages, special precautions are required both for personal safety and to prevent damage to circuitry from careless actions. In addition to the specific safety issues with respect to capacitors discussed below, read, understand, and follow the recommendations provided in the document: Safety Guidelines for High Voltage and/or Line Powered Equipment before attempting any testing or repairs to equipment for which this applies.

Capacitor Testing Precautions

WARNING: make sure the capacitor is discharged! This is both for your safety and the continued health of your multimeter.

A pair of 1N400x diodes in parallel with opposite polarities may help protect the circuitry of a DMM. Since a DMM doesn't supply more than 0.6 V generally on ohms ranges, the diodes will not affect the readings but will conduct should you accidentally put the meter across a charged cap or power supply output. They won't do much with a charged 10 F capacitor or high current supply where you forgot to pull the plug but may save your DMM's LSI chip with more modest goof-ups.

This approach cannot be used with a typical analog VOM because they usually supply too much voltage on the ohms ranges. However, my 20 year old analog VOM has something like this across the meter movement itself which has saved it more than once.

- Back to Capacitor Testing Table of Contents.

Basic Capacitor Testing

Testing Capacitors with a Multimeter

Some DMMs have modes for capacitor testing. These work fairly well to determine approximate uF rating. However, for most applications, they do not test at anywhere near the normal working voltage or test for leakage. However, a VOM or DMM without capacitance ranges can make certain types of tests.

For small caps (like 0.01 uf or less), about all you can really test is for shorts or leakage. (However, on an analog multimeter on the high ohms scale you may see a momentary deflection when you touch the probes to the capacitor or reverse them. A DMM may not provide any indication at all.) Any capacitor that measures a few ohms or less is bad. Most should test infinite even on the highest resistance range.

For electrolytics in the uF range or above, you should be able to see the cap charge when you use a high ohms scale with the proper polarity - the resistance will increase until it goes to (nearly) infinity. If the capacitor is shorted, then it will never charge. If it is open, the resistance will be infinite immediately and won't change. If the polarity of the probes is reversed, it will not charge properly either - determine the polarity of your meter and mark it - they are not all the same. Red is usually **negative** with VOMs, for example. Confirm with a marked diode - a low reading across a good diode (VOM on ohms or DMM on diode test) indicates that the positive lead is on the anode (triangle) and negative lead is on the cathode (bar).

If the resistance never goes very high, the capacitor is leaky.

The best way to really test a capacitor is to substitute a known good one. A VOM or DMM will not test the cap under normal operating conditions or at its full rated voltage. However, it is a quick way of finding major faults.

A simple way of determining the capacitance fairly accurately is to build an oscillator using a 555 timer. Substitute the cap in the circuit and then calculate the C value from the frequency. With a few resistor values, this will work over quite a wide range.

Alternatively, using a DC power supply and series resistor, capacitance can be calculated by measuring the rise time to 63% of the power supply voltage from T=RC or C=T/R.

Ray's Notes on Capacitor Testing

(This section from: Raymond Carlsen (rrcc@u.washington.edu)

The best technique depends on what the cap is used for. A lot of electrolytics are said to be "leaky" when they are really partially open and just not doing their job. Electrolytics that are actually electrically leaky are not as common. You can take each capacitor out of circuit and test it with a cap checker or even a VOM, but in-circuit testing is faster. I don't like to grab for a soldering iron unless I'm pretty sure the part is bad. Time is money.

I first do a visual inspection and see if any electrolytics are bulging (they -are- leaky and usually get hot), or physically leaking (corrosion around terminals). Bulging caps in a switching power supply are a dead giveaway, but can point to leaky diodes as well. Next, if the unit will power up, I look for signs of filter caps open... hum bars in picture, hum in audio, flickering displays, low B+ but nothing gets hot, etc. You can tell quite a lot by just being observent and a makling a few simple checks. Try all controls and switches... you may get other clues. What works and what doesn't?

If you have an obvious fault... like a reduced vertical scan on a TV set or monitor for example, to find the cap that is starting to open up, you can bridge each of them with another cap, one at a time and see if it corrects the problem. (Experience has taught me that bad electrolytics will not -usually- kill vertical sweep completely.) In a TV set that is several years old or more, there could be more than one cap dried out (open). Check them all.

"Popping" filters (as it used to be called) by bridging the original with a like value is not good practice with solid state electronics. The shock to a live circuit is likely to damage other components, or it could shock the circuit into working again... for awhile. Then you get to sit there like a fool and wait for it to act up again... minutes or weeks later. For small electrolytics, I use a trick of bypassing each one with a small 0.1 to 0.47uF capacitor while the set is running. If I see -any- change in the performance, I KNOW the original is not doing its job (greatly reduced in value or open). Of course if you hit the timing caps, it will upset the vertical oscillator a bit... that's normal. For bigger electrolytics like the one used to feed the yoke or power supply main filters, the only effective way to check them is by substitution with the same or larger capacitance. Turn the set off, connect the new cap into the circuit and power it up again.

As I stated before, leaky caps are actually quite rare... but it does happen. They usually upset a circuit a lot more than open ones. Things tend to get hot quickly if the cap is a filter in a power supply. Shorted tantalums and electrolytics in power supplies can literally explode. Obviously, leaky caps must be removed from the circuit to substitute them for test purposes.

Most of the other types of small capacitors: mylar, disc ceramic, etc. are pretty rugged. It is rare indeed to find them bad. It happens just often enough to keep a tech humble.

Gary's Comments on Capacitor Testing

(From: Gary Collins (collgra@preferred.com).)

All an ohm-meter tells you is if the cap is shorted or not if it is an electrolytic of fairly large value it can tell you if a cap is open. I am a tech in a large industrial controls company in the factory service center. We consider any electrolytic cap to be suspect if it's code date is over five years old. We have a Fluke 97 and it is useless for in circuit tests. All a meter like a Fluke 97 can tell you is if the Cap is on the way to being open from electrolyte loss or if it is shorted. Actually not all you need to know. Several other facts you need to know are what is the conductance (internal leakage resistance), it sometimes varies with voltage. You also need to know what a caps power factor is in some cases. That is its ability to pass A.C. This is especially important in computer equipment that has to pass harmonics and noise to ground. Switching power supplies like are found in almost all PC's these days use high frequency voltage converters to regulate voltage. The harmonics and noise produced by this rapid switching heats DC filter caps and causes them to loose moisture from their imperfect seals. This effect causes the capacitor to gradually open or drop in capacitive value.

If you are talking about other types of capacitors you can test their value with a meter but I have seen caps that look good with a meter but break down under voltage. Special cap meters exist that test all these parameters and let you judge whether the cap is good or not but the best test short of that is to replace the cap and see if it works or not. Feel free to ask if that isn't what you wanted to know.

Actually sometimes the best test is to use a oscilloscope to look at what the cap is doing in the circuit.

What About Capacitance Meters?

Simple capacitance scales on DMMs just measure the capacitance in uF and do not test for leakage, ESR (Equivalent Series Resistance), or breakdown voltage. If the measurement comes up within a reasonable percentage of the marked value (some capacitors have tolerances that may be as much as +100%/-20% or more), then in many cases, this is all you need to know. However, leakage and ESR frequently change on electrolytics as they age and dry out.

Many capacitance meters don't test anything else but are probably more accurate than a cheap DMM for this purpose. A meter of this type will not guarantee that your capacitor meets all specifications but if it tests bad - very low - the capacitor is bad. This assumes that the test was made with the capacitor removed (at least one lead from the circuit - otherwise other components in parallel can affect the readings.

To more completely characterize a capacitor, you need to test capacitance, leakage, ESR, and breakdown voltage. Other parameters like inductance aren't likely to change on you.

ESR testers, which are for good for quick troubleshooting, are designed to just measure the Equivalent Series Resistance since this is an excellent indicator of the health of an electrolytic capacitor. Some provide only a go/no go indication which other actually display a reading (usually between 0.01 and 100 ohms so they can also be used as low-ohms meters for resistors in non-inductive circuits). See the section: What is ESR and How Can It be Tested?.

Note: always place the test probes on the capacitor terminals themselves if possible. Any wiring between your meter and the capacitor may affect the readings. Although your user manual may state that you can test capacitors in-circuit, other components in parallel with the capacitor can screw up the readings - usually resulting in an indication of a shorted capacitor or excessively large uF value. Removal is best. Unsoldering only one of the pins is adequate if you can isolate it from the circuit.

Substitution is really the best approach for repair unless you have a very sophisticated capacitance meterd.

The March 1998 issue of Popular Electronics has plans for a digital capacitance tester with a range from 1 pF to 99 uF.

The May 1999 issue of Popular Electronics has plans for an "Electrolytic Meter" which will accurately measure the capacitance and allow the determination of some of the other characteristic of large value capacitors - up to several hundred thousand uF. This is basically a time constant based tester using a constant current source.

More About Capacitor Testing than You Probably Wanted to Know

(From: John Whitmore (whit@hipress.phys.washington.edu).)

First, you need an AC ripple current source. Then, you tune to the frequency of interest (120 Hz for rectifier power supply filter capacitors is usual) and apply both the AC current and a DC voltage bias. Measure the phase shift between the current and the voltage (for a perfect capacitor, this is 90 degrees) and measure the induced voltage (for a perfect capacitor, this is I*2*pi*f*C).

Take the tangent of the difference of the phase shift and 90 degrees. (This is 'tan(delta)' and appears on the spec sheet for the capacitor...)

Then remove the AC, and crank the DC bias up to the voltage surge rating; measure leakage current. Ramp the DC bias down to the working voltage rating; measure leakage current.

Raise temperature and repeat the capacitance, phase shift, and working-voltage measurements at the max temperature the capacitor is rated for.

Yes, it DOES sound rather elaborate, but that's the test that the manufacturers use.

- Back to Capacitor Testing Table of Contents.

Safe Discharging of Capacitors in TVs, Video Monitors, and Microwave Ovens

Why This Matters

It is essential - for your safety and to prevent damage to the device under test as well as your test equipment - that large or high voltage capacitors be fully discharged before measurements are made, soldering is attempted, or the circuitry is touched in any way. Some of the large filter capacitors commonly found in line operated equipment store a potentially lethal charge.

This doesn't mean that every one of the 250 capacitors in your TV needs to be discharged every time you power off and want to make a measurement. However, the large main filter capacitors and other capacitors in the power supplies should be checked and discharged if any significant voltage is found before touching anything - some capacitors (like the high voltage of the CRT in a TV or video monitor) will retain a dangerous or at least painful charge for days or longer!

A working TV or monitor may discharge its caps fairly completely when it is shut off as there is a significant load on both the low and high voltage power supplies. However, a TV or monitor that appears dead may hold a charge on both the LV and HV supplies for quite a while - hours in the case of the LV, days or more in the case of the HV as there may be no load on these supplies.

The main filter capacitors in the low voltage power supply should have bleeder resistors to drain their charge relatively quickly - but resistors can fail. Don't depend on them. There is no discharge path for the high voltage stored on the capacitance of the CRT other than the CRT beam current and reverse leakage through the high voltage rectifiers - which is quite small. In the case of old TV sets using vacuum tube HV rectifiers, the leakage was essentially zero. They would hold their charge almost indefinitely.

(From: Edwin Winet (ewinet@softwareresearch.org).)

Some of us work in areas where capacitors are huge, unusual or sometimes both. Many people believe that only "big" capacitors can kill you, knock you across the room, blow a hole in you, or get your attention. Here are a couple of comments:

When a capacitor is safely discharged, do not stop there. Some capacitors, due to their ability to leak---are "dead" after being safely discharged with a "bleeder resistor" of the right value for the job. Using a resistor that is under-rated - wattage-wise - can result in the bleeder going open circuit DURING a discharge sequence LEAVING some energy! High voltage capacitors, or worse yet, high energy-high voltage capacitors require correct wattage AND correct resistance to be bled safely. Also, high microfarad low voltage capacitors can vaporize a screwdriver and spray metal in your eyes. (Adequate voltage margin is also essential for resistors used in high voltage circuits. --- Sam.)

Certain types of capacitors are made of VERY good materials, which can hold a charge for YEARS! Putting away charged capacitors of this type is an invitation to disaster!

Low inductance capacitors that are used in energy pulse circuitry, many times are of the oil-filled high energy/high voltage type. This type can give a MOST un-pleasant surprise AFTER it has been completely drained by a safe bleeding technique. After the capacitor has been bled, IMMEDIATELY short it, from terminal to terminal AND to the external metal can (if applicable)!!! These capacitors RE-charge from their internal fluid and can STILL deliver a lethal, as they "recover" a certain amount of energy! this type of capacitor, or any capacitor of any high (enough) energy value MUST be LEFT shorted.

Be particularly leery of any capacitor with a broken off lead that is sitting in a drawer! Sometimes, these units break off during testing and don't get thrown out - but remain charged - to kill or shock years later.

Lastly, the word "electrocution" is used in many high voltage device writings. That's bad, because it was only intended for the "electric chair", short for electro + execution.

Capacitor Discharge Technique

The technique I recommend is to use a high wattage resistor of about 5 to 50 ohms/V of the working voltage of the capacitor. This isn't critical - a bit more or less will be fine but will affect the time it takes to fully discharge the capacitor. The use of a current limiting resistor will prevent the arc-welding associated with screwdriver discharge but will have a short enough time constant so that the capacitor will drop to a low voltage in at most a few seconds (dependent of course on the RC time constant and its original voltage).

Then check with a voltmeter to be double sure. Better yet, monitor while discharging (monitoring is not needed for the CRT - discharge is nearly instantaneous even with multi-M ohm resistor).

Obviously, make sure that you are well insulated!

- For the main capacitors in a switching power supply, TV, or monitor, which might be 400 uF at 350 V, a 2 K ohm 25 W resistor would be suitable. RC=.8 second. 5RC=4 seconds. A lower wattage resistor (compared to that calculated from V^^2 / R) can be used since the total energy stored in the capacitor is not that great.

- For the CRT, use a high wattage (not for power but to hold off the high voltage which could jump across a tiny 1/4 watt job) resistor of a 1 to 10 M ohms discharged to the chassis ground connected to the outside of the CRT - NOT SIGNAL GROUND ON THE MAIN BOARD as you may damage sensitive circuitry. The time constant is very short - a ms or so. However, repeat a few times to be sure. (Using a shorting clip lead may not be a bad idea as well while working on the equipment - there have been too many stories of painful experiences from charge developing for whatever reasons ready to bite when the HV lead is reconnected.) Note that if you are touching the little board on the neck of the CRT, you may want to discharge the HV even if you are not disconnecting the fat red wire - the focus and screen (G2) voltages on that board are derived from the CRT HV.

- For the high voltage capacitor in a microwave oven, use a 100 K ohm 25 W (or larger resistor with a clip lead to the metal chassis. The reason to use a large (high wattage) resistor is again not so much power dissipation as voltage holdoff. You don't want the HV zapping across the terminals of the resistor.

Clip the ground wire to an unpainted spot on the chassis. Use the discharge probe on each side of the capacitor in turn for a second or two. Since the time constant RC is about 0.1 second, this should drain the charge quickly and safely.

Then, confirm with a WELL INSULATED screwdriver across the capacitor terminals. If there is a big spark, you will know that somehow, your original attempt was less than entirely successful. At least there will be no danger.

DO NOT use a DMM for this unless you have a proper high voltage probe. If your discharging did not work, you may blow everything - including yourself.

The discharge tool and circuit described in the next two sections can be used to provide a visual indication of polarity and charge for TV, monitor, SMPS, power supply filter capacitors and small electronic flash energy storage capacitors, and microwave oven high voltage capacitors.

Reasons to use a resistor and not a screwdriver to discharge capacitors:

1. It will not destroy screwdrivers and capacitor terminals.

2. It will not damage the capacitor (due to the current pulse).

3. It will reduce your spouse's stress level in not having to hear those scary snaps and crackles.

Capacitor Discharge Tool

A suitable discharge tool for each of these applications can be made as quite easily. The capacitor discharge indicator circuit described below can be built into this tool to provide a visual display of polarity and charge (not really needed for CRTs as the discharge time constant is virtually instantaneous even with a muli-M ohm resistor).

- Solder one end of the appropriate size resistor (for your application) along with the indicator circuit (if desired) to a well insulated clip lead about 2-3 feet long. For safety reasons, these connections must be properly soldered - not just wrapped.

- Solder the other end of the resistor (and discharge circuit) to a well insulated contact point such as a 2 inch length of bare #14 copper wire mounted on the end of a 2 foot piece of PVC or Plexiglas rod which will act as an extension handle.

- Secure everything to the insulating rod with some plastic electrical tape.

  This discharge tool will keep you safely clear of the danger area.

Again, always double check with a reliable voltmeter or by shorting with an insulated screwdriver!

Capacitor Discharge Indicator Circuit

Here is a suggested circuit which will discharge the high value main filter capacitors in TVs, video monitors, switchmode power supplies, microwave oven capacitors, and other similar devices quickly and safely. This circuit can be built into the discharge tool described above (Note: different value resistors are needed for LV, HV, and EHV applications.)

A visual indication of charge and polarity is provided from maximum input down to a few volts.

The total discharge time is approximately:

- LV (TV and monitor power supplies, SMPSs, electronic flash units) - up to 1000 uF, 400 V. Discharge time of 1 second per 100 uF of capacitance (5RC with R = 2 K ohms).

- HV (microwave oven HV capacitors) - up to 5,000 V, 2 uF. Discharge time of 0.5 second per 1 uF of capacitance (5RC with R = 100 K ohms)

- EHV (CRT second anodes) - up to 50,000 V, 2 nF. Discharge time of 0.01 second per 1 nF of capacitance (5RC with R = 1 M ohm). Note: discharge time is so short that flash of LED may not be noticed.

Adjust the component values for your particular application.

The two sets of 4 diodes will maintain a nearly constant voltage drop of about 2.8-3 V across the LED+resistor as long as the input is greater than around 20 V. Note: this means that the brightness of the LED is NOT an indication of the value of the voltage on the capacitor until it drops below about 20 volts. The brightness will then decrease until it cuts off totally at around 3 volts.

WARNING: Always confirm discharge with a voltmeter before touching any high voltage capacitors!

For the specific case of the main filter caps of switchmode power supplies, TVs, and monitors, the following is quick and effective.

(From: Paul Grohe (grohe@galaxy.nsc.com).)

I've found that a 4 watt 'night light' bulb is better than a simple resistor as it gives an immediate visual indication of remaining charge - well down to below 10 V.

Once it stops glowing, the voltage is down to non-deadly levels. Then leave it connected for a little while longer, and finish it off with the `ole screwdriver.

They're cheap and readily available. You can make dozen 'test-lamps' out of an old 'C7' string of Christmas lights (`tis the season!).

Editor's note: where a voltage doubler (or 220 VAC input) is involved, use two such bulbs in series.

(From: Dave Talcott (75711.1537@compuserve.com).)

I built the capacitor discharge tool. I had all the parts to hand except for the series resistor, for which I used a 2 watt axial unit, since the power dissipation is not critical. I decided to package it in probe form for convenience. Except for the series resistor, which lives in a counterbore, everything is surface mounted and communicates through a LOT of cross-drilled holes. A piece of heat-shrink tubing holds everything in place. The only tricky part was making two small recesses to locate the LEDs. The probe tip is a short piece of solid copper wire salvaged from some Romex house wiring and ground to a point.

Voltage Checkers

Whereas a multimeter is intended to measure voltages (and other things), a checker is used mostly to just produce a quick indication of the presense of voltage, its polarity, and other basic parameters. One use is a quick, but reliable indication of the status of the charge on a BIG capacitor. An, example of a simple version of such a device is the "capacitor discharge indicator circuit" described above.

(From: Ian Field (ionfieldmonitors@ic24.net).)

The version of the checker that I have, also contains a miniature 12 V battery for continuity checking - any resistance less than about 22K will produce some glow. It's handy for quick checks of semiconductor junctions - in general if it produces a slight glow it's leaky, but transistor B/E junctions have an inherent zener voltage, so there is usually some glow. Also schottky-barrier diodes give a reverse leakage glow - this does not mean they're faulty, check the Vf with the diode-check on a DMM before binning! Any zener diode above 10-11 V can be given a quick test for S/C, lower Vz will produce some glow - again check Vf before binning.

These checkers are getting hard to obtain, most of the component stockists here only carry vastly over complicated (and expensive) versions with built-in measurement computer and LCD - these wouldn't last 5 min's around flyback circuitry! Some Automotive accessory shops have a simpler version with no battery - always check that it's stated to be capable of measuring AC or DC at 4 to 380 V before parting with money! The internal circuit should contain the LED's, a 15 ohm resistor to limit the maximum surge current when the PTC is cold and the special PTC film-thermistor. The battery can be added with a button from a VCR front panel - but don't blame me if you kill yourself because you didn't insulate the added components properly! There is a more complicated non-battery version with 2 LED's close to the front of the handle to indicate polarity and a row of LED's along the length of the handle to indicate the voltage-range. This version contains 2 special PTC's and a discrete-transistor bargraph circuit - there might be room to add a battery inside the case. As for the special PTC this is the only place I've seen them - one possibility that might be worthy of looking into is the Siemens PTC SMPSU startup thermistor for TDA4600 control chips, this usually has a series resistor of at least 270 ohms and is more likely to turn-up in European TV set's, but I have seen it in early Matsushita IBM displays and a few others (possibly Tandon) the PTC thermistor is always blue and looks like a very-miniature copy of the Philips white-plastic PTC degauss thermistor.

Equivalent Series Resistance (ESR) and Related Parameters

What is ESR and How Can It be Tested?

ESR (Equivalent Series Resistance) is an important parameter of any capacitor. It represents the effective resistance resulting from the combination of wiring, internal connections, plates, and electrolyte (in an electrolytic capacitor). The ESR affects the performance of tuned circuits (high ESR reduces the Q factor) and may result in totally incorrect or unstable operation of devices like switchmode power supplies and deflection circuits in TVs and monitors. As would be expected, electrolytic capacitors tend to have a high ESR compared to other types - even when new. However, due to the electrochemical nature of an electrolytic capacitor, the ESR may indeed change - and not for the better - with time.

Here is a Web site that discusses ESR testing in some detail:

- Stephen M. Powell's ESR Page

When troubleshooting electronic equipment, electrolytic capacitors, in particular, may degrade resulting in a significant and unacceptable increase in ESR without a similar reduction in uF capacity when measured on a typical DMM's capacitance scale or even a cheap LCR meter.

There commercial ESR meters and kits available ranging from $50 to $200 or more. Here are a couple of sites to check out:

- Bob Parker's ESR Meter Site (both low cost kit and assembled versions are available).

- Capacitor Wizard Site

There devices can generally be used to measure really low resistances of non-inductive devices or circuits as well (they use AC so inductance would result in inaccurate readings). Since their lowest range is at least 10 times better than a typical DMM (1 ohm full scale - 0.01 ohm resolution), they can even be used to located shorted components on on printed circuit boards.

Note: always place the test probes on the capacitor terminals themselves if possible. Any wiring between your meter and the capacitor may affect the readings. While usually not a problem, very low resistance components in parallel with the capacitor may result in a false negative indication - a capacitor that tests good when in fact its ESR is excessive.

(From: Larry Sabo (ac274@FreeNet.Carleton.CA).)

I find my ESR meter invaluable for finding high ESR caps, and have never seen a shorted cap that hadn't exploded. It's such a pleasure to zip through the caps in a power supply that's duff and find the ones that have had it, all without touching the soldering iron.

There have been days I wish I had the LC102 for it's leakage measuring capability, but in my limited experience the 10% figure seems high. The LC102 commends itself for the inductance ringer, too, but you sure pay a premium. I'll build Sam's gizmo first.

BTW, I built my ESR meter from a kit purchased from Dick Smith Electronics in Australia, for $A 52.74 + $A 25.00 for delivery. It took about 8 hours to assemble, but I'm a fuss-ass.

More on ESR, DF, and Q

(From: Michael Caplan (cy173@FreeNet.Carleton.CA).)

Before I bought my ESR meter I too wondered--what exactly did it measure? Nevertheless, having heard so much about the meter, I went ahead and bought one. It works, and that's the real bottom line.

A recent question about what exactly in being measured (DF or Q) piqued my interest again. I think I have the answer -- 'think' being the operative word. Here's my interpretation.

In summary, the ESR is indeed related to Dissipation Factor (DF), but it is not the same. A DF measuring device might not as readily identify a bad capacitor as does the ESR meter because the reading varies and is not direct, as described below.

Capacitors may be thought of as having pure capacitance (C) and some pure resistance (R), the two being in series. An ideal capacitor would have only C, and no R. However, there are the leads and plates that have some resistance and constitute real R. Any R in series with C will reduce the capacitor's ability to pass current in response to a varying applied voltage, as in filtering or DC isolation applications, and it will dissipate heat which is wasteful and could lead to failure of the component. As with ESR, a lower DF (or higher Q, it's inverse) may be equated with better performance, all other things being equal.

Now I get a bit more mathematical, but only using basic electronic theory and formulas so I hope most will be able to follow this.

DF is defined as Rc/Xc, the ratio of the R in the capacitor (Rc) to the reactance of the capacitor (Xc). The higher the Rc, the higher the DF and the "poorer" the capacitor. So far so good.

The reactance (Xc) is a function of frequency. Xc=1/(2*pi*f*C). So, as the frequency goes up, Xc goes down. Now look back at the formula for DF. DF is an inverse function of Xc. As Xc goes down, DF goes up, and vice-versa. So DF varies proportionately with frequency.

Here's an example using the ubiquitous 22 uF, 16 V electrolytic that seems to be at fault too often in many switched mode power supplies.

At 1000 Hz, this capacitor has an Xc of 7.2 ohms. If the series Rc is only 0.05 ohms (pretty good), then the DF is 0.0069.

At 50,000 Hz, this same capacitor would have an Xc of only 0.14 ohms. At this frequency, the DF is 0.36, again good.

Now, change the Rc from 0.05 to 25 ohms. At 1000 Hz, DF = 3.4. At 50,000 Hz, DF = 178.

So we see that DF is a function of the test frequency. The higher the frequency, the higher the DF. DF is a measure of the capacitor "quality", but the figure is valid only at the frequency of the test. (A good capacitor, with an ideal Rc of zero, will have a DF of zero regardless of frequency.)

DF can indeed be used to identify a bad capacitor, but the user must interpret the level of measured DF that would indicate a bad component. Any 'go/no go' tables of DF values would be valid only at the specified frequency. As an alternative, the user can calculate the Rc by first measuring both DF and C, and then, knowing the test frequency, determine if the Rc is excessive. (Rc=DP*Xc).

The ESR meter measurement system, however, does not appear to be a function of Xc. It measures the voltage across the capacitor resulting from the application of a very short pulse of current. This short pulse is not enough to charge the capacitor so the voltage being measured across the capacitor's leads is primarily a function of Rx, which is not frequency sensitive. And, with the 'tables' of typical ESR (=Rc) that is provided with the ESR meters I have seen, there is no need to do any further calculations.

The ESR meter is not going to be reliable with very small capacitors. In this case, they will become more fully charged by the applied current at the time the meter samples the voltage. Even if the Rc is an ideal zero ohms, the meter will now read the voltage built up on the capacitor and interpret it as a very high (possibly off-scale) ESR. Thus its advantage, and main purpose, is in testing electrolytics which tend to be larger value capacitors.

(Note: The inability of the ESR meter to test low value capacitors is true only if the meter does not distinguish between in-phase and quadrature voltages, and it does not. If it did sense only the in-phase voltage that is produced across Rx (i.e. in-phase with the applied current), then it would not be sensitive at all to the delayed (minus 90 degrees) voltage built up on the capacitor's plates.)

All testing I have done with small capacitors (less than 0.001 uF) seems to suggest that the (Bob Parker) ESR meter is not phase discriminating and Bob Parker has confirmed this. This is not a great disadvantage. The objective of the ESR meter is to identify capacitors that have gone bad. This is more the case with electrolytics where the dielectric compound tends to dry up. Smaller capacitors usually are not electrolytic and therefore tend to be relatively stable. Faults in the latter (e.g. ceramic, mica, polystyrene) are more likely to be open, shorted, or leaky, all of which will be detectable by capacitance or resistance measuring devices.)

(From: Roy McCammon (rbmccammon@ieee.org).)

Note that "equivalent series resistance" is not necessarily the same as "series resistance".

"Series resistance" is just the resistance in series with the capacitance. This is what most of the descriptions have delt with, and with high currents and frequencies as you tend to see in a switchmode supply, the "true series resistance" is just what you want to know.

"Equivalent series resistance" is the resistance that you would have to place in series with a pure capacitance to produce the same loss. It may be frequency dependent. A cap with a resister in parallel has an esr. At a single frequency, you cannot tell the difference between a cap with a parallel resister and a cap with a series resister. For example, at 100 Hz, a 1 uF and 10 ohm in series has a reactance of 10 + J1591, as does a 1 uf in parallel with 253K, hence both have an ESR of 10 ohms.

You need to know just what your meter is doing. Its best that the measurement relate to your use.

Simple ESR meter schematics and plans

Electronics magazines have published various ESR meter schematics over the years. Here is one that is unique is being able to test caps on live equipment though I'm not sure what great advantage this is:

(From: Pete Culf (pete@topden.com).)

> "The January 2003 issue of Television magazine has an article about a *live* - in circuit electrolytic ESR

> tester. The battery operated project by Ian field is based on a TL431 high gain comparator with the input isolated via an optocoupler. It is designed for live testing. I haven't built the thing yet as it's my habit to wait awhile and read about any problems the other guys find before I try it, but in subsequent issues I havn't read of any problems."

Here are a couple of basic analog ESR meter schematics:

Mark Zenier (mzenier@eskimo.com) has an ESR Meter Schematic which is about as simple as it gets.

(From: Gary Woods (gwoods@albany.net).)

Thanks to a friend with a scanner, ESR meter schematics, theory of operation, and sales literature (From a company that, alas, no longer exists) are on my ESR Meter Page.

Boat-anchor relevance - although the device is sand-state, it's just the ticket for checking out those old 'lytics!

ESR testing without an ESR meter

While, the techniques described below can in principle be applied to any capacitor, they will be most useful for electrolytic types. Of course, make sure to observe the polarity and voltage rating of the capacitor during testing! In addition, take care with the maximum voltage applied to other components if you attempt to test caps in-circuit. It should be small enough that semiconductor junctions do not get forward biased (a few tenths of a volt max) and the impedance should be such that low value resistors don't smoke!

The ultimate in cheap if you have an oscilloscope would be: 99 Cent ESR Test Adapter.

(From: Ron Black (ron.black@pstbbs.com).)

An inexpensive way (for the cost of a resistor) to measure the ESR of a capacitor is to apply a squarewave signal through a resistor in series with the capacitor under test. Monitor the waveform on the capacitor using an oscilloscope. When using a sensible squarewave frequency (a few kHz - not one where the inductance of the circuit becomes an issue) there will be a triangle waveform with a step at the squarewave transition times. The amplitude of the step will proportional to the ESR of the capacitor. Calibrate things by adding a known small value ESR simulating resistor in series with the capacitor. This doesn't have to cost anything if you have a squarewave generator, or can build one cheaply.

(From: Gary C. Henrickson (gary@aloha.net).)

Motivated by the discussions on the virtues of ESR testing, I ordered a genuine ESR meter. While waiting for it's arrival, a large pile of dogs were accumulating in my shop.

To crank out these repairs quickly in the meantime, I constructed an 'ESR meter' by cabling a (50 ohm) function generator output to the scope input and, via a T-connector, on to a set of test leads.

With the test leads shorted, mere millivolts displayed on the scope. Across a good capacitor, mere millivolts. Across a sick capacitor, mucho volts. The defective caps stuck out like a sore thumb.

Wow, this is too easy. Instant in-circuit (power off) fool-proof testing of electrolytics. I wish I had thought of this 50 years ago.

I used 100 kHz and 5 V p-p. With scope set at 0.2 V/div you can also check diodes surrounded by low ohm transformer or inductor windings.

(Editor's note: to avoid the possibility of damage to semiconductors due to excessive voltage, use a lower amplitude signal - say 0.5 V p-p - for in-circuit testing. This will also prevent the most semiconductor junctions from conducting and confusing your readings.

(From: Bert Christensen (70461.2507@compuserve.com).)

I have been reading the various messages about ESR checkers and while I don't doubt their value in electronic servicing, I think that the use of these devices adds an extra and IMHO unneeded step. My method of diagnosing possible electrolytic fault is to use just a scope. Remembering that electrolytics pass AC or signals through them, a scope should show *the same* waveshape on both sides of the cap. If the cap is a bypass cap to ground, then the waveshape should just be a flat line on both sides; if it is a coupling cap, the waveshape should be the same on both sides.

There are some exceptions, one being a cap that is used for waveshaping in a vertical circuit but such applications are few. Most electrolytics are either coupling or bypass.

Using 'my' scope method has several advantages. The main one is that it tests caps dynamically in the circuit they are used in and using the actual signals applied to them in real life. The method is fast because you just have to go from one to another (if you are using the scatter-gun approach) using just the scope prod. But, best of all, it seamlessly integrates a total dynamic approach to servicing using the set's own signals or lack thereof. If you are tracing a video circuit, you can find an open cap, an open transistor, or a defective IC using the same piece of equipment.

I have been running a service business for over 40 years. Most of my business today is doing tough-dog service for other service companies.

But, I must admit that sometimes I fix sets just by changing the caps that are swollen. ;-}

(From: Clifton T. Sharp Jr. (clifto@megsinet.net).)

I still do just enough work that I'll one day break down and buy an ESR meter (I always give in and indulge myself with the toys of my "trade"). For now, though, the quickie method I use is the oscilloscope. It goes something like this:

1. Scope positive lead. Any significant AC? If not, go to next cap.

2. Is the AC more than about 5% of the DC? If not, note this location and go to next cap.

3. Scope negative lead. AC here roughly the same as on positive lead? If so, go to next cap. (If this lead is *obviously* grounded, skip this step.)

4. Set off; note value; jumper in roughly same value at safe voltage rating. (Note: make sure both caps are discharged! --- sam)

   Set on; scope positive lead. Significant difference? If not, note this location and go to next cap.

5. Replace cap. Test set. If not okay, go to next cap.

If that doesn't catch it, a quick review of the "noted locations" often does. This fixes 98% of cap problems. Not exhaustive or perfect, nor is it intended to be. Close cover before striking. Probably causes cancer in laboratory rats. Your mileage may vary.

(From: Tony Williams (tonyw@ledelec.demon.co.uk).)

It is always best when measuring a component parameter to lean the measurement method towards some sort of emulation of the application to which the parameter is important. This is particularly true of power components, because the parameter-value may vary with operating conditions. It is essential with magnetics, less so with electrolytics, but a good habit anyway.

Hold the cap charged up and find some way of applying repetitive square *current* pulses to it, an Amp or more each time, depending on the expected ESR.

If the cap has no ESR then a scope across its terminals will show that each current pulse results in a nice smooth ramping triangle. If the cap has an ESR then each triangle will be preceded by a small vertical step. If the current is known, measurement of that step gives you the ESR-value. You can cross-check the accuracy of the method by seeing the effect of increasing the "ESR" as low-value R's are put in series with the cap, 0.01 to 0.1 ohms.

Be careful about the placement of the scope leads, you don't want to measure the IR-drop in the wiring.

If the size of each step+triangle is small compared to the steady voltage on the cap then the known "constant-I" discharge pulse can be approximated with no more than a resistor and switching Fet.

(From: Oliver Betz (list_ob@gmx.de).)

If you want to the decoupling capability, you maybe want to know the ESR only at the series resonant frequency. It's quite simple:

Use a sine generator, connect some coax cable to its output, at the end of the cable put 47 ohms in series and connect the resistor to one end of the cap, connect a kind of detector in the same way (47R - cable - detector) to the same lead. Other end of the cap (and coax shields) to a small ground plane. Detector can be voltmeter, scope or spectrum analyzer, depends on your equipment and resonant frequency. Spectrum analyzer with tracking generator eliminates need for separate generator, makes measurement easy and enables you to measure even very small capacitor values.

Tune to minimum signal at the detector. With a scope you can check also phase shift (thanks for this hint, Winfield!), cap should be only resistive (no phase shift). ESR can be easily calculated now.

(From: George R. Gonzalez (grg@umn.edu).)

After seeing all the glowing recommendations for ESR meters on the sci.electronics.repair newsgroup, I decided to look into this. Being a cheap sort, I first tried setting up my own ESR meter using stuff lying around the shop: Function generator set to 2 volts p-p, 100 kHz sine wave, hooked up to a BNC tee, one side of the tee goes to some clip leads, other side to the scope, set for 0.1 volts/cm, 10 us/cm sweep.

With the clip leads dangling free, the scope trace is almost invisible, as it's zooming up and down 20 cm 10 times across the screen. With the clip leads shorted, I get about 0.3 cm of a sine wave. With a 1 ohm resistor across the clip leads, I get about 1 cm of sine wave.

I put a GOOD 2 uF capacitor across the clip leads, we see about 0.5 cm of sine wave. Tests with various good electrolytics all give less than 1 cm of sine wave.

Now we can just hop along a circuit board bridging the electrolytics as we go along. A good electrolytic is going to show 1 cm or less of deflection. Many old ones with 1970's date codes will show 2 or 3 cm. Probing around a suspect old pc board revealed that 80% of the caps gave more than 2 cm of deflection!

Now this isn't always a bad thing. You have to use a little judgement. If the electrolytic is in a high-impedance circuit, such as coupling two voltage amp stages, a few ohms isn't going to hurt too much. But if it's a bypass capacitor on a Vcc line, it could be significant. Just realize that a circuit may appear to work just fine even with caps with many ohms of ESR. I usually replace these caps anyway, as they're only going to go downhill from here.

I can't tell you how much time this little set-up has already saved me!. Before I had to unsolder one lead of the capacitor, hook it up to the cap bridge, twiddle the dials until I got a semblance of balance, or if it was a bad capacitor, I'd waste even more time trying to find the missing null. Now I can just probe the caps in-circuit, and mark the bad ones with a big red magic-marker for later replacement. It's quick and great for morale.

This method works well with caps in the range of 1 to 500uf, with medium or high ESR. But it doesn't have enough oomph to drive BIG caps. For this you'd need a generator with a lower output impedance.

Next experiment-- we'll hook up a tranny from an old dead SMPS to lower the generator's output impedance so we can test those big PS capacitors. Stay tuned....

BTW, this isn't meant to take away from built ESR meter sales! It may even increase them as once you see how wonderful this technique is, you may want to buy a dedicated ESR meter.

- Back to Capacitor Testing Table of Contents.

Electrolytic Capacitors and Special Types

Cool Electrolytics - Temperature Rating Versus ESR

(From: Jeroen H. Stessen (Jeroen.Stessen@philips.com).)

Electrolytic capacitors like to be kept cool! If there's anything that these capacitors can't stand, it's heat. It causes them to dry out.

Electrolytic capacitors exist in (at least) two different temperature ratings: 85 C and 105 C. The latter are obviously more temperature resistant. Unfortunately they also tend to have a higher ESR than their 85 C counterparts. So in an application where the heat is due to I^2 * ESR dissipation, the 105 C type may actually be a *worse* choice! If the heat is due to a nearby hot heatsink then 105 C is indeed a better choice.

From: Ralph W. M. (ralphwm@aol.com).)

While it seems true that 105 C electrolytics have about 50% greater ESR when new, compared to similar 85 C electrolytics, IMO, that is not significant in the circuit. If you would (could) perform a long term experiment and install a 85C and a 105 C in the same circuit, and measure the ESR after 1,000 hours, I would expect to see the ESR of the 105 C part after aging/usage, now to be less than the 85 C.

Care, Feeding, and Storage of Electrolytic Capacitors

> "I seem to recollect reading (or is it an old wives' tale?) that electrolytics last longer if you apply a voltage

across them every so often. This to me implies that seldom used devices should be turned on every now and again to make them last longer, not left sitting on the shelf. True or false?"

(From: Ralph W. M. (ralphwm@aol.com).)

Electrolytics have a shelf life. Electrolytics can go bad (i.e., dry out) on the shelf even though they were never used/turned on even once.

Technically, a "stale" electrolytic (more than one year after it was manufactured) would have excessive DC leakage, and should be properly re-formed before using it. In practice, I have never found this to be a problem 99% of the time (only exception is critical timing/direct coupled circuits; very rare these days). The worst I have even noticed, when installing a stale electrolytic, was that the circuit was slightly unstable for 15 minutes, but cleared up and was fine thereafter and NEVER "bounced". (all bets are off if something so old it has "whiskers" is tried though).

How old is too old? I would offer that up to 5 years on the shelf, in practice, should not be a problem. But 10 years stale MIGHT upset things a bit.

Technically, if you read electrolytic specification sheets, you will find that the best (i.e., lowest) DC leakage is not until it has been ACTUALLY used for at least 10% of the total projected lifetime, (i.e., a 1,000 hour @105C electrolytic would not achieve the lowest DC leakage until it was used for 100 hours @ 105C (or used for 600 hours @ 65C; but that conversion is another story).

In practice, IMO, the vast amount of circuitry designs/type of circuits being currently designed, have built into it enough tolerance for above average DC leakage, that (these days), excessive/drifting DC leakage is rarely a problem.

As far as "exercising" seldom used equipment; couldn't hurt.

Some Qs & As about Capacitor Failure

Here is a three part question concerning electrolytic capacitors. This is an automotive computer application.

Problem: Electrolytic capacitors are leaking after a period of time causing computer failure.

Questions:

1. What is/are the physical mechanism which causes the dielectric to leak?
2. Is there advantage to upping the voltage rating for a replacement cap?
3. What are the pros and cons of Tantalum replacements?

(From: Asimov (mike.ross@juxta.mnet.pubnix.ten).)

1. Heat is the enemy of the dielectric, it may be passing a lot of high frequency current for which it was not designed. Leakage current increases exponentially with temperature.

2. This reduces the possibility of rupture of the dielectric junction which, though usually self-healing, can become permanent after repeated episodes.

3. Tantalums will work well into the sub megahertz range. The main problem with them is when their dielectric ruptures and it is connected across a supply with ample current, it can draw some fantastic amount of energy. This usually results in an explosion of the capacitor which sprays hot molten material all around. It goes off like a

gunshot and the tantalum pellet is the bullet.

Comments on ESR and uF Ratings

(From: Asimov (mike.ross@m-net.axess.com).)

I saw a very revealing graph in the Sprague catalog concerning life tests at +130'C plotting ESR versus time. It turns out that for a 10 uF cap, the ESR actually drops during the first 1,500 hours or so. The interesting part is that from 1,500 hours out to 5,000 hours the value then about doubles.

On the other graph the results of a 47 uF cap shows no change in ESR over the whole life time test. However, it's uF value drops by about 2.5%. The 10 uF electro on the other hand shows little capacitance change (less than 1%).

If we extrapolate these results we can see a general trend of the larger value caps losing capacitance over time but their ESR remaining pretty constant and the smaller caps keeping their value but their ESR increases over time. Thus this sort of makes some sense to me as to why those little 1 uF caps are so notorious. Comments welcome...

Voltage Rating of Electrolyitc Capacitors Versus Reliability

Some of the questions go like:

> "I am wondering if there is any problem with replacing a cap of lower voltage rating with one of higher rating. For example, would a 2.2uf 50v cap generally work OK as a replacement for a 2.2uf 16v cap which is used as a filter in a 6 volt or 12 volt circuit? I never used to think twice about doing this, but have seen some discussion recently leading me to question whether an electrolytic will function properly if it is only operated at a small fraction of its rated voltage."

(From: Ralph W. M. (ralphwm@aol.com).)

I know a lot of people try to improve reliability by increasing the volt of the replacement electrolytic. And some companies like Sony issue modification upgrades increasing volt rating. And yes, SOME, (but NOT all) electrolytic manufacturers recommend increasing volt rating to improve reliability of ORGANIC electrolytics. But in my opinion, I would not, and do not.

To improve reliability, I first upgrade the temp. Or I might chose to upgrade to a Low ESR electrolytic. Sometimes, circumstances or logistics prevents the proceeding, and I will increase the uF up to 200% of original IF it is filtering or decoupling application.

Basically, any improvement in lifetime from increasing volt rating would simply come from the larger case size allowing the electrolytic core temp to be perhaps 5C cooler, i.e., the temp reduction comes from the larger case size being a better "radiator". I estimate that increasing the volt rating of the replacement part would not achieve greater than 50% lifetime improvement; BUT at the expense of greater/worse DC leakage, (the greater DC leakage might not be a problem).

On the other hand, I have read some component manufacturers who recommend increasing the uF to improve reliability, and I estimate that 2X the original uF will result in at least 200% improvement (maybe 400%), in component operating lifetime.

And, to anticipate a possible question, i.e., "what if you tried to restore the "1.5X" cap that was operated at a lower voltage to it's original volt rating by trying to carefully, and slowly increasing the applied voltage in order to restore the dielectric". Maybe, I don't know, never performed such an experiment. At a minimum it would require a lot of labor on something that cost relative pennies.

(From: Steve Bell (service@bell-electronics.freeserve.co.uk).)

From experience I see no problem fitting capacitors of slightly higher voltage ratings. I keep a full range of high frequency low ESR 105 deg caps. I find, as an example, when I replace a 47uf 35V cap, it is with a 47uf 50v device. Due to improvements in capacitor manufacturing, the replacement fitted is usually the same size, possibly smaller, and usually has a lower ESR than the original did before failing..

Where problems might occur is if someone fits a much higher voltage cap in a critical area, such as a monitor switchmode power supply or video circuit. Higher voltage capacitors have higher ESR that may be unsuitable for the circuitry.

(From: Robert Macy (macy@california.com).)

The higher voltage electrolytic has a higher esr value.

The ripple current will be the same for both caps and the higher esr means more power dissipated into the cap, drying out the electrolyte and shortening the capacitor's life a lot.

Comments on Old Electrolytics and Failure Mechanisms

A question that often (well, at least sometimes) comes up is what to do with respect to electrolytics capacitors in really old equipment. Replace all?

Without going into an extended discussion (see below):

1. There is no general rule.

2. Equipment that has been heavily used and/or in a hot environment will likely have more problems with dried up capacitors.

3. I would generally just check them and replace any that are much reduced in uF value, have higher ESR, or higher leakage after giving them time to reform. I just was working on a 30 year old Minox strobe. Its electrolytics seem to be as good as the day they were manufactured.

   (From: David Sherman (davids@virtual-cafe.com).)

   I have been "into" electronics for at least 20 years and learned electronics originally on old WWII military surplus gear which was cheap at the time. Since then I have been a degreed EE and professional engineer and an avid junk collector. To really old military gear designers often went to a lot of expense to avoid electrolytics. They' use a big 2-section choke and a couple 4uF oil-filled paper capacitors in a power supply rather than just one big electrolytic because the electrolytics in those days tended to "dry out" and fail with age.

   In early consumer electronics I have often found bad electrolytics. The first thing to do on that old stuff is look and see if anything has leaked out of the capacitors. Next, power it up. It's not unusually at that point for something that has been idle to blow a capacitor with a puff of steam! Then you know which one's bad. Signal capacitors (coupling, emitter/cathode bypass, etc) are not usually a problem because they don't have so much voltage on them as power supply capacitors. After replacing any blown capacitors (and maybe other that look just like it) fire the thing up again. If it doesn't work, check DC voltages across all electrolytics. Even if you don't know what they're for, they should all have DC of the proper polarity and usually within a fair fraction of the working voltage printed on them. Also feel to see if any is hot. I think you're getting the idea.

Now, about salvaging old capacitors. Ones made since, maybe, 1970 are FAR better than ones from the '40s and '50s and are all worth saving unless they have goo leaking from them or the rubber plug is bulging out (kind of like evaluating an old can of beans!). I have never found one in post-1970 gear to go bad from storage. If you want to be sure before installing it in a circuit, simply apply the rated working voltage from a variable power supply (right polarity, of course) and let it sit with it for a few minutes. If you can set the current limit on the supply to a low value, it will prevent a potentially gooey explosion. Applying the DC voltage is actually a good thing. It's called "forming" the capacitor and it builds the insulating oxide film on the aluminum foil.

(From: John Popelish (jpopelish@rica.net).)

There are at least two distinct wear-out mechanisms at work in electrolytics. One is electrolyte loss by leakage from the container. This is made worse by poor seals and heat, so varies a lot depending on the quality of the original package and things like ambient temperature and internal heating by ripple current. If they are stored in cool conditions, they can stay wet for a lot longer than 10 years. The second is oxide deterioration, and this has a thermal and a bias component. Heat speeds up the deterioration during storage, and lack of bias voltage also speeds up the loss. I always plug very old equipment into a variac the first time I bring it up, and apply no more than about 70% line voltage for a while, and check for caps heating up. If everything looks good, I will slowly raise the line to full voltage over about an hour. This allows some oxide recovery to occur without catastrophic thermal rise. I have not had to replace caps wholesale unless reliability was very important (where a later malfunction would be a lot more costly than all the capacitors).

Electrolytic caps have one metal plate and one liquid plate. The dielectric between them is a very thin layer of oxide that is formed on the metal plate after it has been etched to make its surface very spongy and porous. This etching process multiplies the surface area of the metal by many times (increasing the capacitance which is proportional to surface area), but means that the oxide is formed over a very rough surface. So some of the oxide is wrapped around very sharp edges and over points. This is a chemically less stable situation compared to oxide formed over a smooth surface or inside a hollow. Same for oxide formed over metal grain boundaries. Over time, some of this oxide either breaks off, cracks, or reverts to metal and oxygen atoms, resulting in thin spots in the insulating layer.

If the cap is stored with a DC bias, these thin spots draw current which liberates atomic oxygen from the electrolytic which reoxidizes those weak spots as they form. If it is stored without applied voltage, all these spots need reforming at once when the cap is put in service. This makes them leak excessive current, produce lots of gas, and give off heat. If the leakage is bad enough, the cap may self destruct. If large and expensive caps, especially high voltage types, are going to be put in service after extended storage, they can be more gracefully reformed by applying a voltage in series with a current limiting resistance. And they should be checked for acceptable leakage current at rated voltage before being used. I think modern electrolytic caps are expected to last about 10 years in cool storage. Higher temperatures shorten their life.

If you were going to be reforming lots of similar caps, you could build an adjustable DC supply that had both voltage regulation and a current limit that could be set to values appropriate for various sized caps. For one or two, I have used a Variac upstream of a simple unregulated supply. The point is to allow some forming current to flow, but limit it to less than what would cause a noticeable temperature rise in the cap. For a small tubular cap, this on the order of a tenth of a watt. Divide that by the applied voltage, and you have some idea of the current limit needed. For large (fist sized) caps, you might allow the internal dissipation to approach a watt. These power levels would not raise the cap's temperature so that you would notice it with your fingers (though they might cause some quite measurable hot spots at small areas within the cap).

(From: Dbowey)

My recollection of forming electrolytics is that a time-stepped voltage was applied. The timer was me, and I increased the Variac output to a power supply over the span of a day or two, starting with 10% of the rated voltage and ending up with 100%.

(From: Jack Schidt (jack@wintel.net).)

This works well. NOS electrolytic caps should always have this done prior to using. Often, for old gear, NOS or used caps must be used for economics or availability.

Since I do a lot of tube equip repair, I built a small isolated tripler- to easily deliver 450V for the supply electrolytics. I used all new mylar caps.

I modified your procedure slightly by setting the tripler to the working voltage of the cap unloaded, putting a 2 M or so resistor in series with the cap, and connect it to the supply.

For really large (1000 uF+) caps, I use a few hundred K; you want the applied current to be more than the average leakage current of a good cap.

Check the cap voltage periodically with a DVM or VTVM, disconnecting the meter probes immediately after measurement. If you use a high voltage, low leakage transistor as an emitter follower, you can leave the meter connected at all times. I recommend this.

Often you see an older cap get to a particular voltage, then drop dramatically, as its dielectric breaks down, then the process repeats. These should be tossed, as the dielectric clearly has thin spots, and will fail in service.

Some will charge up completely in a few hours [t=RC], some a few days, and some never get off the ground. Toss those that do not charge.

What are These Scored Lines on the Ends of Electrolytic Capacitors?

They are there to channel the debris in a known direction should the capacitor turn into a bomb. Really :-).

However, exploding capacitors aren't all THAT common in properly designed equipment.... (Well, except for that EPROM programmer that had a tantalum electrolytic installed backwards at the factory. Six months later - K-Blam!)

(From: Gary Woods (gwoods@wrgb.com).)

If you look in a DigiKey catalog, they detail the 'Vent Test' in which an electrolytic cap is overloaded in a specified way and the can fails expelling the material *only* through that scored portion. Sounds like material for another urban legend; like the supplier who carefully tested each incoming fuse for blowing in a specified time at a specified overload. Of course, the people trying to *use* those fuses didn't appreciate how nicely they passed these tests!

You can do a vent test by hooking up an electrolytic to your 'suicide cord' and plugging it into 110 VAC. Entertaining. (I did NOT recommend you do this, and am NOT liable!)

Making Non-Polarized Capacitors from Normal Electrolytics

You may find non-polarized electrolytic capacitors in some equipment - usually TVs or monitors though some turn up in VCRs and other devices as well. Large ones may be found in motor starting applications as well. These usually do need to be replaced with non-polarized capacitors. Since polarized types are generally much cheaper, the manufacturer would have used them if it were possible.

For small capacitors - say, 1 uF or less - a non-electrolytic type will very likely be satisfactory if its size - these are usually much larger - is not a problem.

There are several approaches to using normal polarized electrolytic capacitors to construct a non-polarized type.

None of these is really great and obtaining a proper replacement would be best. In the discussion below, it is assumed that a 1000 uF, 25 V non-polarized capacitor is needed.

Here are three simple approaches:

1. Connect two electrolytic capacitors of twice the uF rating and at least equal voltage rating back-back in series:

```
          -  +         +  -
o----------)|-----------|(-----------o
        2,000 uF     2,000 uF
          25 V         25 V
```

   It doesn't matter which sign (+ or -) is together as long as they match.

   The increased leakage in the reverse direction will tend to charge up the center node so that the caps will be biased with the proper polarity. However, some reverse voltage will still be unavoidable at times. For signal circuits, this is probably acceptable but use with caution in power supply and high power applications.

2. Connect two electrolytic capacitors of twice the uF rating and at least equal voltage rating back-back in series. To minimize any significant reverse voltage on the capacitors, add a pair of diodes:

```
      +---|>|----+----|<|----+
      |   -  +   |    +  -   |
o-----+----)|----+-----|(----+------o
        2,000 uF     2,000 uF
          25 V         25 V
```

   Note that initially, the source will see a capacitance equal to the full capacitance (not half). But very quickly, the two caps will charge to the positive and negative peak values of the input across the combination via the diodes. In the steady state, the diodes will not conduct at all and therefore it will be as though they were not in the circuit.

   However, there will be some non-linearity into the circuit under transient conditions (and due to leakage which will tend to discharge the capacitors) so use with care. The diodes must be capable of passing the peak current without damage.

3. Connect two capacitors of twice the uF rating in series and bias the center point from a positive or negative DC source greater than the maximum signal expected for the circuit:

```
                +12 V
                  o
                  |
                  /
                  \ 1K
                  /
         -  +     |     +  -
o----------)|-----+-----|(-----------o
        2,000 uF     2,000 uF
          35 V          35 V
```

The resistor value should be high compared to the impedance of the driving circuit but low compared to the leakage of the capacitors. Of course, the voltage ratings of the capacitors need to be greater than the bias plus the peak value of the signal in the opposite direction.

About Tantalum Capacitors

(From: Ralph W. M. (ralphwm@aol.com).)

First off, you need to identify/specifiy the particular Tantalum you're speaking of. There are both SOLID, and ORGANIC tantalum's. If it is the familar epoxy teardop case style, it is the solid variety; any other package could be either solid or organic, (and they are NOT the same).

Yes, Solid tantalums can explode. But this is either rare in the case of manufactured equipment in original condition, OR someone modified, the circuit and selected/sized it improperly. Solid Tantalums are VERY intolerant of spikes/surges; BUT organic electrolytics are tolerant of spikes/surges; (BUT organic electrolytics are NOT a direct subsitute for solid tantalums!!!).

Solid tantalums are VERY stable in regards to:

1. The uF value.

2. Extreemly stable DC leakage. Notice, I did NOT say low leakage; they have average DC leakages compared to modern electrolytics.

Solid tantalums also have VERY low impedance, at low frequencies; (organic tantalums do not).

The statement that solid tantalums have lower DC leakages when compared to organic electrolytics has become a misnomer, i.e., 20 years ago that would basically be true, but not today. Currently the DC leakages of Solid tantalum's is similar to the average organic electrolytic; there are some organic electrolytics that have approx 50% LESS DC leakage, (after allowing from 2 to 5 minute "warm up"), (BUT solid tantalums have both VERY stable DC leakage, and NO "warm up").

Supercaps and Ultracaps

(From: Nicholas Bodley (nbodley@tiac.net).)

Within the past 2 weeks or so (current date: 11-August-1997), probably prompted by an article in EE Times, I set Excite to dig for 'supercapacitors' and 'ultracapacitors'. I did find that when you use the 'More Like This option' enough, it gives you the same hits.

Anyhow:

What I found was fascinating to an old-timer. Capacitor technology is now at the point where it can do load-leveling to extend the life of electric vehicle (EV) batteries. The high power needed for EV acceleration can be provided by an ultracapacitor. The ultracap. can also absorb energy for regenerative braking, to limit the otherwise very high charging current for the battery.

Noted in passing was a Mazda experimental EV that uses ultracaps. this way; it is called, believe it or not, the Bongo Friendee. No kidding. (I have a collection of 7 or 8 other such names...)

Mentioned were capacitors of 1,800 **farads** at 2.3V. Yup, we're now in the kilofarad era, folks! The capacitor bank comprised a total of 80, in groups of two in parallel, 40 groups in series. Total voltage was 92.

Other specifications noted in passing:

Ultracaps. are now in the 0.1 to 8 kWh (kilowatt-hour) range.

Some are made of carbon aerogels (that must not be news...)

Maxwell has an 8-cell assembly rated at 24V, bipolar, 4.5 Wh/kg. The same company also has a monopolar cell (monopolar?) rated at 2,300 F, 3V; 5 Wh/kg. This one can provide over 100 A !

Some ultracapacitors apparently (pretty sure) do not use electric double layer technology. They use oodles of alternating layers of conductor and dielectric, stacked 'to the thickness of a credit card'. Some keen mind(s) have found out how to make a dielectric layer that is 'intrinsically free of defects'. These caps, fairly sure, use metal conductors; they have quite-low inductance.

Multilayer thin-film caps can be made up to 25 cm^2, to 1,200 V (!), and store 10 joules / cm^2 with applied voltage just below breakdown.

Also noted, but considering the topic, maybe a repeat: Carbon aerogel caps can go to 40 F /cm^3; work excellently as cold as -30 C, and can manage power over 7kW/kg. Self-discharge is in weeks.

I found this info. utterly fascinating. When I get a decent job, I'm getting myself a 100F Elna.

BTW, did you hear that a DMM uses a supercap. for power? I think the figures are that a 3 minute charge will run it for 3 hours.

What are those X and Y Capacitors in the AC Line Input?

> "I have noticed recently that so-called "X" and "Y" capacitors are used at the input power section of power supplies. When I have looked into this further, I find that there are various grades of X and Y - X1, X2, Y1, Y2, etc. Apparently this is code or regulatory agency related.
>
> 1. What is the definition or use of the various classes are (X1, X2, etc.)

2. Where do the regulator agencies say we must use the various types.
3. What is good design practice for noise filtering of a SMPS using these devices et al."

(From: Paul Kasley (kasley@fnal.gov).)

Class X caps are for across-the-line use. Class Y caps are for line-to-safety ground. These caps are constructed to be "self-clearing". That is, if the device develops a short, the energy dissipated in the short will "blow" the short away. A typical line input filter will have a single Class X cap from line to neutral or from line to line and a Class Y cap from each line to ground or from line to ground and neutral to ground. No regulatory agencies require their use. However, you may find you need them to meet EMI/EMC regulations and to meet your own EMI/EMC susceptibility requirements. UL, CSA, VDE, and other safety agencies will require that you use proper components to meet safety standards (which is always good practice) and to receive permission to use their safety markings. As for the precise differences between the types (X1, X2, Y1, Y2), I suggest you contact cap manufacturers such as Vishay-Roederstein for their catalogs and applications books.

Photoflash Capacitors

These are found not only in electronic flash units and strobes, but pulsed laser power supplies and other fast discharge applications. They are designed for rapid discharge with minimum losses and without self destructing. Thus, the ESR and inductance are very low and the internal structure is set up to survive very high peak currents (hundreds or thousands of amps).

The common ones from photographic flash units are electrolytic capacitors but those in more specialized applications may be other types which can have much shorter pulse durations.

Note that photoflash capacitors may have mediocre temperature ratings like 55 °C instead of the 70 to 105 °C normally found in consumer electronic equipment. Thus, they may not be appropriate for use as service parts replacements for general electronics even though the uF and voltage ratings match.

Introduction

Scope of This Document

Note: This document replaces the individual sections in each of major repair guides.

A number of organizations have compiled databases covering thousands of common problems with VCRs, TVs, computer monitors, and other electronic equipment. Most charge for their information but a few, accessible via the Internet, are either free or have a very minimal monthly or per-case fee. In other cases, a limited but still useful subset of the for-fee database is freely available.

A tech-tips database is a collection of problems and solutions accumulated by the organization providing the information or other sources based on actual repair experiences and case histories. Since the identical failures often occur at some point in a large percentage of a given model or product line, checking out a tech-tips database may quickly identify your problem and solution.

In that case, you can greatly simplify your troubleshooting or at least confirm a diagnosis before ordering parts. My only reservation with respect to tech-tips databases in general - this has nothing to do with any one in particular - is that symptoms can sometimes be deceiving and a solution that works in one instance may not apply to your specific problem. Therefore, an understanding of the hows and whys of the equipment along with some good old fashioned testing is highly desirable to minimize the risk of replacing parts that turn out not to be bad.

The other disadvantage - at least from one point of view - is that you do not learn much by just following a procedure developed by others. There is no explanation of how the original diagnosis was determined or what may have caused the failure in the first place. Nor is there likely to be any list of other components that may have been affected by overstress and may fail in the future. Replacing Q701 and C725 may get your equipment going again but this will not help you to repair a different model in the future.

One alternative to tech-tips databases is to search via Google Groups (formerly Deja.com/Dejanews) for postings with keywords matching your model and problem and the USENET newsgroup sci.electronics.repair. See the document: Troubleshooting of Consumer Electronic Equipment for more information.

Safety

The people who compile tech-tips databases assume you know what you are doing, at least to the extent of taking appropriate precautions to minimize the possibility of bodily harm and equipment damage. Before going inside any piece of electronic equipment, make sure you understand and follow the guidelines in the document: Notes on Safety. If you are at all unsure of your understanding of this safety info, take the equipment to a professional for repair or buy a new one. Your life is more valuable than the few dollars you might save by doing it yourself!

- Back to Tech-Tips Table of Contents.

List of On-Line Tech-Tips Databases

This list is a lot shorter than it was the last time I went through and checked the tech-tips sites to be sure they still existed. :(

- Here are some tech-tips sites for computer monitors, TVs, and VCRs:

  - Anatekcorp Tech Forum (Free)
  - Repair World (about $8/month)
  - Electronic Repair Tips Home Page (Free, somewhat limited)

- Here is a site from which you should be able to download a fully operational version of a database with over 115,000 tips for TVs, VCRs, camcorders monitors, microwave ovens, audio equipment, and more. It will work for 14 days and can be purchased and registered during this time. There are versions for both Windows (WinSTIPS) and DOS (SVCTIPS). This from KDTV - Indiana Wholesale Electronics:

  - WinSTIPS and SVCTIPS Page

  They also offer ServiceTalk, an on-line discussion group for electronics repair professionals. This members-only forum has access to a subset of WinSTIPS (about 17,000 tips).

- Here are a couple of comprehensive tech-tips databases just for VCRs that are currently free:

  - Fixer - VCR Repair Instruction (Quite extensive)
  - Vidcam (Australia, but has USA models as well)

- (From: Sidney (sidneybek@yahoo.com).)

  Here is a list of my 390 sites containing free repair tips, forums, free schematics/service manuals & EEPROM access, I have organized them in accordance to subject so you would have to go through them and find which sets have what you need:

  - 390 Web Sites Containing Repair Tips, Forums, Schematics and EEPROM Access

- This has quite a bit of info for TVs. Some may be free but others require a relatively small charge (up to $25) or a monthly or other membership fee. However, this may include a personal reply from a technician experienced with your monitor so it could be well worth it:

  - Shop Helper

- Here is free site just for TVs with some tips mainly for RCA and Sony with a some for "miscellaneous". They also have EEPROM setup parameters for some samples of the RCA/GE/Proscan CTC175 and CTC177 chassis.

- Videotech

- This one is really an amateur radio site but has tech-tips for a variety of (mostly) European TVs:

  - B.A.D.A.R.C. Homepage.

- The following are just for monitors:

  - KMR Technical Services Tech Support ($19.95 charge)
  - ADCC (Tech-tips of the month and 'ask a wizard' options)
  - AMR Monitor Repair Tips
  - Noahtech (Some tips, other repair info)

- This one has monitor schematics and some tech-tips and allows upload of your schematics or tech-tips:

  - Monitory upload page

  - Monitors starting with "s". (I can't find an index to all the monitors, just replace the "s" in "s.htm" with the first letter of your monitor.)

- The following is specifically for microwave ovens. In addition to a large database of specific repairs, there is a great deal of useful information and links to other sites:

  - MicroTech Home Page (Everything you always wanted to know about microwave ovens)

  The next one is provided at the Bucks County Tech School Audio/Video Technology Web site.

  - Tech-Tips for Technicians (Tech-Tips for all sorts of equipment but not very extensive)

These types of sites seem to come and go so it is worth checking them out from time-to-time even if you don't have a pressing need. If possible, download and archive any useful information for use on a rainy day in the future. Some also include many useful links in addition to the tech-tips info so are worth investigating even if you don't have a specific symptom to deal with! The sites in this list were active as of the version date - that's all I'll guarantee! :)

DISCLAIMER

Working on optical storage equipment entails a number of personal risks: electrical, laser, mechanical, as well as the possibility of irreversible damage to the equipment and loss or corruption of data due to improper repair or adjustment.

We will not be responsible for damage to equipment, your ego, county wide power outages, spontaneously generated mini (or larger) black holes, planetary disruptions, or personal injury or worse that may result from the use of this material.

- Back to CD Repair FAQ Table of Contents.

Introduction

Compact discs and the digital audio revolution

The transformation of CD players and CDROMs from laboratory curiosities to the economical household appliances that have revolutionized the musical recording industry and have made possible multimedia computing depend on the availability of two technologies: low power low cost solid state laser diodes and mass produced large scale integrated circuits. Without these, a CD player using 1960's technology would be the size of dishwasher!

Most of us take all of this for granted rarely giving any thought to the amazing interplay of precision optics and complex electronics - at least until something goes wrong. The purpose of this document is to provide enough background on CD technology and troubleshooting guidance so that anyone who is reasonably handy whether a homeowner, experimenter, hobbiest, tinkerer, or engineer, can identify and repair many problems with CD players and possibly laserdisc players, CDROM drives, and optical storage drives as well.

Even if you have trouble changing a light bulb and do not know which end of a soldering iron is the one to avoid, reading through this document will enable you to be more knowledgeable about your CD player. Then, if you decide to have it professionally repaired, you will have a better chance of recognizing incompetence or down right dishonesty when dealing with the service technician. For example, a bad laser is not the most likely cause of a player that fails to play discs - it is actually fairly far down on the list of typical faults. A dirty lens is most likely. There - you learned something already!

Scope of this document

This document was developed specifically for the troubleshooting and repair of the CD players in component stereo systems, compact stereos, boomboxes, car units and portables, as well as CDROM drives (including the Sony Playstation).

The primary differences between these types will relate to how the disc is loaded - portables usually are top loaders without a loading drawer or tray:

However, as a result of the level of miniaturization required for portables and to a lesser extent, CDROM drives, everything is tiny and most or all of the electrical components are surface mounted on both sides of an often inaccessible printed circuit board with the entire unit assembled using screws with a mind of their own and a desire to be lost.

For other types:

- Laserdisc players and optical disk storage units have much in common with CD players with respect to the mechanical components and front-end electronics. Therefore, the information contained in this document can represent a starting point for their troubleshooting as well. However, they may include additional servo systems (optical pickup tilt, for example), as well as additional and/or different signal processing subsystems.

- DVD (Digital Versatile - or Video - Disc) players (which are now widely available and will completely replace CD players in a few years), suffer from many of the same problems as CDs and Laser Discs. Thus, a familiarity with the operating and repair of current technology will give you a head start on the amazing wonders (and similarly amazing problems) to come. There is a great deal of information on DVD technology in the DVD FAQ. Electronics Now, December, 1997, has a nice article by Steven J. Bigelow covering everything from the DVD format to installing and using a DVDROM drive in your PC.

- BD (Blu-Ray) players and recorders. Stay tuned for future developments. However, much of the information on CD and DVD technology applies to these next generation high capacity video and computer storage devices as well.

Note that throughout this document, the term 'CD player' is used most often. However, it should be understood that in most cases, the information applies to CDROM drives, game machines using CDs like the Sony Playstation, laserdisc players, MiniDisk players/recorders, DVD players, and other types of optical disk systems. Also see the document specifically devoted to these other technologies: "Notes on the Troubleshooting and Repair of Optical Disc Players and Optical Data Storage Drives". Also, where I remember, the term 'disc' is used to denote a read-only medium (e.g. a regular audio CD or LD) while 'disk' is used for one that is recordable (e.g., CD-R or MiniDisk).

Note: Links to all the diagrams and photographs referenced from this document can be found in Sam's CD FAQ Files.

Types of problems found in CD players

Many common problems with CD players can be corrected without the need for the service manual or the use of sophisticated test equipment (though a reliable multimeter will be needed for any electrical tests and an oscilloacope of at least 5 MHz bandwidth is highly desireable for servo alignment and more advanced troubleshooting). The types of problems found in a CD player can be classified into several categories:

1. Mechanical - dirt, lubrication, wear, deteriorated rubber parts, dirty/bad limit switches, physical damage. A dirty lens (coated with dust, tobacco smoke residue, or condensed cooking grease) - easily remedied - is probably the number one cause of many common problems: discs not being recognized, seek failure, audible noise, and erratic tracking, sticking, or skipping.

   Even many professionals may mistake (either accidentally or on purpose) these symptoms being due to much more serious (and expensive) faults. Don't be fooled!

   Cleaning of the lens and any other accessible optical components (usually only the turning mirror, if that) and a mechanical inspection should be the first things done for any of these problems (and as periodic preventive maintenance especially if the equipment is used in a less than ideal environment). See the section: General inspection, cleaning, and lubrication.

2. Electrical Adjustments - coarse tracking, fine tracking, focus, laser power. However, some CD players no longer have some of these adjustments. The servo systems are totally digital - they either work or they don't.

3. Power problems (mostly portables) - weak batteries, inadequate, defective, or improper AC wall adapter.

4. Bad connections - broken solder on the pins of components that are stressed like limit or interlock switches, or audio or power jacks, internal connectors that need to be cleaned and reseated, broken traces on flexible cables, or circuit board damage due to a fall.

5. Electrical Component Failure. These are rare except for power surge (storm and lightning strike) related damage which if you are lucky will only blow out components in the power supply. (Or, plugging a 3 V portable into the 12 V of your automobile. You can probably forget about this even being a CD player again.)

6. Incompatible geographic location. :-) This doesn't really apply to CD players but may be a factor with equipment like Sony PlayStations and very likely with DVD players. In their infinite wisdom (or greed), manufacturers are including 'country codes' on the discs so that a game or movie sold in one place cannot be used in another. So, if you bought a disc on the other side of the world and it doesn't work at home, thank the lawyers.....

You can often repair a CD player which is faulty due to (1) or (2) except for laser power which I would not attempt except as a last resort without a service manual and/or proper instrumentation if needed - improper adjustment can ruin the laser. If discs are recognized at all or even if the unit only focuses correctly, then laser power is probably ok. While the laser diodes can and do fail, don't assume that every CD player problem is laser related. In fact, only a small percentage (probably under 10%) are due to a failure of the laser diode or its supporting circuitry. Mechanical problems such as dirt and lubrication are most common followed by the need for electrical (servo) adjustments.

The solutions to category (3) and (4) problems are obvious - but it may take a conscious effort to remember to check these out before assuming that the fault is due to something much more serious.

Category (5) failures in the power supply of component (AC line powered) CD players can also be repaired fairly easily.

Most other electrical failures will be difficult to locate without the service manual, test equipment, and a detailed understanding and familiarity with audio CD technology. However, you might get lucky. I have successfully repaired problems like a seek failure (replaced a driver chip because it was running excessively hot) and a door sensor failure (traced circuitry to locate a bad logic chip). Since so much of the intelligence of a CD player is in the firmware - the program code inside the microcontroller, even the schematic may be of only marginal value since I can pretty much guarantee that the firmware will not be documented. The service manuals rarely explain *how* the equipment is supposed to work - and then perhaps only in poorly translated Japanese!

You can pretty much forget about repairing electrical problems in portable equipment other than perhaps bad connections (usually around the audio or power jacks, internal connectors, interlock switch (since it is stressed), or elsewhere due to the unit being dropped). Nearly everything in a portable (and most CDROM drives for that matter though this is not quite as bad) is itty-bitty surface mount components. There is generally only minimal useful information printed on the circuit board. Tracing the wiring is a nightmare. Even the test points and adjustments may be unmarked!

Repair or replace?

While CD players with new convenience features are constantly introduced, the basic function of playing a CD has not changed significantly in 15 years. None of the much hyped 'advancements' such as digital filters, oversampling, one bit D/As, and such are likely to make any difference whatsoever in the listening pleasure of most mortals. The people who care, do so only because they are more concerned with the technology than the musical experience. Most of these so called advances were done at least in part to reduce costs - not necessarily to improve performance.

Therefore, unless you really do need a 250 disc CD changer with a remote control that has more buttons than a B777 cockpit and 2000 track programmability, a 10 year old CD player will sound just as good and repair may not be a bad idea. Many older CD players are built more solidly than those of today. Even some new high-end CD players may be built around a mostly plastic optical deck and flimsy chassis.

If you need to send or take the CD player or CDROM drive to a service center, the repair could easily exceed the cost of a new unit. Service centers may charge up to $50 or more for providing an initial estimate of repair costs but this will usually be credited toward the total cost of the repair (of course, they may just jack this up to compensate for their bench time). Parts costs are often grossly inflated as well - possibly due to a deliberate effort on the part of manufacturers to discourage repair of older equipment. However, these expensive parts do not really fail nearly as often as is commonly believed - the laser is not the most likely component to be bad! Despite this, you may find that even an 'authorized' repair center will want to replace the expensive optical pickup even when this is not needed. I do not know how much of this is due to dishonesty and how much to incompetence.

If you can do the repairs yourself, the equation changes dramatically as your parts costs will be 1/2 to 1/4 of what a professional will charge and of course your time is free. The educational aspects may also be appealing. You will learn a lot in the process. Thus, it may make sense to repair that bedraggled old boombox after all.

CD Digital Audio Technology

General Introduction to CD Technology

Information on a compact disc is encoded in minute 'pits' just under the label side of the CD. The CD itself is stamped in much the same way as an old style LP but under much more stringent conditions - similar to the conditions maintained in the clean room of a semiconductor wafer fab. The CD pressing is then aluminum coated in a vacuum chamber and the label side is spin-coated with a protective plastic resin and printed with the label.

CD-Rs - recordable CDs use a slightly different construction. CD-R blanks are prestamped with a spiral guide groove and then coated with an organic dye layer followed by a gold film, resin, and label. The dye layer appears greenish and deforms upon exposure to the focused writing laser beam to form pits and lands.

The newest variation - DVDs or Digital Versatile Disks (or Digital Video Disks depending on who you listen to) - implement a number of incremental but very significant improvements in technology which in total add up to a spectacular increase in information density - almost 10:1 for the same size disc. These include higher frequency laser (670 or shorter visible wavelength), closer track spacing, better encoding, and a double sided disc. According to early reports on the final specifications, DVDs will be able to store 8 times the audio of current CDs at a higher sampling rate and bit resolution, 2 hours of MPEG encoded high quality movies, and all kinds of other information. Raw data capacity is somewhere between 5 and 10 GBytes. See the section: Comparison of CD and DVD Specifications for additional information.

On the near horizon is the "Blu-Ray" standard using a blue-violet laser to achieve even higher capacity for multimedia and computer storage applications. See the section: Comparison of CD, DVD, BD Specifications

CD information storage and playback

The actual information to be recorded on a CD undergoes a rather remarkable transformation as it goes from raw audio (or digital data) to microscopic pits on the disc's surface. For commercial or professional audio recording, the process starts with pre-filtering to remove frequencies above about 20 kHz followed by analog-to-digital conversion, usually at a sampling rate of 48 K samples/second for each stereo channel. The resulting data stream is then recorded on multi-track digital magnetic tape. All mixing and pre-mastering operations are done at the same sampling rate. The final step is conversion through re-sampling (sample-rate conversion including some sophisticated interpolation) to the 44.1 K samples/second rate actually used on the CD (88.2 K total for both channels). (In some cases, all steps may be performed at the 44.1 K rate.)

That is followed by extremely sophisticated coding of the resulting 16-bit two's-complement samples (alternating between L and R channels) for the purpose of error detection and correction. Finally, the data is converted to a form suitable for the recording medium by Eight-to-Fourteen modulation (EFM) and then written on a master disk using a precision laser cutting lathe. A series of electroplating, stripping, and reproduction steps then produce multiple 'stampers', which are used to actually create the discs you put in your player (more below).

Of course, it is possible to create your own CDs with a modestly priced CD-R recorder (which does not allow erasing or re-recording). Now, re-writable CD technology with fully reusable discs enables recording and editing to be done more like that on a cassette tape

Like a phonograph record, the information is recorded in a continuous spiral. However, with a CD, this track (groove or row of pits - not to be confused with the selections on a music CD) starts near the center of the CD and spirals (counterclockwise when viewed from the label side) toward the outer edge. The readout is through the 1.2 mm polycarbonate disc substrate to he aluminized information layer just beneath the label. The total length of the spiral track for a 74 minute disc is over 5,000 meters - which is more than 3 miles in something like 20,000 revolutions of the disc!

The digital encoding for error detection and correction is called the Cross Interleave Reed-Solomon Code or CIRC. To describe this as simply as possible, the CIRC code consists of two parts: interleaving of data so that a dropout or damage will be spread over enough physical area (hopefully) to be reconstructed and a CRC (Cyclic Redundancy Check) like error correcting code. Taken together, these two techniques are capable of some remarkable error correction. The assumption here is that most errors will occur in bursts as a result of dust specs, scratches, imperfections such as pinholes in the aluminum coating, etc. For example, the codes are powerful enough to totally recover a burst error of greater than 4,000 consecutive bits - about 2.5 mm on the disc. With full error correction implemented (this is not always the case with every CD player), it is possible to put a piece of 2 mm tape radially on the disc or drill a 2 mm hole in the disc and have no audio degradation. Some test CDs have just this type of defect introduced deliberately.

Two approaches are taken with uncorrectable errors: interpolation and muting. If good samples surround bad ones, then linear or higher order interpolation may be used to reconstruct them. If too much data has been lost, the audio is smoothly muted for a fraction of a second. Depending on where these errors occur in relation to the musical context, even these drastic measures may be undetectable to the human ear.

Note that the error correction for CDROM formats is even more involved than for CD audio as any bit error is unacceptable. This is one of many reasons why it is generally impossible to convert an audio CD player into a CDROM drive. However, since nearly all CDROM drives are capable of playing music CDs, much can be determined about the nature of a problem by first testing a CDROM drive with a music CD.

CD (disc) construction

The information layer as mentioned above utilizes 'pits' as the storage mechanism. (Everything that is not a pit is called a 'land'.) Pits are depressions less than .2 um in depth (1/4 wavelength of the 780 nm laser light taking into consideration the actual wavelength inside the polycarbonate plastic based on its index of refraction). Thus, the reflected beam is 180 degrees out of phase with incident beam. Where there is a pit, the reflected beam from the pit and adjacent land will tend to cancel. This results in high contrast between pits and lands and good signal to noise ratio. Pits are about .5 um wide and they come in increments of .278 um as the basic length of a bit (encoded, see below) on the information layer of the disc.

Each byte of the processed information is converted into a 14 bit run length limited code taken from a codebook (lookup table) such that there are no fewer than 2 or more than 10 consecutive 0s between 1s. By then making the 1s transitions from pit to land or land to pit, the minimum length of any feature on the disc is no less than 3*p and no more than 11*p where p is 0.278 um. This is called Eight-to-Fourteen Modulation - EFM. Thus the length of a pit ranges from 0.833 to 3.054 um.

Each 14 bit code word has 3 additional sync and low frequency suppression bits added for a total of 17 bits representing each 8 bit byte. Since a single bit is .278 um, a byte is then represented in a linear space of 4.72 um. EFM in conjunction with the sync bits assure that the average signal has no DC component and that there are enough edges to reliably reconstruct the clock for data readout. These words are combined into 588 bit frames. Each frame contains 24 bytes of audio data (6 samples of L+R at 16 bits) and 8 bits of information used to encode (across multiple frames) information like the time, track, index, etc:

```
Sync                     (24 + 3).
Control and display      (14 + 3).
Data                     (12 * 2 * (14 + 3).)
Error correction         ( 4 * 2 * (14 + 3).)
                         --------------------
                         588 total bits/frame
```

A block, which is made up of 98 consecutive frames, is the smallest unit which may be addressed on an audio CD and corresponds to a time of 1/75 of a second. Two bits in the information byte are currently defined. These are called P and Q. P serves a kind of global sync function indicating (among other things) start and end of selections and time in between selections. Q bits accumulated into one word made of a portion of the 98 possible bits in a block encodes the time, track and index number, as well as many other possible functions depending where on the disc it is located, what kind of disc this is, and so forth.

Information on a CD is recorded at a Constant Linear Velocity - CLV. This is both good and bad. For CD audio - 1X speed - this CLV is about 1.2 meters per second. (It really isn't quite constant due to non constant coding packing density and data buffering but varies between about 1.2 and 1.4 meters per second). CLV permits packing the maximum possible information on a disc since it is recorded at the highest density regardless of location. However, for high speed access, particularly for CDROM drives, it means there is a need to rapidly change the speed of rotation of the disc when seeking between inner and outer tracks. Of course, there is no inherent reason why for CDROMs, the speed could not be kept constant meaning that data transfer rate would be higher for the outer tracks than the inner ones. Modern CDROM drives with specs that sound too good to be true (and are) may run at constant angular speed achieving their claimed transfer rate only for data near the outer edge of the disc.

Note that unlike a turntable, the instantaneous speed of the spindle is not what determines the pitch of the audio signal. There is extensive buffering in RAM inside the player used both as a FIFO to smooth out data read off of the disc to ease the burden on the spindle servo as well as to provide temporary storage for intermediate results during decoding and error correction. Pitch (in the music sense) is determined by the data readout clock - a crystal oscillator usually which controls the D/A and LSI chipset timing. The only way to adjust pitch is to vary this clock. Some high-end players include a pitch adjustment. Since the precision of the playback of the any CD player is determined by a high quality quartz oscillator, wow and flutter - key measures of the quality of phonograph turntables - are so small as to be undetectable. Ultimately, the sampling frequency of 44.1 K samples per second determines the audio output. For this, the average bit rate from the disc is 4.321 M bits per second.

Tracks are spaced 1.6 micrometers apart - a track pitch of 1.6 um. (This is the nominal specification but may vary somewhat and will be less on those CDs that contain more than 74 minutes of music or 650 MB of data. However, unlike LPs, the pitch is not affected in the slightest by the content.) Thus a 12 cm disc has over 20,000 tracks for its 74 minutes of music. Of course, unlike a hard disk and like a phonograph record, it is really one spiral track over 3 miles long! However, as noted above, the starting point is near the center of the disc. The width of the pits on a track is actually about 0.5 um. The focused laser beam is less than 2 um at the pits. Compare this to an LP: A long long playing LP might have a bit over 72 minutes of music on two sides or 36 minutes per side. (Most do not achieve anywhere near this much music since the groove spacing needs to vary depending on how much bass content the music has and wide grooves occupy more space.) At 33-1/3 rpm, this is just over 1,200 grooves in about 4 inches compared to 20,000 tracks on a CD in a space of just over 1.25 inches! The readout stylus for an LP has a tip radius of perhaps 2 to 3 mils (50 to 75 um).

CD (disc) manufacturing

(From: Reinhart (Lasernut23@aol.com).)

An LP is pressure pressed using a solid vinyl biscuit. A CD, on the other hand, is not manufactured in this manner. CDs are replicated through injection molding, where molten polycarbonate is injected into a mold under high pressure. CDs *must* be manufactured in strict clean room environments. On a side note, when LaserDiscs were released to market by MCA DiscoVision in 1978, this requirement wasn't recognized, or ignored by MCA Corporate in an attempt to keep manufacturing costs of these silver platters down. The first discs were manufactured in an environment similar to an LP plant. As a result, the finished product, while looking visibly okay when observed casually, had major problems playing reliably on many LaserDisc players. Now, of course, we know better, although Pioneer recognized these requirements far more quickly than MCA. Even RCA's Videodisc plant for their needle-in-grove CED (SelectaVision Videodisc) format recognized these requirements better than MCA! CED's market introduction in 1981 did not start as catastrophically like LaserDisc did as a result.

And you thought driving on a narrow winding country road was tough!

To put the required CD player servo system performance into perspective, here is an analogy:

At a constant linear velocity of about 1.2 meters per second, the required tracking precision is astounding: Proper tracking of a CD is equivalent to driving down a 10 foot wide highway (assuming an acceptable tracking error of less than +/- .35 um) more than 3,200 miles for one second of play or over 14,400,000 miles for the entire disc without accidentally crossing lanes! Actually, it is worse than this: focus must be maintained all this time to better than 1 um as well (say, +/- .5 um). So, it is more like piloting a aircraft down a 10 foot wide flight path at an altitude of about 12 miles (4 mm typical focal length objective lens) with an altitude error of less than +/- 7 feet! All this while the target track below you is moving both horizontally (CD and spindle runout of .35 mm) 1 mile and vertically (disc warp and spindle wobble of up to 1 mm) 3 miles per revolution! In addition, you are trying to ignore various types of garbage (smudges, fingerprints, fibers, dust, etc.) below you which on this scale have mountain sized dimensions. Sorry for the mixed units. My apologies to the rest of the world where the proper units are used for everything).

The required precision is unbelievable but true using mass produced technology that dates to the late 1970s. And, consider that a properly functioning CD player is remarkably immune to small bumps and vibration - more so than an old style turntable. All based on the reflection of a fraction of a mW of invisible laser light!

Of course, this is just another day in the entertainment center for the CD player's servo systems. Better hope that our technological skills are never lost - a phonograph record can be played using the thorn from a rosebush using a potter's wheel for a turntable. Just a bit more technology is needed to read and interpret the contents of a CD!

Why does focus need to be so precise?

Since a laser printer doesn't need to have so precise a focus (afterall, paper isn't that smooth), what's all this fuss about focusing with respect to CD, DVD, and other optical disc/k systems? Laser beams remain fairly parallel, no?

Wrong.

First, laser light that remains precisely parallel - doesn't diverge - only can be found in bad Sci-Fi. Laser light still obeys the laws of physics and in order to get the required spot size on the disc - about 1 micrometer (um), 1,000th of a mm, 1,000,000th of a meter, it needs to be focused precisely at the disc surface. Due to manufacturing tolerances for disc flatness (warp), the surface may move up-and-down as much as 100 times this amount. And disc height from player to player isn't that precise either. Large diameter laser beams can be kept quite parallel but a beam 1 um in diameter would diverge at about a 60 degree angle. The lens in the CD player has a focal length of about 4 mm and focuses the light from a beam a couple millimeters in diameter to a 1 um spot on the disc surface and because of the small depth of focus, the distance needs to be kept constant to 1 or 2 um. For DVD systems, the required precision is even greater.

Laser printers DO have focusing optics with correction for the flat paper surface. They don't need to be quite as precise because the spot size is much larger than for a CD or DVD player - a 1,200 dpi printer would have a spot on the order of 50 um. Therefore, the lens can be quite far away from the paper and the depth of focus is much larger. Thus, no active focusing mechanism is needed.

CD optical pickup operating principles

A diagram showing the major functional components of the three-beam optical pickup described below is available in PDF format: CDT3BP.

This design is typical of older optical pickups (though you may come across some of these). Newer types have far fewer individual parts combining and eliminating certain components without sacrificing performance (which may even be better). Additional benefits result is lower cost, improved robustness, and increased reliability. However, operating principles are similar.

The purpose of the optical pickup in a CD player, CDROM drive, or optical disk drive, is to recover digital data from the encoded pits at the information layer of the optical medium. (With recordable optical disks, it is also used to write to the disk medium.) For CD players, the resulting datastream is converted into high fidelity sound. For CDROMs or other optical storage devices, it may be interpreted as program code, text, audio or video multimedia, color photographs, or other types of digital data.

Most of the basic operating principles are similar for single-beam CD pickups and for pickups used in other digital optical drives.

It is often stated that the laser beam in a CD player is like the stylus of a phonograph turntable. While this is a true statement, the actual magnitude of this achievement is usually overlooked. Consider that the phonograph stylus is electromechanical. Stylus positioning - analogous to tracking and focus in an optical pickup - is based on the stylus riding in the record's grooves controlled by the suspension of the pickup cartridge and tone arm. The analog audio is sensed most often by electromagnetic induction produced by the stylus's minute movements wiggling a magnet within a pair of sense coils.

The optical pickup must perform all of these functions without any mechanical assistance from the CD. It is guided only be a fraction of a mW of laser light and a few milligrams of silicon based electronic circuitry.

Furthermore, the precision involved is easily more than 2 orders of magnitude finer compared to a phonograph. Sophisticated servo systems maintain focus and tracking to within a fraction of a micrometer of optimal. (1 um is equal to 1/25,400 of an inch). Data is read out by detecting the difference in depth of pits and lands of 1/4 wavelength of laser light (about .15 um in the CD)!

- The laser beam is generated by a solid state laser diode emitting at 780 nm (near IR). Optical power from the laser diode is no more than a couple of mW and exits in a wedge shaped beam with a typical divergence of 10x30 degrees in the X and Y directions respectively.

Note that despite what some people believe, the laser diode in a CD or DVD player is a true laser and not just a glorified LED. It has a gain medium (the semiconductor), mirrors (on the cleaved parallel ends of the crystal), and an means of excitation (electric current). Its nearly monochromatic single spatial mode (TEM00) beam can be focused to a spot less than 2 um in diameter. No LED or other non-laser light source is capable of this kind of performance.

- A diffraction grating splits the beam into a main beam and two (first order) side beams. (The higher order beams are not used). Note that the diffraction grating is used to generate multiple beams, not for its more common function of splitting up light into its constituent colors. The side beams are used for tracking and straddle the track which is being read. The tracking servo maintains this centering by keeping the amplitude of the two return beams equalized.)

- Next, the laser beam passes through a polarizing beam splitter (a type of prism or mirror which redirects the return beam to the photodiode array), a collimating lens, a quarter wave plate, a turning mirror, and the objective lens before finally reaching the disc.

- The collimating lens converts the diverging beam from the laser into a parallel beam.

- A turning mirror (optional depending on the specific optical path used) then reflects the laser light up to the objective lens and focus/tracking actuators.

- The objective lens is similar in many ways to a high quality microscope objective lens. It is mounted on a platform which provides for movement in two directions. The actuators operate similarly to the voice coils in loudspeakers. Fixed permanent magnets provide the magnetic fields which the coils act upon. The focus actuator moves the lens up and down. The tracking actuator moves the coil in and out with respect to the disc center.

- The collimated laser beams (including the 2 side beams) pass through the objective lens and are focused to diffraction limited spots on the information - pits - layer of the disc (after passing through the 1.2 millimeters of clear polycarbonate plastic which forms the bulk of the disc).

- The reflected beams retrace the original path up until they pass through the polarizing beam splitter at which point they are diverted to the photodiode array. The polarizing beam splitter passes the (horizontally polarized) laser beams stright through. However, two passes (out and back) through the quarter wave plate rotates the polarization of the return beam to be vertical instead and it is reflected by the polarizing beam splitter toward the photodiode array.

The return beams from the disc's information layer are used for servo control of focus and tracking and for data recovery.

- A cylindrical lens slightly alters the horizontal and vertical focal distances of the resulting spot on the photodiode array. The spot will then be perfectly circular only when the lens is positioned correctly. To close or to far and it will be elliptical (e.g., elongated on the 45 degree axis if too close but on the 135 degree axis if too far).

  The central part of the photodiode array is divided into 4 equal quadrants labeled A,B,C,D. Focus is perfect when the signal = (A+C)-(B+D) = 0.

  The actual implementation may use a thick beam splitter mirror (which adds astigmatism) or an astigmatic objective lens rather than a separate cylindrical lens to reduce cost but the effect is the same. Since the objective lens is molded plastic, it costs no more to mold an astigmat (though grinding the original molds may have been a treat!). It is even possible that in some cases, the natural astigmatism of the laser diode itself plays a part in this process.

- The side beams created by the diffraction grating are positioned forward and back of the main beam straddling the track of pits being followed (not directly on either side as shown in the diagram - but that was easier to draw!).

Segments on either side of the photodiode array designated E and F monitor the side beams. Tracking is perfect when the E and F signals are equal.

- The data signal is the sum of A+B+C+D.

In essence, the optical pickup is an electronically steered and stabilized microscope which is extracting information from tracks 1/20 the width of a human red blood cell while flying along at a linear velocity of 1.2 meters per second!

See the sections: "Parts of a CD Player or CDROM Drive" and "Startup Problems" for more information on the components and operation of the optical pickup and descriptions and photos of some typical laser diodes, optical pickups, and optical decks.

The Laser Fundamentals Page has an interactive tutorial (requires JAVA) illustrating the operation of an optical pickup in very simplified form. It doesn't really have much detail but if the explanation above makes no sense, it may be worth viewing.

Optical pickup complexity

The opto-mechanical design of optical pickups varies widely. Originally, they were quite complex, bulky, heavy, and finicky with respect to optical alignment. However, in their continuing effort to improve the design, reduce the size and mass, and cut costs, the manufacturers have produced modern pickups with remarkably few distinct parts. This should also result in better performance since each optical surface adds reflections and degrades the the beam quality. Therefore, the required laser power should be reduced and the signal quality should improve.

- Generally, the most complex types are also the oldest. With these, there were individual optical elements for each stage in the beam path and completely separate laser diode and photodiode array packages. In short, while details varied, the overall construction was very similar to the diagram and description given in the section: CD optical pickup operating principles. These also had several optical adjustments - which in some cases needed frequent attention.

  An example of this type is the Sony KSS110C Optical Pickup. Most components perform individual functions and it is larger and heavier than more modern designs.

- The most common types still have a separate laser diode and photodiode array but may have eliminated the cylindrical and collimating lenses and perhaps the polarizer and quarter wave plate. There are few if any adjustments.

  The Sony KSS361A Optical Pickup is typical of these mainstream designs. With very minor variations (mostly in mounting), various models may be found in all types of CD players and CDROM drives manufactured by Sony, Aiwa, and others.

  Another similar design is used in the Sanyo K38N Optical Pickup which is somewhat newer and more compact.

  For a diagram and detailed description of these mainstream pickups, see the section: Sony KSS series optical pickups.

- Some manufacturers have gone to a combined laser diode/photodiode (LD/PD) array package which looks like a large LD but with 8 to 10 pins. Aside from the objective lens assembly, the only other part may be the turning mirror, and even this is really not needed. Such a pickup can be very light in weight (which is good for fast-access drives) and extremely compact.

Eliminating the components needed to separate the outgoing and return beams should result in substantial improvement in optical performance. The only disadvantage would be that the beams are no longer perfectly perpendicular to the disc 'pits' surface and this may result in a very slight, probably negligible reduction in detected signal quality - more than made up for by the increased signal level.

The CMKS-81X Optical Pickup and Optical Pickup from Philips PCA80SC CDROM are typical of these modern designs.

The smallest ones such as the Optical Pickup from the Philips CR-206 CDROM are only about 1/2" x 5/8" x 3/4" overall - just about the size of the lens cover! For this single-beam pickup, there are absolutely NO additional optical elements inside. A three-beam pickup would have a diffraction grating in front of the laser diode.

Some of these use what are known as "hologram lasers" (a designation perhaps coined by Sharp Corporation). With these, the functions previously performed by multiple optical components. can be done by a "Holographic Optical Element" or HOE. The HOE can simply be a diffraction grating replacement or can be designed to perform some more complex beam forming. A variety of hologram lasers (as well as conventional laser diodes and photodiode arrays) are listed under Sharp Laser Diode Products. The typical Sharp hologram laser (versions for CD, DVD, and other types of optical storage devices) eliminate the normal diffraction grating in the three-beam pickup as well as the polarizing beam splitter and associated components making for a very simple, compact, low cost unit. DVD Laser Holographic Optical Element shows the HOE glued to the front of a DVD laser diode assembly.

For a diagram and detailed description of this type of pickup, see the section: Super simple optical pickups.

For more information on CD technology

The books listed in the section: Suggested references include additional information on the theory and implementation of digital audio, laserdisc, and optical drive technology.

Philips/Magnavox used to have a very nice on-line introduction to a variety of consumer electronics technologies. Although their site has disappeared - and even people who work for them have no clue - I have now recovered several of the articles including those on TVs, VCRs, camcorders, satellite reception, and connections. See the Introductory Consumer Electronics Technology Series.

Also check out:

- A Fundamental Introduction to the Compact Disc Player is a somewhat more theoretical discussion of compact disc audio technology with diagrams and even some equations. If it doesn't put you to sleep, you will find quite a bit of interesting information in this article. In either case, it may prove of value.
- The University of Washington has at least one course in consumer electronics which varies from year to year. Last year (2000) it was on CD technology but most of that info has disappeared. However, there is an on-line tutorials which appears to be an excellent resource providing easy to understand discussions with many diagrams:
    - Audio Compact Disc - An Introduction.
- The How Stuff Works Web site has some really nice introductory material (with graphics) on a variety of topics relating to technology in the modern world. Of relevance to this document are articles on CD technology, motors, remote controls, power adapters, etc.
- The Cimram International, Inc Web site has some information on CD and DVD technology, formats, mastering, and

manufacturing.

The following sites have a variety of information on CD and DVD technology:

- CD Page
- MediaWorld

A site with CD-R specific information including some repair tips is:

- Andy McFadden's CD-R FAQ.

An extensive amount of information on other optical disc/k technologies with many useful links can be found at:

- Leopold's Audio/Video Page
- MiniDisc, DAT, CD-R, DVD-RAM, etc..
- The DVD Page.
- DVD Central at E/Town.
- DVD Demystified (Includes the DVD FAQ).

CD Player Placement, Preventive Maintenance, and CD Care

General CD player placement considerations

Proper care of a CD player does not require much. Following the recommendations below will assure peak performance and long life, and minimize repairs.

- Locate the CD player in a cool location. While the CD player is not a significant heat producer, keeping it cool will reduce wear and tear on the internal components and assure a long trouble free life.

- Don't locate CD players in dusty locations or areas of high (tobacco) smoke or cooking grease vapors. I cannot force you to quit smoking, but it is amazing how much disgusting difficult to remove brown grime is deposited on sensitive electronic equipment in short order from this habit.

- Make sure all audio connections are tight and secure to minimize intermittent or noisy sound.

- Finally, store CDs away from heat. The polycarbonate plastic used to mold CDs is quite sturdy but high temperatures will eventually take their toll. Return them to their jewel cases or other protective container when not being played.

Preventive maintenance

You no doubt have heard that a CD should be cleaned and checked periodically. "Purchase our extended warranty" says the salesperson "because CD players are very delicate and require periodic alignment". For the most part, this is nonsense. CD players, despite the astonishing precision of the optical pickup are remarkably robust. Optical alignment is virtually never needed for a component CD player and is rarely required even for portable or automotive units. In fact, modern CD players often don't even have any of these adjustments - the components of the optical pickup are aligned at the factory and then fixed in place with hardening sealer.

An occasional internal inspection and cleaning is not a bad idea but not nearly as important as for a VCR. Realistically, you are not going to do any of this anyway. So, sit back and enjoy the music but be aware of the types of symptoms that would be indications of the need for cleaning or other preventive or corrective maintenance - erratic loading, need to convince the CD player to cooperate and play a disc, audio noise, skipping, sticking, and taking longer than usual to recognize a disc or complete a search.

If you follow the instructions in the section: A HREF="#cdgicl">General inspection, cleaning, and lubrication, there is minimal risk to the CD player. However, don't go overboard. If any belts are in good condition (by appearance and stretch test), just clean them or leave them alone. Except for the Sony drawer loading mechanism, belts are rarely as much of a problem in CD players as in VCRs.

Of course, acute symptoms like refusal to play or open the door is a sign of the need for emergency treatment. This still may mean that a thorough cleaning is all that is needed.

CD lens cleaning discs

Every CD, stereo equipment, department, discount, store - and even sidewalk venders - carries CD lens cleaning discs. Are they of any value? Can they cause damage?

I generally don't consider CD lens cleaning discs to be of much value for preventive maintenance since they may just move the crud around. However, for pure non-greasy dust (no tobacco smoke and no cooking grease), they probably do not hurt and may do a good enough job to put off a proper cleaning for a while longer. However, since there are absolutely no sorts of standards for these things, it is possible for a really poorly designed cleaning disc to damage the lens. In addition, if it doesn't look like a CD to the optical pickup or disc-in sensor, the lens cleaning disc may not even spin. So, the drawer closes, the drawer opens, and NOTHING has been accomplished!

As if this isn't enough, NEVER put one into a high-X CDROM (DVD player or DVDROM drive). The high speed rotation may cause the cleaning disc and/or player/drive to self destruct. And, don't try a cleaning disc on an automotive CD player that sucks in the disk - it will get stuck.

CD protection and handling

Although CDs are considerably more tolerant of abuse than LPs, some precautions are still needed to assure long life. Also, despite the fact that only one side is played, serious damage to either side can cause problems during play or render the CD totally useless.

It is important that the label side be protected from major scratches which could penetrate to the information layer. Even with the sophisticated error correction used on the CD, damage to this layer, especially if it runs parallel to the tracks, can make the CD unusable.

The CD is read by focusing a laser beam through the bottom 1.2 mm of polycarbonate. As a result of the design of the optical system used in the pickup, at the bottom surface, the beam diameter is about 1 mm and thus small scratches appear out of focus and in many cases are ignored and do not cause problems.

At the information layer with the pits, the beam diameter has been reduced to under 2 um. Still, scratches running parallel to the tracks are more problematic and can cause the optical pickup to get stuck repeating a track, jumping forward or back a few seconds, or creating noise or other problems on readout. In severe cases, the CD may be unusable especially if the damage is in the directory area.

This is why the recommended procedure for cleaning a CD is to use soap and water (no harsh solvents which may damage the polycarbonate or resin overcoat) and clean in a radial direction (center to edge, NOT in the direction of the tracks as you would with an LP). While on the subject of CD care, CDs should always be returned to their original container for storage and not left out on the counter where they may be scratched. However, if there is a need to put one down for a moment, here are some considerations:

- The label side is probably to be preferred since minor scratches have no effect on performance as long as they do not penetrate to the storage layer below (in which case the CD is probably history). Protectors are available to prevent damage to the label side of the disc. Personally, I think this is taking care to an excessive level but, hey, if you use your CDs as frisbies, go for it!

- However, the opposite argument may apply as well: Slight damage to the readout-side will be ignored by the optical system or corrected for by the decoding process And, there are ways of dealing with scratches should they occur.

Thus, I won't offer a hard and fast rule other than to avoid leaving CDs out where the dog can get to them. :)

Never apply sticky labels to the readout-side of a CD or to the label-side unless they are specifically designed for this application. And, if a label was stuck on despite the warnings, don't attempt to remove it (or at least exercise the utmost care) as the lacquer layer and some of your valuable bits may come away with it. This is especially critical for CD-Rs (and maybe CD-RWs) which seem to be more fragile than normal CDs. I've seen samples of CD-Rs literally self destruct due to slight stress on the label side.

CD cleaning

You do not need a fancy CD cleaning machine.

Use a soft cloth, tissue, or paper towel moistened with water and mild detergent if needed. Wipe from center to edge - NOT in a circular motion as recommended for an LP. NEVER use any strong solvents. Even stubborn spots will eventually yield to your persistence. Washing under running water is fine as well.

Gently dry with a lint free cloth. Do not rub or use a dry cloth to clean as any dirt particles will result in scratches. Polycarbonate is tough but don't expect it to survive everything. Very fine scratches are not usually a problem, but why press your luck?

Should I really worry about cleaning my CDs?

Something that not everyone is aware of is the multilevel error handling technology in a CD player. Therefore, a dirty CD may not produce instantly obvious audio problems but can nonetheless result in less than optimal audio performance.

Very severe errors - long bursts - will result in audible degradation including noise and/or muting of the sound. Even this may not always be detectable depending on musical context.

Shorter runs of errors will result in the player interpolating between what it thinks are good samples. This isn't perfect but will probably not be detected upon casual listening.

Errors within the correcting capability of the CIRC code will result in perfect reconstruction.

Not all players implement all possible error handling strategies.

Therefore, it is quite possible for CD cleaning to result in better sound. However, a CD that is obviously clean will not benefit and excessive cleaning or improper cleaning will introduce fine (or not so fine) scratches which can eventually cause problems.

Can a dirty CD or dirty lens damage my player?

So the droid in the CD store warned you that dirty CDs could do irepairable harm to your CD player, your stereo, your disposition, etc. "Buy our $19.95 Super-Laseriffic CD cleaning kit".

The claim made at one major chain was that dirt or dust on the laser eye would cause heat build-up that would burn out the mechanism. This is different from a dirty disc. The cleaner he was pushing was a little brush attached to a CD that brushed off the lens as it played.

This is total rubbish. The power of a CD laser is less than 1 mW and is not concentrated at the lens. And, as noted elsewhere, those cleaning CDs with the little brush are next to useless on anything but the smallest amount of dry dust.

There are a lot of suckers out there. Save your money.

The worst that can happen is the CD will not play properly. There may be audible noise, it may fail to track properly, abort at random times, or not even be recognized. The electronics will not melt down.

It is just about impossible for a dirty CD to do any damage to the player. A dirty lens will only result in disc recognition or play problems similar to those caused by a dirty CD. The laser will not catch fire.

The only way damage could occur is if you loaded a cracked CD and the crack caught on the lens.

You do not need any fancy CD cleaners in any case - soap or mild detergent and water and a soft cloth are all that are required. If the CD looks clean, it probably will be fine. If there are serious smudges or fingerprints, then cleaning could make a significant difference in performance.

For further information, see the sections "CD cleaning" and "General inspection, cleaning, and lubrication".

Rental or library CD considerations

Unlike old or worn video tapes, it is unlikely that a 'bad' CD could damage your player. If the borrowed CD is dirty, clean it as described in the section: CD cleaning. If it is badly scratched, the worst that will happen is that it will sound bad - skipping and audible noise. No damage to your player will result. However, if the CD is cracked or broken (this is really difficult to do but I have gotten cracked CDs from public libraries), don't even attempt to load it - a broken edge could catch on the lens and ruin the optical pickup entirely. An improperly made or defective CD could result in seek/search problems which could eventually overheat and/or damage components but you'd probably notice the lack of music before anything irreversible happened.

(From: Bart Wessel (wessel@home.nl).)

There seems to be a new risk in playing CDs or CD-ROMs borrowed from a public library.

New, because of the fact that (at least at our library) they have a small metallic strip attached to the top of the CD, apparently as a measure against theft. The strip can be activated/deactivated at the counter, just like the system in use in most department stores.

The risk comes from the fact that these strips can come off if you happen to have a CD-ROM player that plays at speeds higher than 40X. There is a warning on the box not to use plates over 40X but who reads the warnings!

Can a CD player damage CDs?

The perhaps unexpected answer is a definite *yes* even though everyone has heard about the virtues of non-contact laser playback. There are several ways that a broken or poorly designed or manufactured player can result in scratched discs:

- If the lens moves too high while attempting to focus and the mechanical stop does not prevent it from hitting the disc, scratches can occur. On some players, the objective lens can easily go this high if focus is not found on the first pass. Note that in most cases, the lens will not suffer since it is protected by a raised ridge which is what actually scratches the disc.

- Mechanical misalignment of the spindle motor or plastic cabinet parts can result in the disc touching the bottom or top of the disc compartment and this can leave scratches. This could be the result of poor or cheap design, shoddy manufacturing, or damage from a fall or other abuse.

- If the control logic gets confused, it may allow you to eject a disc while it is still spinning and not fully supported by the spindle platter. A dirty disc that resulted in failure of the CLV servo to lock can result in a disc speed runaway condition with some players. If the drawer is then opened too soon, the disc will still be spinning because the controller has no way of knowing its present status and will not have provided enough reverse torque to stop the spindle motor - or too much and it will be spinning in reverse.

The likelihood of any of these is increased with dirty, smudged, warped, or previously damaged discs.

Minor scratches may not result in a serious problem and there are products to polish them - don't know how well they work. However, if these scratches can be proven to be a direct consequence of a defective player still under warranty, you should try to get some compensation from the manufacturer for any seriously damaged and now unplayable CDs.

The one thing that is extremely unlikely is that the laser beam itself is damaging the disc. Although this IS in principle possible IF the disc is stationary AND the laser is on and focussed properly, AND laser power were high enough, at most what would happen is that the information layer would have a microscopic hole blown in it (and this would be taken care of by the error correction processing). However, this really is extremely improbable in a normal CD player or CDROM drive with normal CDs, especially if the unit is working otherwise since the disc starts spinning as soon as focus is established. Forget it. Mechanical causes of damaged discs are about a zillion times more likely! :-)

Thus, there is absolutely no way for a software command to the CDROM drive to affect the contents of the disc in any way. The laser power is simply too low to affect the CD and there is no way to boost it, even for an instant. Anything you've heard to the contrary it total rubbish. However, a faulty CD-R or CD-R/W writer could indeed result in damage to CD-R and CD-R/W media from its higher power laser but that's another story.

Repairing a scratched CD

So your five year old decided that your favorite CD would make nice frisbee - didn't really know much about aerodynamics, did he?

Now it sounds like a poor excuse for a 78 rpm record. What to do?

There seem to be about as many ways of fixing scratches on CDs as producing them in the first place. However, they fall into 3 classes of techniques:

1. Mild abrasives: plastic or furniture polish, silver polish, toothpaste. These will totally remove minor scratches. DO NOT use anything that contains solvents including petrolium distillates - if it smells like kerosene, it will likely attack the polycarbonate plastic of the CD rendering it useless. Brasso(tm), a popular product may fall into this

category but I've also heard that it works fine without damaging the CD.

2. Fillers: turtle wax, car wax, furniture wax. Apply over the whole disc and buff out with a lint free cloth. Filling larger scratches should be fairly effective but the disc will be more prone to damage in the future due to the soft wax.

3. Motorized buffing wheel. Sort of a miniature version of what is used for polishing your car. :) See the details below.

4. Blowtorch. At least one person who claims to have worked for several years in used CD store swears by this technique. Supposedly, he uses a pencil-type pocket butane torch and with great dexterity fuses the surface layer of the readout side of the disc so that all of those scratches and unsightly blemishes-well-melt away. Obviously, there are dangers in using fire on plastic and this is likely a last resort. I would assume that you are rolling with hysterical laughter at this point. In any case, I would not take this approach too seriously :-).

For (1) and (2), as with cleaning a CD, when applying or rubbing any of these materials, wipe from the center to the outside edge. A CD player can generally track across scratches that are perpendicular to its path reasonable well, but not those that run the parallel to the tracks.

A mild abrasive will actually remove the scratch entirely if it is minor enough. This is probably more effective where the surface has been scuffed or abraded rather than deeply scratched.

Wax-like materials will fill in the space where the scratch is if the abrasive was not successful. Even deep scratches may succumb to this approach.

A combination of (1) and (2) may be most effective.

Exorbitantly priced versions of these materials are available specifically marketed for repair of CDs. However, the common abrasives and waxes should work about as well.

I cannot comment on the use of the blowtorch or how many years of practice is required to get you CD repair license with this technique. However, I am highly skeptical that this works at all and suspect that destruction of the CD is the most likely outcome - totally melting, warping, or cracking or shattering from the thermal stress. In other words, I don't recommend trying the Blowtorch approach unless you have a stack of AOL or MSN CDs to sacrifice and you have sufficient accident insurance!

Even some of other solutions may make the problem worse or destroy the CD entirely if not done correctly or if the wrong materials or technique is used. So, test any method on a CD you don't care about first.

An alternative to CD home repair are companies specializing in this service. A couple of these are: Aural Tech CD and CD Repairman. I do not have information as to their effectiveness or cost. However, if you have a very special irreplaceable CD that someone used as a skateboard, one of these may be worth considering.

(From: Shawn Stopper (shstop@prodigy.net).)

In the CD repair process, I use a 1/4 horse electric motor, cotton buff, 2 hose clamps, 2 washers, a screw, and brown tripoli rouge. The motor should be mounted to a surface for permanent use. The first hose clamp should be mounted about halfway back on the motor shaft. A shaft about 4 inches in length will be necessary for this application. after mounting the first hose clamp, apply a washer, the buff, another washer, and the final hose clamp. Mount a screw about 1/2 inch above the motor shaft where the outer clamp can be twisted around the screw to keep the buff spinning. When buffing cds, start out using brown tripoli rouge and slowly move the cd from inside to out. Do not apply too much pressure on the CD because this will cause the CD to "splinter", and it will be ruined. Patience is the key to CD buffing. The first few you do may take longer than you expect, but the more you do the better you get at it. At this time, I can buff about 3 to 4 CDs in five minutes. Once again, practice is the key!

Repairing top-side problems on CDs

If scratches penetrate to the information layer, all bets may be off. Much of the optical system compliance with respect to damage depends on the short depth of focus assuring that surface scratches *on the bottom* will be out of focus and ignored. This is not possible with damage to the pits. Even though the CIRC code should be able to deal with thousands of bad bits, such damage can confuse the tracking servos to the point where the disc will be unusable.

What if the aluminum (or gold) reflective layer has come off with no damage to the plastic underneath? First of all, I don't know how this could occur unless you were attempting to clean them with a strong solvent. Any physical damage which removed the mirror coating will also damage the pits and recoating will be useless.

(Note that I have unintentionally removed the gold coating on a CD-R using a solvent similar to what is in Liquid Wrench(tm). I was actually trying to remove the label but went a little too far! The solvent apparently dissolved the greenish coating or binding underneath allowing the gold film and label to just flake off - very strange behavior. Most of the green layer was still intact. I now have a nice greenish somewhat transparent plastic coaster.)

Some discs may still work on some players or drives without the aluminum coating. However, this isn't that likely. How to replace it? Ideally, vacuum deposition is needed. The problem isn't only the reflectance but the micro structure - the original coating was vacuum deposited to conform to the pits and lands of the information layer. It is perfectly uniform below the resolution of the laser beam. Modeling (silver or gold colored) paint is amorphous and rough at these feature sizes and floppy disk write protect stickers or other adhesive backed reflective films don't even come close to contacting the information layer consistently. Mirror paint may work but is a long-shot.

CD Player and CDROM Drive Troubleshooting

SAFETY

While there are far fewer potential dangers involved in servicing a CD or DVD player compared to a TV, monitor, or microwave oven, some minimal precautions are still required when working with the cover removed. These relate to electrical connections to the AC line and exposure to the laser beam:

- Electrical: There may be a few exposed electrically live parts from the power line, usually around the power cord entrance, power transformer, and on/off switch. If there are, tape them over or cover them somehow so you need not be concerned with a low tech shock! Unless you are troubleshooting a primary side power supply problem, there will be no need to go near the AC line.

- Laser (CD): The laser in a CD player is infra red, near IR - 780 nm - border of visible range but for all intents and purposes invisible. However, it is very low power (generally under 1 mW at the lens) and due to the optics, extremely unlikely that you could be in any danger. Nonetheless, don't go out of your way to look closely into the lens while the unit is on!

  As long as the lens is intact, the beam is highly divergent and at anything beyond a few inches, especially at an oblique angle, is quite safe. The only possibility of risk would be if the lens fell out and you were looking directly into a collimated beam from above. While the power is less than that of most laser pointers, there would be no aversion reflex to the nearly invisible IR. And, yes, some models of CD players are known to drop their lenses!

CAUTION: There is usually a very low intensity (in appearance) emission from an IR laser which appears deep red. It will be visible as a spot the size of the period at the end of this sentence when the lens is viewed from an oblique angle. This is just your eye's response to the near IR energy of the main beam. (Some people apparently cannot see this at all.) Do not be mislead into thinking that the laser is weak as a result of how dim this is. The main beam is up to 10,000 times more intense than it appears! It's power output is generally around 1 mW - comparable to a laser pointer. Take care. However, the red dot is an indication that the laser is being powered and probably functional, though it is no guarantee of the latter. You really need a laser power meter or at least an IR detector to confirm the existence of an IR laser beam.

Whenever a full size (5-1/4") CD is in place, there is absolutely no danger of exposure to the laser beam. Reflections of laser light at these power levels are harmless. However, if you are testing with a 3-1/2" 'single' or homemade cut-down test CD (see the section: Useful ways to mangle CDs, avoid staring into the lens if there is any chance the laser is powered.

If you don't want to take even the minimal risk of looking into the lens at all, project the beam onto a piece of paper held close to the lens. In a dark room, it should be possible to detect a red spot on the paper when the laser is powered.

- Laser (CD-R, CD-RW, and other writeable optical drives): These may use IR laser diodes producing 10s of mW. A typical CD-R drive sets the laser power at 3 to 5 mW for read and 25 to 30 mW for write. While the basic precautions are the same, much greater care must be taken due to the much higher power when writing.

- Laser (DVD): The DVD laser pickup is very similar to that of the CD player except that the wavelength is in the 635 to 650 nm range which is a very visible red - about the same as the color of newer laser pointers or a helium-neon laser (632.6 nm). The power is still under 1 mW and everything else above is still applicable.

  One note: If the DVD player is of the dual pickup variety with a separate laser for CDs, that one is IR like a normal CD player and the precautions listed above will apply. Take care because it may not be obvious ahead of time which one (or if both) will be powered!

Troubleshooting tips

Many problems have simple solutions. Don't immediately assume that your problem is some combination of esoteric complex convoluted failures. For a CD player, it may just be a bad belt or dirty lens. Try to remember that the problems with the most catastrophic impact on operation (a CD player that will not play past track 6) usually have the simplest solutions (the gears that move the optical pickup need lubrication). The kinds of problems that we would like to avoid at all costs are the ones that are intermittent or difficult to reproduce: the occasional audio noise or skipping or a CD player that refuses to play classical CDs (depending on your tastes!) of music composed between the years 1840 and 1910.

When attempting to diagnose problems with a CDROM drive, start by trying to get it to play an audio CD. Data readback is more critical since the error correction needs to be perfect. However, with audio playback functional, all of the optical pickup and most of the servo systems and front-end electronics must be working. A CDROM drive which cannot even play a music CD will have no chance of loading Windows 95.

If you get stuck, sleep on it. Sometimes, just letting the problem bounce around in your head will lead to a different more successful approach or solution. Don't work when you are really tired - it is both dangerous and mostly non-productive (or possibly destructive).

Whenever working on precision equipment, make copious notes and diagrams. You will be eternally grateful when the time comes to reassemble the unit. Most connectors are keyed against incorrect insertion or interchange of cables, but not always. Apparently identical screws may be of differing lengths or have slightly different thread types. Little parts may fit in more than one place or orientation. Etc. Etc.

Pill bottles, film canisters, and plastic ice cube trays come in handy for sorting and storing screws and other small parts after disassembly.

Select a work area which is well lighted and where dropped parts can be located - not on a deep pile shag rug. Something like a large plastic tray with a slight lip may come in handy as it prevents small parts from rolling off of the work table. The best location will also be relatively dust free and allow you to suspend your troubleshooting to eat or sleep or think without having to pile everything into a cardboard box for storage.

Another consideration is ESD - Electro-Static Discharge. The electronic components - especially the laser diode - in CD players, CDROM drives, and similar devices, are vulnerable to ESD. There is no need to go overboard but do take reasonable precautions like not wearing clothing made of wool that tends to generate static. When working on component CD and laserdisc players, get into the habit of touching a ground like the metal chassis before touching any circuit components. The use of an antistatic wrist strap would be further insurance especially if the optical pickup assembly needs to be unplugged for any reason.

A basic set of precision hand tools will be all you need to disassemble a CD player and perform most adjustments. However, these do not need to be expensive. Needed tools include a selection of Philips and straight blade screwdrivers, needlenose pliers, wire cutters, tweezers, and dental picks. A jeweler's screwdriver set is a must particularly if you are working on a portable CD player or CDROM drive.

For making servo adjustments, non-metallic fine tip jeweler's screwdrivers or alignment tools will be essential as some of the front-end circuitry may be sensitive to body capacitance - contact with the slot may alter the behavior of the player (for better or for worse). In a pinch, wrapping electrical tape around the part of a normal jeweler's that you grasp will probably provide enough isolation. However, with a tool with a blade made out of an insulator, you will be less likely to accidentally short things out as well

Note that low level signals from the optical pickup like the data (RF) and other photodiode outputs are extremely sensitive to interference picked up from a finger on or near the flex cable, a disconnected ground strap, or possibly even a nearby broadcast antenna. Thus, when the optical deck isn't fully mounted and connected, there may be unusual behavior - this is probably normal. Just be aware of this and don't panic, and adjustments should be made with the unit as close to fully assembled as possible.

You should not need any CD specific tools except in the unlikely event you get into optical alignment in which case the service manual will detail what tools and special rigs are needed.

A low power fine tip soldering iron and fine rosin core solder will be needed if you should need to disconnect any soldered wires (on purpose or by accident) or replace soldered components.

CAUTION: You can easily turn a simple repair (e.g., bad solder connections) into an expensive mess if you use inappropriate soldering equipment and/or lack the soldering skills to go along with it. If in doubt, find someone else to do the soldering or at least practice, practice, practice, soldering and desoldering on a junk circuit board first! See the document: Troubleshooting and Repair of Consumer Electronic Equipment for additional info on soldering and rework techniques.

For thermal or warmup problems, a can of 'cold spray' or 'circuit chiller' (they are the same) and a heat gun or blow dryer come in handy to identify components whose characteristics may be drifting with temperature. Using the extension tube of the spray can or making a cardboard nozzle for the heat gun can provide very precise control of which components you are affecting.

Basic cleaning supplies include Q-tips (you may know them as cotton buds), lint free cloths or paper towels, water, and isopropyl alcohol (preferably 91 percent medicinal grade or better).

For info on useful chemicals, adhesives, and lubricants, see Troubleshooting and Repair of Consumer Electronic Equipment as well as other documents available at this site.

Test equipment

Don't start with the electronic test equipment, start with some analytical thinking. Many problems associated with consumer electronic equipment do not require a schematic (though one may be useful). The majority of problems with CD are mechanical and can be dealt with using nothing more than a good set of precision hand tools; some alcohol, degreaser, contact cleaner, light oil and grease; and your powers of observation (and a little experience). Your built in senses and that stuff between your ears represents the most important test equipment you have.

A DMM or VOM is necessary for checking of power supply voltages and testing of sensors, LEDs, switches, and other small components. This does not need to be expensive but since you will be depending on its readings, reliability is important. Even a relatively inexpensive DMM from Radio Shack will be fine for most repair work.

For servo and other electronic problems, an oscilloscope will be useful. However, it does not need to be fancy. A 10 to 20 MHz dual trace scope with a set of 10X probes will be more than adequate for all but the most esoteric troubleshooting of CD players and CDROM drives.

To determine if the laser diode is working properly, a laser power meter is very useful. Such a device is expensive but is often essential to properly and safely adjust laser power on many CD players and CDROM drives. However, for many problems, simply knowing that an IR laser beam is being emitted is enough. For this, the simple device described in the section: IR detector circuit is more than adequate. Alternatively, an inexpensive IR detector card or even some camcorders can perform the same function.

A stereo amplifier and loudspeakers is essential to allow your most important piece of audio test equipment to function effectively - your ears. A lot can be determined by listening to the audio output to distinguish among dirt, lubrication, servo, control, and other mechanical or electronic problems. I would caution against the use of headphones as a sudden burst of noise could blow your eardrums and spoil your entire day.

For testing of optical pickups, some additional equipment will be needed. However, this will be detailed in the section: Testing of Optical Pickup Assemblies.

Test CDs

An inexpensive test CD is nice to have just to be able to play known frequencies and volume levels. However, it is not essential - any half decent CD will work just fine for most tests. For many players, even an old CDROM disc will be adequate to diagnose startup problems. However, to fully exercise the limits of the player, a disc with a full 74 minutes of music will be needed - Beethoven's Ninth Symphony is a good choice (even if you are not into classical music) since it is usually very close (or sometimes slightly over) this length of time.

Keep those old demo CDs or even obsolete CDROM discs - they can be used for testing purposes. Where an optical deck has a servo problem, the disc will end up spinning out of control. Stopping this suddenly may result is the CD scraping itself against the drawer or or base of the deck and getting scratched. Therefore, some 'garbage' discs are always handy for testing purposes.

To evaluate tracking and error correction performance, any CD can be turned into a test CD with multiple width strips of black tape, a felt tip marker, or even a hand drill! In fact, some professional test discs are made in exactly this manner.

Also see the sections: "Comments on test discs" and "Custom test CDs using CD-Rs".

Useful ways to mangle CDs

These suggestions will allow you to put some of those AOL CDs to good use (well, besides making high tech coasters)!

- For portable CD players where the designers in their infinite wisdom put some of the servo adjustments *under* the spinning disc, a 3-1/2" CD 'single' is extremely handy. A normal CD can be cut down as well - to whatever size you need as long as enough actual tracks are left so that the directory and a few minutes of music/data remain - this could be as little as about 2-1/2" to gain access to the adjustments on some models. This surgery is best done on a band saw with a narrow fine tooth blade. However, tiny cracks may grow in from the edge (overnight, even) if the disc is subjected to any heating or stress from cutting or smoothing. Perhaps some annealing is needed to prevent these from getting started.

  Note that the lower mass (actually the lower moment of inertia for you purists) of the small CDs may alter the servo response somewhat. Putting a heavy metal ring or washer on top should help. However, this is still much much better than continually having to remove a normal CD to get at the adjustments, incrementally moving them one way or another, and then replacing the CD to see how you made out. One can grow old doing this! The little CDs will enable you to monitor the test points as the adjustments are made which is also a definite advantage :-).

  The RCA RP-7903A Portable CD Player is an example of a design where this type of modified CD is invaluable for testing.

- A handy special miniature CD can be made to permit viewing of the focusing action on any CD player or CDROM drive as long as you can get to the top of the deck while testing. Using a band saw, cut a garbage disc down so as to leave only a 1-1/2" diameter center hub with a 1/2" by 1/2" tab sticking out from it. This can then be positioned by hand to just cover the lens while it is supposed to be doing its focus search.

- An alternative that will permit you to view both the laser output (from a safe distance) and the focusing action is to create a window in a garbage CD by removing the label and aluminum layers from an area of the CD at the inner tracks - at least a square inch worth. Lacquer thinner (nail polish remover, with adequate ventilation) will probably work to remove the label. Fine sand paper or steel wool will remove the aluminum and information pits/lands (grooves). Then polish with a buffing wheel or old rag.

CAUTION: when using any of these cut-down or windowed test CDs, or 3-1/2" 'singles', avoid staring into the lens when the laser is powered. See the section: SAFETY.

Getting inside a CD player or CDROM drive

WARNING: you will void the warranty, if any. You may make the problem worse, possibly much worse. If the player partially worked, it may no longer even recognize the disc directory. You may accidentally damage parts that were perfectly fine. If you should decide to then have the unit professionally serviced, you may find that the shop simply refuses to touch it if they suspect your tampering. There is nothing worse than having to undo 'fixes' introduced by a well intentioned do-it-yourselfer where the state of the player is now a total unknown. At best you will be charged for this effort on a time and materials basis. It may be very costly. It may not be worth the expense.

A CD player still under warranty should probably be returned for service for any covered problems except those with the most obvious and easy solutions.

On the other hand, it is possible that you will do a better job than some repair shops. You will probably have a better understanding of the basic theory and will certainly be able to spend much more time on the problem. And, of course, hobbiest/handyman's time is cheap - as in free.

- Component CD players. It is generally very easy to remove the top cover on most CD players. There are usually some very obvious screws on the sides and possibly back as well. These are nearly always Philips head type - use the proper screwdriver. Once all the screws are out, the top cover will lift up or slide back and then come off easily. If it still does not want to budge, recheck for screws you may have missed.

  Once the top cover is removed, the optical deck and electronics board will usually be readily accessible.

  In rare cases, removing the bottom cover will provide access to the solder side of the electronics board. However, with most CD players, the bottom is solid sheet metal and the entire board would need to be unmounted. On some, the electronics board is mounted upside-down so there is full access to the wiring side once the cover is removed.

- With most single play designs, the entire optical deck can be lifted out after removing 3 or 4 screws. One screw may have a grounding contact under it. Replace this in exactly the same position. There may be fragile flexible cables. Be careful so as not to damage any. Usually, these cables plug in to connectors on the electronics board and permit the entire optical deck to be easily replaced if needed (not very common, however, despite what you may have heard).

- For changers, details will depend on the particular model but in general, it is more likely that removal of the entire changer mechanism will be more involved. However, this is usually not needed unless there is an actual mechanical problem with it. With Pioneer cartridge changers, for example, the optical deck is easily removed with just 4 screws.

- For portables, the bottom plate or top cover usually comes off after removing several very tiny screws - use the proper size Philips blade jeweler's screwdriver and don't lose them. Then, you either have access to the bottom of the mainboard or the top of the mainboard blocked mostly by the optical deck. With the RCA RP-7903A Portable CD Player, it is the latter and the pickup and/or normal size CD conveniently block all access to servo adjustments and test points (which as is often the case, are ummarked in this RCA unit). These types of CD players are usually quite a pain to troubleshoot! Of course, there are also many components including most of the large multilegged ICs surface mounted on the *bottom* side of the mainboard which makes for even more fun should probing be required! You can easily see all the 'stuff' packed into a box just slightly larger than a CD!

- For CDROM drives, both top and bottom covers may be removable depending on model. These are more wide open than portables, especially the newer models where everything has been shrunk to a tiny optical pickup and circuit board with a few large ICs. Unfortunately, adjustments (if any) and test points are even less likely to be labeled on CDROM drives. All testing will also require a working PC unless your model has built-in audio play capability.

Make notes of screw location and type and immediately store the screws away in a pill bottle, film canister, or ice cube tray.

When reassembling the equipment make sure to route cables and other wiring such that they will not get pinched or snagged and possibly broken, or have their insulation nicked or pierced, and that they will not get caught in moving parts. Replace any cable ties that were cut or removed during disassembly and add additional ones of your own if needed. Some electrical tape may sometimes come in handy to provide insulation insurance as well. (This applies mostly to portables and CDROM drives - component CD players are very wide open.

CD enhancers

The process of reading a CD is digital. I have seen and heard advertisements for sonic rings or special magic markers to improve the quality of the digital audio reproduction. This is total bunk. Don't waste your money. These products do nothing beyond depleting your pocketbook - and enhancing those of the vendors.

For more amusement, see the section: Totally worthless gadgets for CD enthusiasts.

Along the same lines, some apparently knowledgeable people (knowledgeable in what you might ask!) have asked if offers of software to turn a CDROM drive into a CD-R writer should be believed! This is just utter and total nonsense and what's more likely to happen if you fall for such a SCAM is to become the new owner of some nasty computer virus! Besides, this must be impossible since there is no place for a red "write" LED on a CDROM drive! :)

What about DVD player and DVDROM drive servicing?

DVD players and DVDROM drives have hit the market place in a big way and (if you believe the hype), DVDs are about to replace CDs totally. Realistically, this won't happen for some time. In any case, DVD players and DVDROM drives are *supposed* to accept CDs, CD-Rs, and CD-RWs, so no need to panic just yet. But availability of new CD based devices will disappear because the cost to manufacture a DVD player or drive isn't much more than that of a similar CD unit so manufacturers will want to close down their old production lines and concentrate on DVDs only.

In any case, eventually all things break, and DVD equipment will be no exception. Fortunately for us, the similarities between CD and DVD technology are much more significant than the differences. The inside of a DVD player looks pretty much the same as the inside of a CD player and, for the most part, the same problems are likely to occur. Here are some things to look out for:

- DVD discs look virtually identical to CDs. They are the same size and thickness with the same large center hole and will fit perfectly well into a CD player or CDROM drive - but of course won't do much there. Despite the tracks and pits being closer together, the rainbow/diffraction effects are about the same so a casual glance isn't enough to tell them apart but there is always that DVD logo! However, the information layer is precisely in the center of a sandwich of polycarbonate (each half .6 mm thick). (The DVD standard supports a double sided DVD. This, of course leaves virtually no room for the label!) More info on DVD media, storage capacity, and so forth can be found in the section: Comparison of CD and DVD Specifications.

- The laser in a DVD based device is a very visible red (a wavelength around 650 nm compared to the nearly invisible IR 780 nm laser used for CDs). This is about the same wavelength as used in newer red laser pointers. It is still low power (1 mW or less at the objective lens) but the laser will appear very bright when it is powered and working correctly. As far as hazards to vision, the same recommendations apply - don't look into the beam directly but viewing from an oblique angle at 12 inches or more from the objective lens should be safe. The eye's aversion reflex will prevent damage in any case - you will blink or turn away from a the bright light. CAUTION: Some (probably older) DVD equipment may also have a standard CD pickup to be able to read CDs. For these, obviously, all the IR laser precautions apply.

- It should be easier to determine if the laser is bad by brightness alone though a laser power meter and the manufacturer specifications will still be needed in marginal cases.

- As a result of the march of technology, the optical pickup is likely to of simpler design than that in older CD based devices with even fewer or no adjustments possible. However, there could be additional complexity due to the need to handle DVDs and CDs in the same equipment. The use of combined laser diodes and photodetector arrays is likely to be quite common if not pervasive. However, pickups may also use separate laser diodes and photodiode arrays possibly sharing some of the optics or at least part of the beam path in the optical block. In some pickups, objective lenses for the CD and DVD lasers can be rotated into position as required by applying enough current of the appropriate polarity to the fine tracking coils..

- The same basic functions need to be performed by the front-end electronics including amplification of the photodetector array output, and focus, tracking, and spindle servos. Much this is likely to be done inside large chips with no service adjustments.

- More functions will be incorporated into fewer surface mount chips. Fortunately, failures of the large scale integrated circuits themselves are not nearly as common as simple mechanical problems. Better hope so in any case as troubleshooting of things like an MPEG decoder is way beyond what could be done without a complete service manual, sophisticated test equipment, and probably a whole lot more!

- More plastic and less metal is likely to be used - lighter, flimsier, less likely to be serviceable at all.

So, the bad news is that if something breaks inside a large chip, accept defeat and send the unit in for service. The good news is that most problems will still be mechanical - dirt, dust, gummed up grease, bad motors, abuse. From our experience with CD repair, we should be well equipped to deal with these!

Hopefully, manufacturers have learned from their experience with CDs to make a more reliable robust product but that may be wishful thinking where the bottom line is involved. It's still too early to tell.

CD Player and CDROM Drive Fundamentals

Parts of a CD player or CDROM drive

While CD players and CDROM drives started out and still have much in common, they are diverging. The optical pickups remain similar but the data processing and servo systems needed to support 16X speed CDROM technology are much more sophisticated than those needed for 1X speed CD audio. Therefore, should you peek inside your shiny new CDROM drive, you may see parts that differ considerably from those in a old Discman.

Power supply

In component stereos units, there are normally linear supplies and thus very reliable but easy to repair as well. In portables, they are likely to be switching supplies, possibly sealed in a shielded can (or at least all surface mount components), and difficult to troubleshoot and repair.

Usually, at least three voltages are needed: logic power (e.g. +5 Vcc) and a pair of voltages for the analog circuitry (e.g., +/-15V). However, some designs use a variety of voltages for various portions of the analog (mainly) circuitry.

Electronics board

This contains the microcomputer controller, servos, readback electronics, audio D/A(s) and filters. Most servo adjustment pots will be located here. In many cases they are clearly marked but not always. DO NOT turn anything unless you are sure of what you are doing - and then only after marking their original positions precisely.

The optical deck

This subsystem includes all of the components to load and spin the disc, the optical pickup, and its positioning mechanism. Refer to the section: Typical optical decks for photos of some common models.

- Loading drawer - Most portable and many lower cost CD players or CDROM drives lack this convenience. Most are motor driven. However, some must be pushed in or pulled out by hand.

Common problems: loose or oily belt causing drawer to not open or close, or to not complete its close cycle. There can be mechanical damage such as worn/fractured gears or broken parts. The drawer switch may be dirty causing the drawer to decide on its own to close. The motor may be shorted, have shorted or open windings, or have a dry or worn bearing.

- Spindle, spindle table, or spindle platter, (we will use these names more or less interchangeably) - When the disc is loaded, it rests on this platform which is machined to automatically center it and minimize runout and wobble.

  Common problems: Dirt on table surface, bent spindle, dry or worn bearings if spindle not part of motor but is belt driven, loose spindle.

- Spindle motor - The motor that spins the disc. Most often the spindle platform is a press fit onto the spindle motor. Two types are common: The first is a miniature DC motor (using brushes) very similar to the common motors in toys and other battery operated devices. The second type is a brushless DC motor using Hall effect devices for commutation. If there are more than 2 wires attached to the motor or if it uses exposed coils and control board, it is likely of the brushless type. In very rare cases, a belt is used to couple the motor to the spindle but most are direct drive - the spindle is the motor shaft.

  Common problems: partially shorted motor, shorted or open winding, dry/worn bearings, defective electronics. The brushless type are much less likely to have electrical problems.

- Clamper - Usually a magnet on the opposite side of the disc from the spindle motor which prevents slippage between the disc and the spindle platform. The clamper is lifted off of the disc when the lid or drawer is opened. Alternatively, the spindle may be lowered to free the disc.

  Common problems: doesn't engage fully permitting disc to slip on spindle due to mechanical problem in drawer closing mechanism.

- Sled - The mechanism on which the optical pickup is mounted. The sled provides the means by which the optical pickup can be moved across the disc during normal play or to locate a specific track or piece of data. The sled is supported on guide rails and is moved by either a worm or ball gear, a rack and pinion gear, linear motor, or rotary positioner similar to what is in a modern hard disk drive - in increasing order of performance.

  Note that a single-beam optical pickup can be used with either a linear or rotary mechanism. However, a three-beam pickup will not work with a rotary positioner because the angle of the pickup changes with radial position. Functionally, neither type is fundamentally superior but most manufacturers seem to use the three-beam type. Philips/Magnavox (and their other brand names) appear to be the principal exceptions.

  Common problems: dirt, gummed up or lack of lubrication, damaged gears.

- Pickup/sled motor - The entire pickup moves on the sled during normal play or for rapid access to musical selections or CDROM data. The motor is either a conventional miniature permanent magnet DC motor with belt or gear with worm, ball, or rack and pinion mechanism, or a direct drive linear motor or rotary positioner with no gears or belts.

  Common problems: partially shorted motor, shorted or open winding, dry or worn bearings.

- Optical pickup - This unit is the 'stylus' that reads the optical information encoded on the disc. It includes the laser diode, associated optics, focus and tracking actuators, and photodiode array. The optical pickup is mounted on the sled and connects to the servo and readback electronics using flexible printed wiring cables.

  Common problems: hairline cracks in conductors of flexible cable causing intermittent behavior.

Typical optical decks

Some examples of common optical decks are shown in the following sets of photos. Note: The disc loading components and clampers are not shown.

Note: The resolution of the optical deck photos is 37.5 dpi unless otherwise noted. All other photos include a scale indicator.

The first 4 are from consumer grade CD players:

- The Pioneer CD Player Optical Deck shows a typical sled-type using a PM motor driven screw. This uses a three beam pickup.

  This model (or one similar to it) can be found in both Pioneer single (e.g., PD5100) and changer (e.g., PDM500) type CD players. In the latter case, the assembly is mounted upside-down with the clamper on the bottom.

- The Sony D-2 CD Player Optical Deck shows another common sled-type with a gear driven rack. This model (and as far as I know, all others from Sony) use three-beam pickups.

  This deck (or one similar to it) can be found in the Sony Model D2 and other portable CD players. (The flex cable, a common failure item, has been removed to provide unobstructed views.)

  It uses the Sony KSS220A optical pickup which is virtually identical to the Sony KSS361A Optical Pickup.

- The Sony D-14 CD Player Optical Deck is also uses a gear driven rack. It has a three-beam pickup.

  This deck is from a very old D-14 portable CD player, possibly only the second portable model manufactured by Sony.

  The Sony KSS110C Optical Pickup it uses is distinctly different than other more modern Sony models. In addition to being larger, the optics include a beam splitter prism, a negative lens in the return path, and the objective lens is mounted on a shaft enabling it to slide up and down (for focus), and rotate (for tracking).

- The Philips CD Player Optical Deck provides an example of a unit using a rotary type voice coil tracking actuator and uses a single-beam pickup.

  This one came from a front loading (flip down see-through door) Magnavox Model AH197M37 Modular Stereo System (includes dual cassette, AM/FM radio, and turntable).

  CD players and some CDROM drives manufactured by Philips (this includes the Magnavox and Sylvania brand names) seem to be the only ones still using rotary actuator technology in consumer products. In older versions, parts of the optical pickup (like the laser diode) were pluggable and easily replaced.

The three below are from CDROM drives:

- The Sony CDU-31/33A CDROM Optical Deck is typical of the mechanism found in lower performance models that use a screw drive for sled positioning. The pickup used is a three-beam KSS360A which is very nearly identical to the Sony KSS361A Optical Pickup (only the shape of the mounting bracket differs). Like its consumer CD player counterpart, everything is glued in place at the time of manufacture - there are no adjustments.

The CDU-31A 1X, CDU-33A 2X, and other CDROM drives using this deck were probably the most popular models in the early 1990s. The CDU-31/33A used the Sony proprietary interface (also available on some sound cards) and were certainly nothing to write home about in the speed department. These drives used a high quality brushless DC motor for the spindle while other similar performance CDROM drives of the era had cheap permanent magnet DC motors that were prone to failure. However, they were the only popular front loading CDROM drives to NOT have the convenience of a motorized drawer mechanism - just a solenoid release. Of course, there was less to break down!

- The Sony CDU-8001 CDROM Optical Deck provides an example of a unit using a direct drive linear motor for the coarse tracking actuator. The pickup is a three-beam Sony KSS180A - quite similar to the Sony KSS361A Optical Pickup but appears to be more solidly constructed with at least one additional optical element that may be a collimating lens. Unlike most consumer grade pickups, the KSS180A is not totally glued together and some adjustment of optical alignment is possible.

  This deck came from a Sony CDU-8001 CDROM Drive Unit - a speedy 1X drive (aren't you impressed?) used with a SCSI interface for an Apple MacIntosh computer. The NEC Model CDR-82 CDROM Reader and others of the same vintage also use the same Sony KSS180A pickup.

  These were of the cartridge loading type (loading mechanism removed). The spindle motor is a high quality DC brushless type.

  Some component CD players by Technics (Matsushita) and others (in addition to Sony) also used linear motor technology as early as 1983 (possibly even before) to provide fast (under 1/2 second) music seek times which is better performance than some of the early CDROM drives using screw or gear type actuators.

- The Philips CR-206 CDROM Optical Deck views provide an example of a drive using a rotary actuator for both coarse and fine tracking. This uses a single-beam pickup where the laser diode and photodiode are apparently combined into one package which is mounted in a very simple compact optical assembly.

  This deck came from an inexpensive Philips CR-206 2X CDROM drive (vintage 1994). Note how much smaller this assembly is compared to the Philips CD player optical deck, above, which dates from around 1990.

Interestingly, most common popular higher performance CDROM drives (e.g., 4X, 12X, even 16X or more) do not use linear motors or rotary positioners to achieve rapid seek times. They use a screw or gear drive powered by a cheap permanent magnet DC motor! However, they do all use high quality brushless DC motors for the spindle since these high-X drives put a lot of stress on this component (especially those which are the true CLV type and vary speed based on track location). Although the optical pickups themselves have been simplified and have reduced mass, and the drive mechanism had been speeded up compared to the typical cheap portable CD player, this type of implementation is still far from optimal. Therefore, while the transfer rate may be pretty good (see the section: CDROM drive speed - where will it end? for why this really isn't assured even with a 32X unit), seek times may be mediocre - 250 ms full stroke being typical.

The next two are nearly complete CDROM drives of this type:

- The Philips PCA80SC CDROM Drive Optical Deck is a relatively modern design typical of low cost high spin-rate units. This one is an 8X model. The Optical Pickup from Philips PCA80SC CDROM appears to be a three-beam type.

  Apparently, many manufacturers used this basic mechanism. I have an Aztech CDA-268-01A CDROM drive (2X) which has the same pickup and a very similar optical deck.

- The Teac CD-532S CDROM Drive is another popular design used in late model (1998) low cost high spin-rate units. This one is a 32X (Max) model with a SCSI interface. The 32X (Max) rating really means that it spins at constant speed roughly equivalent to a 13X rate and the 32X spec is only achieved for data located near the outer edge of the disc.

The Sony KSS575B three-beam pickup used in this drive is quite compact but of the more complex design using a separate laser diode and photodiode array with beam splitter. The optical path is equivalent to that of that of the Sony KSS361A Optical Pickup. (See the section: Sony KSS series optical pickups.) The guts are located in a central box-like object about 1.5 cm on a side. However, the pickup is mostly made of plastic - gone are the days of the cast metal optical block! While this does make it weigh less, the difference would hardly seem to be significant for access speed given the primitive screw drive.

The Sanyo K38N Optical Pickup used in the earlier (like all of 3 months!) Teac model, the 16X CD516s, is substantially similar to this but of more solid construction. Teac CDROM drives from 6X (and possibly below) through this 32X unit appear virtually identical mechanically.

Also notice how little electronics there is in this unit - nearly all the circuitry is on the single small circuit board on the left side of the bottom view. On all the other CDROM drives, the logic board occupied all the space (and more in some models) above or below the optical deck!

Finally, here are photos of DVDROM drives:

- The Toshiba SD-M1212 DVDROM Drive is typical of the DVDROM drives shipped with bundled PCs (I believe this was from a Dell Dimension 450 MHz Pentium II system). The most notable feature of the optical deck used here is that it really is so similar in appearance to those used with late model CD players or CDROM drives. In fact, without the DVD logo or other distinguishing markings, it could just as well have been a CDROM drive. (Of course, we know that what's inside is quite different at least in the details.) I wasn't willing to go any deeper since this is still a working unit so there could be internal differences. An update will be forthcoming when I get my hands on a broken one!

  Note that it appears to have only a single objective lens. This would tend to imply that compromises have been made, most likely for CDs, and that performance with them may not be as good as with a dedicated CDROM drive.

  One thing that is obvious is the amount of circuitry compared to say, the Teac CD532s, above, whose PCB occupied less than 1/3rd of the available area. I don't know how much this is due to just being newer technology which hasn't been as highly integrated yet as opposed to the additional complexity required for DVD decoding and support for CD audio and data formats as well.

- The Optical Path of CD/DVDROM from Sony F390 Laptop shows the optics and laser diode assemblies from below. The objective lens would be where the turning mirror faces. This unit has separate DVD and CD lasers, each of the "hologram laser" type with a Holographic Optical Element (HOE) for generating the side beams and replacing the polarizing beam splitter and other components. One of the laser diodes is a Sharp HPD 24T3 according to the markings. The DVD laser diode assembly has a 3 way beam splitter crystal on the front, 'T' shaped, and the other has a two way splitter '-' on the crystal face. DVD Laser Holographic Optical Element shows the HOE on the DVD laser diode assembly. Thanks to John LeBourgeois (john@121email.com) for these photos.

Components of the optical pickup

All the parts described below are in the optical pickup. As noted, the optical pickup is usually a self contained and replaceable subassembly. The actual complement and arrangement of parts depends on the specific pickup design - a number of popular variations on the basic arrangement are used. Thus, should you actually end up dismantling a dead optical pickup, it will probably not match this description exactly. While the relatively old Sony KSS110C Optical Pickup has most of the same components as described below, the very common newer Sony and Sanyo optical pickups combine multiple functions into fewer elements. Typical examples are found in the Sony KSS361A Optical Pickup and Sanyo K38N Optical Pickup. The even simpler CMKS-81X Optical Pickup and Optical Pickup from Philips PCA80SC CDROM combine the laser diode and photodiode array into single package and eliminate all of the other optical components except for the diffraction grating and turning mirror (and the latter could be eliminated where space permits below the deck). The resulting designs are much cheaper to manufacture, more robust and reliable, and should have better performance as well since there are fewer intermediate optical components to degrade the beam.

Also see the section: CD optical pickup operating principles.

Despite its being a precision optomechanical device, optical pickups are remarkably robust in terms of susceptibility to mechanical damage.

- Laser Diode - This is Infra Red (IR) emitting usually at 780 nm - near IR, just outside the visible range of 400-700 nm. The power output is no more than a few milliwatts though this gets reduced to .25-1.2 mW at the output of the objective lens. A photodiode inside the laser diode case monitors optical power directly and is used in a feedback loop to maintain laser output at a constant and extremely stable value.

  The photos below show some of the types of laser diodes you may encounter in CD players, CDROM drives, laser printers, and bar code scanners:

  - A Variety of Small Laser Diodes (CD, laser printer, bar code scanner).
  - Closeup of Typical Laser Diode (from a laser printer).
  - Closeup of Laser Diode from the Sony KSS361A Optical Pickup (seen 'actual size' in the upper left corner of the group photo, above.)

  On an increasing number of pickups, the laser diode and photodiode array are combined into a single package. These are recognizable by their 8 or 10 lead package. See the section: Optical pickup complexity.

  Common problems: bad laser diode or sensing photodiode resulting in reduction or loss of laser output.

- Photodiode array - This is the sensor which is used to read back data and control beams. These are usually integrated into a single chip with a clear plastic cover. On an increasing number of pickups, the laser diode and photodiode array are combined into a single package. These are recognizable by their 8 or 10 lead package. See the section: Optical pickup complexity.

  The photodiode array for a three-beam pickup has 6 segments - 4 in the center (A,B,C,D) and 1 on either side (E,F). Only the center segments are used in a single-beam pickup.

  However, there are some CD players and CDROM drives are fitted with complete three-beam pickups, but don't take advantage of the side beams - the E and F segments of the photodiode array are simply grounded! So, the blurb for these models may say "Featuring three-beam pickup" when only a single-beam is used! Isn't marketing wonderful? :-).

  Common problems: bad photodiode(s) resulting in improper or absence of focus and weak or missing RF signal. A missing bias voltage to the photodiode array would also result in lack of output.

- Collimating lens - This converts the wedge shaped beam of the laser diode into nearly parallel rays. Not present in many (newer) designs.

- Diffraction grating - In a 'three-beam pickup', this generates two additional lower power (first order) beams, one on each side of the main beam which are used for tracking feedback. It is absent in a 'single-beam pickup'.

- Cylindrical lens - In conjunction with the collimating lens, this provides the mechanism for accurate dynamic focusing by changing the shape of the return beam based on focal distance. Modern pickups may actually use a thick beam splitter mirror or astigmatic objective lense to implement this function and/or take advantage of the natural astigmatism of the laser diode itself. The thick mirror approach is used in most common Sony KSS pickups, for example.

- Beam splitter - Passes the laser output to the objective lens and disc and directs the return beam to the photodiode array. There will be no beam splitter (and related optics) if the laser diode and photodiode are combined in a single package. Where this is a thick mirror, it also introduces the needed astigmatism for focusing (most Sony KSS pickups, for example).

- Turning mirror - Redirects the optical beams from the horizontal of the optical system to vertical to strike the disc. Where space permits under the pickup, there is no need for a turning mirror as everything can be vertically oriented.

  Common problems: dirty mirror. Unfortunately, this may be difficult to access for cleaning. Note: the turning mirror is probably not silvered but is coated to reflect IR so do not be surprised if you can see through it.

The previous five items are the major components of the fixed optics. Outside of damage caused by a serious fall, there is little to go bad. Better hope so in any case - it is usually very difficult to access the fixed optics components and there is no easy way to realign them anyhow. Fortunately, except for the turning mirror, it is unlikely that they would ever need cleaning. Usually, even the turning mirror is fairly well protected and remains clean.

Depending on the design of the pickup, many of the components of the optical system listed above may be missing or combined into a single unit. In fact, the most modern pickup designs combine the laser diode and photodiode into a single package with 8 to 10 leads. With this approach, there is no need for a beam splitter or related optical components as the outgoing and return beams take nearly the same path. The overall manufacturing process is simplified, performance is improved, the cost is reduced, and reliability and robustness are enhanced. See the section: Optical pickup complexity.

The following items are associated with focusing the laser beam down to a microscopic point and maintaining it precisely on the CD's tracks:

- Objective lens - High quality focusing lens, very similar to a good microscope objective with a numerical aperture (N.A.) of .45 and focal length of 4 mm. (Should you care, the N.A. is defined as the sine of the angle from the optical axis to the edge of the objective, as seen by the object. An N.A. of .45 implies a very fast high quality lens.)

  If you examine CD player objective lenses closely, you will also note that they are aspheric - the surface is not shaped like the surface of a sphere (as is the case with most of the small lenses you are likely to encounter) but its radius of curvature changes from center to edge (it is somewhat pointed). Because the light source (laser diode) is coherent and monochromatic, a low cost single element plastic molded lens with an antireflection coating (the blue tinge in the central area) can produce a diffraction limited spot (less than 2 um in diameter) at the disc information (pits) layer. An expensive multielement lens system would be required if the light source were not coherent and monochromatic. Of course, the entire technology would not be practical in this case!

  There is usually a ridge around its periphery to prevent the polished surface from being scratched should the assembly accidentally contact the spinning disc.

  Note: Some objective lenses (e.g., Philips/Magnavox) have a perfectly flat front surface. This would appear to be more susceptible to damage but perhaps a mechanical stop prevents contact even at the extreme upper limit.

The lens is suspended to permit movement in two directions: up and down (focus) and toward and away from the spindle (tracking). Common problems: dirty lens, dirt in lens mechanism, scratched lens, damage from improper cleaning or excessive mechanical shock.

- Focus actuator - Since focus must be accurate to 1 micron - 1 um, a focus servo is used. The actuator is actually a coil of wire in a permanent magnetic field like the voice coil in a loudspeaker. The focus actuator can move the objective lens up and down - closer or farther from the disc based on focus information taken from the photodiode array.

  Common problems: broken coil, damaged suspension (caused by mechanical shock or improper cleaning techniques).

- Tracking actuator - Like focus, tracking must be accurate to 1 um or better. A similar voice coil actuator moves the objective lens from side-to-side (relative to the tracks - toward or away from the spindle) based on tracking feedback information taken from the photodiode array.

  Note: On pickups with rotary positioners, there may be no separate tracking coil as its function is subsumed by the positioner servo. The frequency response of the overall tracking servo system is high enough that the separate fine tracking actuator is not needed. These are also always of the single-beam type since the angle of the pickup changes with radial position and three-beam tracking control cannot be used.

  Common problems: broken coil, damaged suspension (caused by mechanical shock or improper cleaning techniques).

Classification of CD player problems

While there are a semi-infinite number of distinct things that can go wrong with a CD player, any set of symptoms can be classified as a hard failure or a soft failure:

1. Hard failure - door opening/closing problems, disc is not recognized, no sound, unit totally dead.

2. Soft failure - skips, continuous or repetitive audio noise, search or track seek problems, random behavior.

Both of these types of problems are common with CD players and CDROM drives. The causes in both cases are often very simple, easy to locate, and quick and inexpensive to repair.

Most common CD player problems

While it is tempting to blame the most expensive component in a CD player or CDROM drive - the laser - for every problem, this is usually uncalled for.

Here is a short list of common causes for a variety of tracking and audio or data readout symtoms:

- Dirty optics - lens, prism, or turning mirror.
- Drawer loading belts - worn, oily, flabby, or tired.
- Sticky mechanism - dirt, dried up/lack of lubrication, dog hair, sand, etc.
- Broken (plastic) parts - gear teeth, brackets, or mountings.
- Need for electronic servo adjustments - focus, tracking, or PLL.
- Intermittent limit or interlock switches - worn or dirty.
- Bad connections - solder joints, connectors, or cracked flex cable traces.
- Motors - electrical (shorted, dead spot) or mechanical (dry/worn bearings).

- Laser - dead or weak laser diode or laser drive (power) problems.
- Photodiode array - bad, weak, or shorted segments or no power.
- Bad/heat sensistive electronic components.
- Bad or missing optical pickup shield ground.

The following two areas cover the most common types of problems you are likely to encounter. For any situation where operation is intermittent or audio output is noisy, skips, or gets stuck, or if some discs play and others have noise or are not even recognized consistently, consider these FIRST:

- Dirty lens - especially if your house is particularly dusty, the player is located in a greasy location like a kitchen, or there are heavy smokers around. Cleaning the lens is relatively easy and may have a dramatic effect on player performance.

- Mechanical problems - dirt, dried up lubrication, damaged parts. These may cause erratic problems or total failure. The first part of a CD may play but then get stuck at about the time location.

  If your CD player has a 'transport lock' screw, check that it is in the 'operate' position before breaking out the heavy test equipment!

Troubleshooting Guide

Instant troubleshooting chart - most common problems and likely causes

The following chart lists a variety of common problems and nearly all possible causes. Diagnostic procedures will then be needed to determine which actually apply. The 'possible causes' are listed in *approximate* order of likelihood. Most of these problems are covered in more detail elsewhere in this document.

While this chart lists many problems, it is does not cover everything that can go wrong. However, it can be a starting point for guiding your thinking in the proper direction. Even if not listed here, your particular problem may still be dealt with elsewhere in this document.

- Problem: CD player is totally dead.
  Possible causes:

  1. Power outlet, wall adapter, or batteries are dead (as appropriate).
  2. Damage to line or wall adapter cord or plug.
  3. Bad connections or faulty component in power supply (including blown fuse).
  4. Defective microcontroller.

- Problem: CD player is operational but there is no display or partial display.
  Possible causes:

  1. Burned out back-light bulb(s).
  2. Bad connections to display panel (totally dead or erratic).
  3. Bad solder connections on display panel (some segment work).
  4. Bad power supply (EL panel filament, driver voltages).

- Problem: CD player ignores you.
  Possible causes:

  1. Bad connections to one or more buttons or sets of buttons.
  2. Microcontroller failed to reset properly.
  3. Missing/bad voltages from power supply.
  4. Defective microcontroller or other logic.

- Problem: Drawer does not open or close.
  Possible causes:

  1. Worn, stretched, oily, flabby, belt.
  2. Dirty mechanism or gummed up lubrication.
  3. Stripped gear or other mechanical damage.
  4. Defective motor or bad connections to motor.
  5. Bad drawer/eject button.
  6. Missing/bad voltages from power supply.
  7. Defective microcontroller or other logic.
  8. Dealer antitheft lock enabled.

- Problem: Drawer operation is erratic.
  Possible causes:

  1. Dirty sense switch contracts or bad connections.
  2. Worn, stretched, oily, flabby, belt.
  3. Dirty mechanism or gummed up lubrication.
  4. Defective motor or bad connections to motor.
  5. Stripped gear or other mechanical damage.
  6. Missing/bad voltages from power supply.
  7. Defective microcontroller or other logic.

- Problem: Drawer does not close (or open) completely.
  Possible causes:

  1. Worn, stretched, oily, flabby, belt.
  2. Dirty mechanism or gummed up lubrication.
  3. Foreign object like toy, rock, or runaway disc blocking drawer.
  4. Stripped gear or other mechanical damage.
  5. Gear timing is messed up.

- Problem: CD changer jams when selecting or ejecting CDs.
  Possible causes:

  1. Bad belts, dirt or need for lubrication.
  2. Foreign objects, chipped or broken gears, or other mechanical damage.
  3. Messed up gear timing.
  4. Defective sensor (microswitch or opto-interrupter.
  5. Defective motor, driver, or power supply.
  6. Logic or microcontroller problem.

- Problem: CD player or CDROM drive damages CDs.
  Possible causes:

1. Broken, bent, or missing part.
2. Messed up gear timing (mainly cartridge changers).
3. Other mechanical fault.
4. Lens hitting CD due to electronic fault or need to adjust focus servo.

- Problem: Spindle table loose or sticks to clamper upon eject.
  Possible causes:

  1. Set screw loosened or glue failed holding spindle to motor shaft.
  2. Parts of spindle table broke.

- Problem: Intermittent or erratic operation.
  Possible causes:

  1. Dirty, scratched, or defective disc.
  2. Dirty lens.
  3. Extended length discs too long for player.
  4. Loading (mechanical) not completed reliably.
  5. Bad connections including missing/erratic optical deck shield.
  6. Cracks in ribbon cable to optical pickup.
  7. Dirty drawer or limit switches.
  8. Power supply or logic problems.
  9. External interference.
  10. Internal damage (e.g., loose parts) in optical pickup.

- Problem: CD player or CDROM drive overheats.
  Possible causes:

  1. Excessive ambient temperature - sauna or hot stereo components.
  2. Failing/marginal part in power supply, logic, or optical pickup.

- Problem: Operation is poor or erratic when cold:
  Possible causes:

  1. Gummed up grease or dirt inhibiting movement until warm.
  2. Condensation on optical components due to temperature change.
  3. Bad connections or dirty contacts affected by temperature.

- Problem: Disc is not recognized displaying 'disc', 'error', etc.
  Possible causes:

  1. Disc loaded upside-down.
  2. Transportation lock engaged.
  3. Dirty, scratched, or defective disc.
  4. Dirty or damaged objective lens.
  5. Loading (mechanical) not completed reliably.
  6. Damaged lens suspension or damaged lens cover preventing free movement.
  7. Dirt, gummed up lubrication, or damage in sled drive mechanism.
  8. Dirty/defective limit switch or sensor.
  9. Defective spindle motor.
  10. Spindle table height incorrectly set.
  11. Bad component in optical pickup.

12. Cracks in ribbon cable to optical pickup.
13. Need to adjust servo (or less likely, optical) alignment.
14. Faulty power supply, electronics, or control logic.
15. Bad connections including missing/erratic optical deck shield.
16. External interference.

- Problem: Disc spins in wrong direction or overspeeds and is never recognized.
  Possible causes:

  1. Disc loaded upside-down.
  2. Dirty, scratched, or defective disc.
  3. Dirty or damaged objective lens.
  4. Tracking or CLV servo out of adjustment or faulty.
  5. Bad component in optical pickup.
  6. Microcontroller or control logic problems.
  7. Bad connections or defective ribbon cable to optical pickup.
  8. Defective spindle motor including worn bearings.

- Problem: Pickup attempts to reset past inner track.
  Possible causes:

  1. Dirty or defective limit switch, bad connections to it, or its electronics.
  2. Broken parts preventing limit switch from being activated.
  3. Tracking servo out of adjustment or faulty.
  4. Microcontroller or logic problems.

- Problem: Player won't let you go near it and/or use your favorite lamp.
  Possible causes:

  1. Missing optical deck shield, ground strap, or other connection.
  2. Outside interference.

- Problem: Seek operations take too long or fail to complete.
  Possible causes:

  1. Dirty, scratched, or defective disc.
  2. Transportation lock engaged.
  3. Dirty or damaged objective lens, suspension, obstruction, etc.
  4. Tracking or CLV servo out of adjustment or faulty.
  5. Mechanical problems with sled movement.
  6. Faulty sled motor or drive IC.
  7. Faulty control logic.
  8. Bad flex cable to optical pickup.

- Problem: Search, seek, or play starts correctly, then loses time or position.
  Possible causes:

  1. Dirty, scratched, or defective disc.
  2. Dirty or damaged objective lens, suspension, obstruction, etc.
  3. Tracking or PLL servo out of adjustment or faulty.
  4. Stuck button.
  5. Defective sled motor drive IC.

6. Faulty control logic.

- Problem: Short distance skipping.
  Possible causes:

  1. Dirty, scratched, or defective disc.
  2. Dirty or damaged objective lens, suspension, obstruction, etc.
  3. Fine tracking servo out of adjustment or faulty.
  4. Weak laser or other defective part in the optical pickup.

- Problem: Playback gets stuck (rapid repeat).
  Possible causes:

  1. Dirty, scratched, or defective disc.
  2. Dirty or damaged objective lens, suspension, obstruction, etc.
  3. Dirt, gummed up lubrication, or damage in sled drive mechanism.
  4. Transportation lock engaged.
  5. Need for servo alignment.

- Problem: Occasional long distance skipping or repeating.
  Possible causes:

  1. Dirty, scratched, or defective disc.
  2. Dirty or damaged objective lens, suspension, obstruction, etc.
  3. Dirt, gummed up lubrication, bad belt, or damage in sled drive mechanism.
  4. Transportation lock engaged.
  5. Need for servo alignment.

- Problem: Player gets stuck at approximately same time on multiple discs.
  Possible causes:

  1. Dirt, gummed up lubrication, or damage in sled drive mechanism.
  2. Sled reaching mechanical stop with extended length (>74 minute) disc.
  3. Transportation lock engaged.
  4. Need for servo alignment.
  5. Defective spindle motor.

- Problem: Various tracking problems on portions of discs:
  Possible causes:

  1. Dirty, scratched, or defective disc.
  2. Faulty spindle motor.
  3. Misalignment of spindle table and sled track.
  4. Need for CLV adjustment.

- Problem: Repetitive noise at disc rotation rate.
  Possible causes:

  1. Dirty, scratched, or defective (possibly warped) disc.
  2. Dirty or damaged objective lens, suspension, obstruction, etc.
  3. Loose spindle or foreign material on spindle table.
  4. Disc not firmly clamped.

5. Bent spindle.
6. Excessive spindle runout due to worn bearing.
7. Need for servo alignment.
8. Weak laser or other component in optical pickup.

- Problem: Audio muting, noise, or distortion.
  Possible causes:

  1. Dirty contacts on RCA jacks on CD player or amp.
  2. Bad connections to RCA jacks.
  3. Dirty/defective muting relay contacts.
  4. Defective components in the analog circuitry (final filter, muting, amp).
  5. Faulty power supply (for audio circuits if used).
  6. Dirty controls (probably on amp unless problem is with the headphones).

General inspection, cleaning, and lubrication

The following should be performed as general preventive maintenance or when erratic behavior is detected. The lens and its suspension, turning mirror, drawer mechanism, spindle, and sled drive should be checked, and cleaned and/or lubricated if necessary and appropriate.

You will have to get under the clamp to access the lens and spindle on drawer loading models but the lens and its suspension, at least, should be readily accessible on portable CD players with pop-up doors. These types can collect a lot of dust, dirt, and even fingerprints! Realistically, you probably won't do any of this for component CD players, CDROM drives, or other drawer loading models until something goes wrong! :-) (I don't blame you - getting one of those out from the tangle of entertainment center wiring, dusting it off, removing the cover, disassembling to whatever level is needed, and so forth can be a royal pain.)

Cleaning the objective lens and turning mirror (if accessible) are the most important general maintenance that can be done. Even minor contamination of their optical surfaces can easily result in 50 percent reduction in the returned signal - and all sorts of problems.

- Objective lens - Carefully clean the lens assembly. Be gentle! The lens is suspended by a voice coil actuated positioner which is relatively delicate. A CD lens cleaning disc is nearly worthless except for the most minor dust as it will not completely remove grease, grime, and condensed tobacco smoke products (yet another reason not to smoke!) and make matters worse by just moving the crud around.

  First, gently blow out any dust or dirt which may have collected inside the lens assembly. A photographic type of air bulb is fine but be extremely careful using any kind of compressed air source. Next, clean the lens itself. It is made of plastic, so don't use strong solvents. There are special cleaners, but isopropyl alcohol us usually all that is needed for CD players and VCRs. (91% medicinal is acceptable, pure isopropyl is better. Avoid rubbing alcohol especially if it contains any additives.) However, sometimes, a drop of water will be needed to dissolve sugar based crud. There should be no problems as long as you dry everything off (gently!) reasonably quickly. DO NOT LUBRICATE! You wouldn't oil a loudspeaker, would you?

  You cannot generally get to the bottom surface of the lens but this isn't nearly as exposed as the top surface so it usually isn't a problem. However, a few models do permit removal and replacement of the entire objective lens assembly without realignment. In such a case, you can get to the bottom of the lens as well as additional optics surfaces (see below) for cleaning.

  Do NOT use strong solvents or anything with abrasives - you will destroy the lens surface rendering the entire expensive pickup worthless.

- Now, inspect the lens. When clean, the lens should be perfectly shiny with a blue tinge uniform over the central surface. Minor (barely visible) scratches will probably cause no harm but any major scratches may result in erratic tracking or total inability to even read the disc directory. The pickup (or lens assembly) will need to be replaced in this case.

  It is easy to be misled into thinking that there are serious problems at the root cause of discs not being recognized, audible noise (CD players) or data errors (CDROM or optical drives), and tracking problems like skipping, sticking, or seek failures. However, in many cases, it is simply a dirty lens! Even people who repair CD players regularly may make an incorrect diagnosis since many of the symptoms **are** similar to those caused by a bad laser, spindle motor, or major logic failure.

- Turning mirror or prism. If you can get to it under the lens without disturbing anything, clean this as well using the same procedure. Cleaning this may be at least as important as the lens. Unfortunately, the turning mirror may not be accessible without major (and difficult) disassembly.

  Cleaning the turning mirror is nearly as important as cleaning the lens (especially for Sony pickups apparently since it is relatively exposed).

  However, for the typical Sony pickup (also used in Sony PlayStations and by AIWA and other manufacturers), it is really pretty easy. First, remove the black protective cover by prying the clips out on either side. Use a toothpick or Q-tip stick to GENTLY lift up on the lens assembly taking care not to damage any of the fine wires. Blow out any dust using an air bulb. There will be just enough room to get a Q-tip in between the lens and mirror.

  Note: The turning mirror is not silvered so don't expect a normal mirror appearance - it looks just like a piece of glass. However, it is coated to be an excellent reflector for the 780 nm IR laser light.

  Of course, this procedure doesn't get to the beam splitter, photodiode, or laser diode window - but you can't have everything! :-) Fortunately, these are usually better protected and less likely to collect dust and grime.

- Lens suspension for focus and tracking. Check this for free movement and damage:

  - Focus: The lens should move up and down without sticking (turn the player or pickup upside-down carefully to watch the lens move without power and/or move it gently with a dry Q-tip). It should remain parallel to the deck throughout its range and return to the center or just below center when released. However, it is hard to say just how far below the center is enough to consider it bad. Even a bottomed out lens might work - the focus servo can correct to a large extent - but could result in more susceptibility to skipping or other erratic operation particularly with less-then-perfect discs. Also, see the section: [Comments on Sony KSS pickup suspension problems]

  - Tracking: Use a Q-tip to gently move the lens toward and away from the spindle. It should move easily without sticking and remain parallel to the deck. When released, it should return to approximately the middle position.

  A suspension which fails any of these tests probably means replacement of the pickup - or CD player - is needed. However, the lens with its suspension is one of the few components of the optical pickup assembly that may be replaceable - at least in principle. See the section: [Interchangeability of components in the optical pickup].

- Spindle bearing - Check the spindle bearing (this is primarily likely to cause problems with repetitive noise). There should be no detectable side to side play. I.e., you should not be able to jiggle the platform that the CD sits on. If you find that the bearings are worn, it is possible to replace the motor (about $10 from various mail order houses), though removing and replacing the disc platform may prove challenging as a result of the usual press fit mounting.

The focus servo can compensate for a vertical movement of the disc surface of 1 mm or so. A small bearing side play can easily cause larger vertical errors - especially near the end (outer edge) of the disc. Even if you are not experiencing problems due to bearing wear, keep your findings in mind for the future.

Sometimes there is a bearing runout adjustment screw on the bottom of the spindle if the spindle is not driven by a standard permanent magnet motor. I have seen this in a Sony Discman which had a custom motor assembly. A small tweak to this may fix a marginal spindle problem.

To access the drawer mechanism and sled drive in component units, you will probably need to remove the optical deck from the chassis. It is usually mounted by 3 long screws (one of which may have a grounding doodad - don't lose it. In portables and CDROMs, the bottom panel of the unit will need to be removed. Try not to let any of the microscrews escape! A good set of jeweler's screwdrivers is a must for portables.

- Drawer mechanism (if present) - Check for free movement. Test the belt (if used) for life - it should be firm, reasonably tight, and should return to its original length instantly if stretched by 25% or so. If the belt fails any of these criteria, it will need to be replaced eventually, though a thorough cleaning of the belt and pulleys with isopropyl alcohol (dry quickly to avoid damaging the rubber) or soap and water may give it a temporary reprieve. Some models may use other types of drawer mechanisms but similar recommendations apply.

  Also, check the gears and motor for lubrication and damage and correct as necessary. Clean and lubricate (if necessary) with high quality light grease suitable for electronic mechanisms such as MolyLube or Silicone grease. A drop of light oil (electric motor oil, sewing machine oil) in the motor bearings may cure a noisy or dry bearing.

- Sled drive - check the components which move the pickup including (depending on what kind of sled drive your unit has) belt, worm gear, other gears, slide bearings. These should all move freely (exception: if there is a lock to prevent accidental damage while the unit is being transported the pickup may not move freely or very far). Inspect for damage to any of these components which might impede free movement. Repair or replace as appropriate.

  If the there is evidence of dirty or hardened grease, clean the gears and track thoroughly as this may interfere with free movement. Use a sharpened toothpick or (very carefully) a pin or other tool to get in between each of the gear teeth as well to be sure that it is not hard and caked there as this may result in erratic operation and skipping.

  Then lubricate (if necessary) with just a dab of high quality light grease suitable for electronic mechanisms such as MolyLube or Silicone grease). A drop of light oil (electric motor oil, sewing machine oil) in the motor bearings may cure a noisy or dry bearing. Also see the section: Testing the sled for mechanical problems.

Try to play a disc again before proceeding further. I guess you have already done this.

Cleaning the inside of the optical pickup

Except under extreme circumstances (like dropping the CD player in the bathtub), the interior of the optical pickup should remain relatively clean and dust-free. However, what happens if you DO drop the CD player in the bathtub? Well, there will no doubt be other problems to deal with but once those are taken care of (if ever), that leaves the optical pickup.

For many, the turning mirror is accessible by gently lifting up on the lens assembly after removing the protective shroud. But, even this may not be possible for some models. And, cleaning all of the other optics may be difficult or impossible.

For example, on many Sony models, there is a metal plate fastened with a single screw underneath the pickup. This plate can be removed without disturbing any adjustments revealing the angled beam splitter and diffraction grating (of the three beam pickup) in the barrel attached to the laser diode. These can be cleaned with a Q-tip and alcohol.

However, there is no way to get beyond this point. So, if any water got in there, the only chance of success would be via an alcohol? soak. Forget about further disassembly - realignment would be totally impossible without the factory jigs. A replacement pickup will probably be needed.

Each manufacturer has their own way of assembling a pickup. The only way to determine if access is possible will be by careful exploration!

Lubrication of CD players

The short recommendation is: DO NOT add any oil or grease unless you are positively sure it is needed. Most moving parts are lubricated at the factory and do not need any further lubrication over their lifetime. Too much lubrication is worse then too little. It is easy to add a drop of oil but difficult and time consuming to restore an optical pickup that has taken a bath.

NEVER, ever, use WD40! WD40 is not a good lubricant despite the claims on the label. Legend has it that the WD stands for Water Displacer - which is one of the functions of WD40 when used to coat tools for rust prevention. WD40 is much too thin to do any good as a general lubricant and will quickly collect dirt and dry up.

A light machine oil like electric motor or sewing machine oil should be used for gear or wheel shafts. A plastic safe grease like silicone grease or Molylube is suitable for gears, cams, or mechanical (piano key) type mode selectors. Never use oil or grease on electrical contacts.

Unless the unit was not properly lubricated at the factory (which is quite possible), don't add any unless your inspection reveals the specific need. In a CD player or CDROM drive, there are a very limited number of failures specifically due to lubrication.

Note that in most cases, oil is for plain bearings (not ball or roller) and pivots while grease is used on sliding parts and gear teeth. If the old lubricant is gummed up, remove it and clean the affected parts thoroughly before adding new oil or grease.

In general, do not lubricate anything unless you know there is a need. Never 'shotgun' a problem by lubricating everything in sight! You might as well literally use a shotgun on the equipment!

- Back to CD Repair FAQ Table of Contents.

General System Problems

CD player is totally dead

Check input power, power cord, fuse, power supply components. Locate the outputs of the power transformer and trace them to the rectifiers and associated filter capacitors and regulators. While the actual voltages will probably not be marked, most of the power in a CD player will be typically between +15 and -15 VDC. Sometimes, the voltage ratings of the filter capacitors and/or regulators will provide clues as to correct power supply outputs. Don't forget the obvious of the line cord, line fuse (if present), and power switch - or outlet. Most component CD players use linear power supplies so troubleshooting is straightforward.

Portables CD players and CDROM drives often use DC-DC converters to produce the various voltages required, and these are much more difficult to troubleshoot even with a complete service manual. Doing anything other than checking for shorted or open components is virtually impossible without an accurate schematic. If an incorrect power adapter was used (or this happened when you plugged or unplugged the power connector of a CDROM drive with power on - a no-no), then major damage can result despite the various types of protective measures taken in the design. However, check for the obvious - a blown fuse on the mainboard near the power connector. These may be picofuses(tm) which look like little green resistors, IC Protectors which look like tiny transistors with only 2 legs, or something else marked F, ICP, etc. You might get lucky.

I inherited a Sony Discman from a guy who thought he would save a few bucks and make an adapter cord to use it in his car. Not only was the 12-15 volts from the car battery too high but he got it backwards! Blew the DC-DC converter transistor in two despite the built in reverse voltage protection and fried the microcontroller. Needless to say, the player was a loss but the cigarette lighter fuse was happy as a clam!

Moral: those voltage, current, and polarity ratings marked on portable equipment are there for a reason. Voltage rating should not be exceeded, though using a slightly lower voltage adapter will probably cause no harm though performance may suffer. The current rating of the adapter should be at least equal to the printed rating. The polarity, of course, must be correct. If connected backwards with a current limited adapter, there may be no immediate damage depending on the design of the protective circuits. But don't take chances - double check that the polarities match - with a voltmeter if necessary - before you plug it in! Note that even some identically marked adapters put out widely different open circuit voltages. If the unloaded voltage reading is more than 25-30% higher than the marked value, I would be cautious about using the adapter without confirmation that it is acceptable for your player. Needless to say, if the player behaves in any strange or unexpected manner with a new adapter, if any part gets unusually warm, or if there is any unusual odor, unplug it immediately and attempt to identify the cause of the problem.

See the document: Audio Equipment and Other Miscellaneous Stuff for more info on linear power supplies. See the document Small Switchmode Power Supplies for more info on DC-DC convertors.

CD player is operational but there is no display or partial display

Where the display is very dim or totally out, suspect one or more burned out bulbs for the backlight. Sometimes the display uses miniature incandescent lamps and these burn out. Usually, alternatives to the high priced exact replacement bulbs can be located. Test the bulbs with an ohmmeter. Measure the voltage across the light bulb connections and then replace the bulb with one of about 25-50% higher voltage. These may not be quite as bright but should last forever.

If the light bulbs are not at fault or there are no light bulbs, then check for power to the display including bad connections or connectors that need to be reseated. There could also be a power supply (e.g., missing voltage to the filament or segments for a vacuum fluorescent display) or driver problem.

If only portions of the display are bad - some segments on multiple digits, for example, check for bad connections to the driver chip. The displays are usually multiplexed meaning that a single output of the driver chip actually is used for the same segment in multiple digits or even apparently unrelated words or icons. Thus, a single failure can result in strange display behavior. If no bad connections are found, the driver chip or actual display could be at fault. Since the player works otherwise, unless you are a purist, it make sense to just leave it alone.

In the case of a portable or car CD that uses a 'zebra stripe' type rubber compression connector, cleaning the rubber piece, display, and circuit board with alcohol and reinstalling may solve the problem. If it uses a glued on printed flex cable, DO NOT attempt to remove it. Take extreme care when working on such equipment as it is virtually impossible to repair a cable of this type should it tear or pull free.

CD player ignores you

Symptoms are that the display comes up normal when power is turned on but all (or certain) commands are ignored.

This could mean several things:

- Front panel problem - one or more buttons are not responding. Reseat internal cables, clean or replace offending push button switches. If your CD player has a remote control, see if it operates correctly.

- Reset failure - the player has failed to reset properly and is not ready for user input. Try pulling the plug for a couple of minutes to see if it will reset. Check power supply voltages, clean and reseat internal connectors.

- Controller and/or driver electronics for the affected functions are defective. Check power supply voltages, reseat internal connectors.

For all but the first one, a service manual will probably be needed to proceed further if the problem is not with a bad power supply or bad connections.

Drawer does not open or close

If the drawer doesn't open when the front panel button is pressed, listen for motor attempting to open the drawer. If you hear it whirring but nothing happens, check for an oily/loose belt or other mechanical fault like a gear loose on the motor shaft or a slipping rubber wheel. Such a gear is probably split and a replacement will be needed. Rubber parts may be cleaned for a temporary repair but replacement will be needed eventually.

If there is no attempt, motor, control chip, or front panel pushbutton (try with the remote if you have one to eliminate this possibility) could be bad. Sony players seem to have a built in timer that triggers the belt to go bad after the warranty runs out. Also see the section on "Small Motors in CD Players".

Another slight possibility is that the player has gotten into a "Dealer Antitheft" mode which prevents people from stealing CDs or DVDs from demo units in a store. Consult your user manual or ask the place where you bought it for the key sequence. to reset it.

Drawer operation is erratic

You are about to remove your favorite CD but the player beats you to it, closes the drawer, and starts playing it over again. Or, the drawer reverses course halfway out. Or, the drawer motor continues to whir even after the door is fully open or closed and the front panel is then unresponsive.

This is usually due to dirty contacts on the door position sense switches. There are usually 3 sets of switch contacts associated with the drawer mechanism. If any of these get dirty, worn, or bent out of place, erratic operation can result:

- Drawer closed sense switch - dirty contacts may result in the drawer motor continuing to whir after the door closes and the front panel may then be unresponsive. Eventually, the drawer may open on its own.

- Drawer open sense switch - dirty contacts may result in the drawer motor continuing to whir after the door opens and the front panel may then be unresponsive. Eventually, the drawer may close on its own.

- Drawer pushed sense switch - most CD players allow the user to start play by gently pushing on the drawer which depresses a set of switch contacts. If these are dirty, the result may be the drawer deciding to close on its own or reversing direction in the middle of opening or closing.

The solution to all these problems is usually to simply locate the offending switches and clean their contacts. These switches contacts are usually not protected from dust, dirt, and grime so that these types of problems are quite common.

If the drawer simply doesn't respond to your wishes - sometimes, there may be a bad belt or bad motor.

- Sometimes, how long the player has been powered will affect the 'stickiness' of the belt - leave it on long enough and the belt will loosen and be too weak to operate the drawer. See the section: Drawer does not open or close.

- The drawer motor may have a 'dead spot' or be partially shorted. See the chapter: Motors and Spindles.

Drawer does not close (or open) completely

This is a symptom that may not be obvious. The drawer may appear to close but a loose or oily belt can prevent the mechanism from completing the close cycle. This can result in erratic behavior since the disc clamping action is often controlled by the movement - sometimes not recognizing disc, sometimes just opening the drawer, or more subtle things like tracking problems, etc. Clean the belt and see if there is any improvement. Belt replacement will be necessary eventually. Check for gummed up lubrication as well.

If it goes through the motions of closing and then stops short without any further sounds, a gear may have jumped a tooth or broken some. The result is either that the mechanism is now incorrectly timed or not able to complete the operation. Examine the mechanism closely for broken parts. Cycle it manually by turning the appropriate motor pulley or gear to see if the drawer gets hung up or is much more difficult to move at some point.

If it continues to make a whirring sound after the drawer stops, there might be some other kind of mechanical damage resulting in an obstruction or really gummed up lubrication not allowing the operation to complete.

If you have small kids around, don't overlook the possibility that your CD player is being used as a storage cabinet! A favorite toy, rock, gummy bear, jelly bean, or other organic or inorganic object may have found its way into the CD compartment. Or, perhaps, someone, somehow, managed to lodge a disc inside despite the best efforts of the CD player's designers. (This might happen if it was transported upside-down, for example).

CD changer jams when selecting or ejecting CDs

Unfortunately, this is the sort of problem one has to see to be able to make specific recommendations.

- Check for flabby/oily belts (if any), dirt, or and gummed up lubrication.

- Double check that it is in good condition mechanically - no chipped gear teeth or broken parts.

- Gear timing may be messed up (especially if someone worked on the unit previously though I don't know which, if any CD changers, depend on this for proper operation).

Try to cycle the mechanism manually by turning the appropriate motor shafts.

- A defective sensor - either a microswitch or opto-interruptor - can result in improper commands being issued to the motors.

- If movement is weak, erratic, or non-exitent, check for bad connections, defective motors and drivers, and power problems.

- A logic problem is also possible but not very likely.

Get a bunch of garbage AOL or MSN (your choice) CDs to experiment with - it should be able to cycle them just fine but the audio may sound weird :-). (Hint: Turn the volume way down!) Then, try to determine exactly what it is trying to do and how it screws up.

For auto changers where one disc doesn't come out:

(From: Tony (tony@buffnet.net).)

Try removing all the CDs from the magazine and inserting the empty magazine into the changer. Now turn on the unit and see if the cd goes back into the magazine. If it does not, look for a reset button on the changer. It will be a tiny hole near the eject button that requires a paper clip or toothpick to be inserted to contact the switch. Try pushing this with the magazine inserted. If you do not see a reset switch on the changer look for one on the face of the radio or, if it is a removable face radio, remove the face and see if there is a switch on the panel behind the face and try that. If all of this does not work, the changer will have to be disassembled for the CD to be removed. If the unit is under warranty, take it back so as not to void your warranty by disassembling the unit.

CD player or CDROM drive damages CDs

Thankfully, this sort of problem is not very common - the last thing you want is for your equipment to damage the media!

First, use a garbage CD and attempt to determine exactly where it is hitting or scraping. That may be enough to identify the culprit. Most of the time, this will be a simple mechanical fault like a broken plastic part causing things to jam, or a bit of that part getting in the way. Or, perhaps, your ace system administrator got just a bit carried away in frustration and stomped on the top of the drive. :)

On cartridge type changers, a bad or missing belt or gear timing problem could result in the CD getting hung up or scraping as it is extracted or replaced.

In some cases, an electronic failure or improperly adjusted focus servo could result in the lens hitting the CD on the top of its excursion.

A lot of newer equipment - especially high-X CDROM drives - is built so cheaply that repair may not be possible or cost effective and replacement is the only viable option.

Spindle table loose or sticks to clamper upon eject

When you remove the CD, you may have an added surprise - the platform upon which the CD sits pops off as well, possibly jamming everything. There may also be startup and spindown problems.

Various models use different techniques to fasten the spindle table to the motor shaft but this is strictly a mechanical problem. Either a set screw has worked loose, adhesive has weakened, or a press fit has come undone.

If there is no set screw, a drop of Epoxy may be what is needed. However, height is important to guarantee proper focus range so some care will be needed if there no definite stop. The disc and rotating clamper magnet must be clear of any fixed structures and the correct distance from the optical pickup. Where something irreversible is involved like adhesive, checking the service manual is highly recommended - the specification is usually .1 mm accuracy.

A loose spindle table may also result in continued spinning upon eject or sluggish or noisy startup or seek since the if the spindle is loose, the motor will not be able to properly control disc speed during speed changes.

Intermittent or erratic operation

When a CD player appears to have a mood problem - playing fine sometimes or for only part of a disc or aborting at random times, there can be several possible causes including a dirty lens, dirty or worn interlock switch or bad connections to interlock switch (mainly portables and boomboxes), flex cable with hairline cracks in one or more conductors (or just misrouted and close to a metal part of the chassis!), other bad connections, marginal power supply, defective or extended length disc.

- Dirty, scratched, or defective CD - confirm that the CD is not the problem. Clean the disc and/or try another one. However, not all CDs are created equal. Both the overall quality of the information layer and plating as well as the amount of lead-in and blank space between music tracks varies. Thus, where some aspect of the CD player's optics or electronics is not perfect - or even variations in the microcontroller's programming - can result in the player not properly dealing with some discs. The use of CD-Rs represents even more variability since they are increasingly written on low cost equipment of questionable quality.

- Dirty lens - a player that accepts some discs and not others or accepts discs sporadically may simply need its eyeglasses cleaned.

- Extended length discs - some players will simply not play discs which exceed about 74 minutes (the legal limit for CD playing time) to the end (or possibly at all). Such CDs may be as long as 78 or 80 minutes or more. This means that certain aspects of the CD specifications were compromised. Both mechanical and electronic problems are possible. See the section: Problems with extended length discs.

- Mechanical - oily, flabby belts preventing full drawer closing or gummed up lubrication on the sled (may fail depending on ambient temperature). For example, if the music gets stuck at about the same time on every disc, then there may be gunk on the end of the sled track preventing the sled from moving any further. This is especially likely if you just purchased a disc with an unusually long playing time - it has nothing to do with the musical tastes of the CD player! (There was this Chinese restaurant where the Chinese cooking grease apparently collected on the unused end portion of the sled track and when they tried to play an extra long CD.....)

- Bad connections - there are often many little connectors used to get signals and power between the optical deck and main circuit board. These are usually cheaply made and prone to failure. Wiggling and reseating these may cure these problems. There may even be bad solder connections on the pins of connectors or board mounted switches. Slight flexing or just expansion and contraction may result in intermittent shutdown or other problems. These problems are more likely with portables and boomboxes which may get abused.

  The connectors for any flex cables are particularly prone to developing erratic contact. Where a locking bar is used, pull it up to release the cable; remove, clean, and reinsert the cable; and press the locking bar firmly into place may help. Where there is no lock, gently pull the cable out of the connector, clean, and install. I have seen problems of this type on a couple of CDROM drives - portable and component CD players use the same types of cables.

- A missing shield between the analog ground and the optical deck can result in all kinds of erratic behavior. If these weird problems started after you had the player apart for some reason, check that you replaced the grounding strap or metal strip and/or didn't accidentally disconnect or break any shield connection on the ribbon cable to the optical deck.

- Cracks in ribbon cable - The moving and fixed parts of the optical pickup are often joined with a printed flexible cable. Constant flexing may cause one or more of the copper traces to crack. This may show up as an inability to get past a certain point on every disc - the player may shut down or start skipping at around 23 minutes into every CD.

- Dirty switches - oily film or oxidation may be preventing any of the limit or interlock switches from making reliable contact. If this is the case, the player may stop at random times, fail to accept a disc, close the drawer without your permission, etc. Use contact cleaner and typing paper to clean the contacts. Disassembly may be required for enclosed switches.

- Power supply or logic problems are also possible but rare. However, if you have a scope, check the power supply outputs for ripple - a filter capacitor may have dried up and lost most of its capacitance.

- External interference from a powerful local radio station (probably AM but could also be CB or a ham operator), light dimmer, or other source. Sometimes reversing the AC plug, repositioning the equipment, or using higher quality cables may help. Unfortunately, there are often no easy solutions to these sorts of problems. A missing or broken optical deck shield ground (see above) could make the player more susceptible to this.

- Internal damage (e.g., loose parts) in optical pickup. A partially detached lens in Pioneer type pickups (see the section: Objective lens popped out) or loose grating in Sony pickups can result in all sorts of strange and non-reproducible behavior.

  (From: David Kuhajda (dkuhajda@locl.net).)

  What we normally see on some Sony pickups like the KSS240 is the grating plate glue breaks loose on one end inside the optics, which allows it to move around. The exact position of this is extremely critical to the proper operation of the cd player. Unfortunately the only way to fix this is to replace the optics and realign it as needed.

CD player or CDROM drive overheats

A CD player which becomes noisy or a CDROM drive that fails to recognize discs or reliably read data after a few minutes may have a component that is heating up and changing value.

Before blaming the CD player, confirm that the ambient temperature is not excessive - CD players may not like to operate in a sauna. High power stereo components surrounding the CD player may elevate its internal temperature enough to cause erratic operation or total failure. CDROM drives sandwiched in between high capacity hard drives (this used to be more of a problem than it is today) may overheat.

Assuming your CD player is in an environment which is cool as a cucumber:

In general, there should not be much change in behavior from the instant power is applied until the next millennium. There is not much in a CD player or CDROM which runs hot and might change characteristics. However, components do sometimes fail in this manner. Problems of this type need to be diagnosed in much the same way as one would find overheating components in a TV or computer monitor.

You will need a can of cold spray ('circuit chiller') and an oscilloscope, if available. Even a hair dryer on the no-heat setting will work in a pinch.

You are going to have to try cooling various components to try to determine which one is bad. However, on a unit that dies completely and suddenly after it warms this will not be much fun since you will not have ample opportunity to detect changes in behavior. On a CD player that will play but with tracking problems and/or audio noise, you should be able to monitor the playback quality by simply listening for improvement when you have cooled the flakey part. For a CDROM drive, play an audio disc if possible since this will provide the feedback you need to locate the bad part without (hopefully) it constantly shutting down due to data errors or inability to reliably access the file system.

First, I would recommend running with the covers removed and see if that has an effect confirming a thermal problem. Try blowing cool air over the exposed innards if nothing obvious occurs. Where components are mounted on both sides of the circuit board, it may be a bit tricky to get airflow to the bottom without disassembly. Assuming you can set up a situation where the problem occurs, use the cold spray on individual components like the LSI chips - quick burst, wait a few seconds for something to change. Where the unit behaves with the cover off, use a hair dryer instead. Make a funnel out of paper to direct the air flow. You will need to be more patient with this approach.

If you have a scope, it would be nice to look at the RF 'eye' pattern during this time and see if it decreases in amplitude and/or quality over the course of an hour. If it does, you may have an overheating problem in the laser diode or its power supply.

(For unknown reasons, the name 'RF' is often used to denote the raw signal from the pickup. Since it's at a few MHz, it is in the RF range of the electromagnetic spectrum. There is no radio transmitter inside a basic CD player! :) However, a few CD players DO have an RF modulator for transmitting the audio to a nearby FM radio for wireless operation but that is a totally different use of the term being AFTER the audio circuits.)

Operation is poor or erratic when cold

This is somewhat the opposite of overheating and is usually NOT due to a failing part - electronic components generally misbehave when hot, not cold.

For a system that is not exposed to the elements (e.g., a portable taken from sub-zero outdoors and immediately put to use indoors), the most likely cause is mechanical: Gummed up grease and dirt are stiffer when cold and inhibit motion of the sled and other moving parts until the unit warms up.

However, for automotive units and portables - which are not well sealed, condensation can form form on the optics if a cold player is exposed to a humid environment. This may be the case when you get into your car on cold days until the CD player itself warms up to ambient temperature. If a VCR or camcorder detects condensation, it will flash a DEW warning and refuse to do anything to protects itself. For VCRs, this is critical because you could end up with a mess and expensive repair bill if the video tape were to stick to the spinning video head drum. Unfortunately, CD players don't have this feature since nothing catastrophic would happen. A warning would be nice, however!

A third possibility is that there are bad connections or dirty contacts in the unit that are affected by temperature resulting in erratic behavior as they expand.

Startup Problems

What is a startup problem?

Startup problems cover all situations where the player does not successfully read the disc directory. Nearly everything in the optical deck and much of the mainboard electronics needs to be functional to read the directory. Therefore, a single failure in any of a large number of places can prevent successful startup (and subsequent play).

- On a single play unit, failure of the startup sequence may result in a display of no disc, disc, error; a full calender but no disc info; or it may just open the door and challenge you to provide it with a proper meal.

- On a changer, failure of the startup sequence will likely result in a similar display but then the unit will move on to the next position in the carousel or cartridge. It will likely remember that it was unsuccessful at loading a disc for each position and eventually give up once all possible discs have been tried.

Possible causes for startup failure include: defective disc, dirty lens, defective laser or photodiode array, bad focus or tracking actuator or driver, dirty track, lack of or dried up lubrication, dirty or bad limit switches or sensors, defective spindle motor, faulty electronics or control logic, damaged parts, faulty optical alignment or need for servo adjustments, a missing optical deck shield, or outside interference.

On the one hand this is a large number of possibilities. The good news is that with such a large number of possibilities, there is a good chance the problem will be minor and inexpensive to fix.

Don't overlook the trivial: are you loading the disc correctly? Most CD players want the disc label-side up. However, some, like Pioneer magazine type changers want the label-side down. If you have just acquired the CD player, don't overlook this possibility.

On some poorly designed players - or where you are located in proximity to a high power (or possibly not so high power) radio station - outside interference can get into the player via the audio cables or line cord. A light dimmer on the same circuit might also produce interference via the power supply. Once inside, almost any type of behavior is possible. See the section: A HREF="#cdpwlygni">Player won't let you go near it and/or use your favorite lamp for testing procedures.

Startup sequence

There will be variations on the exact startup sequence of events depending on the type of player and its design. The result may be a blank display, display of the word 'disc', 'error', --:--, flashing display, etc. In any case, you don't get your music. By understanding the following summary as it applies to your player, you should be able to determine what is going wrong.

A dirty lens - perhaps not even visibly dirty to your naked eyeball - can result in any number of startup (or other) problems. Therefore, cleaning of the lens should be done before suspecting more obscure mechanical or electronic faults. See the section: General inspection, cleaning, and lubrication.

BTW, as hard as it may be to believe, there have been rare instances of the objective lens falling off! So, if you don't see one, check for it bouncing around in the bottom of the player! See the section: Objective lens popped out.

If this is a new player (at least for you) or has just been moved, check to see if it has a transportation lock to prevent the pickup from bouncing around during shipment. This is common on older units but you may find such a feature on the latest CD players and CDROM drives where a linear or rotary positioner is used to achieve high speed access. The lock migh prevent the sled from moving to the area of the disc directory (and of course, from playing properly).

What the CD player should do when a disc is inserted:

1. Drawer closes (or with portables, lid is closed manually) and CD is clamped to spindle.
2. Interlock (if present, always in portables) engages. In others, there may be an optical sensor or the optical pickup may act as its own disc sensor assuming a disc is present when it detects reflected light from the disc's reflective information layer.
3. Pickup resets to starting (index) location toward center of disc usually found with limit switch or optical sensor.

For the following, refer to the diagram below or the slightly nicer version: CD Player Front-End showing the photodetector organization typical in units with a 'three-beam pickup'. E and F will be absent in units with a 'single-beam pickup', though there may be other segments. The four quadrant photodetector is present in all systems.

The front-end circuitry shown is for descriptive purposes only; refer to an actual CD player schematic for details.

```
                     |<--- Photodiode Array ---->|
                               +---+---+

   Track--->           | E |- | +---+---+ | -| F | _________
                       +---+  | | C | D | |  +---+          ---------
```

```
                        |    | +---+---+ |    |           Track--->
                  /|    |    |   |   |   |    |
    Focus       / +|----|----+---|---+   |    |
    Error o---<    |    |    |   |   *   |    |    |\
    (A+D)-(B+C) \ -|----|----|---+-------+    +----|+ \       Tracking
                  \|    |    |   *       |         |    >---o Error
              FE Amp    +--------------------------|- /       (E-F)
                             |           |         |/ TE Amp
    * Since the photodiodes  |           |
      are current sources,   |           |         |\
      the simple junctions   |           +---------|+ \       Data Out
      implement a sum.       |                     |    >---o RF Test Point
                             +---------------------|- /       (A+B+C+D)
    All Amps: current mode inputs.                 |/ DO Amp
```

The main return beam is detected by the array, ABCD. The tracking beams return to E and F. E is offset slightly off track on one side and F on the other. Average signals from E and F will be equal when centered on track.

The following three steps may or may not be performed concurrently:

4. Laser is turned on and focus search routine is started to position lens at correct vertical position. Once correct focus is achieved, focus servo is activated to maintain it. Focus, which must be accurate to 1 um, operates as follows: The optical path in the pickup includes a cylindrical lens (or this may be a thick beam splitter mirror or astigmatic objective lens) which causes the laser beam spot to be circular when correctly focussed but elliptical otherwise with the major axis of the ellipse being offset 90 degrees depending on whether the lens is too close or too far (e.g., major axis of +45 degrees for too close and -45 degrees for too far). Focus Error = (A+D)-(B+C) = 0 for correct focus since with the circular spot, the outputs of all four quadrants will be equal.

5. Disc starts spinning up to 500 rpm and Constant Linear Velocity (CLV) servo is activated to maintain correct speed. CLV servo uses a PLL to lock to clock transitions derived from data read off of disc. Data is derived from A+B+C+D. (A buffered version of this signal can be monitored at the 'RF Test Point'.) A partially shorted spindle motor can result in the disc spinning but never quite reaching the required 500 rpm.

6. Tracking servo is activated to maintain laser beam centered on track. With 'three-beam pickup', 2 additional laser spots are projected onto the disc in front of and behind main beam. These are offset on each side of the track just enough so that Tracking Error = E-F = 0 when centered.

   With a 'single-beam pickup', similar information is derived using only the main beam since Tracking Error = (A+B)-(C+D) = 0 for correct tracking.

At this point, data is available for digital processing.

7. Disc directory is read and displayed.

8. Unit shuts down awaiting command or goes into play mode depending on how it was activated.

If any of steps 1 to 7 fail, then the laser is turned off and the machine will display some kind of error no disc message (typically, it may display Error, Disc, or go blank) and return to idle mode, or in the case of a changer, load the next disc and try again.

Procedure for validating the startup sequence

The following procedure is used when the disc is not recognized but the drawer closes completely.

First, double check the drawer closing/opening mechanism. Without exception, Sony CD players which have belts need them cleaned and eventually replaced. If the drawer does not close completely, then the disc may not be clamped properly or other erratic problems may occur.

Once you have verified that this is ok, you need to determine that the lens is clean. In general, the lens should look shiny with a blue tinge. Any scum or crud can degrade performance. You may have to remove part of the clamping mechanism to be able to see the lens. If it is not perfectly shiny, clean it using the procedures in the section: General inspection, cleaning, and lubrication.

Assuming that this does not improve the situation, the next step is to verify that the pickup has reset itself to the inner (center) track of the disc. If necessary manually move the pickup away from the center by turning the appropriate pulley or gear, or in the case of a linear actuator or rotary positioner (no gears or belts), just push the pickup gently and observe the behavior when a disc is loaded. If you are not able to move the pickup smoothly from one stop to the other, make sure any shipping lock is disengaged! The pickup should move smoothly toward the center, usually tripping a limit switch and stopping. If there is no movement or movement is jerky or the pickup gets stuck at some point, then lubrication may be needed or the motor or drive circuitry may be faulty. Also, check for broken or damaged gear teeth, a slipping belt, and misaligned or damaged tracks. Measure the voltage on the motor that moves the pickup. If there is none or it is very low (under a volt or so), then there is a problem with the motor, its driver, or the system controller.

Determine if the machine attempts to focus. On portables, it is sufficient to defeat the door interlock to get the operations associated with reading of the disc directory to begin (you may need to press play - this is model dependent). In some component CD players, a disc actually has to be present to block an optical sensor. You should see the lens moving up and down (at least one of these directions will have smooth movement) once or twice about 2 mm. If a disc is in place, then the lens should quickly stop at the appropriate focus position. Admittedly, observing the lens may be difficult or impossible with the disc in place. Dentists are probably good at this!

If the focus action is identical whether a disc is in place or not - i.e., it keeps up the search pattern and then gives up - verify that the laser is being powered. In most cases, you should be able to see a tiny spot of red appearing light when the lens is viewed from an oblique angle during the focus search. From a safe distance of at least six inches and 45 degrees or more off to one side, you should be able to see this dim red light in a darkened room while the unit is attempting to focus. If you see this, you can assume that the laser is being powered though it is not a sure test for an actual IR laser beam or proper optical power output. In most cases, however, the red light indicates that the laser is working. If there is no dot of red light, then either the laser diode is bad, it is not being powered, or you are not looking from the correct angle. An IR detector would confirm at least that there is an IR emission which in most cases means the laser is working (though possibly not at the proper power level):

- You can purchase an inexpensive IR detector card from an electronics distributor.
- A tester can be constructed using a photodiode, a few resistors, a general purpose small signal transistor, and an LED running off a 9 V battery. See the section: IR detector circuit. This will useful for testing IR remote controls and other IR emitters as well.
- If you have a modern camcorder (one with a CCD pickup, not a tube), it may be sensitive to IR as well but using one to test a CD laser would be pretty clunky to say the least (you would probably need to grow an extra arm or two). However, viewing the beam pattern projected on a white sheet of paper will enable the gross alignment to be checked easily - it should be fairly symmetric and centered above the lens.

If there is no IR emission while the lens is moving up and down, see the section: Testing the laser diode while in the player for more info on determining if this is a laser diode or driver problem.

If the lens is hitting the disc at the top of its excursion, there is a possibility that the spindle table has been pushed too far down - by something falling on it, for example. (A bent shaft and wobbly spindle is also a possibility in this case.) Such an occurrence is much more likely to have happened to a top loading boombox or protable than a drawer loading machine. (A friend of mine used to pound on his Sony boombox when it would not cooperate and this didn't help matters.) While hitting the disc with the spindle table set at the correct height is not impossible on some players, it is unlikely. (On most lenses, a ring around the outside of the lens itself prevents the critical central area from actually contacting the disc so accidental contact does not usually damage the lens but may scratch the disc. However, I have a portable where even this was not enough - the lens was seriously scratched somehow).

Similarly, if the spindle is too high, the lens may not be able to reach up to the proper focus position.

On a player with the height adjusted properly, there is usually about 2 mm between the laser shroud and the bottom of the disc. The spindle height is not super-critical but if it is way off, proper focus cannot be established. See the section: Spindle motor replacement.

Incorrectly adjusted focus offset or gain may result in the lens search pattern being too high or too low as well.

Once focus is established (and sometimes concurrent with this operation), the spindle should begin to turn and quickly reach 500 rpm. The speed may be ramped up or controlled in some other search pattern since there is no speed feedback until the data coming off of the disc is available. A partially shorted motor will prevent the spindle from reaching 500 rpm even though the disc will spin. Check the voltage on the spindle motor when it starts the disc spinning. It should reach 2 volts or more. If less than this but not zero, a partially shorted motor or weak driver is likely. If zero at all times then there may be a bad driver or the machine may not realize that focus was established and is not issuing the spindle motor start command. The required speed of 500 rpm - just over 8 revolutions per second - can be estimated by using a disc with a dramatic label or putting a piece of tape on the side of the disc that is visible and watching it spin.

Note that a dirty lens can sometimes result in symptoms similar to a bad spindle motor so cleaning the lens should always be the first step when servicing a CD player. I almost learned this the hard way.

Once the disc reaches the correct speed, the speed control (Constant Linear Velocity, CLV) and tracking servos will be activated (or the tracking servo may actually have been active all along) and directory data will be read off of the disc. Either of these could be faulty and/or misadjusted making it impossible to access the disc directory.

During the time that the disc is spinning and the player is attempting to read the disc directory, listen for that 'gritty' sound that CD players make during normal operation. It is a byproduct of the focus and tracking servos constantly adjusting lens position - the rapid movements of the lens produce audible sound like a loudspeaker - and its presence is a good indication that (1) the laser is working and (2) focus is being maintained.

On certain CD players, for example many Pioneer models, there is a TEST mode which enables many of the individual functions such as focus and tracking that are normally automatic to be manually enabled. This is a very useful aid in diagnosis and in adjusting a machine from an unknown state as would be the case if someone else twiddled every internal adjustment they could find! See the section: Pioneer PD/M series test mode.

Disc spins in wrong direction or overspeeds and is never recognized

The CD should always spin clockwise as viewed from the label side of the CD. This is usually the top but for some players you load the CD upside-down (e.g. Pioneer magazine type changers). If the CD should consistently start spinning counterclockwise and continue for more than a fraction of a revolution, or should the CD ever spin at a much faster rate than normal - as though it is about to take off, there may be a serious problem with the optical pickup, spindle servo, or control logic. However, behavior of this type could simply be the result of any of a number of minor faults which you can diagnose and repair including a dirty lens, the disc being loaded upside-down, or the internal adjustments being messed up due to someone violating rule #1 - never wildly tweak any internal adjustments!

First confirm that the disc is loaded correctly and that the lens is clean.

Check for bad connections and cracks in any printed flexible cables to the optical deck as well. Clean and reseat connectors just to be sure. Where a brushless DC type spindle motor (rather than a PM motor) is used, even a bad connection to the motor could result in strange behavior due to a missing phase or feedback signal.

If this does not help, attempt to perform a servo system adjustment. If you have a service manual, by all means follow it! If not, see the chapter: "Servo Systems and CD Player Adjustments". If it is a Pioneer CD player or changer, see the section: Pioneer PD/M series servo adjustment procedure (this may also apply to other non-Pioneer models with only minor changes).

(From: Michael Caplan (cy173@freenet.carleton.ca).)

Two faults I've seen: The upper bushing in the spindle motor is worn, or the commutator brushes are bad. A worn upper bushing leads to disc wobble. The spindle motor servo can't get a good feedback signal from the disc and it starts to hunt. Similarly, if the brushes are worn and making poor contact, the motor does not respond properly to the drive and the servo starts to send full drive signals to the motor to get it going, only to end up with the disc spinning flat out. In the CDs I've had with these spindle motor related problems, the added noise is this on and off drive torque hitting the motor.

Pickup attempts to reset past inner track

Sled motor doesn't stop at the inner track but keeps clicking, clunking, or whirring until the controller gives up and displays an error.

This may be due to a dirty, worn, or gummed up limit switch, bad connections, bad mechanical alignment or broken parts, or logic problems.

Most limit switches are mechanical and easily checked with a multimeter. Those that use exposed contacts can be cleaned and burnished; sealed switches found to be erratic should be replaced though spraying inside though any openings may help. I have disassembled and cleaned similar type switches (they snapped apart) but it is not fun.

Make sure the limit switch actually gets tripped when the sled reaches the area of the innermost track.

Check for bad connections between the switch and the controller.

Logic problems may be difficult or impossible to locate even with schematics. However, you might get lucky as was the case with a CDROM drive with a bad 74LS04 in the drawer switch interface!

Player won't let you go near it and/or use your favorite lamp

Symptoms may include a player where the audio becomes noisy or even stops completely or stuttering or skipping occurs, if you touch or go near it!

Note that there is an entire chapter: "Tracking (Seek and Play) Problems". However, since a possible cause of this sort of behavior is more general in nature and can affect many different aspects of CD player operation, these faults are described separately.

- One area that may be overlooked as a cause is the shielding of the pickup low level signal cable and any metal parts of the optical deck. These should all be connected to analog ground of the electronics board. If this is missing or broken, there can be all kinds of strange symptoms. If you have recently disassembled the unit and it is now behaving in this manner, this is a very slikely - easy to fix - possibility. Check for a missing ground strap, jumper, or clip. Hint: it has probably fallen under your workbench!

- External interference from a high power (or not so high power) radio station or even a light dimmer on the same circuit may make its way into the electronics and produce all sorts of strange behavior.

  On some poorly designed players - or where you are located in proximity to a high power (or possibly not so high power) radio station - outside interference can get into the player via the audio cables or line cord. A light dimmer on the same circuit might also produce interference via the power supply. Once inside, almost any type of behavior is possible. If your problems seem to depend on the time of day, check out this possibility by relocating the CD player and seeing if the behavior changes substantially. Disconnect the audio cables and see if it now displays the disc directory and appears to play properly - try headphones if possible.

  It may be difficult to eliminate the effects of this interference without moving the radio station or not using your favorite lamp. However, relocating the CD player or even just its cables and/or plugging it into a different outlet may help. Fortunately, these sorts of problems are not that common.

Tracking (Seek and Play) Problems

Description of seek and play problems

The term 'seek' refers to the operations needed to move the pickup and locate the exact position (time) on the disc to begin or continue play (during programmed track selection). The term 'play' is self explanatory and refers to the condition of reading off data continuously while outputting audio signals to the headphones or amplifier. Somewhat in between are the actions performed during audible search forward or backward.

When playing at normal speed (e.g., 1X for music), the fine tracking servo maintains the laser beam centered on the track (pits of the information layer) of the CD while the coarse tracking servo moves the entire optical pickup as needed to keep the tracking error within well defined limits. See the section: Servo systems. Failures or marginal performance of any of these systems can result in audio noise, skipping, sticking, or failure of seek and search operations.

The following types of problems are common:

- Seek failure resulting in the inability to locate the starting track.
- Short or long distance skipping backward or forwards or sticking.
- Occasional or repetitive noise, clicking, or muting.

A dirty or badly scratched or warped disc, a dirty lens, damage to the lens suspension or a smashed lens cover, a defective or improperly set AC adapter (voltage too high, too low, inadequate current capacity, poor regulation, or too much ripple), weak batteries or wrong type of batteries (NiCds may not work in a player designed for normal 1.5 V AAs), or a missing optical deck shield ground connection can result in similar symptoms as well.

Thus, if you experience any of the problems discussed in the next few sections, first confirm that the disc is not dirty, scratched, smudged, warped, or otherwise defective - inspect and clean it if necessary and/or try a different one. Check the AC adapter or batteries. If no problems are found, manually clean the lens. If you recently had the player apart, check the grounding of the optical deck.

The importance of doing these simple things first cannot be overemphasized as many apparently unrelated problems can be caused by a bad disc, dirty lens, or bad power.

Then, check for obvious mechanical faults like gummed up lubrication or a worn spindle bearing. Only after these efforts do not solve your problem or at least identify the cause, should you consider adjusting any of the servo systems.

The seek process

Proper readout of the digital audio or data on a CD depends on the proper functioning of the focus, and tracking servos and the system controller. The basic operation of these has been confirmed by successful reading of the disc directory. However, additional logic and drive electronics are called into action to actually seek to a particular track (even if it is the first) and switch to play mode.

When initiating play or seeking to a particular track, the player must go through the following 4 steps (exact details may vary depending on the design of your particular CD player):

1. The sled motor moves the pickup to the estimated position of the selected track based on its time code. For long jumps, this may be done partially open-loop. However, at some point - possibly from the start - the time code on the CD will be sampled periodically to determine instantaneous sled/pickup position.

   To access the time code, tracking must be stable for long enough to read 1/75th of a second of data (requiring tracking lock for up to 1/37th of a second if it just missed the start of a data block). This is possible even when the sled is moving since the fine tracking servo can backtrack to maintain tracking lock.

2. Once in the vicinity of the selected track, the sled is moved in small increments forward (and backwards if it overshoots) until the lens is within the 'acceptance window' of the fine tracking servo.

   Again, the time code is read and a direction and distance is selected by comparing it with the desired destination. On many players, you can actually hear this iterative process (by listening to the player - not the speakers) when using the >>| or |<< select keys.

3. With the fine tracking servo is engaged, the position of the lens is then jogged to home in on the exact time of the start of the track usually without moving the sled. Once it is within, say 25 frames prior to the desired starting location (1/3 second), it will just start playing but with the sound muted.

   Sometimes, it may be possible to have stopped at just the wrong position just out of range of where it wants to be (using the fine tracking servo alone) so that the sled would then move based on the normal tracking error criteria - exceeding a threshold (since the fine tracking locked).

4. Once the exact starting point is located, audio is unmuted and normal play begins.

Though all of these steps require the optical pickup to be operational, they each depend on different parts of the servo circuits - a failure could result in one of these steps not operating properly.

Audible search maintains the fine tracking lock but jogs the lens to move forward or backward. Audio is unmuted for a fraction of a second and then this process repeats. Thus, (3) and (4) are repeated (with the jog direction determined by which button is pressed) continuously.

Issuing a PAUSE command results in the fine tracking servo jogging the lens to maintain a constant position (time code).

While playing, searching, seeking, or in pause, focus must be maintained continuously despite spindle runout, a moderately warped disc, and minor bumps or vibration. Thus if focus adjustment is marginal, loss of focus may complicate your diagnosis of tracking problems - make sure focus is solid before moving on to tracking or rotation problems.

Diagnosis of erratic play

If you have a suitable oscilloscope, the following approach may help to narrow down and correct the problem. If not, you can use the alternative techniques outlined in the sections relevant to your symptoms. See the section: The CD player 'eye' pattern for a description of typical test points and signals.

Start with the RF test point. It probably should be about 1 V p-p. (However, the exact value will depend on model.) This should be the eye pattern.

Determine if it is weak, noisy, or erratic. If you can get it somewhat stable, try tweaking the various offsets (RF, focus, tracking) just a bit to optimize its appearance. The waveform should look approximately like the diagram in the the section: The CD player 'eye' pattern.

Adjustment of the focus controls will probably affect mostly the amplitude of the eye pattern and the amount of noise; adjusting tracking may also affect side-to-side jitter.

If the eye pattern is erratic, look at the focus error and tracking error test points. These should look like high frequency random noise but not be jumping or changing erratically. The DC offset of the tracking error should increase gradually as the lens moves to follow the spiral track and then jump back once the sled motor kicks in to re-center the pickup.

Use the buttons that move the sled to see if the rotation speed is correct at the beginning, middle, and end of a disc. (500-350-200 rpm). If it has trouble at the beginning, a bad spindle motor or driver is possible; if it has trouble at the end of the disc, a bad driver is possible. Adjustment of the PLL or VCO pot may correct for these types of problems. Check the eye pattern at the start and end of a long disc as well.

Seek operations take too long or fail to complete

This means that attempting to seek to a particular music track results in this never completing or going to the wrong place. Alternatively, even pressing the search forward or backward buttons may result in the failure to go where directed. The player may abort the disc and stop or (in the case of a changer) go on to the next one. Even the first track may never be played. However, it is assumed that the disc directory is read reliably.

Common causes: dirty lens, bad disc, tracking or CLV PLL adjustments needed, transportation lock engaged, mechanical problems with pickup movement, faulty sled motor or drive IC, faulty control logic, bad flex cable.

- If your CD player has a 'transport lock' screw, check that it is in the 'operate' position.
- Inspect the disc for badly scratched or smudged areas and other defects or try another one. Clean the lens.
- Eliminate the possibility of mechanical problems - see the section: Testing the sled for mechanical problems.
- Check for a printed flex cable that has hairline cracks in one or more traces. As the pickup moves past a certain location, a critical connection may open up resulting in this behavior. Such a cause is more likely if the player aborts without warning during a seek or search.

If none of this uncovers the problem, there may be sled motor driver, logic, controller, or other electronic problems.

Search, seek, or play starts correctly, then loses time or position

You may select music track 5, the player goes there quickly, starts to play but immediately jumps to another location forward or backwards or resets to the start of the disc. Or, if play is started at any location, instead of playing forward as would be expected, the numbers in the display count down.

Common causes include a defective disc, dirty lens, stuck button, need to adjust coarse tracking offset or tracking balance, bad sled motor drive IC, or faulty control logic.

- First, try a different CD to make sure it is not defective. Or, try different locations on the same CD as the CD would likely not be defective over its entire surface.

- A dirty lens is always possible. Clean it.

- This may be a problem with coarse tracking offset or tracking balance. See the section: .Adjustment procedure for noise or skipping.

- To eliminate the possibility of a stuck button, it may be possible to operate the player with the relevant part of the front panel control unplugged using the remote control (if it has one) or the 'press the drawer' method of starting play. If either of these results in the disc playing normally, then a stuck or dirty button is likely. This will most likely require the disassembly and cleaning or replacement of the affected push button switch.

- It is possible that the sled motor driver IC or its logic is bad: when the tracking servo is closed, its output is highly unbalanced due to an internal failure. Unless you want to take a shot in the dark and replace the chip, further troubleshooting of this problem will likely require a service manual. However, I have lucked out when the driver IC on a Pioneer CD player was running excessive hot - replacing it cured this problem.

Types of skipping problems

The general behavior will usually fall into one of the following categories:

1. It gets stuck and repeats a fraction of a second (1 rotation).

2. It gets stuck, jumps back, and repeats a few seconds.

3. It starts having repetitive noise at the disc rotation rate - about 200-500 rpm (3-8 Hz).

4. It starts skipping continously or every few seconds either forward or backward.

Assuming your CD is clean and undamaged (check with different CDs), then this sounds like a mechanical problem - proabably dirt in the optical pickup worm screw or lack of or dried up lubrication. It could also be a worn spindle bearing or an electronic adjustment.

If problems are most severe at the start of a disc, then spindle motor problems or PLL adjustments are likely possibilities.

If problems are most severe near the end of a disc, spindle bearing, track lubrication, and PLL adjustments are likely possibilities.

The next few sections deal with these types of problems in detail.

Short distance skipping

This means jumping forward or backward by a fraction of a second. It may occur occasionally or may appear as though the pickup is bouncing across the disc.

Common causes include dirty lens, dirty or damaged disc, need to adjust fine tracking offset/gain or tracking balance, weak laser or other defective part in the optical pickup.

First, inspect the disc for badly scratched or smudged areas and other defects or try another one. Clean the lens. See the chapters: "Servo Systems and CD Player Adjustments" and "Testing of Optical Pickup Assemblies".

Playback gets stuck (rapid repeat)

This means repeating the same track or a small number of tracks (meaning disc rotations, in this case). The effect is somewhat like a 'broken record' with an LP but at a much faster rate - 3 to 8 repeats per second when repeating only a single track.

The most common underlying cause is a damaged or dirty disc. However, if the tracking (and sometimes focus as well) servos are not properly adjusted, the CD player may exhibit excessive sensitivity to disc problems.

If the focus or tracking gain is set too high or the offsets/balance are not centered, slight disc imperfections, scratches, or dirt may result in this set of symptoms.

See the chapter: "Servo Systems and CD Player Adjustments".

Occasional long distance skipping or repeating

Usually, several seconds of music will play without any trouble and then there will be a skip forward or backwards by a few seconds or longer. In the latter case, the net effect may be to constantly repeat a section of the CD. Make sure you do not have any repeat modes enabled!

Common causes include a dirty lens; dirt, foreign materials, or lack of lubrication in pickup drive; defective disc (surface defects, dirt, or fingerprints); mechanical damage causing mechanism to bind.

- First, inspect the disc for badly scratched or smudged areas and other defects or try another one. Clean the lens.

- A mechanical fault is quite likely. These symptoms generally indicate that the coarse tracking servo is unable to properly move the pickup easily as it should - it is getting stuck and then either jumping back once the error is too great or breaking free and moving forward in spurts. Common problems include gummed up lubrication, dirt or other debris on the tracks or gears, bad belt slipping, misaligned parts.

  See the section: Testing the sled for mechanical problems.

  Note that some CD player models had problems like this due to poor design. For example, the Sony D2 Diskman would develop problems like this requiring reduction adjustment to a spring and wiper to reduce the force required to move the sled.

There could also be a problem in the electronics but first eliminate the possibilities listed above

Player gets stuck at approximately same time on multiple discs

Common causes: transportation lock engaged, gummed up lubrication on pickup tracks or worm gear, other mechanical problems like an obstruction or errant wire getting in the way. A flex cable with a hairline crack in one or more conductors might also cause this symptom.

- Make sure the transportation lock, if any, is disengaged.

- Carefully inspect the sled gears and tracks for dirt and gummed up lubrication. If the player has been in commercial service always playing the same CD or set of CDs and now you are attempting to one that is someone longer, this may happen as the end of the track is unused and dirt collects at the boundary.

- Check for mechanical damage and obstructions like wires or cables.

- If you are attempting to play a CD which is longer than 74 minutes, the player may not be capable of accessing the last part of the CD. It might either abort or get stuck and keep repeating a fraction of a second or several seconds. See the section: Problems with extended length discs.

- If play deteriorates gradually as the pickup moves toward the outer edge of the disc, the CLV servo may need adjustment or the spindle motor may be defective.

Various tracking problems on portions of discs

This means that one part of the disc (start or end) plays properly (or at least with less problems) than another. For example, the disc may play flawlessly until approximately the 30 minute point and then develop noise, skipping, or other similar problems.

Common causes: defective disc, faulty spindle motor, misalignment of spindle table and sled track, need for CLV adjustment.

- Try some other discs to eliminate a defective disc as a possibility.

- If the problem is most severe at the start if the disc, the spindle motor may have trouble reaching the required 500 rpm rotation rate consistently. See the chapter: "Motors and Spindles".

- The spindle table and track on which the sled moves may be misaligned. This is especially likely if the player was dropped or otherwise abused. See the section: Testing the sled for mechanical problems.

- An adjustment of the servo that controls the Constant Linear Velocity (CLV) drive to the spindle motor may be needed. See the chapter: "Servo Systems and CD Player Adjustments".

Repetitive noise at disc rotation rate

Common causes: dirty lens, bent spindle, excessive runout (wear) of spindle bearing, loose spindle, foreign material on disc table, disc not firmly clamped, warped disc, need to adjust focus or fine tracking offset/gain, weak laser.

- First, inspect the disc for badly scratched or smudged areas and other defects or try another one.

- Clean the lens.

- Check for a loose spindle (sometimes there is a set screw that needs to be tightened or some adhesive may have broken free.

- Make sure there is no dirt or other foreign matter on the spindle table that could cause the disc to seat improperly.

- Observe the disc as it spins. Is the edge moving up and down by more than a total of about 1 mm? If so, the disc may be excessively warped, or possibly the spindle bearing is worn resulting is unacceptable runout, or (unlikely unless the player was thrown off a cliff) the spindle is bent. The focus and fine tracking servos may be incapable of correcting such a large wobble.

  This could also be due to a disc clamper that is not working properly - the drawer closing mechanism may not be quite completing its cycle or possibly the magnet may have weakened. Gently press down on the rotating part of the clamper while playing - if this reduces or clears up the playback and/or if you can feel the disc seat better, then this is a possibility.

- If the problem developed gradually and has been getting worse, than a worn spindle bearing is a distinct possibility. Adjustment of focus and fine tracking offset (or possibly gain but usually less critical) may help.

- Alternatively, focus or fine tracking offset (or possibly gain but usually less critical) may simply have drifted a bit and adjustment is all that is needed.

- A weak laser may also result in these symptoms but do not attempt to adjust laser power until other possibilities have been investigated fully.

Marginal play - internal controls are not marked

This may mean that some discs play properly while others have problems with skipping, sticking, repeating, or noise in the audio. Unfortunately, many players, particularly portables and CDROM drives, do not have adjustments that are labeled. (For some portables, you may need the special test discs described in the section: Useful ways to mangle CDs.

Since one possible cause of these types of problems (after the lens and mechanics have been ruled out) are servo adjustments. See the chapter: "Servo Systems and CD Player Adjustments".

Then, I would mark the precise positions of all the controls. While playing a disc that works but has minor skipping, noise, or similar problems, carefully try adjusting each one on either side of its current position to see if that will help. Then if this helps, change to progressively more problematic discs to see if you can home in on the optimal settings. By observing the behavior as you tweak each control, it may be possible to determine their functions.

Testing the sled for mechanical problems

Binding or obstructions would be indicated by any long distance skipping, jumping, repeating, or failure to seek or search past some location (time) on multiple discs. Defective or erratic limit switches may result in jamming or overrun at start or end of disc or unreliable reset during startup.

Check for free movement of the optical pickup sled on its tracks or bearings. Manually rotate the appropriate motor or gear or in the case of a voice coil (linear or rotary) positioner, gently move the pickup back and forth throughout its range. There should be no sticky positions or places where movement is noticeably more difficult. If there are, inspect for mechanical problems like broken or damaged gear teeth, dirt or other material that should not be there, and gummed up lubrication - or that you didn't forget to release the transportation locking device! Damaged parts will need to be replaced (or repaired - sometimes a fine file, Xacto knife, or dental pick will work wonders but don't count on it). Otherwise, cleaning and lubrication may be all that is needed. Remove the dirt and the old gummed up lubricants and lubricate the tracks and/or gears using the proper oil or grease. (See the sections: "Lubrication of CD players"

Inspect the alignment of the track with respect to the spindle motor. If the spindle motor shaft is not at an exact right angle to the sled movement, tracking may be affected on certain portions of the disc. One best way to this is to clamp a disc onto the spindle table and then manually move the sled from end-to-end measuring the distance between the pickup and disc at both extremes. It should be equal. A variation of more than a fraction of a mm can cause tracking problems.

If these tests come up negative, check out the pickup (sled) motor for defects such as a shorted or open winding, dead spot, partially shorted commutator, or dry or worn bearings. See the section: Testing of motors.

As a double check, disconnect the motor from its driving circuit (extremely important!). Use a 3 V battery in series with a 25 to 50 ohm variable resistor or a variable low voltage (e.g., 0 to 5 V) DC power supply to drive the motor. Start at the highest resistance or lowest voltage and adjust it until the sled just starts moving. Run it from end-to-end in both direction. The sled speed should be fairly uniform with no sticking or binding. There should not be any excessive noise or grinding sounds. If this is not the case, there are still problems with motor or sled mechanism.

Another check would be to substitute a 15 ohm 1 W resistor for the motor and see if a few volts appears across this when the player should be resetting since this usually involves moving the sled to the inner limit. If there is none, the driver may be blown or lack power, or the controller is not providing the proper commands.

In addition, check the proper functioning of any limit switches that are present on the optical deck. There will almost always be one for the inner (reset - startup) track and there may be one for the outer track (end-of-disk) as well. Run the pickup manually or using the battery (see above) to both ends without forcing and check for reliable operation of the switch contacts.

- Back to CD Repair FAQ Table of Contents.

Miscellaneous Problems

Audio problems - muting, noise, or distortion

Silly me, what other kinds of problems are we talking about? OK, I should have said: audio signal chain problems. The player appears to be working fine (the disc is spinning; the time is incrementing correctly; seek, search, and play operations behave normally) but there is either total silence, noise, or distortion, on one or both channels.

However, also see the section: Types of skipping problems and those that follow since these sorts of audio symptoms may be mistaken for those caused by problems with servo alignment, the optical pickup, or front-end electronics.

There is a distinct boundary between the digital section where audio information is encoded digitally and the analog domain where it is an electrical waveform.

Problems with the digital circuitry

Problems in the digital domain will usually be obvious to the point of being gross - extreme noise, noise correlated with the signal level, extreme distortion, tones or frequencies that with no stretch of the imagination were present in the original music, etc.

Characteristics will be distinctly different than the kind of noise or audio distortion we are accustomed to in stereo equipment. Small errors in the digital reconstruction can result in totally gross changes in the audio output. For example, a single bit error if in the MSB can totally corrupt the resulting waveform. Simple errors can result in sound frequencies not present in the original. Fortunately, these sorts of errors are relatively rare as most of the circuitry is inside of very reliable LSI chipsets.

However, if the CD is recognized and appears to behave normally except that there is absolutely no audio output, there can be problems in the audio decoding LSI chips. Other than hoping for an obvious bad connection, this is way beyond the scope of anything you can hope to repair without the service manual, test equipment, and a miracle.

Problems with the analog circuitry

Problems in the analog sections - D/A(s), sample-and-hold(s), post analog filters, and muting relays - produce effects that are more familiar: noise, decrease in signal strength, and distortion. Except for parts of the D/A which may be shared, there will be identical left and right channels to compare if an audio problem develops.

If only one channel is affected, then the problem most likely has nothing to do with tracking, the laser, or the mechanism. Coming off of the disc, the left and right channels are interleaved on a sample (16 bit word) basis so any disc or pickup problem would equally impact both L and R.

You are left with the D/A and sample-and-hold or D/As or the final analog filter and muting circuitry. Many CD players multiplex the D/A between L and R, so in these, even the D/A is ruled out since most of its circuitry is common.

Swapping components one at a time between the identical left and right channels is also a valid diagnostic technique.

- With a single D/A, there will be sample-and-hold circuits for each channel as well.
- Players without digital filters (or oversampling) have fairly complex analog filters after the D/A. A bad or noisy component could conceivably be your problem. Even players with fancy oversampling have some kind of a final analog (antialiasing) filter. On an older player, there is probably a lot of discrete circuitry in the audio section.
- If you can get to the components in the analog filter (some are potted), then with a test CD which has a 'silence track' and a scope or signal tracer, you should be able to find out where the noise is being introduced. If it has separate D/As, then one of these would also be suspect.
- There may be separate power supply outputs for the audio section (this will be more likely with fancy expensive players). In this case, a failure of one of these may result in either distorted audio or no sound at all.

The following will mostly result in static type noise, hum, or erratic audio (sound not coming on or partial or total dropout for one or both channels):

- Don't overlook the simple problems of dirty contacts on the RCA jacks or bad connections where they are soldered to the main circuit board. Test by jiggling the cable connectors and/or prodding the circuit board near the RCA jacks. The cable may be bad (from flexing) as well - try another one.

  Check the connections and controls on your amplifier and other audio components as well! Any bad connection in the audio path can lead to these symptoms. Clean, repair, or replace as appropriate. Perhaps your poor, helpless CD player isn't even at fault!

- Dirty muting relay contacts may result in intermittent or noisy output. If tapping the relay affects the symptoms, this is likely the problem.

  To test, remove the relay and bypass the suspect contacts with jumper wires. CAUTION: Turn your amplifier's volume control down when you start to play a disc - there may be unusual loud noises during startup that are now not blocked by the muting circuitry.

If CDs now play without any audio problems, a bad relay is confirmed.

It may be possible to snap off the cover(s) and renew them with contact cleaner and a burnishing tool or a strip of paper. Otherwise, replacement will be required.

Problems playing/reading certain CDs

While you may be tempted to blame *Big Brother* and some sort of diabolical copy protection scheme, I doubt that CD dependent behavior has anything to do with a lower intelligence at work. :) More likely, it is a bad quality control on the pressing. (This assumes your CD isn't one of those which has 85 minutes of music squeezed into a 74 minute space. See the section: Problems with extended length discs.)

First, check for physical damage or imperfections on both sides of the CD. Even if you find nothing, trying a replacement disc would probably be a good idea before ripping apart your CD player.

However, it may just be CD which produces an unusually low signal level.

Depending on manufacturer, the signal level from CDs can vary by quite a large amount - maybe 30 percent (just guessing). Telarc discs were (maybe still are) particularly bad in this regard. CD-Rs are also quite variable and generally worse than normal CDs. (See the section: Problems reading CD-Rs). If the player is somewhat marginal to begin with (no way to really predict this), low signal level may mean either it won't recognize the disc at all or will be subject to skipping, audible noise, and other play problems.

An internal adjustment might help but my advice would be that if it only occurs with a small percentage of CDs, better to leave well enough alone.

However, a proper lens cleaning won't hurt! See the section: "General inspection, cleaning, and lubrication". If you really won't sleep knowing there might be something else you can do, see the "General servo adjustment procedure". I definitely don't recommend attempting to boost laser power - which would be considered a last resort.

Note that newer CD players and CDROM drives may be more tolerant of damaged discs as well as CD-Rs (which became popular only relatively recently) - you may just be expecting too much from that 15 year old machine!

Problems with extended length discs

The specifications for the length of an audio CD is just over 74 minutes. I have seen them as long as 78 or 80 minutes which means that some of the basic CD specifications have been compromised - either the track pitch has been reduced or the track extends closer to the outside edge of the disc - or both. If the track pitch has been reduced, there could be tracking or audible noise problems throughout the disc. If the track extends closer to the outer edge, there could be problems near the end of the discs. The player may not these discs at all. Any of the following symptoms are possible:

- No problems. Your player is one of those that is perfectly happy playing really long CDs. Most players will indeed be unaffected.

- The disc may be rejected resulting in the display showing 'disc' or 'error' as though damaged, improperly inserted, or missing. In this case, the CD player's microbrain simply thinks anything with a total playing time exceeding 74 minutes and 15 seconds is invalid.

  Unless you want to redesign the player, there is nothing you can do to play these CDs. It might only require changing a single byte in the player's firmware :-).

- There may be more of a tendency for skipping, sticking, or audible noise (probably near the end though it could happen anywhere if the track pitch has been reduced - including inability to read the disc's directory) since the servos are operating slightly outside their normal range. The actual likelihood of these types of problems are very slight, however.

  It may be possible to adjust the servos as described in the chapter: "Servo Systems and CD Player Adjustments". As with any adjustments, there is some risk of affecting performance for all discs - or totally messing things up. Or, if problems only occur near the end of these discs, just don't play them to the end!

- The sled on which the pickup is mounted ventures into new territory where no sled has ventured before (at least on this player). Dirt, gummed up grease, hair, and other garbage may have collected there resulting in the sled drive mechanism getting stuck. You may hear whirring, buzzing, or clicking as the motor attempts to move the immovable - or nothing at all. Eventually, the player should probably shut down. In any case, kill power or remove the batteries to prevent damage to the gears.

  With luck, all you need to do is move the sled manually toward the spindle by turning the proper gear (freeing it up first, if necessary). Then clean and relube the track and gears. Hopefully, nothing is actually damaged since locating a replacement part may prove to be a challenge.

- The sled simply overran the end of the rack and the drive gear no longer is capable of returning it to more familiar territory. You may hear some whirring, buzzing, or clicking as the gears attempt to mesh but do not quite succeed.

  Manually moving the sled so that the drive gear meshes with the rack - and then turning it a bit to be sure - should restore operation but, of course, you should not attempt to play these extended length discs to the very end in the future.

Problems reading CD-Rs

CD-Rs (recordable CDs, usually gold on the label side and greenish (or with newer ones like various PlayStation discs, some other strange color) on the readout side) can be quite variable in quality. They are often produced on a low cost writer of questionable design and calibration. It is quite common for a CD-R disc to play/read fine on one drive and not be recognized at all on another. There may not be any relation between cost of the CDROM drive and its reliability with CD-Rs.

Note that newer CDROM drives (and probably CD players as well) may be more tolerant of CD-Rs (as well as of damaged normal CDs). 1X and even 4X CDROMs (as well as older CD players) predated the wide availability of CD-Rs so they weren't designed with them in mind. As a byproduct, newer technology may be more tolerant of bad normal CDs as well. So, there may in fact be an advantage to using high-X CDROM drives! So, it still has nothing to do with the high-X part, just that the low level circuits are smarter!

Problems recording CD-Rs

Consistently recording high quality CD-Rs is by no means as fool-proof as reading typical CDs. Any problems affect the recording quality permanently.

- Media - there is significant variability in the quality and consistency of CD-R blanks from different manufacturers. You may have to experiment with multiple brands to determine those that work for you in your CD-R writer.

- Recorder - there may be significant variability in the performance of various manufacturer's hardware. High price may not translate into high quality especially considering the rapid changes in the industry.

- Writing speed - while it really should not matter whether you record at 1X or 4X (or whatever your machine supports), this may not actually be the case. If the servo systems are less stable at the higher rate, the quality of the recorded information may suffer. Thus, writing at a slower rate may be better - or may not matter. In any case, experimentation at different writing speeds should determine if this is an issue.

- Media cleanliness - you only get one shot. A speck of dust or fingerprint - which might just decrease the signal to noise ratio when reading a CD - can degrade the writing laser beam resulting in malformed pits (oh no, not the dreaded malformed pit disease!). Inspect each CD-R blank before inserting it into the writer. Reject it if you see any visible surface damage or manufacturing defects. Use clean, dry compressed air if necessary to blow off any dust or fluff. Clean the surface as you would a CD to remove any fingerprints or smudges.

- Equipment maintenance - keep the recorder clean - periodic inspection and cleaning similar to that used for CD players may be needed if it is used in a less than ideal environment - dust, smoke, and cooking vapors can quickly coat the lens leading to lower quality recordings. Inspect, clean, and replace (as necessary) the caddies (if used) as well since dirty or damaged caddies can cause problems as well.

- Data under-runs - where the recorder does not have an internal buffer of sufficient size (yeh, like 650 MB!), it expects to be fed at a high enough rate to always have data available to send to the writing laser. Any failure will likely result in incorrect data being written - and probably a ruined disk. Some recorder software will simply abort. Even running another application like a screen saver can result in uncertainties with respect to data availability. When in doubt or where time is available, run the recorder at a slower speed to reduce the required datarate.

- Mechanical shock - locate the recorder on a stable surface - not the top of a printer or other equipment that may be subject to movement during the duration of a recording session. Any vibration transmitted to the optical deck may cause a momentary shift in the position of the lens and laser beam reducing the recording quality. Bump it hard enough and the result will be mistracking and a ruined disk.

(From: Filip M. Gieszczykiewicz (filipg@repairfaq.org).)

There's an area of the CD-R disc used specifically to "calibrate" the laser. Since all disks have different needs (gold versus blue/green dye, for example) one-for-all power level won't do. If you laser has lost its power (they DO have a very finite life) which may be due to end-of-life OR dust on the lens (always consider a lens and any other accessible optics cleaning first!), it will FAIL this write-test and you will get what you are seeing. I would try a different color dye CD-R disc and see if there is one type it can still write to.

From what I read, there is enough "write-space" in the laser-power-test area of the CDR for close to 1000 tests - which is why a new drive may work fine with your rejected discs.

So, clean the lens, then try different types/colors of CD-R discs and then, if that still yields no results, write off the drive as "got my money's worth" and use it as a reader.

Voice (almost) missing from CD playback

My first thought would be to say "how can the electronics know about the voice separately?" Well, the answer is "it cannot". However, due to the way vocals are often recorded, this behavior is possible, if unlikely. What must happen is for the audio output to be the difference between the left and right channels mostly cancelling the centered vocal track but not having as much effect on the audibility of the instruments.

It is possible for this to happen as a result of a bad ground connection or an electronic fault in the analog circuitry following the D/A stage but it is quite unlikely to be due to a problem in the optical pickup or digital decoding - though not out of the question.

What is suggested below can happen by accident should the shield connection to the headphone or line out jack or cable become disconnected.

(From: Frank Fendley (frank.fendley@datacom.iglou.com).)

Actually, it is possible. Modify a headphone so that the two ground conductors are still connected together and to each earpiece, but no longer connected to the sleeve of the headphone jack. The two "hots" remain connected to tip and ring on the jack. Plug it in to a portable CD player and listen to a pop or country CD with (preferably) a solo vocalist.

The vocals will almost disappear, while the instruments will still be quite audible (although now in mono).

Normally, the lead vocals are 'centered' in the stereo imaging and are in phase on each channel. The instruments are panned more or less left or right. When you rewire the headphones, you effectively place the two transducers in series, and they are now wired out of phase with each other (the two "-" terminals are connected together on what used to be the ground lead, and the two "+" terminals are connected to their respective signal outputs from the channels - effectively since they are now in series, they are wired out of phase). Any signal which is "identical" and "in phase" on both left and right channels tends to cancel - the vocals. Signal which is not identical on each channel appears as the difference between the two sides - the instruments.

Some recordings are not made this way and this will have little or no effect - you may have to try a few CD's to experience the 'phenomena'.

Problems with anti-skip buffers

Newer portable CD players often offer an extra cost option of an 'anti-skip' capability - usually about 10 seconds of buffer memory. While there is probably little you can do to repair an electronic or logical problem with this memory, there are a couple of points to keep in mind which may lead to the repair of problems like erratic anti-skip performance, noise, dropouts, skipping, and other symptoms dealt with elsewhere in this document.

Anti-skip is actually implemented by reading ahead on the CD and storing up to 10 seconds of digital audio in dynamic random access memory (DRAM). This has a direct impact on optical deck performance and power requirements:

- To read ahead, the player must actually operate at a higher than normal (1X) speed. Watching a player with this feature, it would appear to be close to 2X. This puts a greater strain on motors and servo systems so anything in the optics or servo alignment that is marginal - or even a dirty lens - may result in problems which do not show up with the anti-skip feature turned off. In addition, there are likely to be more problems reading marginal CDs or CD-Rs. See the section: CD player with skip buffer fails with some CD-Rs.

- Power requirements are also greater with anti-skip on - the spindle motor and servos need to work harder and the buffer DRAM may require greater power when being accessed. Therefore, weak batteries or an inadequate wall adapter may result in erratic operation. If possible, try fresh batteries or a different adapter before warming up the oscilloscope.

CD player with skip buffer fails with some CD-Rs

This was an odd problem posted to the newsgroup sci.electronics.repair:

> "I am having an odd problem with my new portable cd player. It is a Panasonic with 10-second skip protection. I made an audio compilation CD with my CD-burner. This CD works fine with my CDROM

drive and home CD player. In fact it works fine with the Panasonic UNTIL I turn on the skip protection. Then it plays for awhile, and for no apparent reason the seconds run out and it hangs up and displays the message 'Sorry'."

(From: Mike Schuster (schuster@panix.com).)

Your player is having trouble tracking the CD-R. Likely causes:

1. The CD-R burner or software is producing discs whose layout is slightly off spec. A firmware or software upgrade may help if available.

2. The CD-R burner works better with some types of blanks than others; and you've just discovered the ones it DOESN'T work well with. Try a different brand and color.

3. You are using poor quality CD-R blanks which have an unacceptably high bit error rate, eccentricity of the spiral groove, or both.

4. You are burning the disc as a speed which does not give the lowest error count with the media you are using - try faster or slower. Usually 2X write speed gives the best pit structure on the widest variety of media.

5. Your CD-R burner is in need of calibration or laser replacement, resulting in poor pit shape. Have you tried an OPC test to see if it is delivering the right power?

I have a Panasonic portable and have experienced the same thing with two Maxell CD-R's received in a trade. Of the dozens of CD-R's I own, these two, burned by the same person, are the only ones that cause trouble. For that reason I believe it is not the player but the discs that are "off".

(From: Andy Cuffe (baltimora@psu.edu).)

In skip protection mode the disc is played a double speed so it can keep the memory full. It must be having trouble tracking these discs at the higher speed, but is able to play them at normal speed. It's either a problem with the CD-Rs or just the way the player is.

Problems with CDROM drives

The newest CDROM drives operate at 12X speed or greater. Such performance puts significant strain on the motors and servo systems. Even 2X speed means substantially higher demands of the electronics and power systems. Thus, you may find that a drive will play audio CDs flawlessly but have trouble reading data files. While there is probably little you can do to repair an electronic or logical problem without schematics - which are almost certainly not going to be available, there are some things to keep in mind which may lead to the repair of problems like erratic or total failure of data readback.

The first test for any CDROM problem is to force the drive to the 1X (or some slower speed than its maximum specifications) and see if that helps. Your drive may have come with instructions/software to operate at a selected speed.

Data readout must be flawless. Uncorrectable errors which may not be noticed for audio playback would result in corrupted files. Thus, anything that is marginal may significantly impact performance. If it still has trouble with data even at the 1X speed, something may be marginal or there may be a true problem in the decoding logic or computer interface.

- Multi-X performance puts a much greater strain on motors and servo systems so anything in the optics or servo alignment that is marginal - or even a dirty lens - may result in problems which do not show up with audio CDs played at the 1X speed. Thus, once a dirty lens is ruled out by cleaning it, some fine tuning of the servo systems may be needed.

- At the high rotation rates used with the latest drives, even the slight imbalance caused by a label that is not uniform across the disc can result in enough vibration to affect the servo systems and result in an increase in data transfer error rate, mistracking, or even loss of focus and shutdown. There may be no problem with the drive itself - just the disc. It may be possible to add a small sticky label to the disc in a strategic location to improve balance. However, if the label is not very secure, it may fly off due to centrifugal force at high rpms and create yet another problem inside the drive. Some quick drying paint might be better. If only there were a tire balancing type machine for CDs!

- Power requirements are substantially greater at the higher speeds - the spindle motor and servos need to work harder and even the electronics may require greater power. Therefore, weak batteries in laptop computers or CDROM drives operated off of laptop power or an inadequate wall adapter may result in erratic operation. If possible, try fresh batteries or a different adapter before warming up the oscilloscope.

Portable CD player/CDROM drive power considerations - batteries

As with all equipment operated from a batteries, there are specific requirements that must be met for reliable and safe operation.

Batteries must be of the proper type. Some devices will work on either Alkaline or rechargeable NiCd types. However, since NiCds put out less voltage than fresh alkalines, there may be a selector switch or the instruction manual may state that NiCds should not be used. Batteries should be fresh - the motors, servo systems, and electronics in a CD player or CDROM drive can be a significant load when seeking or spinning up. A weak battery may cause it to shutdown erratically or never be able to find the selected track. Do not mix new and used cells. This can result in poor performance and may actually result in damage to the cells where rechargeable (NiCd) types are involved.

Some CD players use a sealed lead-acid battery pack. For long life, these must be recharged immediately after use. Leaving a lead-acid battery pack in a discharged condition will significantly shorten its life. And these are not cheap! A pack for a typical Sony CD player may cost more than $20.

Portable CD player/CDROM drive power considerations - AC adapters

As with all equipment operated from a wall adapter, there are specific requirements that must be met for reliable and safe operation:

1. Voltage. The CD player or other device will specify the nominal input voltage. This must be adhered to - you cannot connect a 3 V CD player to a 12 V adapter (or auto battery, for that matter). It will become toast. However, not all wall adapters are created equal. Some are very poorly regulated meaning that even though its label says something like '9V', the actual output may be as much as double this (or more) with no load. This may not be acceptable. The device may overheat or be damaged or destroyed nearly instantly. Internal protection devices may blow (if you are lucky!). It is safest to follow the manufacturer's recommendations (though, admittedly, they may be pushing their own brand of adapter). My rule of thumb is that if the unloaded output voltage is within about 25% of the specified requirements, it is probably safe to use. However, when connecting for the first time, be on the lookout for any strange behavior (or strange odors!).

2. Current. The required current should be stated somewhere - either on the device itself or in the instruction manual. If only power is specified (i.e., 9 V, 4.5 W), then divide power in watts by voltage to get the current rating in A. (1 A = 1000 mA). The adapter must be capable of putting out at least this amount of current though a modestly higher current rating should be no problem. Using an adapter with an inadequate current rating may result in erratic behavior or overheating and failure of the adapter.

3. Polarity. All the portable CD players and CDROM drives I know of operate on DC. Thus polarity is critical. Get it

backwards and at best nothing will happen but nothing will work either. However, the equipment and/or adapter may be damaged - permanently. Internal protection devices may blow - if you are lucky.

4. Regulation. It is often impossible to determine whether the device expects regulated power or whether a given AC adapter provides it without tests. There are both types. Higher voltage AC adapters (say, 6 V or above) often tend to be just rectifier/filter capacitor types. However, low voltage adapters (e.g., 3 V) may have an IC regulator built in.

As noted in the section: CD player is totally dead, it is easy to destroy a portable device using an improper power adapter or a universal adapter that is configured incorrectly.

Boomboxes and compact stereo systems

These combine a stereo receiver and a single or dual cassette deck, and/or a CD player or changer, and a pair of detachable speakers, into a single unit. Most are fairly portable but larger boomboxes and compact stereos may require a forklift to move any great distance.

While the individual subsystems - CD player for example - are usually relatively self contained electrically except for a common power supply, mechanically, everything tends to be jumbled together - even on units that have an outward appearance of separate components. Both cassette transports are usually driven from a single motor. Getting at the CD player may require removal of both cassette decks, audio amplifier, and power supply. Working on these is not fun. As usual, take careful notes as you disassemble the unit and expect it to require some time just to get to what you are after. Be especially careful when removing and replacing the individual modules if printed flex cables are used for interconnections.

Refer to the relevant sections on cassette transports, loudspeakers, and power supplies for problems with these units.

Since these do get abused - bumped, dropped, dunked, etc., bad connections, and other damage is very common. See the sections: "Intermittent or erratic operation" as well as "Audio muting, noise, or distortion".

CD player was dropped or got wet

I have never heard of a component CD player being dropped or rained on. However, this does happen to portables. While a service shop may not even want to tackle such a unit, it is quite possible that damage is minimal - even for a CD player.

With a CD player that has been dropped, unplug it from the AC line or remove the batteries immediately. This will prevent further damage should anything be shorting internally.

For one that has gotten wet, dry it immediately (you knew that!).

See the document: Audio Equipment and Other Miscellaneous Stuff for more info on restoration of abused audio equipment.

Repairing flexible printed cables

It seems that more and more consumer devices from pocket cameras to laptop computers are being built with miniature multiconductor flexible printed cables. Very often one or more traces to develop hairline cracks due to repeated flexing. In addition, damage from moving circuit boards and modules during servicing is all to common.

Needless to say, repairing any kind of flex cable is a real pain. I have succeeded by carefully scraping the plastic off with an Xacto knife and then soldering fine wire (#30 gauge wire wrap for example) to the traces. This presumes that the conductors on your cable will even take solder. I then cover up the joints with a flexible sealer for electrical and mechanical protection.

However, you need to make sure that the wire you use can be flexed or that the joint is set up in such a way that the wire does not flex much - else you will just end up with broken wires pretty quickly.

Here is another alternative if the flexing of the cable prevents the use of ordinary wire for jumpers: Find a piece of somewhat similar flex cable cable from a dead piece of equipment. Use it to jumper across the high stress area and then solder it to the other cable with short wires if necessary. Then coat the connections as above.

Soldering from end point to end point if possible may be preferable. Even going to only one endpoint would reduce the risk of immediate damage and reliability problems in the future.

With multiple traces broken or damaged, you are probably better off replacing the cable entirely. With the typical flex cables found in CD players, there is often no way to repair a large number of broken traces and retain your sanity.

CD player whine

CD players are generally nearly silent during play (though they may make a variety of whirring and clicking noises when loading discs, initializing, or seeking). The only sound normally eminating from inside the machine during play might be a very faint gritty noise from the focus and tracking actuators.

Thus, a sustained whine would generally be considered abnormal.

(Portions from: Larry Sirignano (sirig@esslink.com).)

There are two likely causes:

1. Worn spindle motor bearings can result in a high pitched whine. In this case, adding a drop of oil may quiet it down temporarily but replacement will eventually be needed.

2. The whining noise may be the laser/chassis assembly resonating with the CD as it spins. Depending on the model, there is a cure - adding a weight or damping material to the pickup or the chassis to change the resonant frequency.

   To confirm that this is your problem, gently rest your finger on the rotating clamper disk and/or other parts of the optical deck while it is whining - the whine should change or disappear. If you can locate a particularly sensitive spot, try gluing a piece of heavy rubber to this location (even if it is the clamper disk) with rubber cement. If this solves the whine problem, confirm that discs seek and play correctly for all tracks before buttoning it up.

For more details on Sony problems, see the section: Audio whine (not from speakers) and/or muddy sound with Sony CD players.

(From: Joel B. Levin (levinjb@gte.net).)

If this were the problem it would be highly dependent on the CD's speed of rotation, which varies as the disc is played. If it always happened N minutes into the disc and went away a few minutes later as the disc slowed down (and came back if you repeated the track) I would consider that definitive of a resonance problem.

(From: Mark Z. (mzacharias@aol.com).)

I would try lubricating the shaft of the spindle motor, and check to see if the motor brushes might be partially shorted. (not to worry you at this early stage, but sometimes Sony pickups, especially the KSS240 and KSS212 and 213, have resonance problems, often just as the disc is coming to speed.) This is the subject of at least a couple service bulletins. Can often be heard as a whistling tone coming from the mechanism usually intermittent, and can be observed in the focus error and tracking error lines as a sine wave overriding what should be essentially a random noise signal. Occasionally the resonance gets so pronounced the disc won't even spin up.

It happens with some Pioneers as well. It's not a common symptom, but it is the pickup at fault. Look at the focus error line and you'll see a sine wave riding on it. There is essentially a feedback loop existing between the spindle motor/subchassis and the pickup. I've seen various attempts to damp it out but replacing the pickup fixes it every time in my experience.

(From: Matt Kruckeberg (sackmans@ndak.net).)

It's possible that a loose lens can result in a resonant condition so check that the lens is secure. If it falls out in your hand, gluing it back in place should solve the whining and prevent a future problem.

Noisy CD player

CD players are not silent despite all the hype to the contrary. The focus and tracking actuators act like voice coils in loudspeakers produce various chirps and hisses while playing a CD. When seeking, the sled motor adds its own additional instrumental accompaniment. :)

As they say, "If it ain't broke, don't fix it." Assuming it plays CDs fine and has always been this way (or you don't recall how it was when you first got it), leave well enough alone.

If you do decide to twiddle pots, mark their original position carefully before doing anything! The ones most likely to have any effect are the gain controls for focus and tracking. Lowering the gain slightly (perhaps 1/8th of a turn counterclockwise) will reduce the noise level - but may also result in more susceptibility to skipping from vibration. Turn them too far and the disc will no longer even be recognized. These adjustments don't generally change on their own so think several times before possibly making matters worse.

Perhaps, putting the CD player in a box padded with sound deadening insulation would be a simpler solution if the noise bothers you!

Also see the section: CD player whine.

Objective lens popped out

Don't expect to see this one too often. However, on some Pioneer changers in particular, where the pickup is mounted upside-down, tired pickup suspension grommets, excessive heat, age, long use with warped discs, or just bad luck, has apparently resulted in the adhesive holding the objective lens in place to come unglued, as they say. :-) In some cases, it is still attached but loose, which will also prevent the player from working but may be easier to fix than one that is rolling around at the bottom of the cabinet.

The best solution is to replace the entire pickup. However, you have nothing to lose by attempting to reattach the lens IF you can locate it AND its optical surfaces are undamaged from the ordeal. If either of these is not the case, you will probably have to install an entire new pickup. Swapping of a lens from another player is even less likely to work unless it uses a similar pickup from the same manufacturer and then only with great pain.

It may be essential to line up the lens in EXACTLY the same position as it was originally in terms of centering as well as the same orientation to have any chance of success:

- The lens must be centered for the return beam to be properly aligned with the photodetector array.

- It is possible that some lenses are astigmatic (not circularly symmetric) to implement the focus servo (rather than using a separate cylindrical lens or thick beam splitter mirror for this purpose). For these, the orientation is also critical. When this is the case, there will be a reference on the lens for this purpose. On Sony pickups, for example, there is a flat filed on one edge of the lens. (You always wondered why the lenses in all your Sony CD players appeared to be 'damaged', didn't you?) However, I do not know of any Sony or other models that actually use an astigmatic objective lens. (Sonys usually have a thick beam splitter mirror for this purpose. Pioneer players for which the dropped lens syndrome is quite common don't have an astigmatic lens because people have reported replacing the lens in any position without problems.)

  However, matching up the lens position with the old glue line will likely result in it being better aligned with the internal optics so it's still worth doing if possible.

Alignment isn't so bad if you can see the failure line in the old glue or if the lens isn't completely detached. Otherwise, you will need to compare the orientation with an intact sample of a pickup from the same manufacturer that uses a similar optical configuration. Just guessing may not work!

Carefully position the lens and put the tiniest drop of adhesive such as 5 minute Epoxy at three points roughly equally spaced around the edge of the lens. DO NOT use anything with a volatile solvent like windshield sealer, Duco Cement, or especially instant glues like (Gasp!) Krazy Glue (cyanacrylic, even if you have mastered that disaster!) The vapors may condense on the lens or other (more inaccessible optical surfaces). Take care to prevent any glue runing down into the suspension or elsewhere. Once the glue has set, reinstall the pickup and try it. If behavior seems reasonably normal, put a tiny bead of adhesive all around the lens to anchor it securely. Some servo adjustments and/or optical alignment may still be needed to correct for the slight shift in lens position that is unavoidable from this surgery.

I experienced the problems of instant glue when a colleague brought in a Pioneer changer in which he had attempted to reattach the lens. Looking into the lens, it appeared as though there was an aperture behind it. After prying the lens back off, it became apparent that the effect was caused by a haze which had formed a sort of ring around the underside of the lens. Fortunately, multiple cleanings with isopropyl alcohol removed most of it and allowed the player to recognize and play discs, though I don't think it will ever have quite the same performance.

Before powering up, check the pickup suspension grommets for wear or deterioration, your discs for serious warp, and any other mechanical problems that could cause the same thing to happen again. Don't use seriously warped discs. Replace bad grommets or at least raise the pickup by installing washers under it for testing.

(From: Dave (albrecht@se-iowa.net).)

A local radio station uses about 20 Pioneer PD-M510s. I've been replacing a lot of lenses that are starting to fall out. I usually do a "shake" test, recover the lens and glue it back in place. Not bad considering most haven't been shut off and have played for 4 years now.

(From: David Kuhajda (dkuhajda@locl.net).)

The lens falls out because of 2 factors: (1) The laser is mounted upside down or (2) the rubber grommets that support the pickup wear out after time as does the spring in the optical pickup allowing the lens to be hit by the disc slide tray in the changer as the player loads each disc. (In marginal cases, the lens may actually scrape and scratch the disc during loading or play but will still be attached.)

Sometimes regluing the lens is enough to allow the unit to play, but not a good repair unless the rubber grommets are replaced and the sagging height of the lens measured to ensure enough clearance. Then the laser output and RF level must be checked. I have only found one laser that had the lens fall out that was not way below specification and needed replaced to make for a reliably playing unit.

That being said, most people are happy to pay just the minimum to have the lens glued on and the 3 ring paper hole reinforcement pads put in as spacers to allow the unit to play as the cost of the optics and rubber grommets alone are close to replacement cost of the unit.

Testing the optical pickup

See the special section "Testing of Optical Pickup Assemblies" for detailed procedures for determining basic functionality of most of the optical, electronic, and mechanical components in the pickup assembly. These techniques do not require sophisticated test equipment and will identify most common failures. However, you should not consider such involved tests until you have eliminated other possibilities for your particular problems.

Replacing the optical pickup

If after these tests (or for other reasons) you are fairly confident that the optical pickup is defective and not salvageable, replacements are usually available from both the original manufacturer and service parts suppliers like MCM Electronics and others. If the sticker fell off and you need to identify the type (or are just curious), the ANEX Laser Pickup Page has photos of pickups from many manufacturers. (ANEX is a Polish company so I'm not advocating buying replacements from them, just thought the photos might be of interest!)

Costs range from less than $40 to well over the price of several new CD players so you need to decide (1) how confident you are in your diagnosis (pickups are probably not returnable) and (2) how much you are willing to invest in a repair.

The actual replacement procedure is usually straightforward but care must be taken to avoid damage to the usually fragile flex cables. Also, take ESD precautions since the laser diode, in particular, is quite sensitive to static. There will usually be a solder jumper between a pair of traces shorting across the laser diode to prevent such damage - remove this only after the pickup is fully installed and its connectors are plugged in. (However, if you don't recall such a jumper and you are experiencing a 'dead laser' symptom, check for it!

Note: Some pickups like those from Pioneer apparently come from the factory unaligned. I have no idea how the test them! :) In any case, this means that substantial work is needed to get them to work, probably requiring a service manual, oscilloscope, and a test disc (though I don't believe the latter is absolutely necessary).

- Back to CD Repair FAQ Table of Contents.

Servo Systems and CD Player Adjustments

Servo systems

There are several servo systems in a CD player:

1. Focus - maintains a constant distance to within 1 um (1/25,000th of an inch!) or so between the objective lens and the disc. This must be maintained even with a slightly warped or uneven disc and in a portable player, with a certain amount of movement as well. Focus is accomplished with a voice coil type of positioner (similar to operation of a loudspeaker) using optical feedback from the disc surface. See the chapter: "Startup Problems" for a description of how this and fine tracking (below) operate.

2. Fine tracking - centers the laser beam on the disc track (to within a fraction of a um) and compensates for side-to-side runout of the disc and player movement. This also uses a voice coil positioner and optical feedback from the

disc surface. (Note: on rotary type pickups, there may be no separate tracking coil as its function is combined with the rotary positioner.)

3. Coarse tracking - moves the entire pickup assembly as a function of fine tracking error exceeding a threshold or based on user or microcontroller requests (like search or skip). Coarse tracking uses several types of positioners depending on performance requirements. It may either be a worm drive, a gear drive, a linear motor, or rotary positioner - in order of increasing access speed.

   The linear motor and rotary positioner have no gears and simply use a coil and permanent magnet to move the entire pickup very quickly - similar to a voice coil but on a larger scale. CDROMs, especially the high performance models, usually use this type of actuator to achieve their relatively fast access. These may have some type of lock to prevent the pickup from banging around when the unit is moved with power off. Note: for a CDROM drive that uses a caddy - always remove the caddy before transporting the drive or the equipment that it is in. The loading of the caddy often unlocks the pickup permitting it to flop around during movement and possibly being damaged.

   A linear motor or rotary positioner driven pickup should move very smoothly and easily by hand when unpowered and unlocked.

   Note that the use of a rotary positioner is no guarantee of fast response. One of the earliest CD players - a Magnavox unit apparently manufactured by Philips - has about the slowest track seek time I have ever seen and uses a rotary positioner. Watching it go from one track to another is like watching an inch worm crawl along - ssst, ssst, ssst (the sound made as the focus actuator vibrates while crossing tracks), ssst, ssst.

4. Spindle speed - maintains constant linear velocity (CLV) of disc rotation based on a PLL locking to the clock signal recovered from the disc. Spindle drive is most often done with a permanent magnet DC motor connected to the disc platform. It may be similar to the other motors in CD players and VCRs, (as well as toys for that matter), or a higher quality brushless DC motor.

Play adjustments

You will see a circuit board, hopefully in your unit it is readily accessible with component markings. For each servo, there will be 1 or 2 pots to adjust. Unfortunately for our purposes, some CD players have no adjustments! In this case about all you can do is confirm that the lens is clean and clean and lubricate the mechanism.

The adjustments will be labeled something like:

1. Focus - F.G. (focus gain), F.O. (focus offset)
2. Tracking - T.G. (tracking gain), T.O. (tracking offset), maybe others.
3. Spindle PLL, PLL adj., Speed, or something like that.

DO NOT TOUCH THE LASER POWER ADJUSTMENT - you can possibly ruin the laser if you turn it up too high. Sometimes, just turning it with power applied can destroy the laser diode due to a noisy potentiometer. This adjustment can only be made properly with the service manual. It may require an optical power meter to set laser output. Very often the adjustment is on the optical pickup itself so it should be easy to avoid. Sometimes it is on the main PCB. The laser optical power output is feedback controlled and unlikely to change unless the laser is defective - in which case adjustments will have little effect anyway. If you run out of options, see the section: Laser power adjustment - last.

DO NOT JUST GO AND TWEAK WILDLY. You will never be able to get back to a point where the disc will even be recognized (without test equipment and probably a service manual).

First, somehow mark the EXACT positions of each control. Some of these may require quite precise setting - a 1/16 of a turn could be critical, especially for the offset adjustments.

Sometimes, there will be marked test points, but even then the exact procedure is probably model dependent.

Adjustment procedure for noise or skipping

The assumption here is that you can get the disc to play but there is audio noise skipping, or other similar problem.

Play a disc at the track that sounds the worst - put it into repeat mode so it will continue for awhile. Get it to play by whatever means works.

Repetitive noise at disc rotation frequency

Try to locate the adjustments for focus. Try the focus offset first, just a hair in each direction. If you go too far, you will loose focus lock totally, the servo will go into focus search mode and/or the unit will shut down. Return the control to the exact original position if there is no improvement. You can also try gain, but in my experience, the gain controls are not critical to normal play but determine how the unit will handle dirty and/or defective discs. However, if they are way off, there could be general problems. Too low a gain setting (this applies to focus as well as tracking) will make the unit very prone to skipping as a result of minor bumps. Too high a setting will make the unit skip as a result of minor disc defects.

Short distance skipping or sticking

Try to locate the adjustments for tracking. Try the fine tracking offset first, just a hair in each direction. If you go too far, you will loose servo lock totally, the pickup will slew to one end of the disc, and/or the unit will shut down. Return the control to the exact original position if there is no improvement. Then try the other tracking offset if there is one and also the gain (though this is probably not the problem).

Always return each control to its original position after the test so you don't confuse things more.

General servo adjustment procedure

If you have a service manual for your player, by all means follow its recommendations or at least read through its adjustment procedures before attempting the one given below. If you have an oscilloscope of at least 5 MHz bandwidth, using it to monitor the RF testpoint during these adjustments will be of great value. However, a scope is not essential.

- Once focus lock is established, there should be a strong signal at the RF testpoint - typically around a volt or so. It may initially appear somewhat random, however.

- Once tracking lock is established, this signal should appear similar to the 'eye' pattern (see section: The CD player 'eye' pattern for details. However, while seeking, this may be jumping around somewhat as it attempts to home in on the correct track location.

If your CD player has a TEST MODE, see the section: Pioneer PD/M series servo adjustment procedure and modify it accordingly. The following procedure is for a typical unit without such a test feature. It assumes that the unit is functional but internal controls are not in their correct position. This might be the case if you violated rule #1 - never wildly tweak any internal adjustments! Or, if a major subassembly like the optical pickup or mainboard has been replaced.

If you have not touched the internal controls and no major parts have been replaced, there is no need to perform this procedure. Use techniques and observations discussed elsewhere in this document.

The following are assumed:

- Controls on the main board are in an unknown state but not any laser power adjustments (hopefully, these were on the optical pickup itself or its flex cable and were not touched.

- The player is otherwise functional - there is no physical damage.

You may need to modify this procedure based on your particular model. Some of the adjustments may go by different names or be non-existent. Use your judgement. Except for the laser power adjustment, which should be avoided, it is unlikely that any settings of these controls will result in permanent damage.

Some of these adjustment will need to be performed while the unit is in the startup sequence attempting to read the disc directory. Until focus and possibly tracking and CLV lock are established, it may give up fairly quickly. You will just need to keep cycling power or opening and closing the drawer to get it to repeat the attempt. Once some subset of the servo adjustments are set within reasonable limits, the player may continue to spin the disc ad-infinitum.

Hopefully, the adjustments on your player's mainboard are clearly marked. This is not always the case. I have restored a totally messed up portable with totally unmarked controls to a marginal state of happiness using an incremental procedure while observing changes in behavior and the signal at the RF testpoint with an oscilloscope. It was not fun and I never was able to really make it fully functional - seeks still have a problem though it will start track 1 most of the time and once started, play is flawless. (I suspect that there may be actual electronic/optical problems with this player in addition to the randomly tweaked controls). I even had to poke at random (testpoints were marked only with TP numbers) to locate the RF testpoint!

Use both your eyes and ears. The following may not apply but are probably worth considering:

- If the sled slews to one end of the track immediately upon power-on or loading of the disc, there may be a coarse tracking balance control that is set incorrectly.

- If the disc does not start spinning at all, focus lock is probably not being achieved. Concentrate on the RF and focus adjustments.

- If the disc spins hessitently or in the wrong direction or the sled slews to one end of the track after the disc starts spinning, there is a good chance that the tracking adjustments need attention.

- If the disc goes into overdrive, check the PLL/VCO/CLV adjustment (whatever it is called on your model).

- If the disc starts spinning and continues to spin at the correct speed (500 to 200 rpm depending on track position) without the player shutting down, a valid data-stream is probably being read. This indicates at least marginal RF, focus, tracking, and PLL/VCO/CLV settings. This doesn't mean you can ignore these adjustments but at least it is progress!

- If the disc directory (TOC) is read successfully but the player has trouble locating a track to begin play (even track 1), concentrate on the tracking adjustments - focus and PLL/VCO/CLV are probably fine.

If the player works but there are noise or tracking problems and you have an oscilloscope, see the section: Diagnosis of erratic play first as the simplified procedure described there may be more appropriate.

1. Precisely mark the current positions of all internal adjustments - just in case they were already set correctly!

2. Set all main board controls to their midpoint.

3. Adjust TR BAL (Tracking Balance) to the center of the range over which the sled remains stationary. Outside this range, the pickup will slew to one end or the other. Not all CD players have this control. A CD may need to be in place for this adjustment to have any effect. If you are unable to get the pickup to remain stationary, try fine tracking offset (TR.OFF) as well.

The following two items should be done with no disc in place. If your player does not have suitable test points or if these controls have no effect without a disc in place, skip them.

4. While monitoring the testpoint for focus error (e.g., TP.FE), adjust focus offset (FO.OFF) for 0 volts (+/- 10 mV or so). This may not be the optimal setting but will get you in the ballpark.

5. While monitoring the testpoint for tracking error (e.g., TP.TE), adjust fine tracking offset (TR.OFF) for 0 volts (+/- 10 mV or so). This may not be the optimal setting but will get you in the ballpark.

6. If you have a DMM, VOM, or scope, put it on the Focus OK testpoint if there is one.

7. Load a disc and press PLAY if necessary to initiate the startup sequence.

8. Confirm that focus is established. There is an adjustment range for Focus Offset over which focus will be reliably achieved. Outside this range:

    - he lens will hunt up and down - possibly with clicking sounds as it bumps into the end stops.

    - The Focus OK testpoint will not be asserted or will be jumping around as well.

    - The disc may never start spinning or spin erratically (model dependent).

    - Single play units will give up and enter stop more with display of 'disc', 'no disc', 'error', etc. Changers will come up with similar display and then move on to the next position of the carousel or magazine.

    Center the focus offset within the range for which focus is stable if it was not already there.

At this point there is a fair chance that the disc has started to spin and even that the disc directory has been displayed. If not, there are still two sets of adjustments remaining.

9. With focus stable, the disc should spin up. It needs to reach and lock at about 500 rpm - roughly 8 revolutions per second. If it does not move or overspeeds, try adjusting the PLL/CLV control (may be called PLL.ADJ, VCO.FR, CLV.ADJ, etc.). Note: this assumes that the spindle motor and driver are in good condition. If there is any doubt, see the section: Testing of motors.) WARNING: if the disc spindle speed runs away, turn power off and wait for spindle to stop completely. PLL/CLV control may be set to high; turn it counterclockwise 1/4 turn and start try again. There will be some range of this control where the speed will not run away but will be within the required limits.

Now, there is an even better chance that the disc has started to spin and that the disc directory has been displayed. If not, there is still one set of adjustments remaining.

10. Fine tracking offset may still not be quite right. Try some slight adjustments on either side of the current position. You may have to cycle power or open and close the drawer if you go too far. Some adjustments of alternately fine tracking offset and PLL/CLV may be needed.

Hopefully, you now have a disc directory and play may be operations though perhaps with audio noise and/or skipping or sticking.

The following are best done with a scope monitoring the 'Eye' pattern or other testpoints but if you do not have one, use your ears.

11. Adjust PLL/CLV control to midpoint of range in which disc plays correctly. Test this at both the start and the end of a full length (74 minute) disc. The optimal setting will result in the control being centered within the range over which the player works reliably at both ends of the disc.

12. Adjust any RF Offset (RF.OFS) control to the midpoint of the range over which play continues normally with no audio noise.

13. Set Focus Gain (FO.GAIN or FO.G) to the midpoint of the range over which it locks. CAUTION: the disc may enter a runaway state if you go to far. Check at both the beginning and end of the disc. Focus gain may need to be increased if the player is overly sensitive to bumps or disc wobble It may need to be decreased if sensitivity to disc defects is too high.

14. Set Tracking Gain (TR.GAIN or TR.G) to the midpoint of range over which it locks. CAUTION: the disc may enter a runaway state if you go to far. Check at both the beginning and end of disc. Tracking gain may need to be increased if the player is overly sensitive to bumps or disc wobble. It may need to be decreased if sensitivity to disc defects is too high.

15. Press STOP and then PLAY again to confirm that the disc loads properly and the directory comes up quickly and the music starts without excessive delay, hunting, or hesitation.

16. Test forward and reverse search and seek functions for proper behavior. Some slight adjustments to tracking balance or fine tracking offset may be needed to equalize the forward and reverse search or seek speed.

17. Player should now operate normally. However some tweaking of the gain controls may be necessary (as described above) for optimum defective disc and track seek performance over entire disc.

If you have an oscilloscope capable of at least 5 MHz bandwidth, you can now optimize the amplitude and stability of the 'eye' pattern at the RF testpoint by going back and touching up the various offset (RF, focus, fine tracking) adjustments. Unless otherwise instructed by the service manual, it is probably safe to assume that the RF signal should be maximum when everything is properly adjusted. For example, if the tracking offset and/or E-F balance is not set properly, you may find that the RF signal amplitude *decreases* when the tracking servo is closed since the laser beam is consistently off-center with respect to the row of pits and lands. (With the servo loop open, the beam was crossing tracks more or less at random so it was sometimes centered!)

Tips for adjusting CDROM drives

The following assumes that your CDROM driver and MSCDEX load without errors and that your IRQ, DMA, and any other software settings are correct but that seeks take a long time to complete or fail and/or data reads are unreliable.

If you can get the CDROM drive to play an audio CD, that can be used to do an initial alignment. The procedure below provides a way of monitoring data read performance while performing final servo adjustments since this is more critical than audio. Assuming, of course, that (1) there are any controls to adjust and (2) that you can get to them with a disc in place!

If after using the procedures described in the section: General inspection, cleaning, and lubrication, and possibly even servo alignment using an audio CD, the drive still produces data errors or cannot be read at all, it is time for more serious testing:

(Portions from: the_tooth_wraith (the_tooth_wraith@ptel.net))

Locate a copy of Disk Detective or another CD-ROM diagnosis program.

I'm pretty sure that Disk Detective (the limited version rather than professional version) can be downloaded over the internet from filelibrary.com (click on DOS collection, followed by Utilities-Disk then files beginning with C). I use the limited version that ships with a new Mitsumi IDE drive. It works perfectly on IDE, Mitsumi, SCSI, and likely any other interface drives, and it does not require the presence of any Mitsumi drive or controller. If you can't find Disk Detective, then search for CD-ROM, CDROM, or CD ROM at: http://www.shareware.com, and you'll find CD-ROM diagnostic programs.

In Disk Detective, there is a Test Disk menu option that scans the entire disk, and gives a continuous output to the screen of read errors it encounters, giving the type of error and the average data throughput.

Now using Disk Detective (or a comparable program), load a disk into the drive and select the test disk option, and tell it to scan the disk from beginning to end, and tell it not to stop when it encounters an error. Disk Detective should start trying to read the disk at sector zero, and will display read errors as it encounters them.

You might have to load an audio disk rather than a data disk in order to be able to get to the Test Disk screen.

With the Test Disk screen displaying the errors as it attempts to read the drive, it will be possible to carefully tweak each of the servo adjustments (as described elsewhere in this document) to minimize errors and maximize throughput.

Low laser power

Indications of reduced laser power include erratic startup, noisy playback. excessive variation of playback quality depending on the particular disc, or total lack of startup.

WARNING: improper adjustment of the laser power may result in the absolutely instant destruction of the laser diode - the heart of your CD player. There will be no warning. One moment you have a working laser diode, the next you have a DELD - Dark Emitting Laser Diode. Read the relevant sections fully before attempting any adjustments.

Nothing will help a dead laser diode - whether as a result of your efforts or natural causes - short of replacing the optical pickup.

Very likely, low laser power indicates a sick laser as well and adjustments will have limited if any effect since optical feedback normally maintains laser diode output at the proper level and it may be doing all that is possible.

However, sometimes due to component drift (this one way of saying: I haven't got a clue), the power will drop slightly or the sensitivity of the photodiode array will decrease resulting in a marginal signal.

If you have the service manual and it provides a procedure not requiring a laser power meter (which you probably do not have), then by all means follow that procedure.

Otherwise, see the section: Laser power adjustment for procedures that may be used as a last resort.

Optical alignment

Unless the unit was dropped, optical realignment of the laser assembly is not likely to be needed. All critical components are screwed, sealed with loctite, or glued, and should not change alignment under normal use. Don't fall for the line 'CD players are very delicate and will need frequent alignment - buy our extended service plan'. CD players are remarkably robust. Portables, even when nibbled on by large dogs, often survive unscathed. I even carried a component type CD player home from a garage sale 5 miles on the back of a 10 speed road bike over city streets complete with potholes! No problems. In fact, it improved. The seller claimed that it was broken but I could find nothing wrong! One possible exception is for automotive units which are subjected constantly to bumps and vibration which eventually take their toll.

If you really believe that optical alignment is needed, I strongly recommend that you obtain the service manual. Special test discs or jigs may be required and some test equipment will be required. As with other adjustments, make sure you can get back to your starting point should the need arise. Again. eliminate other possibilities first if possible.

Motors and Spindles

Small motors in CD players

Conventional miniature Permanent Magnet (PM) motors are usually used for:

- Drawer/tray opening/closing.
- Spindle rotation.
- Pickup position (coarse tracking) unless the unit uses a linear motor or rotary positioner drive.
- Disc changing (changers and jukeboxes only).
- Optical pickup tilt (laserdisc players only).

These are DC motors with commutators and metal brushes and are very similar in construction and quality to typical motors found in cameras, toys, portable tools, and other electronic equipment like VCRs and audio cassette decks.

They usually run on anywhere from a fraction of a volt up to 10 or 12 volts DC on-off (e.g., drawer) or from a servo controller (spindle).

Some CD players and CDROM drives use brushless DC motors for spindle driver rather than the cheap PM brushed variety. The commutation circuitry for these may be external to the motor itself. Troubleshooting beyond searching for bad connections will probably require a schematic.

Sled movement in high performance CD players and CDROM drives often uses either a linear or rotary direct drive (voice coil) mechanism. Since these are integral parts of the coarse tracking servo system, the only thing that can be tested without a schematic is for coil continuity.

Problems with small PM motors

These motors can fail in a number of ways:

- Open or shorted windings - this may result in a bad spot, excess load on the driver, or a totally dead motor.
- partial short caused by dirt/muck, metal particle, or carbon buildup on commutator - this is a common problem with spindle motors which fail to reach proper startup speed.

- dry/worn bearings - this may result in a tight or frozen motor or a spindle with excessive runout.

Testing of motors

If your player uses a brushless DC motor for the spindle then you may not be able to perform any electrical tests as the commutation control may be external on the circuit board somewhere. These do not fail very often, either.

An open or shorted winding may result in a 'bad spot' - a position at which the motor may get stuck. Rotate the motor by hand a quarter turn and try it again. If it runs now either for a fraction of a turn or behaves normally, then replacement will probably be needed since it will get stuck at the same point at some point in the future. Check it with an ohmmeter.

Also check between each terminal and the case - the reading should be high, greater than 1M ohm. A low reading indicates a short. The motor may still work when removed from the equipment but depending on what the case is connected to, may result in overheating, loss of power, or damage to the driving circuits when mounted (and connected) to the chassis.

Clip the ohmmeter leads to the motor terminals and rotate the shaft extremely slowly. The motor will act as a generator as your spin it resulting in the resistance readings increasing or decreasing depending on direction. However, the readings should stabilize once you stop.

The resistance should be fairly constant as the shaft is rotated with periodic dips where pairs of commutator segments are shorted by the brushes. The number of cycles per revolution is determined by the number of commutator segments used (most use only 3). Any extremely low reading may indicate a shorted winding. An unusually high reading may indicate an open winding or dirty commutator.

Cleaning may help a motor with an open or short or dead spot as noted below.

Typical resistance of these motors will be 10 to 25 ohms (though I have seen some apparently good motors reading as low as 5 ohms), fairly constant as one rotates the shaft except for dips at 3 points where the brushes short out each pair of commutator segments (there are generally 3 segments on these motors).

A motor can be tested for basic functionality by disconnecting it from the circuit board and powering it from a couple of 1.5 volt alkaline cells in series (3 V) or other power supply up to 9 V or so.

WARNING: Never attempt to power a motor with an external battery or power supply when the motor is attached to the circuit board - you may blow electronic components on the circuit board and complicate your problems. Disconnect *both* terminals and label the wires or motor orientation so you can reconnect it with the proper polarity.

If you use a variable power supply, the motor will start spinning slowing at less than a volt and continue without tending to stop at some point in its rotation. Using your fingers to monitor the torque produced as it rotates can also provide an indication of its health. It should be fairly uniform with slight periodic dips due to the commutator construction and number of segments.

Another approach is to power the motor from the low voltage source through a low value series resistor and monitor the voltage on the motor with an oscilloscope. It should have a periodic ripple at the rotation times the commutator (probably 3) rate. If there are sharp dips at the based rotation rate, there is a short either due to conductive gunk or actual shorted turns in the windings. If there is excessive noise in the waveform, the brushes and/or commutator may be dirty or worn.

It is also possible to confirm that the electronics are attempting to drive the motor by substituting a 15 or 20 ohm 1 W resistor for the motor. The driver circuit should develop a few volts across this load when it is supposed to be active. If there is no voltage at any time, then the driver may be blown or not have power, or the logic is not instructing the motor to spin!

Reviving a partially shorted or erratic PM motor

Conductive material bridging the gaps on the commutator of these small permanent magnet DC motors can result in intermittent contact and erratic operation. One theory baseed on an analysis done for a major manufacturer was that the origin of the contamination is the original lubricants used in the motor. Carbon or metal particle buildup can partially short the motor making it impossible for the controller to provide enough voltage to maintain desired speed. Sometimes, a quick squirt of degreaser through the ventilation holes at the connection end will blow out the shorting material. Too much will ruin the motor, but it would need replacement otherwise anyway. This has worked on Pioneer PDM series spindle motors. I have heard of people using carburetor cleaner successfully but I would recommend something a little less harsh to start. Contact, circuit board, or tape head cleaner may work.

Another technique is to disconnect the motor completely from the electronics and power it for a few seconds in each direction from a 9 V or so DC source. This may blow out the crud. The long term reliability of both of these approaches is unknown.

WARNING: Never attempt to power a motor with an external battery or power supply when the motor is attached to the circuit board - you may blow electronic components on the circuit board and complicate your problems. Disconnect *both* terminals and label the wires or motor orientation so you can reconnect it with the proper polarity.

It is sometimes possible to disassemble the motor and clean it more thoroughly but this is a painstaking task best avoided if possible.

If you do manage to revive it, also see the section: Spindle motor drive modification to minimize chances of future problems.

Replacement motors

The spindle motor should be replaced with an identical unit though it doesn't have to be the exact manufacturer's part number - universal substitutes are often available at a much lower price.

However, there may be alternatives for other types. Most of the other small PM motors found in CD players and CDROM drives (as well as VCRs and other consumer electronics and small appliances) are basically pretty similar. The important differences are mainly mechanical - size, mounting, shaft length, etc. There may be variations in nominal voltage and current usage but for non-critical applications like drawer loading or disc changing, if you can make a generic replacement fit the space and attach to the drive components, There is a good chance that it will work well enough. Such replacements may be available from companies like those listed in the section: Recommended parts suppliers. Check a few catalogs!

Motor bearing problems

A dry or worn bearing can make the motor too difficult to turn properly or introduce unacceptable wobble (runout) into the shaft as it rotates.

Feel and listen for a dry bearing:

The shaft may be difficult to turn or it may turn with uneven torque. A motor with a worn or dry bearing may make a spine tingling high pitched sound when it is turning under power. A drop of light machine oil (e.g. electric motor oil) may cure a dry noisy bearing - at least temporarily.

For spindle motors (these are the only motors in CD players where runout is critical), try wiggling the shaft from side-to-side - any detectable movement is an indication of runout. At some point, this will be bad enough such that the focus and tracking servos will be unable to compensate for the runout and audio noise and skipping may result. Some oil may help but a spindle motor with a worn bearing will require replacement eventually. Furthermore, it may prove impossible to reach the bearing(s) to lubricate them properly.

See the section: Spindle motor problems for more information.

Spindle motor problems

The following are some indications that the spindle motor may be defective or need attention. However, insufficient spindle motor voltage or current could also be due to spindle motor driver faults, incorrect power supply voltages, or logic problems.

Note: If the disc doesn't spin at all, try rotating it by hand while it is trying (or with the servos enabled if it has a TEST mode). If you hear that 'gritty' sound, the focus and probably tracking servos are working but the spindle motor or driver are faulty.

- Focus is successful but disc does not spin (dead motor or dead spot on motor, shorted motor, bad connection).
- Disc spins but at too slow a rate or is erratic or needs some help (weak motor or dead spot). Reading of disc directory may be erratic. (Try helping motor out by hand).
- Voltage across spindle motor is only 1 V or less while attempting to spinup and read the directory and climbs to 5 V or more with the motor disconnected (partially shorted motor).
- Spindle bearing runout is excessive (i.e., detectable by wiggling the spindle from side to side) or spindle motor bearing is dry or tight (try lubricating if possible).
- Repetitive noise or dropouts at the disc rotation frequency or twice the disc rotation frequency. This may get worse toward the end or outer tracks of the disc. (Excessive spindle bearing runout or bad windings).

Check the motor before replacement (see the section: Small motors in CD players for general motor problems and testing). You should be able to easily confirm or eliminate the spindle motor as the cause of your problems. If either of the cleaning or rejuvenation techniques make a significant difference in performance, then the motor is almost certainly at fault. If the player now functions normally - leave it alone or, perhaps, try the circuit modifications suggested in the section: Spindle motor drive modification to minimize chances of future problems.

The spindle motor is often blamed for everything from long distance skipping (coarse tracking problem) to disc spinning too fast or in wrong direction (a control problem). Spindle motors do fail but they are not at the root of all problems.

If you suspect a dry or bad spindle motor bushing (bearing):

(From: Jeff Cook (jacook@ibm.net).)

A little trick I came up with when my Sony CDP-550 player started skipping: Tape a coin (a penny seems to work fine) to the top of a CD that skips. If it cures the skipping, then the problem is likely the spindle motor bushings need lubricating.

Spindle motor drive modification to minimize chances of future problems

This suggestion is directed toward Pioneer players of the PD and PDM series with known common spindle motor problems. It may apply to other Pioneer models and other brands as well. It can be used whether you have just rejuventated an existing motor or installed a replacement.

For Pioneer players, there is actually a circuit modification to reduce the possibility of repeat problems but it requires changes to the wiring - cuts and jumpers - which I prefer to avoid.

My recommendation is to try the following which can usually be added at the motor terminals. (I have not done this yet, so no guarantees):

Put a series string of 4 1N400X diodes in parallel with another similar string in the opposite direction across the motor terminals. This will limit the maximum voltage to about 3 V instead of the 6 V or more that it is now. The reduced voltage should reduce chance of damage to the commutator at spin-up. On the Pioneers at least, the motor driver should not mind the extra load during any peaks where the diodes kick in.

It may take a couple seconds extra to start up but I believe it will still work fine otherwise.

If you do this, let me know how it works.

Spindle motor replacement

Mark the height of the old spindle platter before you attempt to remove it. The best approach is to make a shim that will fit between the bottom of the spindle platter and the motor as a stop. The height is usually specified to a precision of 1/10 of a mm. Too low or too high and the disc may rub. This is probably overhill - 1/2 mm is probably good enough but try to get it as close as possible. The focus servo offset adjustment will make up for any height error in so far as focus is concerned.

The spindle is often press fit and difficult to remove without damage. It is critical that when the spindle is replaced, it be mounted perfectly with no wobble. If you can obtain a new spindle platter with the new motor, this is the best option. If not, take every precaution to prevent damage to the spindle platter during removal - even it it means destroying the old motor in the process. See the section: Spindle platform pulling.

When press fitting the new spindle, the use of an arbor press or drill press is highly recommended. Put a block of wood under the bottom of the motor and your previously made shim between the spindle platter and the motor. Press straight down - slowly and firmly. Err on the side of being to high and check the height. Repeat until you get it perfect. It is much easier to press a little more than to raise the height if you should go to far.

If there is a set screw, your job is much easier. Other mounting schemes may be employed - use your judgement in replacement procedure. For non-press fit installations, a drop of loctite or nail polish will reduce the chance of it working loose.

The new motor may come with a shim to set the proper height or it may be included as part of the player:

Note that the precise length of the spindle motor shaft may be critical on some CD players to help center the disc. Thus, when you order a replacement, don't assume that a slightly shorter shaft will be adequate just because it will hold the platter securely - check it out first.

(From: Mark Z. (mzacharias@aol.com).)

Most Pioneer models have a spindle height jig molded onto the subchassis. It snaps off and slips between the disc table and motor base to set the height.

Unknown spindle platter height when replacing spindle motor

What was your excuse for not marking it? Oh, an elephant sat on the player and that is why the motor needed replacing but the height was already messed up :-).

If the player operates normally after spindle motor replacement, as they say "If it works, use it". I wouldn't worry about it. The focus servo has a wide range. If you are curious, try to locate the test point for focus error. It should probably be a noisy waveform centered around zero volts. However, this may not be the case and you would need the service manual to be sure of what it should be. As long as the player seems to locate the disc directory quickly and plays normally, leave it alone!

However, if it now has problems either taking a long time to start play or exhibiting unusual noise or skipping during play, you should probably try to obtain the spindle platter height specification and set it more accurately.

I definitely would not recommend mucking with the spindle platter height unnecessarily if it is a press-fit. You would probably end up with a bent shaft and need for yet another replacement motor. However, if the spindle platform is secured with a set screw, you can try to adjust it to minimize focus error and/or optimize playback performance.

Spindle platform pulling

I was able to remove the spindle platform on a Philips CD pickup using the lawn mower engine flywheel pulling approach - levers under both sides of the platform so the pressure is upwards and not sideways while tapping on the center of the shaft with a thin punch. Thus, there was no shaft bending. I believe that the motor survived without damage.

I was actually going to 'machine' a mini-flywheel puller but then I said: "What the heck, that is too much work :-)"

In any case, the spindle platform is completely undamaged and the motor could probably be reused.

However, be careful what you are prying against - the mounting may use tiny screws into plastic or something equally fragile.

Of course, if you plan on doing any serious hammering, remove all the delicate optical and electronic components first!

Correcting spindle platform wobble

This assumes the bearings are in good condition but the shaft has somehow gotten slightly bent. You might ask: How could this happen? Once cause could be using an improper technique to remove or attempt to remove or install the spindle platform from/to the motor shaft or something heavy falling on the player. Right, I know; in this case, a bent shaft will likely be the least of your problems! :-)

(From: Filip M. Gieszczykiewicz (filipg@repairfaq.org).)

I use something as simple as a pencil. Start the motor going and put the pencil right above - but not touching - the part that is bent. Now move it in tiny increments towards the bent part. When you hear the first tiny "scrape", stop the motor and note where the pencil mark appears. This is the place you want to press down to even it out.

This is loads of fun with a CD spindle motor and sometimes it's just easier to get a replacement. Trust me.

Sled motor problems

The following applies to sled positioners using conventional permanent magnet motors with the typical gear or screw mechanism. (Those using linear motors use closed loop servo systems with a drive coil and sense coil. About all you can do to test these without a schematic is to check for continuity of the two coils.)

Sled motors tend to be less likely to fail than spindle motors but can suffer from similar afflictions.

The following are some indications that the spindle motor may be defective or need attention. However, insufficient sled motor voltage or current could also be due to sled motor driver faults, incorrect power supply voltages, or logic problems. These problems could also be of an erratic nature if the motor has a dead spot or is partially shorted.

The sled motor (or its driver and associated circuitry) may be at fault if:

- The sled fails to reset to the inner track.
  - Focus is established and the disc begins spinning at the proper speed for the current pickup location but the pickup fails to move to the selected track location.
  - There are problems with discs repeating more-or-less the same musical segment every few seconds (the sled gets stuck) or long distance skipping (the sled sticks but then once enough of a fine tracking error develops, breaks free and overshoots the proper location).

The motor may have a dead or weak spot in its rotation. Rotate it by hand 1/4 turn or so and see if it now spinds normally or a fraction of a turn. See the section: Testing of motors.

Of course, any of these could also be due to mechanical problems as well so eliminate these as possibilities first.

Sled motor drivers

The sled motor may actually receive its drive from two sources (maybe more) as shown conceptually in the diagram below. These may or may not be separate physical outputs tied together:

```
                               Slew+ o--------+
                      |\                      |
         Tref+ o------|+ \                    |
                      |    >------------+     |
                   +--|- /              |     |    |\  Sled Drive
                   |  |/ TE+ Comp       |     +----|+ \
                   |                    +----------|+   \
Tracking Error o---+                               |      >--------o + Sled
                   |                    +----------|-   /      +---o - Motor
                   |  |\ TE- Comp       |     +----|- /       _|_
                   +--|+ \              |     |    |/          -
                      |    >------------+     |
         TRef- o------|- /                    |
                      |/                      |
                               Slew- o--------+
```

1. Slew driver - this is used when the pickup is resetting or moving across the disc. The motor is commanded to move smoothly in either direction or is searching for the general vicinity of the starting location (time code).

   Where the pickup is unable to reset to the inner track or unable to move to an outer track during seek operations, a part of this driver or its associated circuitry may be at fault.

2. Coarse tracking driver - this is used to move the sled a small amount during play to recenter the pickup once the fine tracking error exceeds a threshold. Many designs will do away with explicit comparators (as shown above) and just use the friction of the sled motor/mechanics to result in movement once the voltage on the motor becomes large enough. This would seem to waste power, however, and be undesirable for battery operated portables, at least.

   Where the seek operation completes normally and the music starts playing but then gets stuck or jumps back and repeats after a few seconds, the coarse tracking driver or its associated circuitry may be at fault.

Any of these symptoms may also be caused by a defective sled motor or mechanical problems - probably more likely than bad electronics.

Notes on Specific Equipment

Pioneer PD/M series players/changers do not recognize discs

(Refer to the photo of the Pioneer CD Player Optical Deck for parts identification.)

Where a Pioneer player or changer does not recognize discs, the most common causes are:

1. Partially shorted spindle motor due to 'crud' on commutator. Cleaning may be possible. Generally, disc will spin but at insufficient speed. Try TEST MODE toward latter (outer) part of disc as the required rotation rate is lower and/or check voltage to motor, below. See the section: Reviving a partially shorted or erratic PM motor.

2. Cracks in flex cable to optical pickup assembly - replacement of flex cable will be required. This may also result in erratic operation while playing. The Pioneer replacement part number for the improved version of one common cable is PNP-1343 but confirm this is correct for your model before you order. Sometimes, the flex cable is just not positioned properly (clear of the metal cover) and just needs to be 'adjusted'.

3. Collapsed rubber suspension grommets. There may be a scraping or clicking sound associated with this failure. For changers, gently lift up on the optical pickup assembly while the disc is attempting to spin to see if the disc is recognized and will play. Replace the deteriorated grommets.

4. Lens fell out. This is somewhat rare and applies mostly to changers (possibly only those made by Pioneer) where the pickup is mounted upside-down, but apparently the adhesive dries out and may fail completely during use or as a result of the player being moved. See the section: Objective lens popped out. Note: If you do attempt to reattach the lens, replace the rubber grommets as well as collapsed rubber grommets are common on these pickups as well - and may even have been the cause of the lens problems (disc contacting lens).

For general information, see the sections starting with: "Startup sequence".

Pioneer PD/M series test mode

The TEST mode available on some CD players is extremely useful for narrowing down problems. The following are for the Pioneer PD/M series of CD players and changers:

- To enter TEST mode, press the TEST button while turning POWER ON and then hold it on for at least 1 second.

    - Some models only have a set of contacts - Pioneer saved 2 cents on a switch! Short between these with a piece of wire or a paper clip instead of pushing the button.

    - On players with a standby mode (not a hard on/off switch), plug the unit in while pressing the TEST button or shorting the contacts.

  The TEST button or contacts are located on the main board (usually near the front right corner - may be obscured by cables).

Once TEST mode is engaged, the servos can be controlled from the front panel:

- STOP turns all servos OFF.
- TRACK FWD (>>|) enables FOCUS servo (and loads disc 1 in changer).
- PLAY enables SPINDLE servo.
- PAUSE enables TRACKING servo.
- MANUAL SEARCH FWD (>>) or REV (<<) to move the optical pickup.

Depending on model, the specific functions and behavior of the front panel buttons in TEST mode may vary slightly. Some may use PROGRAM to turn on laser, PLAY to enable focus servo, second push of PLAY to enable tracking servo, etc. You may have to experiment.

WARNING: Normal safety checks are disabled in TEST mode. Thus, the laser may remain on as long as focus/tracking/spindle servos are engaged even if no disc is in place. Take care.

Power cycle (by unplugging if necessary) to return to normal mode.

Pioneer spindle motor voltage (operating normally)

Here are the typical measurements for the PD/M series players:

- Spinup: >2.5 V.
- Time to lock (est): 1 to 2 sec.
- Start of disc (500 rpm): 1.0 V.
- End of disc (200 rpm): 0.5 V.

Pioneer spindle motor problems

When bad, spindle servo drive tops out at .6 V and 100 ma. Player is unable to spin up to required 500 rpm to read disc directory.

While exact cause is unclear, theory is that large voltage applied at startup followed by long periods of very low voltage (.5-2 V) operation allows conductive crud (carbon) to build up on commutator eventually reducing resistance to the point where the driver cannot apply enough voltage to achieve 500 rpm.

A short squirt of degreaser through motor access hole had an immediate dramatic effect returning operation to normal. It is not known how long this will last. (Also see the alternative procedure in section: Reviving a partially shorted or erratic PM motor.)

Collateral symptom: Spindle motor servo drive IC becomes quite warm when attempting to power shorted motor. However, it does not appear to be harmed.

Use TEST mode to play disc at outer track. If this is normal, then spindle motor is probably bad as the rotation speed at the outer tracks is less (200 rpm) and a partially shorted motor may still run fast enough for this.

Pioneer PD/M series servo adjustment procedure

The following procedure assumes that unit is functional but internal controls may have been moved from their correct position. This procedure has been determined experimentally and is subject to change without notice. If you have not touched the internal controls, there is no need to perform this procedure. Use techniques and observations discussed elsewhere in this document.

A number of Pioneer CD players have used very similar designs. However, technology sometimes the implementation changes dramatically between units with virtually identical model numbers. It is known that this adjustment procedure applies to many older Pioneer single disc players (e.g., PD5100) and magazine changers (e.g., PDM400/500/600 etc,). However, newer models that appear virtually identical to these may require a totally different adjustment procedure. Therefore, use at your own risk! With minor (and obvious) modifications, this general approach should also apply to many CD players from various other manufacturers as well.

I also recommend you read the section: General servo adjustment procedure in its entirety before proceeding to tweak your Pioneer player.

Assumptions:

- Controls on the main board have been moved or are in an unknown state but not on the flex-cable or optical pickup assembly.
- The player is otherwise functional - no physical damage.

And now for the fun:

1. Set all the main board controls to their midpoint.
2. Power up the unit in TEST MODE (hold down the TEST button while powering on.
3. Adjust TR.BAL (Tracking Balance) to the center of the range over which the sled remains stationary. Outside this range, the pickup will slew to one end or the other.
4. While monitoring TP1-6 (FO.ER, Focus Error) with a VOM or DVM, adjust FO.OFS (Focus Offset) for a reading of 0V +/- 10 MV. Note: I have found that on some players, this may not actually be quite optimal and fine adjustment be beneficial.
5. While monitoring TP1-2 (TR.ER, Focus Error) with a VOM or DVM, adjust TR.OFS (Tracking Offset) for a reading of 0V +/- 10 MV. Note: I have found that on some players, this may not actually be quite optimal and fine adjustment be beneficial.
6. Load a magazine with a disc in slot 1 and press >>|, TRACK SEARCH Forward. This should load the disc and enable focus servo.
7. Use MANUAL SEARCH REV (<<) to position sled at beginning of disc.
8. Press PLAY. This enables the spindle servo. Disc should now spin up and lock at at around 500 rpm. If disc does

not start or appears not to reach correct speed, check voltage on spindle motor. It should be greater than 2.5 volts during spinup. The most common cause of low voltage is a dirty partially shorted commutator/brush assembly inside the motor; clean or replace as necessary. WARNING: if the disc spindle speed runs away, turn power off and wait for spindle to stop completely. VCO control may be set to high; turn counterclockwise 1/4 turn and start from the beginning.

9. Press PAUSE. This locks the tracking servo. The display should show the disc TRACK and TIME. Alternately pressing >> or << should move pickup, then press PAUSE to start play again. Audio will be correct at output. Correct display and sound only near end of disc indicates a spindle motor unable to achieve sufficient speed (see above).

10. Adjust the VCO control to the midpoint of range in which disc plays correctly.

11. Set RF.OFS to the midpoint of the range over which play continues normally.

12. Set FO.GAIN to midpoint of range over which it locks. CAUTION: the disc may enter a runaway state if you go to far. Check at both the beginning and end of the disc. FO.GAIN may need to be increased if the player is overly sensitive to bumps or disc wobble. It may need to be decreased if sensitivity to disc defects is too high.

13. Set TR.GAIN to the midpoint of range over which it locks. CAUTION: the disc may enter a runaway state if you go to far. Check at both the beginning and end of the disc. TR.GAIN may need to be increased if the player is overly sensitive to bumps or disc wobble; it may need to be decreased if sensitivity to disc defects is too high.

14. Press STOP. The disc should unload. Exit TEST MODE by turning power off and on again. Confirm that the disc loads properly and that the directory comes up quickly and the music starts without excessive delay, hunting, or hesitation.

15. Test forward and reverse search and seek functions for proper behavior. Some slight adjustments to tracking balance or fine tracking offset may be needed to equalize the forward and reverse search or seek speed.

16. The player should now operate normally. However some tweaking of the gain controls may be necessary (as described above) for optimum defective disc and track seek performance over entire disc.

If you have an oscilloscope capable of at least 5 MHz bandwidth, you can now optimize the amplitude and stability of the 'eye' pattern at the RF testpoint by going back and touching up the various offset (RF, focus, fine tracking) adjustments. Unless otherwise instructed by the service manual, it is probably safe to assume that the RF signal should be maximum when everything is properly adjusted. For example, if TR.OFS is not set properly, you may find that the RF signal amplitude *decreases* when the tracking servo is closed since the laser beam is now consistently off-center with respect to the row of pits and lands. (With the servo loop open, the beam was crossing tracks more or less at random so it was sometimes centered!) For the Pioneers I have seen, it appears that the FO.OFS and TR.OFS may *not* be set optimally by the static adjustments (4) and (5), above.

Pioneer 6 disc cartridges (magazines)

There are usually pretty robust but if something was forced, in addition to damaged plastic parts, a bunch of steel balls (about 1/8" diameter) may escape. DO NOT attempt to use the cartridge without these - they are part of the mechanism which assures that only one tray will come out at a time. If they are missing, as one tray is pulled out, another may come along and jam up the works. :(I believe there are 5 total (for a 6 disc cartridge) and you need every one of them! Assuming there is no actual damage, it is possible to reinstall the balls by carefully disassembling the cartridge. If I recall correctly, they go in a channel formed by a hole on each tray next to the hinge and a spring holds them in place. Buying a new cartridge may be the way to go. :)

Comments on Pioneer CD Player Adjustments

(From: David Kuhajda (dkuhajda@locl.net).)

There are a lot of adjustments that must be done per the service manual, but the guide is much easier to follow.

1. Grating.
2. Tangential tilt.
3. focus offset.
4. tracking offset.
5. focus gain.
6. tracking gain.

The spindle motor height is also extremely critical in these older Pioneers. Recommend you get the correct one.

If it has the old white flat cable going to the optics it also must be replaced, the white ones would go bad and intermittent.

If the lens fell out, the 4 rubber grommets must also be replaced. We typically reglue the lens on very carefully (works about 75% of the time), replace the rubber grommets, check the spindle motor, and do the adjustments to fix ones like these.

(From: TEX (zedex@geocities.com).)

The grating is the most important. The laser are not adjusted and you will need a small hex driver or a small blade screwdriver to adjust this. I only worked this out after spending two weeks on a unit and wondering why a second hand laser woked fine and a brand new unit didn't. If you want a copy of the service manual, try your local pioneer distributor - they may be able to Fax it to you.

Pioneer PD-7010 adjustment procedure (from Davidson)

Note: See Pioneer TEST mode description in the section: Pioneer PD/M series test mode.

1. Laser Power - Normal mode. Press PLAY - Laser power should be set to:

   .26 mW +/- .02 mW. Adjust VR1 to spec.

2. PLL VCO Free Run Frequency:

   - Set the player to TEST mode.

   - Press STOP to switch all servos off.

   - Press TRACK FWD to enable the FOCUS servo.

   - Press PLAY to enable the SPINDLE servo.

   - Observe the waveform at pin 8 of IC8 (2/2) using a scope set to .5 V/div. This waveform can be found easily at the legs of C47.

     Note the center value of this waveform.

- Using a core driver, adjust VL1 (VCO coil) so that the center value of this waveform is the same when PAUSE is pressed to switch on the TRACK servo.

3. Tangential Adjustment:

    - Enter TEST mode and load the TEST disc??
    - Use the MANUAL SEARCH FWD key to put the pickup at the end of the disc.
    - Press TRACK FWD, PLAY, and PAUSE in that order to enable all servos.
    - Use the Scope to observe TP2, Pin 4 (RF Output). Adjust the Tangential Adjustment Screw to obtain the clearest eye pattern. This is the midpoint between the places where the pattern begins to deteriorate.

4. Tracking Offset and Focus Offset:

    - Enter TEST mode.
    - Adjust the voltage at TP1, Pin 9 TR (Tracking Return) to 0V +/- 10 mV by turning VR2 (Tracking Offset).
    - Adjust the voltage at TP1, Pin 3 FO.ER (Focus Error) to 0V +/- 10 mV by turning VR6 (FO.OF, Focus Offset).

5. Focus Gain:

    - Enter TEST mode.
    - Press STOP to disable all servos.
    - Adjust the frequency and output voltage of CH1 of the F.T.G. to 878 Hz and .2 V P-P. What if I do not have an F.T.G.?
    - Connect the F.T.G. adjuster. Right :-).
    - Press TRACK FWD, PLAY, and PAUSE in that order.
    - Adjust VR3 FO.GA so that the green LED just comes on. Right.

Alignment after replacing Pioneer optical pickups

Unlike Sony pickups, which are aligned at the factory and then sealed with something like hot-melt glue to prevent tampering, Pioneer pickups require alignment, possibly even before a disc will be recognized. I wonder whether this is just due to cost cutting (but how could they even test the pickup?) or they just feel that it needs to be matched to the CD player....

Both optical alignment of the pickup itself and then possibly servo adjustments will be needed. I have done these adjustments without the service manual using just an oscilloscope and a music CD (no test disc) on an existing pickup (not a replacement) by basically maximizing the amplitude of the 'eye pattern' but the proper equipment and documentation would help!

(From: Mark Z. (mzacharias@aol.com).) d

Pioneer pickups are shipped unadjusted. Some of the newer models happen to work without additional adjustment but not all of them. Unfortunately some of the service manuals OMIT the final adjustment on the grating. One should adjust for a smooth null THEN for maximum output with a slight adjustment either clockwise or counterclockwise depending on whether the pickup is upside down or not. I can never remember which. I have seen at least a couple Pioneer manuals where the adjustment instructions END with the reference to the "smooth null". Frustrated technicians result because they think they've done what the instructions say, which they have - they just didn't get a full set of instructions. This is a common discussion point at Pioneer training schools.

Radial and tangential adjustments must be done first. These are the metal screws visible through the pickup PC board. Have a scope on the RF test point and adjust each for maximum while playing a disc. Some discs may work better than others during initial adjustments. If you're lucky you may not have to adjust the grating after the other are done.

The older Pioneers' pickups were shipped with the tangential adjustment ALL THE WAY to one side. This applies ONLY to the older ones with the mainly metal chassis. It was a white nylon screw which jammed the underside of the spindle motor mounting plate, and actually prevented the pickup from moving on its' track until loosened.

On the newer models, there are radial and tangential adjustments which can be adjusted in test mode. Both older and newer ones have grating adjustments, but the newer ones don't generally need adjusting. Don't get into grating adjustment unless you really have to.

Pioneer pickup replacement saga

(From: Stefan Toftevall (stefantoftevall@swipnet.se).)

As a guy around here had problems with his Pioneer PDS-501 CD player, he asked me if I could help him to fix it. Ok, I thought, just a cd-player, probably a bad spindle-motor or a dirty lens. Well, I sure got a surprise after taking away the cover. I heard something's gone loose somewhere into it and soon I noticed the lens on the pickup had popped out. I spoke to the owner and he told me to change the entire pickup, as he didn't wanted to throw it away yet. Said and done. The new pickup were easily changed, about 10 minutes or so. Time for the first test. I suspected nice music streaming out of the player, but unfortunately all I could hear was: Sccchhh, stk, stk, stk... And off it went. What the heck! It didn't even recognize my test CD! The display showed all zeros. I started to check for bad connections. Didn't find any. Didn't find anything unusual. Hmm....

After several days of investigation and a new spindle-motor, no improvement. I felt real stuck. Until I got a tip (from here) that they solder a jumper on the flex cable to prevent damage to the laser diode until the pickup is installed. OK, I threw myself over the player and unsoldered the jumper. Hopefully testing again: Sccchhh, stk, stk, stk... Off! God, what's wrong?

After several hours of thinking I noticed that the pickup were not in horizontal position. I adjusted it for a proper position. Testing again... Scchhh, stk, stk, stk..

After this I realized that new Pioneer pickups come totally unadjusted from the factory. After adjusting the grating, I made the player able to recognize CD's again and even play them! So, be awake when changing a Pioneer pickup, cause they'll not make it easy for you!

Sony KSS240 optical pickup adjustments

The functions of the pots on the pickup itself (from left to right): Focus, Tracking, Laser Power. (This determined from one sample. I don't know if all revisions are the same!) See other sections of this document for adjustment procedures. DO NOT touch laser power except as a last resort.

Yamaha CD3 adjustment procedure (from Davidson)

1. Laser Power:
   - Remove the flapper.
   - Player should be in focus search mode.
   - Short terminals FD1 and R together.
   - Laser power should be .24-.30 mW.

     (Apply -9V +/- .5 V if the pickup is off the circuit board.)
2. HF Level:
   - Monitor HS with scope. Peak to peak level should be between 1.5 and 2.5 V.
3. Focus Offset:
   - Set the TEST disc to PLAY. Make the adjustment at the center of disc rotation (35 DHS).
   - Connect the oscilloscope to HS. Adjust VR101 for the best eye pattern.
4. Tracking Gain:
   - PLAY mode.
   - ACVM to terminal Q and VE.
   - Apply 800 Hz, 100 mV rms to TD1 and GND with a 220K resistor in series from the audio oscillator.
   - Adjust VR104 so that ETE = (EQ + 5 dB) +/- 1 dB.

Audio whine (not from speakers) and/or muddy sound with Sony CD players

Generally, the only symptom is a CD players that sounds unhappy - there are no audio or tracking problems. However, in severe cases, there may also be audio degradation described as "muddy sound".

(No doubt, a non-Sony approved weight would work equally well for the solution below.)

(From: Lance Edmonds (lanceedmonds@xtra.co.nz).)

The whine problem usually occurs with KSS240A and KSS213A optical pickups, and is caused by a mechanical resonance. There are at least 2 service bulletins describing the fault and the cure.

Sony sells a special weight to fit to the pickup, and also a felt pad to add to the bottom of the top clamp assembly. Both these items cure this problem. Some machines may only require the weight.

In rare circumstances the resonance can interfere with the tracking/focus servos enough to cause skipping. Usually the problem is not easily repeated, however certain light weight disc's may trigger the problem repeatably.

Note that the resonance usually only occurs on the first few tracks if at all, and some disc's will play with the problem never showing up. Seems to be a disc weight/thickness/density problem.

Contact your official Sony service office for the part numbers etc.

Notes on Sony CDU31/33A CDROM drives

(Refer to the photo of the Sony CDU-31/33A CDROM Optical Deck for parts identification.)

Both these drives use similar optomechanical technology. The CDU31A is 1X (though I have heard that some versions of this may be 2X, unconfirmed) and CDU33A is 2X.

Many have complained about the lack of a motorized tray. What this does provide is a very simple robust mechanical design. A solenoid latch keeps the drawer shut. When the solenoid is activated (or the emergency release is pressed) the drawer pops out about an inch. Pulling the rest of the way is manual. The movement of the drawer clamps/unclamps the disc to the spindle with a powerful magnet. Except from gross abuse, there is little to go wrong mechanically.

There are only two major components: the Printed Wiring Board where all the active electronics are located and the Optical Deck including laser, optics, and pickup worm drive mechanism.

The other parts include the upper plastic casting and metal shroud, solenoid latch assembly, right and left guide rails, drawer assembly, and front bezel, two springs, bottom plate, 6 screws.

There are only two electrical connectors inside: one flat printed cable linking the PWB and optical deck and a two pin connector supplying power to the eject solenoid. This is in pleasant contrast to some other CDROM drives I have seen with a half dozen or more small connectors spread all over the PWB making removal and testing very difficult and risky.

Disassembling the Sony CDU31/33A CDROM drive

The only major cautions are to not lose any of the small screws or springs and to avoid damaging the multi-conductor flexible cable linking the electronics to the optical assembly.

The following procedure takes about 5-10 minutes:

0. Place the unit upside-down on a soft surface.

1. Remove 4 philips head screws securing bottom cover. Set bottom cover aside.

   You will now have access to the electronic adjustments for focus, tracking, etc. If this is what you are after, no further disassembly is needed.

2. Unclip the front bezel. Slide it out with the tray as far as it will go. You may need to manually activate the eject mechanism with a paperclip.

3. Remove 2 philips screws securing Printed Wiring Board (PWB). Gently lift PWB and disconnect connector to latch solenoid assembly in front of unit.

4. Gently lift PWB further and disconnect flexible cable connector on optical assembly. Mark the orientation so there

will be no doubt about getting it correct if you need to reassemble on the workbench for testing. There is a latch at each end which you push away from the connector 1 mm or so. The cable will than come out easily.

You now have partial access to the optical assembly sled drive. Cleaning and lubrication of these components is now possible.

5. Lift the latch solenoid assembly up, remove and set aside.

6. Using a pair of fine needlenose pliers or tweezers, disconnect and set aside the two tray retraction springs. Note their position and orientation.

7. Remove the two plastic guides - one on each side. There are little tabs that you will need to depress and then lift each guide straight up.

8. The entire deck can now be slid forward and lifted off. The opto/mechanical assembly can then be removed from the tray. Set the tray aside. The mechanism shown in the photo of the Sony CDU-31/33A CDROM Optical Deck is screwed into the rubber shock mounts.

9. If you prop up the PWB and reconnect the flexible cable - note the orientation marks you made previously - you can then run the drive with full visibility of the mechanism and optics. With a CD in place, there is no danger to you from the laser beam. Just make sure the PWB cannot short to anything and that the whole affair cannot tip over.

Reassemble in reverse order. Be especially careful reinstalling the flex cable. Make sure no wires are being pinched and that nothing is obstructing free movement of the optical pickup. This is actually pretty easy for this drive.

Sony Playstation (and other game machine) problems

The following information applies directly to the Sony Playstation but other CD/CDROM based systems use similar technology.

Note that the Playstation (and other newer game machines) are programmed to only work with discs released for the same country or general geographic location in which it was purchased. Thus, if you got a good deal on a used system, you may now know why: it might only work with Japanese software! :-(.

I believe Sony has a flat rate ($100 or so) repair fee for these - probably toss the guts and replace them - but this is barely justifiable for a $200 system. Many complaints are similar to the following with symptoms of marginal play of audio or game discs, skipping, erratic operation, etc.

Other service centers have both cheaper and DIY kits for Playstation repair. For example, Video Specialties advertises a $45 flat rate and also sell a repair kit they say will handle loading, skipping, and other optical pickup problems. I have no idea of its price or whether these claims are accurate.

There is an excellent comprehensive PSX repair site at:

- Modstation PSX Repair/Adjustment Instructions

The repair page includes many diagrams and photographs to guide you through the diagnostic, adjustment, and replacement procedures. There are links to much other useful information.

The following appears to be a sort of a mirror site for the above:

- Game Junkez

Some PSX info including specifications, circuit description, photos, and block diagrams at:

- SONY Playstation's Inside Unveiled

Playstation appears dead

(From: Jerry Jessop (jjessop1@home.com).)

Quick test for symptoms of no power:

With the Playstation top cover off and no CD installed press down on the door switch. What should happen is the CD will not spin, but the laser pickup should move up and down attempting to focus on a CD.

WARNING: Laser is exposed - don't stare into it! See the section: SAFETY. --- Sam.

If the above does not happen the following problems may exist, in order of probability:

1. Door switch broken
2. No 8 VDC to CD, usually a blown ICP "fuse" on the motherboard, or bad power supply.
3. CD controller toasted (bad)

PSX controller unreponssive

(From: Jerry Jessop (jjessop1@home.com).)

For no response from controller problems:

The controller port ICP (integrated circuit protector) is blown and you are not getting 3.3 VDC to the controller ports. Check for continuity on each ICP, they are near the front of the PCB just below the CD ROM ribbon cable. They will have a 15, 20, 50 etc labeled on each. The one labeled as 15 is blown :). It is an 800 ma fuse.

BEWARE of non-Sony approved peripherals as they blow these fuses, especially non-Sony mem cards inserted with the power on.

General problems reading PSX discs

> "I have a Sony Playstation, it starts up OK as in power-up etc. But, insert a disk and it does not seem to want to read the TOC. The disc spins up to speed and the laser goes through the motions of focusing, but then zilch, nada, no-zinks! Funny thing is it seems to play audio disks correctly, but not Playstation game disks"

Of course, first clean the problem discs and lens. See the relevant portions of this document for instructions and other general troubleshooting tips. All the usual problems of normal CD players and CDROM drives apply.

Note that in general, it may be possible to play music discs with few or no problems and still not be able to reliably play games (or as applied to CDROM drives, reliably access data). Readout of programs and data must be totally error free while errors can be tolerated for audio tracks with little or no detectable degradation in sound quality. Another reason is that audio is always read at the 1X rate; the system may be more tolerant of a marginal disc or servo alignment at the 1X compared to 2X or higher rate.

Some of these problems may actually be a result of poor design due to extreme and unacceptable cost cutting on Sony's part. After all, the Playstation reader is essentially the same as a 2X CDROM drive - which should be mature technology by now!

(From: Rusty Burke (rustyb@maritronix.com).)

A common problem on Playstations is the lens 'sled positioning' assembly. The lubricant that they used on this gets 'a little' solid.

Solution: remove old lube (all the way back to the motor worm gear) and use a long-lasting lubricant. I use a mixture of tri-flow and graphite grease. This seems to cure the problem.

Apparently what happens is that the CPU requests a read of a certain sector of the CD, and the sled can't get the lens to the proper location quickly enough.

(From: (mj1129@aol.com).)

A lot of Sony Playstation had this problem. Sony knows this problem, and they suggest to adjust the optic laser power to 1 V p-p (at the RF test point) or change the optic.

CAUTION: adjusting laser power is always a risky operation. Replacing the optical pickup may not be a realistic option as Sony probably charges more for the replacement part than for an entire Playstation! --- sam.

(From: Malik Dad (psxpic@goliath.mersinet.co.uk).)

Check the focus bias adjustment. These machines are really very finicky when it comes to laser alignment.

There are many machines out there with similar problems to yours. This is usually caused by a laser servo that has been badly set up. The symptoms are jumping and/or skipping on the FMV (full motion video) intro sequences and jumping and/or skipping on the music. In the worst case, certain gold (CD-R) discs will not boot. The pits on CD-R are never as well defined as a pressed disk resulting in around a 1/4 to 1/2 volt reduction in the RF eye pattern.

The problem can generally be cured by carefully adjusting the bias control on the main board near the laser ribbon connector. turn this a little bit clockwise or counter-clockwise until you have decent results. when you are happy leave it alone. It can be tempting to keep adjusting for different disks trying to get it spot on. There are not many machines that will play every single gold disk perfectly. Most will skip and jump occasionally no matter how carefully they are tweeked. DO NOT touch any other adjustments!

See: http://www.gpl.net/paulmax/psx for more info on Playstation modifications.

Not sure of which of the following it more appropriate. Just make sure you mark the original positions of the pots --- sam.

(From: Mike Walker (vdospec@werewolf.net).)

Caution: for the following, I would avoid touching the pot on the pickup itself unless you have exhausted all other possibilities - this is laser power and can easily result in a ruined laser --- sam.

Sony will not give out any procedure, we have done it before many times...

As far as the beam, the adjustment is on the CD sled itself right by the eye.

The gain is located on the main board listed as gain, don't mess with the bias adjustment, try moving the gain about 1/8 inch or less clockwise, then check the play of your CD's, most of the time this takes care of the problem, if not try moving the beam focus about the same and same direction. Not to much on either it's been known you can burn out the laser.

We like to mark our original postion with a red marker pen, you can lose where you were and really goof it up.

Use ESD precautions, the laser is sentitive to static also.

Also, try and replace the grease on the gear drive also, we have found that this helps a great deal also. Remove old, use new lubriplate or similar.

(From: Jerry Jessop (jjessop1@home.com).)

You have it backwards, adjust the Bias and leave the gain alone. If you set the bias level on wiper of the Pot to around 1.60 vdc with a CD loading that is "generally" a good figure. Now adjust the gain during an FMV sequence until it stops reading at one extreme. Then the other, and set it in the middle. Regrease the rails using "LaBelle 106" a white grease with teflon designed for plastic components found in hobby stores.

Of course more than likely the optical sled has groves worn in it and now the laser azimuth is out of alignment. The only solution is to replace the entire pickup assembly. MCM claims to be getting a new shipment of Playstation optical pickups soon - their price is $39.95 (as of November, 1997).

(From: Cyberchaos (cyberchaos@aol.com).)

All earlier productions of the playstation utilized a plastic sled rail construction which collapses and causes this problem. These must be replaced with the upgraded steel versions. Cleaning is a very short term cure.

Bouncing picture on some (Zenith) TVs when using Playstation

The problem of a shaking picture on some TVs (notably, Zenith models) is due to a problem in the PlayStation sync generation, not really a TV failure.

(From: Jerry Jessop (jjessop1@home.com).)

PlayStations will sometimes slowly "bounce" on older Zenith chassis sets, this is due to the way the vertical sync is outputted on the PlayStation.

Call the PlayStation 'hotline' and explain the problem, it is well known and the system will be modified at no charge to you and you will get a free game for your trouble!

A small daughter board will be installed that will correct the problem.

Testing of Optical Pickup Assemblies

Introduction

Identifying front-end problems in CD players, CDROM drives, laserdisc players, and other optical drives is often thought to be a mysterious and difficult task. This section describes basic techniques confirming functionality of the laser diode, focus voice coil actuator, tracking voice coil actuator, and photodiode array. No exotic test equipment is required.

It is strongly recommended that you read and become familiar with the other information in this document. For general optical pickup information, see the section: CD optical pickup operating principles. For a description of some common types, see the section: Sony KSS series optical pickups.

Don't immediately conclude that your problem is in the optical pickup. It is likely elsewhere and you will not need to undertake the testing described below.

If the unit is able to read the disc directory, if even erratically, then these tests are unnecessary (unless you suspect an intermittent in one of these subsystems) as all of major parts of the laser pickup assembly must be properly functioning in order to do this. However, this does not guarantee that there are not some marginal components such as a weak laser diode or shorted turns in the focus or tracking coil - more on these problems later.

Don't ignore the trivial: have you cleaned the lens? Sometimes a dirty lens will result in symptoms that may be mistaken for much more serious problems.

For intermittents, first carefully inspect the pickup assembly for bad solder connections and hairline cracks in the flexible printed cables. Interlock switches may be dirty or worn. Mechanical problems may result in intermittent behavior as well.

When and why to test the pickup

If you have examined the 'RF Test Point' with a scope and found a proper 'eye pattern', then as noted, these tests are not needed as this indicates proper functioning of all the major components of the optical pickup. If, however, any of the following are observed, then testing of the laser diode, focus and tracking actuators, and/or photodiode array is suggested:

- The startup sequence does not complete due to obvious failure of the pickup to perform some action. For example, there is no attempt to focus.
- Focus appears to be established but the directory is never displayed even though the disc spins at the correct speed - or overspeeds or does not spin in correct direction (clockwise as viewed from the label side is correct for CDs).
- The 'eye pattern' is weak, distorted, or missing at the RF test point.

Try to eliminate alternative causes before undertaking these tests as there is a slight chance of damage due to accidents or electrostatic discharge.

Will it be worth the time and effort? Only you can decide how much your time is worth. There is a good chance that these tests will only confirm that the pickup is dead - not many of the faults you will be able to locate have easy fixes. You will learn something if that matters. However, with the cost of new single disc CD players less than $70 and changers less than $100, any rational analysis of the expected value for this undertaking may recommend the dumpster. But, we all know that hobbiest's time is not worth much - as in free.

The descriptions below assume that the pickup is still installed in the player but selected portions are disconnected when required. This enables us to conveniently use the circuitry of the player to control certain functions for the 'live' laser diode and photodiode tests.

It is also possible to test the pickup stand-alone but this will require an alternative power supply to drive the laser diode. Since the microcontroller will not be imposing its own will on those parts of the pickup still connected to the player, this may be preferable. However, if you are uncomfortable in providing a substitute power supply for the laser diode, then leave that function to the player.

Caution: whenever applying external power to any component, totally disconnect it (by unpluging or unsoldering - label each wire if there is any ambiguity) to prevent damage to the circuitry on the logic board.

Required tools, documentation, and test equipment

Only a minimum of tools and test equipment are required for these testing techniques to be effective. An oscilloscope is desirable but a VOM or DMM can substitute in a pinch since no high frequency measurements are needed. However, we will assume a scope is available. This section does not address mechanical problems in the sled drive, or the drawer or spindle motors. These problems are adequately handled in the elsewhere in this document. It is assumed that these components have been verified to be functional as there correct operation may be required for some of the tests described below.

A schematic will help greatly if available. Depending on the design of the unit, you may be able to infer enough about the front-end electronics to get away without one. The design of the components of the optical pickup are sufficiently similar among manufacturers to make the tests relatively model independent. What may differ are polarities of photodiodes, laser diodes, connector pinouts, etc. These can usually be determined fairly easily.

Despite the incredible precision of the focus and tracking servos, we can perform meaningful tests without sophisticated or specialized test equipment.

Also see the sections: "Troubleshooting tips" and "Test equipment".

The following tools and test equipment will be required:

1. Basic hand tools including precision jeweler's screwdrivers.

2. A VOM or DMM.

3. An oscilloscope (for photodiode/RF tests). For most of the tests, almost any scope will do as long as it has a DC coupled vertical amp. As noted above, a scope is not essential but is highly desirable.

4. A 0 to 5 volt variable DC power supply (400 mA). The power supply can be a 4-5 V 'wall wart' with a Variac. Alternatively (but not as desirable), you can use a fixed 5 V supply with a series adjustable resistor (100 ohms for focus and tracking actuator testing, 250 ohms for laser diode testing). A highly regulated supply is not needed.

5. Resistors: 22 ohm 1W, 5 ohm 1W, 50 ohm, 1 M ohm.

6. Assorted test clip leads, a few feet of #24 solid hookup wire (RS232 quad or multiconductor phone cable is good source).

7. IR detector circuit, IR detector card, or IR sensitive camcorder (for laser diode tests).

8. (Optional) Slow speed sweep or function generator (1-10 Hz) with low impedance output or amplifier, see text.

For the following discussions, a component CD player is assumed to be the unit under test. Make appropriate adjustments in interpretation if it is a portable CD player, CDROM drive, or optical drive.

Precautions

Reread the section: SAFETY for your own protection.

To minimize the chances of damage to the laser diode - which is extremely sensitive to static and excess current - leave its connector plugged into the main board as much as possible and do not attempt to test the laser diode with a VOM (which on the low ohms scale may exceed the current rating of the laser diode - poof, even if only for a microsecond.

As with all modern solid state equipment, preventing electrostatic discharges to sensitive components is critical. An antistatic wrist strap is desirable. In any case, work in an area where static is minimized - not on a carpet prone to static. Make it a habit to touch the metal chassis first to discharge yourself.

Basic description of optical pickup

Also see the more detailed description (including a diagram) of the typical optical pickup components and operation found in the section: CD optical pickup operating principles.

In order for information or music to be read off of a CD, several systems must work closely together:

1. Laser must be emitting a coherent beam of sufficient power and stability. Optical system must be clean and properly aligned. Laser power is maintained constant via an optical feedback loop controlling laser diode current. Therefore, a weak laser may not be salvageable as the feedback loop may have done all that is possible.

2. Photodiode sensors must be functioning correctly for data recovery and focus and tracking feedback. In a 'three-beam pickup', there are six segments: the central segments A-D are used for focus and data recovery; the outer segments E and F are used for tracking feedback. In a 'single-beam pickup' segments E and F are omitted.

3. Lens must be focused to within a fraction of a um of optimal to produce a diffraction limited spot. This is less than 2 um in diameter at the disc 'pits'. The lens is actually positioned several mm from the disc surface and is maintained at the correct distance through optical feedback controlling the lens position using the focus coil. Note: um = micrometer = 10E-6 meter; mm = millimeter = 10E-3 meter. 1 meter is 39.37 inches.

4. Lens must align to within a fraction of a um of the center of the track. Tracks on a CD are spaced 1.6 um apart. Tracking is maintained via optical feedback controlling the radial lens position using the tracking coil (or radial positioning unit on some rotary positioners).

Note that if the behavior while the CD player is attempting to read the directory changes whether a disc is in place or not, (and there is no separate disc sensor), then some or all of these components are functioning correctly. For example, many CD players will not attempt to rotate the spindle until proper focus has been established. Thus, if the CD rotates when in place but the bare spindle does not, it is likely - though not guaranteed - that focus is being established successfully.

Identifying connections to the optical pickup

In order to perform many of the tests described below, you will have to locate the drive and/or signal connections to the optical pickup. While there are many variations on the construction of optical pickups even from the same manufacturer, they all need to perform the same functions so the internal components are usually quite similar.

Here is the connection diagram for a typical Sony pickup:

```
              R1                  +---|<|----o A   |            +----o F+
           +-/\/\---o VR          |      PDA       |           (
      PD1  |   |                  +---|<|----o B   |           (    Focus
  +---|<|--+---+----o PD (sense)  |      PDB        > Focus/   (    coil
  |                               +---|<|----o C   |  data     (
  |   LD1                         |      PDC       |            +----o F-
  +---|<|--+--------o LD (drive)  +---|<|----o D  _|
  |       _|_                     |      PDD      _             +----o T+
  |       --- C1                  +---|<|----o E   |           (
  |        |                      |      PDE        > Tracking (  Tracking
  +--------+--------o G (common)  +---|<|----o F  _|           (    coil
                                  |      PDF                   (
   Laser diode assembly           |                             +----o T-
                                  +----------o K (Bias+)
   (includes LD/PD and                                        Focus/tracking
    flex cable with C, R).       Photodiode chip                actuators
```

The laser diode assembly and photodiode chip connections are typically all on a single flex cable with 10 to 12 conductors. The actuator connections may also be included or on a separate 4 conductor flex cable. The signals may be identified on the circuit board to which they attach with designations similar to those shown above. The signals A,C and B,D are usually shorted together near the connector as they are always used in pairs. The laser current test point, if present, will be near the connections for the laser diode assembly.

It is usually possible to identify most of these connections with a strong light and magnifying glass - an patience - by tracing back from the components on the optical block. The locations of the laser diode assembly and photodiode array chip are usually easily identified. Some regulation and/or protection components may also be present.

Note: There are often a pair of solder pads on two adjacent traces. These can be shorted with a glob of solder (use a grounded soldering iron!) which will protect the laser diode from ESD or other damage during handling and testing. This added precaution probably isn't needed but will not hurt. If these pads are shorted, then there is little risk of damaging the laser diode and a multimeter (but do not use a VOM on the X1 ohms range if it has one) can be safely used to identify component connections and polarity.

Testing the laser diode while in the player

Without a laser power meter, it will be difficult to fully verify laser functionality. However, determining that IR is emitted will provide a reasonable assurance of laser operation.

For this test you will need an IR detector. A simple circuit is described in the section: IR detector circuit. This unit is also useful for testing of remote controls and other IR emitters. You can also use an IR detector card - available at an electronics distributor. In a pinch, CCD based camcorders are often sensitive to IR. It will appear as a bright spot if the laser beam is projected onto a white paper screen. However, you will probably need 3 or 4 arms to position the screen, push the play button, and hold the camcorder while attempting to view the detected spot through the viewfinder!

You will need to gain access to the lens. This may require the removal of the clamper assembly.

Once this is accomplished prepare to position the photodiode of the IR tester within 1/8" of the lens. Plug the unit in and turn it on. On portables, you will need to defeat the door interlock - use a toothpick or bit of cardboard. Sometimes a CD player will have a disc detect sensor separate from the laser assembly - this will need to be defeated in order for this test to work without a CD in place. If it is a simple optical sensor, a piece of black tape or paper should suffice.

The first thing that should happen once a CD is in place and the play button is pressed is for the laser to be powered. You should be able to detect this in a darkened room because there is usually a very faint red appearing emission which you can see as a tiny red dot of light if you look at the lens from a safe distance of at least 6 inches at an oblique angle (WARNING: Do not look directly into the lens from directly above or from very close as the invisible IR is much stronger than the faint red emission and potentially hazardous). If you see the faint red light, you know that at least power is being applied to the laser diode.

With the laser lit, the lens should go through a few focus search cycles - between 2 and 8 typically. While it is doing this, position the IR detector above the lens. If the laser is working, you will get a positive indication of IR in about a 30 degree cone on either side of the lens. While you have no way of knowing if the power output is correct, this is a reasonable indication of laser operation. Due to the wide angle of the beam, the power decreases rapidly with distance so you will need to be very close to the lens for a positive result.

Note that if the lens moves smoothly in at least one direction (up or down), you have also confirmed that the focus actuator is functional.

If the IR detector does not pick up a beam and you do not see the red dot, then either the laser diode is really dead or there is no power being applied by the control circuits.

At this point, you have four options:

1. You can give up. However, you would not have gotten this far if you were likely to be defeated so easily.

2. You can attempt to obtain a schematic if you do not already have one so that you will be able to test the control circuits to determine if the laser diode is being powered.

3. You can attempt to trace the laser power circuits in the hope that you will find something absolutely obvious that is amiss - a bad connection or open resistor, for example, resulting in no power to the laser diode. See the section: Electrical testing to see if laser diode is being powered.

4. You can perform some simple but risky tests on the laser diode itself in an attempt to light it from an external power supply. As noted below, laser diodes are easily destroyed and you will have no warning. One nanosecond it will be a laser - the next it might be a DED - Dark Emitting Diode. See the section: Testing the laser diode with an external power supply.

Electrical testing to see if laser diode is being powered

Where there is absolutely no indication of an IR emission or that tiny red dot of light, but the lens is moving up and down attempting to focus, the next step is to determine if the laser diode is being powered - or is totally dead.

- If you have a service manual, follow the instructions in there for checking the laser diode - usually a place to check laser diode current by measuring a voltage drop across a sense resistor or other testpoint.

    - If the reading is very low or 0, there is likely a fault in the driver or optical feedback circuitry.

    - If the reading is very high, the laser diode is likely bad and the driver is unable to compensate for low or no emission.

- Without a service manual, look for a testpoint labeled 'laser power'. Even if you don't know what a correct reading should be, anything other than 0 would be a good indication that the driver is being enabled.

- Where you have no service info, it may be possible to *carefully* measure across the laser diode with a multimeter to determine if there is any voltage there when it is supposed to be active. A normal reading would be 2 to 3 V.

  - For Sony and other similar pickups, there is a chip capacitor across the laser diode. The trick is in being able to attach meter probes to these points without destroying everything!

  - The flex cable may also have a pair of solder pads. It should be possible to attach fine wires to these for your multimeter. But, you must use a fine point - preferably grounded and temperature controlled - soldering iron to prevent damage.

  WARNING: Improper testing of the laser diode can damage it but a DMM with ESD precautions can probably be used. Make all connections with power OFF as the momentary glitch from attaching the probes and/or an accidental short circuit can easily toast the laser diode and other parts.

Testing the laser diode with an external power supply

Consider the following only if there is no indication of laser output while connected to the player and you do not have schematics or a service manual to determine if the laser power circuits are functional.

Typical currents are in the 30-100 mA range at 1.7-2.5 V. However, the power curve is extremely non-linear. There is a lasing threshold below which there will be no output. For a diode rated at a threshold of 30 mA, the maximum operating current may be as low as 40 mA. A sensing photodiode is built into the same case as the laser diode to regulate beam power. It is critical to the life of the laser diode that under no circumstances is the safe current exceeded even for a microsecond!

Laser diodes are also extremely sensitive to electrostatic discharge, so use appropriate precautions. Also, do not try to test them with a VOM which could on the low ohms scale exceed their safe current rating. Even connecting the test leads can blow the laser diode from static on a bad day. In addition, always make or break power or test connections with the player turned off.

Locate the laser power connector by tracing back from the three pins on the laser diode assembly. Note: the following only applies if the laser diode is directly connected to the cable. If the power regulating circuit is on the pickup, you will need to trace its circuit or obtain the schematic as there are now too many variations to recommend a specific procedure.

Use the 0 to 5 VDC linear supply (a switching supply may put out laser diode destroying pulses) with a 50 ohm resistor in series with the diode. This is preferred over the variable resistor power supply as there is less likelihood of any potentially laser destroying overshoot or noise. If you do use the variable resistor, make sure it is at its maximum resistance when you start and that this is sufficient to keep the current under 20 mA. Keep in mind that a wall wart rated at 5 V may actually put out 8 V or more when unloaded - check the current into a short circuit before connecting the laser diode.

Slowly bring the current up until you get a beam. Use an IR detector for this! If you get the polarity backwards or are actually measuring across the internal photodiode, the voltage across the diode will go above 3 volts or will be less than 1 V. Then, turn power off and reverse the leads. Note: some laser diodes will be destroyed by reverse voltage greater than 3 V - a spec sheet will list the reverse voltage rating. The ones I have tried out of CD players were fine to at least 5 V in the reverse direction.

Without a laser power meter, however, you will have no way of knowing when the limit on safe beam power (safe for the laser diode, that is) is reached. For this test, increase the current only until you get an indication on the IR detector or you see the red dot. You are not trying to measure power, just to see if it works at all. A typical threshold is around 30 mA. Sometimes, the operating current is marked on the pickup. If this is the case, do not exceed this current.

If you detect a beam and there was none before, then your problem is most likely located in the player's control or power circuits, not in the pickup.

Laser power adjustment

If you have the service manual and it provides a procedure not requiring a laser power meter (which you probably do not have), then by all means follow that procedure.

As noted elsewhere, it is possible to destroy the laser diode by attempting to adjust its output power. However, if you suspect a weak laser as indicated by noisy playback or poor tracking performance (not a dead one as this will not help), and have exhausted all other possibilities such as the servo adjustments - and feel you have nothing to lose, you may attempt one of the procedures described below (with some risk) to determine if the laser diode is at fault.

Note that what adjusting laser power is probably doing isn't compensating for a decrease in laser diode intensity, but rather a buildup of dust and other junk on the optics (possibly internal and inaccessible) which reduces the beam intensity at the CD and the return beam intensity even more. There is a subtle difference as the optical output of the laser diode itself is feedback controlled and shouldn't drift much and the result of an adjustment will be an increase in laser output power beyond its normal range - which may indeed shorten its life substantially. If the laser output power HAS actually decreased, there is probably nothing that can be done as the feedback circuit is maxed out and the adjustment will have little effect. Thus, make sure the optics are as clean as possible before you touch laser power!

The following requires that you can play a disc - even if it has some problems with noise or tracking. This is best done with an oscilloscope. However, if you do not have one, you can still try the procedure. The risk is that without a visual indication of the signal amplitude, you will turn the control too far before you realize it and destroy the laser diode.

- If you have an oscilloscope, put a probe on the RF test point. While the disc is playing, you should see the eye pattern. Mark the exact amplitude of the peaks. Also, note the 'playback quality' so you will recognize if it changes. Note: while the correct voltage for the eye pattern is not the same in all players, typical values are in the 1 to 2 V range. If you see a few hundred mV or less, there is likely a problem. Caution: a weak eye pattern can also be due to improper focus bias adjustment (check it) or an electronic problem. The laser power may be normal.

  It may be safer to turn the laser power adjustment with player power off to avoid the possibility of electrical noise causing current spikes. Your choice. Mark the exact position of the laser power adjustment so you can get back to it if there is no effect or it makes things worse.

  Turn the control the slightest amount clockwise. Caution: this control may be very sensistive - 'slightest' really does mean just a very small amount. Turn power back on and/or note the eye pattern amplitude. If the laser diode is not at the limit of its power and thus bad, you should see the amplitude change from what it was. If it has decreased, try the other direction.

  Note the playback quality. Has it changed any? If not, then laser power is probably not your problem. If the amplitude of the eye pattern is unchanged, you either are turning the wrong control or the laser is at its power limit - and probably near the end of its life. Try the same test in the counterclockwise direction if the amplitude decreased - not every designer knows left from right.

  If there is improvement, you can risk leaving the control at the new (most likely) higher power setting realizing that you may be shortening the ultimate life of the laser diode. Do not push your luck by continuing to turn up the power unless you have exhausted all other alternatives.

- If you do not have an oscilloscope. you can still attempt the procedure above, using audio listening exclusively to determine if there is any change. It is just a little bit riskier. As noted, the laser power adjustment may be very sensitive you will have no direct way of knowing how much you have increased the setting.

Testing the focus and tracking actuators

If there is a question of whether the lens is focusing or tracking properly, perform the following. Again, if the unit is able to read the disc directory at all, then these tests are not needed. Note that if you have a CD player with a rotary positioner, there may be no separate tracking coil as coarse and fine tracking may be combined.

Typical linkages between the lens/coil assembly and the body of the pickup are (1) a sliding shaft (focus) and rotation on the shaft (tracking) or (2) a hinged-hinge. With (1), the slide can get gummed up preventing reliable focus and tracking. With (2), one or both hinges can break - they are often made of thin flexible plastic. Repair is not really possible.

First, identify the cable leading to the focus and tracking voice coil mechanism. This is usually a 4 conductor cable separate from the data and laser cable (at least at the pickup end). Disconnect it from the mainboard before testing. Using a DMM or VOM, you should be able to locate a pair of coils with very low resistance - a few ohms. One of these is focus coil and the other is the tracking coil.

Construct one of the following test circuits:

1. Your 4-5 V DC wall wart plugged into a Variac with its output connected to a 22 ohm 1W resistor in series with a pair of 2 foot #24 insulated wires.

2. Your 5 V DC power supply connected in series with the 100 ohm variable resistor and 22 ohm 1W resistor with a pair of 2 foot #24 insulated wires.

Gain access to the lens for visual inspection. This may mean ejecting a disc, opening the drawer, or in some cases, actually removing the clamper. In a portable or boombox, the lens will be readily accessible. Unplug the CD player from the wall or remove the batteries - you will not be using its internal power.

Locate one pair of the two pairs of low resistance connections you identified above. With your power supply off or the Variac turned all the way down, connect the #24 leads to one of these pairs. Now, turn on the power and slowly adjust the Variac or reostat while watching the lens. If you are connected to the focus coil, you may see the lens moving up and down. If you are connected to tracking coil, you may see it moving from side to side.

If there is no motion, turn off the power supply, reverse the polarity and try again. For a typical pickup, the 4-5 V power supply and minimum of 22 ohms should cause the lens to move through the entire range of motion up and down or side to side as appropriate. Once you have exercised the first coil, switch connections and repeat for the other. If the motion is jerky, the lens assembly may be dirty.

Clean it carefully first with a bit of compressed air (not high pressure, a photographic air bulb is fine) and then with Q-tips and isopropyl alcohol. Do not lubricate. Repeat the tests after the cleaning.

If both the tests are positive, you have confirmed operation of the focus and tracking actuators. If either you were unable to locate both pairs of coils or one or both actuators did not move, then you have located a problem. An open coil can be due to a cable problem or a break at the coil. If the break is right at the solder connections which are usually visible once the plastic protective shroud is popped off, then it may be possible to repair it. This will require a great deal of manual dexterity and patience - the wire is really really fine.

It is still possible for there to be shorted turns in the fine coils or an intermittent that was not detected.

- Shorted turns would reduce the frequency response of the servo, reduce the reliability of focus or tracking, and increase the needed servo driver power. A CD player that is overly sensitive to slight disc defects even after all the proper adjustments have been performed may conceivably be a result of this type of fault. An additional symptom may be an unusually hot servo driver IC. However, many of these ICs run hot normally so don't panic as the possibility of shorted turns is really quite remote.

- An intermittent may only show up during dynamic operation or with certain particularly finicky CDs or other peculiar circumstances. The intermittent could be at the solder connections or the fine printed ribbon cable that connects the moving lens assembly to the remainder of the pickup.

Testing the photodiode array

The photodiode array in a optical pickup consists of an IC with typically 4 or 6 detector segments. Four segments may be used for the less common 'single-beam pickup' while 6 segments are used in the 'three-beam pickup'.

These segments are usually designated A-F. A, B, C, and D are the main detector which is used for both focusing and data recovery. Segments E and F are used in a 'three-beam pickup' for fine tracking feedback.

We will assume a three-beam pickup for the remainder of this discussion.

All 6 photodiodes are connected to a common point which during operation has a DC bias voltage on it typically around 5 V. If they are connected common anode, it will be negative; if common cathode, it will be positive. The reason is that the photodiodes need to be reverse biased for normal operation. The outputs of the photodiodes feed several operational amplifiers which are set up to amplify the current from the photodiodes. The normal connections may be at virtual ground potential or they may feed into large value resistors.

The connector to the photodiode array is usually separate and will typically have at least 8 wires - photodiodes A-F, ground, and bias voltage.

You will need to identify the wiring. First locate the ground using the ohmmeter. Then locate the bias - it will probably go to a low value resistor and then to the supply. Another way to identify the bias wire is to turn on the player and measure each of the possibilities. The bias will be the highest or lowest and will be solid with no noise or ripple. It will probably be powered all the time.

Now for the photodiode segments. Very often the connections or some of the connections are marked on the circuit board. For example, there may be several labeled test points designated A+C, B+D, E, and F. Since the A and C segments and B and D segments are usually shorted together on the circuit board, this provided all the info needed to identify the photodiode connections. It is not important to distinguish between A and C or B and D for the following tests though you will want to be able to separate them.

With power off, there is essentially no light on the photodiode array. Unplug the photodiode connector from the main board.

Using your ohmmeter, test each diode for opens and shorts as you would test any signal diode. There should be a junction drop in the forward direction and very high resistance in the reverse direction. If you are using a DMM with a diode test mode, the junction drop will typically measure .7-.8 V. There may be a very slight difference between the readings for segments A to D and those for E and F.

An initial test of photodiode response can be made using an external light source - a flashlight or other incandescent bulb or IR remote control shining into the lens from directly above. With the multimeter connected to reverse bias each diode segment, shine the light into the lens. The resistance reading should drop somewhat - possibly dramatically. Segments A to D should show reasonably similar sensitivities but these may differ from segments E and F (which should be similar to each other).

Similarly, with with the photodiode connections restored to normal, you can use an oscilloscope to monitor the RF test point. A source of IR directed into the lens from above may result in a detectable change in the signal - but only when the photodiode array is properly biased. This may be all the time that the CD player is turned on or only when it is trying to focus or perform some other operation. With an IR remote, you should actually see the pulsed signal for each key-code. On a typical Sony CD player, I was able to get about a 0.1 V signal at the RF test point using a VCR remote control as an IR source.

However, even on a functional pickup, due to the nature of the optics, these responses may be very weak or undetectable. Thus, failure of either of the above tests is not strong evidence of a bad photodiode array.

Any unusual readings such as a significantly lower resistance for one of the diodes, a short or open of a particular diode, a short between diodes, or variations in sensitivities is an indication of a problem. While it is possible for there to be a cable or soldering defect, this is somewhat unlikely though bad solder connections or breaks in the flexible cables are not out of the question.

A defect found in the photodiode array will usually mean that the laser pickup is not salvageable with reasonable effort. Even if you could locate a replacement photodiode array, aligning and soldering the (most common) surface mount package would be quite a challenge without the factory jigs.

Assuming these tests do not turn up anything, the next step will verify that the photodiodes are picking up an optical signal and will evaluate the relative strengths of each segment using the laser diode, optical system, and disc combination. Note that for these tests to confirm proper operation, the optical alignment must also be correct.

For the tests using the internal laser diode, we will need to setup one of the following. Method (2) is more straightforward but requires the optional signal generator for best results. In each case the objective is to cause the lens-disc distance to sweep through perfect focus without requiring that the focus servo loop be closed. This will then result in a signal that will include the point of maximum signal amplitude on a periodic basis. Alternative methods may be used to accomplish the same purpose.

Both techniques require the adjustable power supply previously used to test the focus coil.

1. Adjustable focus with continuously rotating spindle. For the spindle motor, you will need a 1.5 V battery or your power supply with a suitable series resistor to cause the spindle to turn at approximately 1-2 Hz (rps). Warning: disconnect the motor from the mainboard! The unavoidable wobble of any disc is essential in this case and will sweep the focus distance by more than enough to cover the entire focus range of interest.

Note: this assumes that the spindle is driven by a conventional PM DC motor. If it is a brushless DC motor, then some of the control electronics may be external to the motor and you will not be able to just provide a DC voltage to get it to rotate. If this is the case, you must use method #2.

2. Stationary spindle but sweeping focus. This is the better method but requires a signal generator for easiest use. You can do this by hand using a Variac or reostat (this is easier if you have three functioning hands). A better method is to use a 1-10 Hz sinusoid or triangle wave from a low frequency signal generator with a low impedance output or feeding an emitter follower or audio amplifier to boost the current. This signal is then fed into the coil along with the focus offset derived from your power supply.

Note: it may be possible to dispense with these test setups and just use the normal focus search of the CD player to provide the sweep. However, since we will be interfering with the proper feedback by removing selected sensors, there is no telling what the microcontroller will do. Therefore, breaking the feedback loop as we are doing is preferred. If the CD player appears to make many attempts at focus, this may be worth a shot, however.

You will also need a disc - preferably one you do not care much about as sometimes it will get scratched due to opening the drawer accidentally or something equally idiotic while the disc is still rotating.

Locate a 1 M ohm resistor and securely fasten it to a ground near the photodiode connector. Put your scope probe on the other end with its ground clipped to the same ground point as the resistor. Bend the free lead of the resistor completely over so that it will be able to hold the end of a wire like a mini-clip lead.

Make sure you remember or mark down exactly how the connector is wired so that as you remove individual wires, you will be able to get them back in the proper spot. Presumably, you have already made a diagram of the photodiode connector wiring. Component players often have connectors with individually removable socket pins. A fine jeweler's screwdriver or paper clip may prove handy in removing these one at a time.

Turn on your power supply and adjust the focus to about midrange. Start the spindle rotating or turn on the signal generator to provide a small sweep - about 1/10 V p-p as measured on the coil should be fine.

Making the photodiode measurements

Remove the wire corresponding to the photodiode (say, A) to be tested from the connector but leave the connector itself plugged into the main board. Set the scope for 1 V/div. vertical on a slow free running sweep.

Clip the A wire into the resistor. Now, turn on power to the CD player. While the player thinks it is focusing, slowly adjust the focus voltage while observing the scope. As you approach proper focus, you will see the signal increase (depending on polarity) greatly, pass through a maximum, and then decrease. Depending on the design of the CD player, you may need to turn it off and on several times before you locate the signal as the microcontroller may give up pretty quickly with no focus or tracking coil servos (since you disconnected the actuators). If you have the service manual it may tell you how to force the laser to be powered all the time. Leave the focus set near the middle of the region of high signal.

If you are using the signal generator to perform the focus sweep, you may need to optimize the amplitude of the signal by adjusting the signal generator output and offset from your power supply.

You probably should not need to touch the settings for the remaining photodiode segment tests.

Repeat the above procedure for each of the photodiodes A-F. All should produce fairly similar signals, say within 20 % of one another in amplitude. If A,B,C,D or E,F differ from one another by more than say, 20 %, there may be a serious optical alignment problem in the pickup (the player may have been dropped or bounced around without securing the hold-down screws, if any). Alternatively, the photodiode array may be bad. It is also possible for there to be partially shorted photodiode segments in which case, the outputs will not be independent as they should be. Loading one segment's output with a resistor may affect the output of one or more other segments.

In any of these situations, such a discrepancy in A-D will prevent the establishment of proper stable lens position at the optimal focal distance. This will prevent the formation of a proper 'eye pattern' and subsequent data recovery. A significant difference between E and F (beyond the adjustment range of the tracking or E-F balance control) will prevent proper tracking. Note, however, that the signal amplitude from A-D and E,F may differ as A-D operate off of the main beam and E,F operate off of the first order diffracted beams which are weaker. As with the basic photodiode tests above, a failure here usually will require the replacement of the entire optical assembly.

As noted, if the pickup's optical alignment is way off, there could be significant differences in photodiode responses. On component type units, it is unlikely that the optical alignment would shift on its own. Portables that have been dropped or automotive units subject to constant bumps and vibration could have alignment problems, however. If this is your last hope, then some experimentation with adjustment of the optical alignment on a successive approximation basis might be worth the effort. Mark the original position of any adjustments and try small variations on either side to determine their effect. You might get lucky. If this eventually results in improved uniformity of photodiode response, alignment may be the problem. If you can more or less equalize the response, reconnect the servos and attempt to get an eye pattern. If you can, optimize the eye pattern stability and amplitude using the optical alignment adjustments and servo adjustments.

Sony KSS series optical pickups

Note: For general information on optical pickups see the section: CD optical pickup operating principles.

These are probably the most common optical pickups in the universe. Many variations - many dozens if not hundreds - on the basic design have been produced from before 1988 until the present. In general, they are compact, simple, robust (despite what you may have heard), and no doubt dirt cheap to manufacture. The ANEX Electronics Sony Pickups Page has photos of just a few of the common KSS models. (ANEX is a Polish company so I'm not advocating buying replacements from them, just thought the photos might be of interest!)

Depending on the type of player and mechanical constraints, the specific optical arrangement and construction will differ. Many brands of CD players and CDROM drives actually use Sony pickups. While these are all recognizable for their octagonal black lens cover and parallelogram type lens suspension for focus and tracking (neither of which has changed noticeably in 10 years), the construction of the fixed optics has gone through quite an evolutionary process:

- Early KSS pickups were quite complex with most of the components described in the section: CD optical pickup operating principles mounted as separate components. These had accessible optical alignment adjustments and were also quite large and bulky compared to today's pickups. An example of one of these is the Sony KSS110C Optical Pickup.

- Most of the KSS pickups found in consumer CD players and older CDROM drives combine some optical elements and eliminate others. For example, types like the very common KSS361A do not have a separate collimating lens or cylindrical lens. All parts are totally glued at the factory so no possible optical alignment adjustments are possible.

  A diagram showing the organization of the Sony KSS361A optical pickup is available in PDF format: CDKSSP.

- The newest KSS series pickups appear to have combined the laser diode and photodiode into a single package. They are offset by a very small distance so the outgoing and return beams pass through the same optics and thus there is no longer a beam splitter - more cost reductions! By eliminating the optical components for redirecting the two beams, performance should also be better since this operation was not 100 percent efficient and additional optical surfaces can only degrade the beam quality. The small reduction in the clarity of the detected analog signal resulting from the very slight non-perpendicular (with respect to the disc 'pits' surface) beams should be more than made up for by these simplifications.

  While I do not yet have a sample of a Sony pickup of this design, the CMKS-81X Optical Pickup and Optical Pickup from Philips PCA80SC CDROM combine the laser diode and photodiode array into single package and eliminate all of the other optical components except the diffraction grating and turning mirror. I expect that Sony versons are similar.

The description below is for pickups similar to the KSS361A and KSS210A. These are horizontally organized and less than 1/2 inch thick. The laser diode, grating, and beam splitter are mounted inside the casting of the optical block. The turning mirror is glued to its base plate, the photodiode array is glued to a port on its side and the objective lens and its focus and tracking actuators are mounted on a self contained removable unit.

Please refer to the closeup views of the Sony KSS361A Optical Pickup.

The following can be seen from the underside after removing a cover plate (1 screw). The descriptions are for the outgoing beam which originates at the laser diode, passes through the diffraction grating, then reflects from the dichroic beam splitter mirror on its way to the objective lens:

- Laser diode. This is clamped and glued in place in a nicely finished brass barrel which is itself clamped and glued in place in the optical block. An adjustment for optical power sensitivity, is mounted on the flex cable next to the laser diode. This may mean that identical model pickups should be interchangeable without laser power adjustments - hopefully. Many players don't have a laser power adjustment pot on the electronics board.

  The front face of the laser diode package is angled so that the exit window (anti-reflection coated) is also mounted at what may be the Brewster angle, probably to further prevent stray reflections from the window's surfaces from feeding back into the laser diode's cavity or interfering with the detected signal. (At the Brewster angle, light polarized parallel to the window is totally reflected and light polarized perpendicular to it is totally transmitted. The output of these edge emitting laser diodes is polarized.)

  The Closeup of Laser Diode from Sony KSS361A Optical Pickup shows the angled front face and optical window. The reason it appears so HUGE is that the photo was scanned at 600 dpi - this is not a monster laser diode! It can be seen more like 'actual size' in the upper left corner of the group photo, A Variety of Small Laser Diodes.

- Diffraction grating. Glued onto the end of the barrel in which the laser diode is mounted. The grating is at a 45 degree angle to produce the 3 spots for tracking in the appropriate orientation. (Once reflected through the lens the spots are in the direction tangential to the tracks).

- Collimating lens. On some versions, there is an actual collimating lens. However, the most common models do not appear to have one. There is nothing really wrong with such a design, it is just unexpected. Their optical efficiency will be lower since some of the beam will be lost to the side walls but other than that, a shorter focal length objective lens should be able to compensate fully for a non-parallel beam. The optical path is so compact in these pickups that the losses are likely to be small. It is also not clear why otherwise very similar model pickups in very similar model CD players differ in this respect.

  A test of the laser diode barrel assembly removed from a KSS361A pickup shows that its output is an ellipsoidal beam with a divergence of at least 10 degrees on the narrow axis (across the grating) and somewhat greater than this in the orthogonal direction. These angles are consistent with a raw laser diode. If there were a collimating lens, the beam should be much less divergent. (My curiosity finally got the better of me and I ripped the laser diode from the barrel to confirm that there was indeed no collimating lens hiding inside!)

- Polarizing dichroic beam splitter mirror. This thick mirror is mounted at a 45 degree angle and glued in place. The outgoing beam is reflected by the mirror toward the turning mirror and/or objective lens.

  The thick mirror also introduces astigmatism into the beam and this is how focusing servo feedback is accomplished. See the section: What happened to the cylindrical lens?.

The outgoing beam reflects off of the turning mirror and then passes through the objective lens:

- Turning mirror (models with horizontally oriented optics only). This is implemented as a coated glass front surface mirror glued to a 45 degree angled support which is in turn glued to the casting. The coating is mostly transparent to visible wavelengths of light - it is not aluminized.

- Lens assembly. This appears to be very similar for all models. Of course, there are probably variations in focal length and other optical properties which cannot be determined by inspection.

  - Objective lens uses a double convex plastic molded design glued into a plastic frame which mounts the focus and tracking coils and is attached to the lens' suspension. Both surfaces are coated and the top surface, at least, is aspheric. A raised guard ring protects the optical surface from damage should the lens come in contact with the spinning disc.

- Focus actuator is a pair of rectangular formed coils surrounding a pair of vertical magnet pole pieces.

- Focus suspension is a parallelogram molded plastic design. This assures that the lens remains parallel to the disc as it moves up and down. The four hinges appear to be just very thin portions of the molded 4 sided box structure. These hinges are susceptible to weakening or failure.

- Tracking actuator is a set of 4 circular coils glued to the outside surfaces of the focus coils and moving with respect to the same magnetic fields.

- Tracking suspension is a single vertical molded hinge of similar design to that of focus. A second vertical hinge is also present but is restricted from free movement by a resilient rubber material. This appears to protect against sideways shocks. These hinges are susceptible to failure.

- The magnets appear to be of a rare-earth type - very strong for their size.

- A short flex cable links the terminals of the coils to 4 solder pads where the flex cable would normally connect from the electronics board.

- Optical alignment is achieved with a 3-point mounting arrangement for the lens assembly. One of 3 screws with a spring clamps the frame. The two other screws are used for adjustment. The entire affair is aligned and then glued in place at the factory so adjustment in the field is virtually impossible - and unneeded in any case.

- The lens assembly can be removed by unsoldering the 4 solder pad flex cable and unscrewing two very small Torx type screws from the top (these will succumb to a roughly .7 mm hex wrench. It then lifts off. Optical alignment should not disturbed.

  Note: Just loosening the Torx screws permits lens assembly to be shifted slightly though some small amount of adhesive may need to be removed to free it. This should have an effect on optical alignment. I will do some experiments at some point to determine its precise effect.

After passing back through the objective lens and reflecting off of the turning mirror, the return beam passes through the dichroic beam splitter mirror and hits the photodiode array.

- Photodetector array. Glued to a plate with the 8 pins (7 connected) poking out the back and soldered to the flex cable. Approximate dimensions of actual sensor area shown.

          v   |       |        |        |     |
         ---- +-------------------------------+
```

These are the 6 segment silicon photodiodes (for a three-beam pickup. (For a single-beam pickup, there will be 4 but as far as I know, all Sony pickups are all 3 beam types). Note that the entire active area is a fraction of a mm in each dimension. This emphasizes the likely critical nature of optical alignment. Nonetheless, with everything screwed and/or glued in place, the likelihood of this ever changing is small.

- Flexible cables. In most cases, there are two - a 12 or so conductor cable for the laser power and photodiode return signals and a 4 conductor cable for the focus and tracking actuator drive. However, there are many many variations on the specific layout. These are either soldered to the electronics board or more commonly, terminate in clamp-type connectors.

What happened to the cylindrical lens?

It would appear that the mystery is solved:

(From: Vlad Chekavinskii (vchek@usa.net).)

Dear Sam! I've just read your greatly updated article on CD repairment and found out that your investigation on SONY KSS pickups is pretty similar with mine (I've spent a half year aligning KSS210A and was successful with it at last), but your uncertainty about where the astigmatic element should be very disappointed me... because I've screwed my head chewing out the same thing! Nonetheless I've come to conclusion that the THICK mirror is thick very intentionally - the astigmatism of flat parallel surface plate turned on a 45 degree angle is a very sizable thing and corresponds with dimensions of ABCD photodiodes.

(From: Sam).

Fabulous! That has to be it. I even just did an experiment with a 1.5 inch think piece of Plexiglas and a lens - the astigmatism was clearly visible and it isn't a subtle effect. The astigmatism of the laser diode may contribute but probably is small compared to the result of passing through the thick beam splitter. I should have wondered why Sony would use extra material if there weren't a good reason! :-)

A possible explanation of my version is the position of ABCD diodes on its chip: they are always tailored to the mirror in different systems with different mirror position: compare SONY and SANYO, so that the A-C (or B-D) line is parallel to corresponding sides of the mirror, at the same time the axes of astigmatic spot of the inclined mirror are also parallel to the mentioned sides. Interesting, that the position of EF can be either on the A-C line or between A-C,B-D lines, that means that diffraction grating molded with laser unit can be so or other way turned in the whole system but I suspect that it is always tailored to wedge beam of laser, so the proposed astigmatism of laser is hardly used.

Interchangeability of Sony KSS pickups

If you have looked inside a variety of CD players, you probably have noticed (1) that many use Sony pickups (the characteristic octagonal black lens cover) and (2) that many of *these* appear similar even if their model numbers differ. A closer examination will reveal that many many different types use what would appear to be the identical optical block - the casting that mounts the lens and its actuators, the laser diode, and photodiode array. If you delve even deeper, you would find that the optical paths are identical as well. The only obvious difference in many cases are in the mounting and the way the sled is driven, and in the configuration of the flex cable and its connections. So, are the optical blocks themselves indeed interchangeable?

The answer is a definite 'maybe' and servo adjustments may be needed in some cases (where none would possibly be necessary with an exact replacement). However, there could be cases where where differences are too great.

I am not sure I believe the differences listed below since much of the pickup behavior in terms of bump immunity and drop-out performance is based in the servo loop electronics, not the pickup. So, while I do not know for sure, my guess is that the A and B versions would be totally interchangeable if the CD player electronics have enough adjustment range.

(From: Lance Edmonds (lanceedmonds@xtra.co.nz).)

Sony KSS150A is compatible with KSS210A and KSS212A. However, due to signal levels KSS210A and KSS210B have differing specs. The rule here is that a KSS210B can be used in place of a KSS210A, but for optimal performance, an A should not be used in place of a B.

- B versions designed for "ghetto-blasters" (lower drop-out performance and higher vibration resistance).

- A versions for desk-top models (higher drop-out performance, lower vibration resistance).

Source of info: Sony Japan Designer who visited me a few years ago. Yes they actually send their technical staff around the world to get an idea of what happens to the products after sale! Not often, but it does happen. Over the years I've met designers, technical managers, technicians, and a load of marketing folks from Japan and Singapore.

Super simple optical pickups

Some of the modern generation designs are about as simple as possible and still perform the needed functions of a single-beam or three-beam optical pickup. While the objective lens assembly with its focus and tracking actuators is of standard construction, there are few additional components.

The CMKS-81X Optical Pickup and Optical Pickup from Philips PCA80SC CDROM are typical of such designs. Sony also manufactures such a pickup, apparently used in some revisions of its PlayStation PSX and elsewhere.

The smallest ones such as the Optical Pickup from the Philips CR-206 CDROM are only about 1/2" x 5/8" x 3/4" overall - just about the size of the lens cover!

A diagram showing the organization of these simplified three-beam optical pickups is available in PDF format: CDS3BP.

This diagram shows the three-beam type. The only difference for a single-beam pickup would be to eliminate the difraction grating (and its side beams) and segments E and F from the photodiode array (or simply not use them).

- The laser diode and photodiode array (LD/PDA) are combined into a single package about the size of a larger LD by itself but with 10 pins - 3 for the LD and its monitor photodiode and 7 for the PDA (a single-beam pickup such as used in Philips/Magnavox products would only need an LD/PDA with 8 pins).

- A glass block or plate roughly 3 mm on a side is glued to the front of this LD/PDA package. In the center is a spot about 1 mm in diameter etched on the surface which is the diffraction grating. This is directly over the emitting facet of the LD. The laser beam passes through this diffraction grating on its way out but the return beam is offset to hit the PDA and misses the spot entirely. (A single-beam pickup would not even require this diffraction grating!) DVD Laser Holographic Optical Element shows a similar HOE glued to the front of a DVD laser diode assembly.

- The LD/PDA is pointed at the objective lens (either directly or via a simple turning mirror depending on design).

  The pickups in the photos use a turning mirror but this is not needed if there is adequate space below deck since the turning mirror's only function is to redirect the beam to minimize physical height.

By placing the LD and PDA very close together, the outgoing and return beams can follow almost the same path forward and in reverse through the optics. This eliminates all parts associated with separating these beams including the polarizer, polarizing beam splitter, and quarter wave plate. There may be a very slight reduction in signal quality since the optical 'stylus' does not strike the disc at a precisely perpendicular angle but this is probably very minimal and more than overcome by the reduction in losses due to the multiple surfaces and less than perfect performance of the redirection optics. Thus, performance is probably better overall, robustness and reliability are improved, and manufacturing cost is greatly reduced. Everyone wins!

   Spindle speed:           200 to 500 rpm (1X, constant linear velocity).
   Linear speed:            1.2 to 1.4 meter/second (1X).
   Modulation:              Eight-to-fourteen modulation, RLL(3,11).
   Error Correction:        Cross Interleave Reed-Solomon Code - CIRC.
   Laser type:              Semiconductor Diode GaAlAs.
   Laser wavelength:        780 nm (most common).
   Laser power:             .1-1 mW. typical (at lens).
   Frequency response:      5 to 20,000 Hz +/- 3 dB.
   Harmonic distortion:     .008 % at 1 kHz.
   Dynamic range:           Greater than 90 dB.
   Signal to noise ratio:   Greater than 85 dB.
   Wow and flutter:         Below measurable limit (as good as crystal).
```

Comparison of CD, DVD, BD Specifications

CD = Compact Disc/k, DVD = Digital Versatile Disc/k, BD = Blu-Ray Disc/k.

```
    Parameter                         CD          DVD          BD
 ------------------------------------------------------------------------
   Disk diameter                    120 mm      120 mm       120 mm
```

Disk thickness	1.2 mm	1.2 mm	1.2 mm
Disk structure	Single substrate	Two bonded 0.6 mm substrates	??? 0.1 mm substrate
Laser wavelength	780 nm	650 nm	405 nm
Numerical aperture	0.45	0.60	0.85
Track pitch	1.6 um	0.74 um	0.32
Minimum pit/land lgth	0.83 um	0.4 um	0.138 um
1X speed (CLV)	1.2 m/sec	4.0 m/sec	
1X data rate (mode 1)	1.2 Mb/sec	11 Mb/sec	36 Mb/sec
(mode 2)			
Number of data layers	One		One or two
Number of sides	One		One or two
Data capacity	~680 MB	4.7 GB (1L) 8.5 GB (2L) 17 GB (2L/2S)	27 GB

The reduced track pitch and pit length made possible by the shorter wavelength and advances in optical readout technology accounts for the almost 8-fold increase in data storage capacity on a single layer.

A down-to-earth comparison of digital and analog recording

Digital solutions to anything are not inherently superior to old style analog approaches. Digital storage and playback can result in truly terrible sound if the underlying technology specifications and implementation are inadequate. However, for storage, there is a fundamental difference which can be expressed in simple terms:

(From: Michael A. Covington (mcovingt@ai.uga.edu).)

The way I explain digital recording to people is this:

- Digital recording is like hiring somebody to type a paper for you, from a typed original. If they hit the same keys you did, there is no loss of fidelity at all. If they make an error, you can find it and correct it.

- Analog recording is like hiring an artist to copy a painting. It is going to come out a little different no matter how good they are.

What is oversampling?

CD audio reads 16 bit samples off of the disc at a rate of 44.1 K samples per second (for each channel). This is the 1X rate. It is possible to produce *perfectly* faithful sound reproduction at 1X. However, digital sampling theory and the Nyquist criterion then require an analog filter which has a flat frequency response in the audio passband - 20 Hz to 20 kHz, and 0 at 22.05 kHz (1/2 the sampling rate) and above. The filter is necessary to remove 'aliasing' artifacts which would produce frequencies in the output not present in the original recording. Such filters are are possible but very difficult to design and tend to have nasty phase response as you get near 20 kHz since the filter response needs to go from 1 to 0 within a very small frequency range (20-22.05 kHz). The phase response may have an effect on stereo imaging and instrument localization. Whether you can hear any of this depends on whether you have 'golden ears' or not.

Enter oversampling. Instead of putting out the original CD samples at 44.1 kHz, digitally interpolate intermediate samples so that the D/A converter can work at 2X, 4X, 8X or more. The digital filters can be designed with very good performance and are part of the VLSI chipset in the CD player. For example, with 4X oversampling, three interpolated samples will be inserted between each original 44.1 kHz sample and the D/A will run at 176.4 kHz. An analog antialiasing filter is still needed at the output but its response only needs to go from 1 to 0 over the range 20 kHz to 88.2 kHz - a much much easier filter to design.

Which will sound better? There is a lot of hype. It may depend more on the quality of either design rather than the basic technique. So many other factors enter into the ultimate listening experience that the difference in in frequency and phase response around 20 kHz can easily be overshadowed by errors introduced throughout the recording process as well as playback considerations such as speaker quality and placement, room acoustics, and listener location.

Most consumer grade CD players now use oversampling. The newest fad is the 1 bit D/A with 256X (or more) oversampling. This is largely cost driven as well: you don't even need a high quality 16 bit D/A anymore. The simplest way of describing this approach is that it is a combination of pulse width modulation and sophisticated interpolation. The net result is audibly the same as all the others.

For more information, see: Aspects of Sampling, Oversampling, Quantisation, Dither, and Noise Shaping, as Applied to Digital Audio by Christopher Hicks.

What is an anti-aliasing filter

Antialiasing filters are needed in a sampled data system (of which digital audio is one example) to guarantee that out-of-band signals do not confuse the digitization process or find their way into the output.

1. Prior to sampling and digitizing, an antialiasing filter is used to cut off all frequencies above Fmax where Fmax is the highest frequency that it is desirable to reproduce. Sampling per Nyquist must be at least at 2*Fmax but making it somewhat higher than this enables the antialiasing filter to be more easily designed.

   For example, CDs reproduce 20 kHz as Fmax and sample at 44.1 Ks/sec. The antialiasing filter must have a response which is substantially flat to 20 kHz and then rolls off to 0 before 22.05 kHz.

   If this is not done, frequencies between 22.05 kHz and 44.1 kHz (as well as any above) will be reflected back in the digitized samples resulting in aliasing noise which is mighty peculiar sounding!

   Thus, the signal flow for input is:

```
Mic or \|  +-----------+  +-------------+  +---------+  +-----+    Digital
other   +->+   Audio   +->+ Antialiasing +->+ Sample/ +->+ A/D +--> proc.,
source /|  | Amplifier |  |    Filter    |  |  Hold   |  +-----+    storage.
           +-----------+  +-------------+  +---------+
```

2. Following the D/A, an antialiasing filter with a similar roll off is used to remove all frequencies above Fmax introduced by the D/A process.

   Thus, the signal flow for output is:

```
                                                                      /
            +-----+  +--------------+  +-----------+    |/
   Digital o-->+ D/A +->+ Antialiasing +->+   Audio   +-->+  Loudspeaker
   Sample      |     |  |    Filter    |  | Amplifier |    |\
            +-----+  +--------------+  +-----------+      \
```

The output antialiasing filter is not for antialiasing in the same sense as the input filter (before digitization) but without it, similar audible effects can take place in subsequent amplification stages which respond in a non-linear fashion to any high frequency (out of band) sample or clock noise that gets through.

3. Oversampling techniques can be used on both input and output to simplify the filter design. Prior to the D/A, additional digital samples are interpolated between the original samples read off of the CD. Thus, the digital samples will typically already be at some multiple of 44.1 kHz. The D/A then runs at a much higher sample (clock) rate decreasing the demands on the analog filer. See the section: What is oversampling?.

How good are the digital filters in digital audio systems?

(From: Winfield Hill (hill@rowland.org).)

The digital filters within a typical CD-sound sampling system are very good indeed.

I'm looking at a few AES papers reprinted in the 1994 Crystal Semiconductor databook (so we're talking "old" technology!), and I see the amazing performance possible with the linear-phase finite-impulse-response (FIR) filters in the delta-sigma A/D chips.

For example, the Crystal CS5328 has a flat response to 22.5kHz and then drops like the proverbial rock to a first -105dB dip at 26kHz. Ditto for the filters in a high-quality D/A like the CS4328.

Also, the in-band frequency response is very good. Passband ripple within +0.00025 and -0.0004dB to 10kHz. Hmmm, deteriorating to -0.0006dB at 17.5kHz. And for the D/A chip, a flat line on the chart (I can't see under 0.01dB) to 20kHz with a slight 0.1 dB rise by 22kHz.

Strike that "very good," insert PERFECT.

The Crystal CS5328 A/D has a very low -105dB distortion with full-scale analog input, and -125dB with -10dB input. That works out to under 0.0005% at full scale and even less for typical signals. The CS4328 D/A is not quite as good, with under -92dB (0.0025%), but I'll not complain! Also, they and others (e.g. Analog Devices) make better parts for the purist.

Instant oversampling theory

(Mostly from: Lasse Langwadt Christensen (fuz@control.auc.dk).)

When you have a signal from a CD sampled at 44.1 kHz, the resulting frequency spectrum looks something like this after the D/A converter:

```
 Amplitude
    |
    |
 ___|______      ___________
```

```
   |     \     /           \
   |      \   /             \
 --+--------+--------+----------> Frequency
   0       Fs/2      Fs             Fs=44.1 kHz
```

After the D/A converter you then need a antialiasing filter to remove the frequencies around the sampling frequency (Fs). That filter has to pass the frequencies you need 0-20 kHz and remove (-96dB) the frequencies above Fs/2 (22.05 kHz). Thats a pretty sharp filter - which is a problem, since it has to be an analog filter.

This is where oversampling come in. If you insert one zero sample in between every real sample, you get a signal looking something like this:

where X = originally sampled values, 0 = inserted zeroes

Note: The analog signal would look like a line connecting the the X's, not ASCII friendly :-).

```
 Amplitude
   |
   |
   X         X
   |         |         X         X
   |         |         |         |
 --+----0----+----0----+----0----+---> Time
   0        1/Fs      2/Fs      3/Fs    Fs=44.1 kHz
```

The sampling frequency has now been increased to 88.2 Khz (2X oversampling) and in frequency it would look something like this:

```
 Amplitude
   |
   |
 __|_____      ___________     ____________
   |     \     /           \   /            \
   |      \   /             \ /              \
 --+--------+--------+----------------+-----------> Frequency
   0       Fs/2      Fs              Fs*2            Fs=44.1 kHz
                                                     new_Fs=88.2 kHz
```

If you now filter that signal with a digital filter (before the D/A), with the same specifications as the previous analog antialising filter, (it is a lot easier doing it digital than analog, you get a signal something like this in frequency:

```
 Amplitude
   |
   |
 __|_____                        ___________
   |     \                      /           \
   |      \                    /             \
```

```
 --+--------+--------+--------+--------+----------> Frequency
   0       Fs/2      Fs               Fs*2             Fs=44.1kHz
```

And in time domain would look something like this:

```
 Amplitude
   |
   |
   X    I    X
   |    |    |    I
   |    |    |    |    X    I    X
   |    |    |    |    |    |    |
 --+----+----+----+----+----+----+---> Time
   0        1/Fs      2/Fs     3/Fs     Fs=44.1kHz
```

As you can see from the signal in the frequency domain, the analog antialiasing does not need to be as sharp as before, it still has to pass the frequencies from 0-22.05 kHz but it only have to remove frequencies above 44.1kHz (the new Fs/2). This is much much easier.

If you look at the signal, in time domain, you can see that the original samples (X) are still where they where, but the I`s has been moved, so they are placed as if the signal had really been sampled twice as fast. Since the extra samples are interpolated from the original samples, are they only limited in accuracy, by how many bits that was used in the filter. So the signal after the digital filter could in theory be any number of bits, and thats why a 18, 20, or 22 bit D/A-converter is sometimes used.

Is there a difference between CDs for 1X, 2X, or 25X CDROM drives?

A CD may be recorded at a 1X, 2X, 4X, etc. rate but what is on the CD is supposed to be the same.

However, the location of the information on the disc may have been optimized for use readout at a 1X, 2X, 4X, etc. rate on a particular drive/computer combination but again what is on the CD is coded the same way and should be read properly regardless of the speed of the CDROM drive. However, actual performance including interactions with multimedia programs, and sound and video devices may be vary dramatically.

For CDROMs, the 8X specification is not related to the 8X oversampling of an audio player. An 8X CDROM drive can actually spin at up to 8 times the normal speed of an audio CD. It can transfer data at 8 times the 1X (audio) speed of 150 KB/second or about 1.2 MB/second. However, note that the actual access time for an 8X CDROM drive may not be dramatically better than that of a 1X drive once the seek time is taken into consideration.

A CDROM drive must get the data unaltered even with defects on the disc. An occasional unrecoverable error on an audio CD will never be detected. However, a dropped bit could render a program disc useless. Therefore, a CDROM disc is coded with additional levels of error correction and a CDROM drive has the required decoding logic to deal with this information. The interpolation used for oversampling and the interpolation and/or muting used for dealing with unrecoverable errors in audio players are not useful for data. How the CDROM drive actually deals with audio playback is a totally separate issue from its data readout performance.

For example, an 8X CDROM may actually use 4X oversampling for its audio playback but nothing else.

Conceivably, an 8X CD ROM could buffer and read ahead - and re-read a segment of the disc if errors are found (as some people think normal CD players do but generally do not - at least not in the context of oversampling).

Sophisticated programs reading audio data off the CD could certainly do this on a greater than 1X drive. I do not know whether any CDROM drives themselves would do this given that audio performance is not something that is generally considered that important on a CDROM drive.

An audio player using oversampling never need to spin the disc faster than the 1X speed but implement the interpolation to simplify the analog filter design. However, portable players with a 'bump immunity feature' have several seconds of audio sample memory and will read (prefetch) the audio information off of the disc at higher than 1X speed to assure that the buffer can be kept as full as possible even if the player is unable to track for a couple of seconds.

CDROM drive speed - where will it end?

CDROM drives advertised as 16X are now common. Taken literally, this would mean that at the inner track, this drive must spin the CD at 500*16 or 8,000 rpm. Geez, they must have a Kevlar shield around the perimeter to catch any shrapnel should the CD disintegrate! (Apparently, this isn't as rediculous as it sounds - see the description of an "event", below.) Have you ever seen the slow motion video of a jet engine exploding? Just about one year ago, I was 'proving' why such technology would never be practical. So much for predicting the future. Have I mentioned that my crystal ball has been in the shop for the last few years awaiting repair? :-)

However, most 16X drives really are not 16X CDROM drives.

Some drives do advertise '16X max' which might indicate a constant rotation apeed of a much more reasonable 3,200 rpm resulting in a transfer rate which approaches 16X only near the edge (outer tracks where 1X would be 200 rpm). The transfer rate could be as 'low' as 6.4X near the center.

Another possibility is a hybrid approach called Partial Constant Angular Velocity (PCAV) with a more modest 8X speed (around a constant 4240 rpm) for the inner tracks topping off at 16X near (5/6ths of the way radially to) the outer edge (at which point the rotation speed decreases to limit the peak transfer rate to 16X).

12X drives typically run at a true 12X rate with the CLV varying between 6360 and 2400 rpm across the disc. These will actually have a faster transfer rate than '16X max' drives since most discs are not full and the most frequently accessed data is near the center - where the '16X max' drives are only really operating at 8X.

One factor limiting the performance of present drives is the speed of the Digital Signal Processing (DSP) chipset which is used to perform the decoding and error handling (i.e., EFM and CIRC). This is one area where there will no doubt be rapid advances.

There is nothing to prohibit a fully Constant Angular Velocity (CAV as opposed to CLV or PCAV) approach from being used as long as the DSP can keep up. This would mean that the transfer rate varies continuously across the disc. An added bonus would be that CAV would actually greatly reduce stress on the spindle motor and its servo system allowing for much lower cost components and improved reliability.

There are other ways, at least in principle, of increasing the performance of CDROM drives without spinning the discs at hyperwarp speeds. These involve the use of multiple laser beams or entire laser pickups to read data from multiple tracks in parallel. However, the hardware and software for these schemes become extremely complex and expensive to implement due to the CLV encoding, CD tolerances, and other factors. Therefore, spinning the disc faster has become the solution of choice.

In addition, the seek time of the CDROM drive will dominate for short file transfers. Since this specification is not as hyped as the 'X' rating, these are often pathetic - 200 to 300 ms full stroke being typical even for high-X (e.g., 16X) CDROM drives.

Of course, ultimately, it is the speed of the computer interface, system bus, CPU, and software, which limits actual performance. Just because you have a high speed CDROM does not mean it will behave as expected on your system.

There is some question as to whether discs manufactured to current tolerances can be spun much above 6,000 rpm without vibrating themselves to pieces. Other than this slight 'problem', there really isn't any fundamental reason why faster drives could not be built. Perhaps, discs will simply need to be approved for high perfomance drives (sort of like grinding wheels: "Do not exceed 8,500 rpm") - "Do not use above 40X".

Therefore, a drive spun at a constant 8,000 rpm with an advanced DSP chipset could operate with '30X max' performance. Are you marketers listening?

Now (August 1997) some company is offering a 24X CDROM drive!

Stay tuned for "Safety precautions and recommended body armor when using or troubleshooting a 100X CDROM drive" :-).

Here are a couple of data points on ultimate CD speed limits:

For the following, if one assumes the worst case, 1X is equivalent to 500 rpm. You can do the heavy math. :-)

(From: Richard Griffin (rjgriffin@viewlogic.com).)

I just thought I would chip in with my 2 cents worth......

There have been studies into just how fast you can spin your average CD without structural problems occurring. I believe Philips (UK) conducted the study. They found that spinning a disc up to the equivalent of 45X caused the disc to stretch enough due to the centripetal forces to make it impossible for the laser to track the track (if you catch my drift). Just for the sheer hell of it, they wound the test discs up to 56X at which point they scattered themselves in a very artistic 'splinter' formation all over the test lab.

(From: Scott May (scottmay4@home.com).)

My wife was browsing a the contents of a CD-ROM on her computer when suddenly there was a loud noise, followed by shards of what was once her CD-ROM, now raining down on our heads. The door to the Memorex drive (model CD-482E) was blown off its hinges, and left dangling by a small spring.

About the room were fragments of the CD, mostly in splinters, and few larger than dime. Inside the CD-ROM drive were the remains of the disc. I was able to open the door using the manual release, but could not open more than halfway. Internal drive parts were blasted off and mixed with CD rubble.

We are both very lucky not to have suffered injuries, because of flying debris. But I'm dumb-founded as to the cause of this major malfunction. I've never heard of this happening to anyone before. And to be honest, I wouldn't believe it if it hadn't happened to me. The drive was about a year old, but we have no idea if the CD had any surface flaws or physical defects.

(From: Sam.)

There couldn't have been any major structural defects or it wouldn't have been usable. That's why I suggested Kevlar encased CDROM drives. With these high-X drives, a failure of the spindle motor servo control could easily put it over that 55X disintegration limit. I bet the manufacturer would be interested in knowing about this incident. Think of what a good slicky lawyer could do with it. :)

CDROM spins continuously even when not in use

The complaint may be that it sounds like a jet engine all the time and is annoying or just a matter of curiosity. I don't know whether it is normal or not for your combination of hardware and driver, but CDROM drives rated above about 12X are typically CAV (Constant Angular Velocity) - they run at a constant speed - not CLV (Constant Linear Velocity) like normal audio players (though they may drop into that mode when playing audio CDs). (The X speed rating is a MAX and you only get this performance for the outer tracks (which may be the later files in the directory unless they specifically placed them).

Thus, your 24X CDROM drive actually spins the disc at a constant 4,800 rpm or so and you only get the specified access times if it is already spinning. Therefore, by one argument, it makes sense to keep it spinning whenever a data disc is in place.

Also see the section: CDROM drive speed - where will it end?.

Golden ears and technohype

You have no doubt encountered various claims of how player A uses such-and-such a technology and therefore clearly has superior sound compared, no doubt, with all others in the explored universe. There may be people who can hear such differences in noise, frequency response smoothness, and such. Perhaps even you could hear a difference under ideal conditions. However, once all the variables that make *music* are included - the chain from artist and recording studio, microphones, recording, mixing, and resampling as well as your speakers and room acoustics - not just sinusoids played in anechoic or resonant chambers, the very slight differences between players are virtually undetectable to human ears. If you are interested in playing test discs all day, then worry about the last percentage point of noise floor or frequency response. If you really want to enjoy the music, this stuff should not bother you. There are more important things to worry about than an undetectable blip in your CD player's frequency response curve. Anyhow, with the introduction of the DVD technology pending, your carefully optimized ultimate stereo system will be as obsolete a year from now as a 78 turntable. Consider that! Only PC technology has a shorter lifespan. I bet you won't sleep tonight. :-)

I would be curious as to the results of any true double-blind listening tests comparing CD players implemented with differing technologies (analog vs. digital filters, 4X or 256X oversampling, 1 or 2 D/As, etc.) on actual music (not test tones) in realistic listening environmemts. Such tests should be with people who are interested in the overall musical experience and not just the nth decimal point of technological specsmanship. There must, of course, be no vested interests (financial or otherwise) in the outcome of such tests. I would bet that the results of such tests would make for some fascinating reading and surprises for some manufacturers of high-end audio equipment.

That last little decimal point

Someone was hyping his high-end CD player (with a stratospheric price tag no doubt as well) claiming that it uses **mechanical** relays instead of transistors to perform the muting function (between discs or tracks) in the final audio amplifier. These mechanical relays are supposed to have less capacitance and thus not affect the 'fluency' or some other equally meaningless non-measurable characteristic of the sound. According to the same article, "only cheap CD players costing less than $900 use transistors for muting. All more expensive players use relays". If this claim is true, then how can manufacturers claim a +/-0.3db response curve from 20Hz to 20kHz even for CD players costing a lot less than $900?

Well, my 10 year old Technics SLP-2 uses relays and it sure cost a lot less than $900. Shall we do a little calculation:

Parasitic capacitance, say 100 pF (much much larger than likely). Highest frequency of interest: 20 kHz.

The magnitude of the impedance of this parasitic capacitance will be:

|Z|=1/(2*pi*f*C) = 1/(2*3.14159*2E+4*1E-10) = 80 K ohms

Compare this to the output impedance of a typical final audio stage, say less than 1 K ohms (usually a lot less, but this will do for a back-of-the-envelope calculation). Yeh, right, I will loose a lot of sleep over that. There are better things to worry about than an immeasurable blip in your frequency response curve: Are the transistors at the very output? Oh my gosh, you better start investigating super ultra low capacitance audio cables costing at least $1000 each with water protected oxygen free tapered oriented strand conductors. But wait: you are connecting to an amplifier with non-infinite input impedance (perhaps, horrible as it may seem, non-uniform as well)? Your setup must sound like crap! How can you even have it in the same house with you? There are so many variables involved in the reproduction of high fidelity digital audio that this is about as significant as a pimple on an elephant.

Ask for a scientifically designed and implemented A-B comparison. You won't get one because the revelations might be too shocking for the audio industry should the 'Golden Ears' fail to reliably distinguish between players at the two ends of the price spectrum.

Totally worthless gadgets for CD enthusiasts

Here are descriptions of a few of the items sold to born-every-minute suckers to improve the performance and audio quality of their stereo systems with respect to CDs. (These are strictly CD or digital audio related. There are many many more for general audio 'enhancement'.)

Save your money. This stuff is total garbage:

- Sonic rings to put on your CDs to stabilize them. The argument goes that this reduces wow and flutter by helping the servo system. There is none to begin with since pitch is determined by a quartz crystal.

  Note: these may even make your performance worse due to the added inertia of the rings. In addition, any added thickness could cause mechanical problems with some players like Pioneer changers (cartridge type) - loading, unloading, or during play.

- Magic markers for used on the edge to reduce errors. The rational is that the colored edges will absorb any stray laser light and minimize interference with the main readout beam. Forget it. Such reflections are very minimal. Furthermore, the digital processing means that if there is a slight drop in the signal-to-noise ratio, there will be no - zero - audible effect.

- Special digital clock you sit near your stereo to improve sound. I have no idea of the basis for this but I heard about it on a supposedly serious audio show. To clarify, I am talking about a time-of-day clock as in 12:34:56 with LEDs that has no direct physical connection to the audio equipment, not some high precision atomic cesium beam time-base unit! Perhaps, the added digital noise floating around will add some dithering to the signals and improve linearity? Right.... :-).

- Special cleaning solutions. Soap and water just isn't good enough for Golden Ears. No doubt, CDs should be stored under pyramids as well for optimal longevity.

- Fiber optic patch cords to reduce phase distortion. No kidding, I am sure there is at least one biological life-form in the universe that could detect the nanosecond or so phase shift introduced by the ordinary copper variety used by the rest of us. You don't suppose all the electronics involved will introduce any distortion of its own, do you?

(From: Zev Berkovich (ah392@freenet.toronto.on.ca).)

I recently was sent one of those audiophile magazines, and out of all the really stupid things advertised there, these two I found the funniest:

- A demagnetizing CD. Play this on your system and it is supposed to demagnetize your equipment and make it sound better. The one I have seen the ad for claims: 10 times the effective demagnetization of other discs. Less than 1/100th the heat dissipation (!!!??) of other discs. Complete demagnetization of all frequency selective circuits.

  The fax I got was pretty funny. They claim on their fax that it also removes residual magnetism from the slight impurities present in the copper wires. (Maybe it will degauss my TV! --- sam)

  Of course, the disc is made with 99.999% pure 24 karat gold (for a higher reflected signal level, whatever that means). (This, too, is of course bogus. Gold will have the same or lower reflectance at the IR wavelength of the CD laser. It just looks way cool. --- sam).

- Special solder, which tells you to remove all the solder on your amplifier, and redo all of it with this "Wonder Solder UltraClear". "For mere pennies you can solder (or reflow) a whole amp or speaker, and make it sound like one twice as expensive". (Sure sounds like a fun project to me - solder reflow in your toaster oven! --- sam).

More on CD enhancers - magic markers and anti-vibration disks

(From: someone I will leave anonymous).

> "I just had to comment on what you said about CD enhancers. I had the opportunity to test both a special green magic marker and a plastic anti-vibration disc that you stick on top of the CD to improve sound. The magic marker didn't work but the anti-vibration plastic did work. What I heard it do was enhance the spatial quality of the music. The separation was better. It sounded like the various instruments were a good foot or two farther apart on each side. That said, the demo was conducted on a $20,000 stereo system and I felt that $50 for the plastic disc was a bit high and I wasn't convinced that I could hear a difference on my more modest system."

Sorry to be skeptical - go do an A/B comparison. Unless that player has an excessive error rate - and I doubt that to be the case with a $20,000 system - there is simply no way that any meaningful difference is possible. A CD is not like an LP - small variations in speed are irrelevant and thus improving the stability or whatever is also irrelevant. The data readout is fully buffered - meaning that even if there is wow and flutter or vibration in the CD rotation, it does not matter.

Show me a double blind A/B comparison and I will reconsider. For now, the physics doesn't make sense.

The guy doing the demo wasn't by any chance trying to sell $50 disks, now was he? :-)

And, no, I have not done a double blind test. But, I would not mind being proven wrong. Just that based on the physics and technology, unless the CD player had a high error rate to begin with due to an underdamped servo system - he could have jimmied it - then there simply is no basis for expecting such things to improve a digital datastream. If the error rate decreased due to his discs, then perhaps there would be some sonic improvement. But, it should not have been high to begin with. Error rate reduction is the only possible mechanism I can think of to explain any possible audible differences. However, virtually all errors due to disc imperfections and scratches are *fully* corrected and thus undetectable in the output by human or machine.

BTW, was he also selling $1000 speaker cables?

Why is speaker cable like spaghetti?

(From: Keith Mayes (Mayes@d-m-g.demon.co.uk).)

A survey was carried out in the 70's. People were given two bowls of spaghetti, one coloured blue and one coloured spaghetti colour. Most people claimed to prefer the taste of the spaghetti-coloured spaghetti.

This was a real effect, with real people who had nothing particularly to gain or lose either way. Naturally, there was no instrumentally measurable difference in flavour between the two types.

The same applies to speaker cables. People who have fancy cables will quite probably hear an improved sound, in their judgement. There is more to perceived sound quality than vibrating eardrums.

Someone who has already bought fancy cable will not appreciate this story. If they hear an improved sound, then that's their good fortune.

Someone who is considering buying fancy cables may well benefit from this story. It may save them a small fortune.

In reality, the Emperor's response to being told that he was naked was:

1. Deny it and prove it with signed affidavits.
2. Have the kid locked up under a section of the mental health act.

To believe in the power of a fancy cable surely pales into insignificance beside belief in a deity, and there are plenty of people who go for that.

Can a CDROM disc damage a CD player?

Some CDROMs include audio tracks that are entirely playable. However, data-only CDROMs may not even be recognized by newer CD players. With older ones - designed before the CDROM standards had been developed - the player may come up with a bogus track directory. Attempting to 'play' such a disc will probably not damage the CD player but will sound, shall we say, strange. I have done this and it really gets pretty boring pretty quickly. But, like pointing the camcorder at the video monitor, is something that is irresistible to try once. If you do this experiment, TURN DOWN THE VOLUME!!!. None of the rules which govern real-world audio frequencies and amplitudes are obeyed with data discs. You may blow out your speakers (or ear drums) if the volume is set too high or even at normal listening levels. I wonder what WIN.EXE or vmunix really sounds like!

Another less common possibility is that a CD-R or CD-R/W that was aborted during writing (or damaged CD or CDROM of any variety) could result in the reader to repeatedly attempt to access a non-existent tract causing excessive sled movement - possibly even into the stops. This *could* conceivably result in overheating of servo components and motors and permanent damage though I've never heard of this happening. More below.

Notes on Killer CDs and DVDs

I am not referring to popularity, but rather instances where a defective CD or DVD can either lock up a player or drive, or in the case of some DVD-R or DVD-RW drives, even destroy the drive.

The latter case has occurred (Fall, 2002) and involves certain DVD-R and DVD-RW drives using Pioneer pickups and electronics. See: New Scientist DVD Article. In short, a firmware bug in over 1 million Pioneer CD-R and CD-RW drives (Some Macs use these), and stand-alone players and recorders, may result in a burnt out laser when attempting and failing to recognize new high speed blank media. Apparently the firmware went in before the standard was fully developed (or at least fully debugged!). There is a firmware patch to fix the problem in existing equipment.

A normal CD player or CDROM drive could lock up but would probably not be damaged except by physically damaged media (e.g., a broken disc catching on something or disintegrating at high speed) but in principle, the same could happen to

CD-R or CD-RW drives. However, I am not aware of any such problems.

(From: Dave Platt (dplatt@radagast.org).)

I have seen situations in which these new "copy protected" discs have caused CD players to lock up quite seriously. These have been in cases where the CD player was based on a CD-ROM mechanism (i.e. an "internet appliance" type of device).

Some of the new copy-protection techniques work by creating an invalidly-formatted multisession disc. A standard Red Book audio CD player won't even try to look for the second session, so it'll play the disc just fine. A CD-ROM drive - or any appliance based on one - will see that the disc is multisession, try to read the second session header, and become badly confused by the misformatted disc.

In one case I witnessed, the CD-ROM drive's firmware became "stuck in a loop" trying to locate the malformed sessions. It never succeeded in accessing the disc, and it refused to respond to the "eject disc" button or the eject commands by the unit's control software. The only way to get the disc out of the drive was to shove an unfolded paper clip into the "emergency drawer open" hole in the front plate.

I've been told that many of the higher-tech car CD players actually use CD-ROM mechanisms and the "rip the data" method of playing, in order to allow the data to be spun at higher speeds than 1x and then buffered in RAM. This allows extremely good bump/shock protection.

If this is the case, then I expect that these types of car CD player will be unable to play these "copy protected" discs. Worse yet: imagine what will happen if such a disc locks-up the firmware in a slot-loading CD player which doesn't have an emergency-eject paper clip hole?! Put the disc in the player, it swallows it, the CD player freezes up and won't give the CD back, and you've got a useless CD player which requires a trip to the dealership for repair!

If this does, in fact, ever happen, I fully anticipate that some savvy lawyer will arrange to file a huge class-action lawsuit against the disc manufacturer, on the grounds of "strict liability". The disc manufacturer "knew that these discs were deliberately manufactured in a way which would 'freeze' certain types of CD player, and knew or should have known that this could result in expensive damage to certain types of CD players."

I'm heartened to note that Philips has put the disc vendors on notice that these discs *cannot* be caused by the "Compact Disc" name, or use the Compact Disc logo, or promise Compact Disc compatibility, since they do not meet the standards required by the license agreements.

Performance testing of CD players

The question arises: "How do I determine if my new, newly acquired, newly repaired or adjusted, or other CD player is actually performing up to specifications?".

Note that in this section I am not addressing questions like: "Is my THD less than .003% (or whatever)?" but rather general usability issues like immunity to disc defects. If the music sounds right, the audio circuits are working. Subtle problems with the audio circuitry are rare.

The best approach is to use the test disc(s) that most manufacturer have made available for their own CD players. However, this is probably an unacceptable expense unless your repair volume can justify it. No single test disc will be suitable for all brands. One problem is that CD players from different manufacturers (and even models from the same manufacturer) have varying amounts of tolerance to CD defects and varying levels of error correction (by design). Therefore, what plays on one may result in dropouts or skipping on another.

Without the test discs, no quantitative measurements can be made. However, general types of tests can be done.

My general recommendation would be to use a good quality music CD which is a full 74 minutes (e.g., Beethoven's 9th Symphony) to test basic seek and tracking capabilities. Exercise the player with track-track and full disc seeks in both directions to confirm stability and that none of these times are excessive. Evaluate bump immunity with your calibrated finger tap at the start, middle, and end of the disc.

Also see the sections: "Comments on test discs" and "Custom test CDs using CD-Rs".

Want to have fun?

Find a garbage CD - one you don't really care about - and add imperfections of your own to the non-label side - using it as a frisbee or hockey puck should qualify. I would also suggest smudges but these are not permanent and what we want is something that will not change over time. Maybe try some fine sandpaper or steel wool. Painting fine strips of black radially (up to a width of 2 mm or so) may also be instructive though in reality, although the error correction may be capable of dealing with these, there may still be skipping or other mistracking.

As long as the CD does not have any edges for the lens to catch on (it is not cracked or broken), there is little risk to your player.

Scratching through the label side to the pits (information) layer may also be intersting. In this case, the data and tracking will be affected directly since the benefits of the out-of-focus surface (the non-label side) are lost.

With this 'scientifically designed test CD' you should be able to gain a feel for how your unit-under-test compares to the CD player you normally use. However, don't be too disappointed if one or the other falls down in some respect. CD players are just not all designed alike. You may find that your $100 portable doesn't even hiccup on defects that send your $1000 audiophile model (which you thought was the ultimate in the state-of-the-art) straight to the showers.

Finally, if you take reasonable care of your CDs (and don't position the CD player in front of your Megablaster-1000 speaker systems, you won't be 'pushing the envelope' during normal use and your CD player will not have to deal with marginal discs and vibration that often.

For more fun, see the article: "Where is CD Date Physically?".

Comments on test discs

> "Is a special expensive test CD needed for typical servicing? Can anyone recommend a test CD disk. I want test tones more than recorded music, single note sinewaves rather than sweeps."

I ordered one from MCM Electronics called the "Diagnostic Test CD" for about $5. It has over 40 tracks mostly of pure tones (sinusoids) of various pitches (frequencies) and amplitudes.

However, as noted below, an appropriate test disc is more likely to be useful for evaluating tracking performance than for audio distortion problems. Any music CD will suffice for the latter - these faults are usually quite obvious even to your average chimpanzee (or someone who is tone deaf).

Test discs like the following will provide nice quantitative info and should be useful in comparing the defect tolerance of various CD players. However, you will need to know what the specifications are of the player-under-test to really be able to determine if it is performing properly.

(From: Dave A. Wreski (dawreski@nic.com>).)

We don't think that test tones are so important in real life. The few CD players that have audio distortion problems are usually so bad it does not take a trained ear to hear. What we found much more important is the ability to track through damaged or dirty sections on the disc. Although not the, final the test disc we use has been proven to provide us with a "standard" that we judge the overall performance of the servo's and the laser condition. Very rarely do we have to ask an owner for the disc that exhibits his problem. This disk is from Technics and is about $35.00. It is P/N SZZP1054C. It has the necessary test tones (17 tracks) but more important it has defects at calibrated levels. First it has missing pits at .4 to .9 mm in length and second it has calibrated black dots from .3 to .9 mm in size. These checks will give you a very fast and reliable way of seeing how good the system is working. We could not live without it. Try it once and you will like it forever.

(From: Armand (mondo@voicenet.com).)

Try the "Ultimate Test CD" on Wodford music. 32 different sine waves and more. Found it at Tower Records for $6.

(From: Dan Dugan (dan@dandugan.com).)

My favorite test discs are put out by the National Association of Broadcasters. More expensive but comprehensive. I use #1 (there are 2) almost every day for level setting.

(From: Brian Newman (b.newman@qcm.gu.edu.au).)

I normally use a Sony type 4 test disc, but if you are after tones, I would recommend the test disc put out by Dennon. It has standard tones as well as left/right sweeps.

Custom test CDs using CD-Rs

With the continuing decrease in the prices of CD-R recorders, this approach will likely become much more common. If you have access to one at work, then there is no problem - it is probably not being used for its intended purpose anyhow :-). The only caution is that since CD-Rs are not quite the same as CDs in terms of optical behavior, some adjustments may not be optimal and should be rechecked with a normal CD or test CD.

(From Kenneth Aaron (kennetha@geocities.com).)

I have created a test CD using a CD-R.

Using a program like Cool-Edit you can create perfect waves of different frequencies and amplitudes, silence tracks, and nearly anything else. With a program like Disc-at-Once delays can be added between tracks.

After you burn the CD, holes can be drilled in the disc as well. I left a 2 minute gap between adjacent tracks so I could see the spaces between tracks. Drilling holes from .2 mm to 2 mm with .2 mm increment is allright. The disc is fantastic and it was made to fit my needs.

Controlling the pitch of a CD player

While it is easy to vary the pitch of a turntable or tape deck by controlling motor speed, this will not work with a CD player.

Spindle motor speed is only loosely related to audio pitch. CD players use Constant Linear Velocity recording, meaning rotational speed varies from inner-most track to outside track. Reading a CD is more like transferring data from a hard drive under computer control - there is extensive buffering and the instantaneous spindle speed is not the main factor that determines pitch. For this reason, wow and flutter are generally so small as to be undetectable even with audio test instruments since readout is controlled by a very stable quartz crystal master clock, not anything electromechanical.

Digital audio data is read from the disc into a FIFO (First in First Out buffer). Various processing is performed including decoding and error checking/correction and it is then fed to the DACs at a constant rate (determined by a crystal). If the FIFO gets too low, the motor speeds up. If the FIFO gets too full, the motor slows down. Very simple. Change the rate that data is read and the motor follows right along (up to a point).

The actual frequency of the crystal varies from design to design but a typical value is 11.29 MHz (256 times the audio sampling rate of 44.1 kHz. If may be possible to substitute a variable frequency oscillator for the crystal to provide some amount of pitch control.

With care and possibly some tweaking of the PLL servo adjustments, a pitch range of +/- 6% (about 1 semitone) should be possible. Some commercial CD players may do +/-12% such as the Technics SLPD-967 and some people have apparently achieved as much as +/- 20% by substituting a variable oscillator. But beyond this, strange things will likely happen with the spindle servo and the anti-aliasing (analog) filter. However, a schematic is really needed - and possibly more like chip specifications - to determine if simply injecting an external oscillator signal will work.

Where a large change in pitch is desired, it may be easier to convert a CD player having an anti-shock memory since that capability means that the system inherently only calls for data when it needs it and actually reads the data off the disc at a much faster rate (e.g., 2X or 4X). This would also be the scheme used in players designed with a large range of pitch control. In any case, locating the clock that controls data readout (rather than the main microcontroller) would be the place to start. That may use a separate crystal. The more completely the player is based on digital processing, the less aliasing and other funny speed related effects will be present since everything will scale equally with readout rate. The only changes that may be needed to eliminate aliasing effects may be to the output antialiasing filters and may just be one or two capacitors in each channel. Needless to say, a schematic will be highly desirable.

All in all, transferring the audio to another medium that allows for easy pitch control would be a whole lot simpler! There are cassette decks that can provide a 2:1 change in pitch while maintaining reasonable audio quality. Or convert to MP3 and do whatever you want in software. :)

See Pitchman's Mixing Setup Page for a description and schematic of one approach that works for some CD players. It's just a simple variable speed clock that replaces the timing crystal of the CD player.

Converting a CD player into a CDROM drive

Why anyone would seriously consider this project other than for the curiosity value is not clear, but the question does seem to pop up from time to time.

If you mean audio making a CD player into a CDROM drive. Forget it. Don't waste any neural bandwidth on such considerations. While the optics and front end electronics are similar, the CD player is missing the circuitry needed to decode the CD data, CDROMs used more involved error correction, the control inputs are not there, and it is virtually impossible to obtain detailed schematics or firmware listings.

And, in the end, it would be a state-of-the-art 1X drive since the servo systems and motors in an audio CD player are not capable of operation at more than 1X speed. Unless, that is, you are willing to butcher a CD player with an anti-skip buffer! :) You can probably pick up a 1X CDROM drive for $5 or less probably much less, like free. They practically come in cereal boxes these days (or was that 1G hard drives? Technology moves so quickly).

Similar comments also apply to the nth degree with respect to converting a CD player or CDROM drive into an MPEG video device or something more exotic.

Using a CDROM drive as a stand-alone CD player

Since nearly all CDROM drives are capable of playing audio CDs, a natural question is whether it is possible to just supply power and be able to use an old 1X (or 2X or 10X) CDROM drive as a CD player without attaching it to a computer.

For many types, the answer is yes. These provide some way of starting play and moving between tracks on the front panel. Usually, this is a pair of push buttons which combine play, eject, and next track functions or a volume control that can be pushed to start play and move to the next track. All these CDROM drives usually need is power to operate as audioCD players. For headphone listening, just use the front panel jack. A suitable adapter will permit the line outputs in the rear to be connected to the CD or AUX inputs of your stereo system.

Some will automatically play CDs upon powering up or closing the drawer if a jumper is set properly. The Eject button will then control play, track selection, stopping, ejecting, depending on how long it is held down.

Where the drive does not have these features, this may be more difficult.

- It is probably not worth it for SCSI or IDE drives as special commands will need to be set up.

- I don't know how difficult it is with the custom interfaces like Sony and Mitsumi. These may have a simpler command set but I doubt that it is just jumpering a signal to ground somewhere.

- For the once popular Panasonic CDROM drives with the custom interface (e.g., CR562, CR563), the interface specifications are available at:

  - Interfacing details of Panasonic SLCD CD-Roms

  Some logic will likely be needed to allow the drive to play music CDs but it should not be that complex. Here is an example of one solution that works:

  - Gary Tait's Home Built (almost) Panasonic/MKE/CR56x CD-ROM Interface

Note that the audio performance of CDROM drives is usually a notch below that of the typical audio-only CD player. The audio circuits are basically an afterthought for a CDROM drive. Therefore, don't expect quite the same level of frequency response, dynamic range, and lack of noise as your are used to with your stereo system or even your portable CD player. Of course, in a Jeep, this may not matter much.

In addition, the bump immunity is probably not spectacular - PCs are usually not expected to deal with pot holes. Therefore, unacceptable rates of skipping and repeating may result if a converted CDROM drive is used in your car or back pack.

However, some people claim to have used retired CDROM drives in vehicles with great success (see below). Therefore, it is worth a try if your model doesn't require a PC to be dragged along to play music CDs!

CAUTION: Since the interface (if unused) will be disconnected, some people have expressed concern that leaving the inputs floating may be bad for the circuitry and/or that they will pick up spurious signals resulting in erratic behavior even if just using the front panel buttons. Therefore, it may be worth identifying the inputs and tying them inactive (pullup or pulldown as appropriate). I don't really know if this is ever a problem - just something to consider. Well designed systems *should* already have this built-in to handle the case where the cable becomes disconnected accidentally.

(From: Dougie (blair@irnbru.enet.dec.com).)

I use a 2X CDROM Drive in my car and have done so since a local shop sold off all their drives for a fiver each!! I used a 5 volt regulator to make an in-line adapter to give me 12 and 5 volts to run the drive. You don't need any front panel controls since the eject button is used on most drives as FF/skip button. As far as bouncing and skipping is concerned. I originally put the drive inside my glove compartment and it jumped like crazy. But I now have it on the passenger's side floor under the seat and I can't remember the last time it jumped. You'll find a good spot in your car that works best.

I've even thought of putting on one of these flexible goose neck platforms that are used for portable cd players, but since it works fine where it is I haven't bothered.

I'm always interested in what other 'experts' tell you about the differences in internal electronics between PC CDROM drives and in-car CD players, but I work in a lab and spend every day carrying out failure analysis on CDROM drives of all types and I've always had the opinion that the only way to find something out for certain is to try it your self....

I have collected 6 of these drives now and am in the process of making them into a multi-CD player to be housed in my boot/trunk. All CDs will run continuously and only the audio will be selected and digitally switched. It should be fun and cheap.

SP/DIF digital audio interface

(From: Arny Kruger" (arnyk@flash.net).)

SP/DIF is common on most newer ATAPI CD and DVD drives, and specifically very rare on SCSI drives.

Toshiba, Teac, Panasonic, etc, have SP/DIF. I think the long term idea is to eventually drop the headphone output and DAC in the CDROM and route SP/DIF to the sound card which will, or is being put on the motherboard. I have a number of new motherboards with SP/DIF inputs but I have not yet tested them in this mode. I know that the digital performance of the sound chip used on these particular boards (the HT1869) is horrible. Hopefully, somebody will do it 'right', as this is technology with promise.

I've tested some CDROM's SP/DIF output with external audio DACs and good quality sound cards with digital inputs and they work, pure and simple. The performance of a $80 CD ROM and a $200-300 DAC (specifically the Technics SH-AC-300) can eclipse more expensive equipment, in technical terms.

Can I use the pickup from a CD player or CDROM drive for optical experiments?

With the nice precision optics, electromechanical actuators, laser diode, and photodiode array present in the mass produced pickup of a CD player, CDROM drive, or other optical disc/k drive, one would think that alternative uses could be found for this assembly after it has served for many years performing its intended functions - or perhaps, much earlier, depending on your relative priorities :-).

People sometimes ask about using the focused laser beam for for scanning or interferometry. This requires among other things convincing the logic in the CD player or CDROM drive to turn the laser on and leave it on despite the possible inability to focus, track, or read data. The alternative is to remove the optical pickup entirely and drive it externally.

If you keep the pickup installed in the CD player (or other equipment), what you want to do isn't going to be easy since the microcontroller will probably abort operation and turn off the laser based on a failure of the focus as well as inability to return valid data after some period of time.

However, you may be able to cheat:

- If the unit has a 'Test Mode', it may be possible to force the laser to remain on despite a total lack of return signal - or even without the focus and tracking actuators even being connected, for that matter. Many models have a Test switch, jumper, or pair of solder pads on the mainboard (enable before powering up). Then, there may be a key sequence to enable the laser, move the sled, etc. See, for example, the section: Pioneer PD/M series test mode.

Where such a feature is not provided:

- First, whatever is used to detect a disc must be defeated. Usually, this is a reflection of the laser (most common).)but may be a separate sensor.

- Then, the 'focus ok' signal must be provided even if you are not attempting to focus the laser beam. It may be possible to tie this signal to the appropriate logic level to do this.

- Even if it is not possible to access these signals, depending on design, you may be able to locate the logic signal to turn on the laser and enable it there. However, some systems bury this inside a chip based on the controller to activate it. Getting a schematic will probably be essential - but this may be difficult (especially for a CDROM).

It may be easier to just remove the pickup entirely and drive it directly. Of course you need to provide a proper laser diode power supply to avoid damaging it. See Sam's Laser FAQ in the chapter: "Diode Laser Power Supplies" for details. You will then have to provide the focus and/or tracking servo front-end electronics (if you need to process their signals or drive their actuators) but these should not be that complex.

CAUTION: Take care around the lens since the laser will be on even when there is no disc in place and its beam is essentially invisible. See the section: SAFETY.

Some people have used intact CD player, CDROM, and other optical disc/k drive pickup assemblies to construct short range interferometers. While they have had some success, the 'instruments' constructed in this manner have proven to be noisy and finicky. I suspect this is due more to the construction of the optical block which doesn't usually take great care in suppressing stray and unwanted reflections (which may not matter that much for the original optical pickup application but can be very significant for interferometry) rather than a fundamental limitation with the coherence length or other properties of the diode laser light source itself as is generally assumed.

In any case, some of the components from the optical block of that dead CD player may be useful even if you will be substituting a nice HeNe laser for the original laser diode in your experiments. Although optimized for the IR wavelength (generally 780 nm), parts like lenses, diffraction grating (if present and should you need it), and the photodiode array, will work fine for visible light. However, the mirrors and beam splitter (if present) may not be much better than pieces of clear glass!

Unfortunately, everything in a modern pickup is quite small and may be a bit a challenge to extract from the optical block should this be required since they are usually glued in place.

Taking a CD player overseas (or vice-versa)

Fortunately, the standard for the CDs themselves is the same everywhere in the explored universe. Yes, even Australia :-). Thus, there should be no issues of incompatibility. The differences will relate only to the power supply needed for your player.

First, check your user's manual (which you of course have saved in a known location, right?). It may provide specific instructions and/or restrictions.

Most component type CD players use a simple power supply - a power transformer followed by rectification, filter capacitors, and linear regulators. These will usually only require a small step up or step down transformer to operate on a different voltage. Since power requirements are minimal, even a 50 VA transformers should be fine. WARNING: never attempt to use one of those cheap lightweight power adapters that are not true transformers to go from 220 V to 110 V as they are designed only for heating appliances. They will smoke your CD player (or other equipment not designed to handle 220 V to 240 V input).

Some CD players may have dual voltage power transformers which can be easily rewired for the required voltage change or may even have a selector switch on the rear panel or internally.

The frequency difference - 50 or 60 Hz should not be a problem as nothing in a CD player uses this as a timing reference. The only slight concern would be using a CD player specified for 60 Hz on 50 Hz power - the transformer core may saturate and overheat - possibly blowing the internal fuse. However, I believe this to be a rather remote possibility.

For portable CD players, if your wall adapter does not have a voltage selector switch, obtain one that is rated for your local line voltage or use a suitable transformer with the one you have. As with power transformers, a frequency difference may cause a problem but this is not likely.

Sony portable service mode

This applies to the D33 - don't know about other Sonys. At least only a single jumper is involved. On the D88, it was necessary to both remove one jumper and add another. After several of these cycles, the circuit board tracks started to disintegrate :-(How about pads for a microswitch which would be part of the standard Sony service kit?

(From: Jxrn-E. Ernes (joern-ea@online.no).)

Remove the power supply (batteries or whatever you have) and the bottom cover. Now make a soldered interconnection between the two jumper TEST terminals and apply power again). Pressing the PLAY button should cause the spindle to spin continuously.

That would make it easier to determine whether the motor is OK or not.

Portable CD player Q & A

The following questions and comments may give you a better feel for the considerations on attempting to repair a portable CD player (or CDROM drive for that matter).

> "I've read the relevant sections in the FAQ already. My problem concerns a Sony D-99 discman, it started skipping, etc., but within a matter of days degenerated to the point that it won't even read the TOC any more and is essentially dead. All the motors work fine.
>
> I'm assuming that the problem has to be something to do with the laser optical subsystem or its setup. The fact that it sort of worked for a while but rapidly degenerated suggested nothing has died totally but something has a terminal disease. I'm guessing either that the calibration has drifted to (and now beyond) the limits it can accept, or that the laser's power output is deteriorating.
>
> 1. Do lasers age significantly assuming they aren't abused as noted in the FAQ (i.e. turn into DEDS)?"

They really should not 'wear out'. Certainly not in the span of a few days after having been faithful servants for several years. The quoted life of a typical laser diode is 5,000 to 10,000 hours. But that assumes proper drive There is no way of knowing for sure. FWIW, there is a disc player that I repaired for a mechanical problem that is used something like 8 to 10 hours a day, 6 days a week for the last 5 years or so. It is still going strong.

> "2. Since it is a small Discman, I worry a little that it will either go 'pling' when I take the back off (not that that ever stopped me opening things before) but more seriously there will be little I can do when I get in

there."

Portable CD players tend to be fairly well behaved when the covers are removed. However, I am not optimistic about your chances of repair. Some careful exploration should not harm anything (not that it is likely to matter). I have found from my experience with portables that working on those things is a pain. This is especially true of older Sonys where the mainboard is connected to the optical pickup with many fine soldered wires in addition to soldered in flexible cables.

> "3. Sony have *not* been helpful. They will likely charge me the same as it costs to buy a new one, which is a shame because this old girl is actually made of metal and I hate the horrid plastic feel of the new toys, even if the batteries last longer and it sounds as good. The Sony man himself said that the new ones are built down to a lower price."

Forget Sony. If I interpret the model correctly, that one is fairly old. You would be lucky to get their attention for something 1 day out of warranty.

> "4. Should I pay the man?"

The temptation of some repair places is to blame the optics without even doing any testing - which alone will set you back more than the price of a new basic player (well, it will do everything yours will do but weigh half as much!).

> "5. Should I throw it away?"

That would be a shame but it depends on how much you value your time versus the cost of a new one. I really do respect the look and feel of those old Sonys.

Needing to reseat internal connectors, dirty controls, mechanical problems, are still possibilities.

Also, if you are using an AC adapter, make sure *it* is not the one that is terminal!

However, adjustments may not even be marked and if it is now totally unresponsive, there is no way to really tweak them without a service manual.

> "6. Should I take the back off, nothing to loose, then most likely throw it away?"

First, clean the lens and check the mechanics, and the AC adapter.

Next, see the chapter: "Startup Problems".

Then try to identify how far it is getting. This can probably be done without taking the back off.

You can pretty much forget attempting to repair the circuitry - most components are surface mount - both very tiny discrete parts and large multilegged ICs. It is difficult to obtain data sheets for many of these. The service manual is not always complete enough to be much help. Even probing test points without shorting anything out or having the whole mess fall on the floor while balancing the guts of the player and pushing buttons typically requires a minimum of 4 hands.

> "7. Do I stand a chance to find someone who will give me a better likelihood of success at a reasonable price than the local sony man (who to be honest looks like his idea of repair is to replace it in any case, certainly on a module level)?"

IMO, unlikely. It takes more time to get into one of those than a full size. Time is money, etc. They would probably have to order the manual which is an added expense that may never be useful for a future customer.

> "Sorry if 'throw it away' isn't in the spirit of things, but hey."

Sometimes it is. :(

> "P.S., one improvement to the FAQ would be to outline the likelihood that things actually have worn/died with age, rather than simply how to adjust or repair something that just doesn't work for some reason. This one has had a lot of use over five years."

Unfortunately, aside from things like grease gumming up or mechanical parts collecting dirt, optics getting coated with dust, tobacco smoke or cooking grease residue, motor bearings wearing out, the electronics and optics really should not age. Of course, there are all kinds of ways that this could happen through use and abuse (e.g., large dogs, toilets, and salt air) or bad design.

CD players in vehicles

Although a CD player mounted in an automobile or ATV is subject to much greater levels of vibration and shock than a home stereo (though perhaps not more than a well used portable), this may not be the primary factor affecting the long term survival of these devices. Other considerations are cycles of heat, cold, and humidity; dust and tobacco smoke; and the harsh environment of the vehicle's electrical system.

Temperatures under the dash or in the trunk can easily vary from below 0 F to more than 110 F during the year. Humid and salt air are particularly nasty. The confines of the passenger compartment concentrate tobacco smoke products so the lens and optics may suffer more in this environment.

While these must perform the same basic functions as their more stationary counterparts, there are some additional considerations:

- Environmental - hot, cold, humidity, exhaust fumes, tobacco smoke. All of these can result in more wear and tear on the mechanism, temporary or long term problems.

- Vibration - Unless you live in an earthquake zone, your home stereo system doesn't get bounced around much. However, in a car or truck, constant bouncing is to be expected. CD players designed to be used in mobile situations should have more robust and compliant shock mounts. This is one reason why using a surplus CDROM drive as a mobile CD player may not work well (but some will be fine).

- Power - The quality of the power to the accessories is often pretty poor compared to a stereo system or PC. High voltage spikes may result in permanent damage if there is inadequate protection. Ignition noise may feed through to the audio and require special line filters or other means to reduce the whine or buzz to acceptable levels. Either of these may also result in erratic behavior.

- Accessibility for repair - Finally, these systems are generally difficult to work on when repairs are needed. This includes removing the unit(s) from the dash/trunk, providing proper power and possibly control, and simulating the conditions that are causing the problems in the first place!

Here is one example illustrating the additional uncertainties of these units:

> "I have recently install a Panasonic in-dash CD, My problem is the CD player does read and play but it will stop suddenly and eject itself, few of my friends have told me it could be due to dirty lens and I have seek a second opinion from a pro car audio installer and they told me is my lens is damaged and needs repair."

The "pro car audio installer" probably doesn't have a clue but mentioning the lens is sure to impress - NOT!

(From: Filip M. Gieszczykiewicz (filipg@repairfaq.org).)

If you installed a *new* player, I doubt that this is the problem. Most likely, alas, is a wiring mistake or a bad connection. Did you follow the instructions and use the recommended wire harness adapter? Did you provide a good, solid ground? What wire-splicing method did you use? Did you tape/heat- shrink all connections? Did you mount the radio securely in the dash?

Most car CD-players will spit out the disk when power is interrupted to them. Does it happen when you hit a bump or are going over rough road?

Check over the wiring, then check the ground, but first check *when* exactly the problem appears!

Take it for a test-drive over a bumpy road: does the light flicker before the disk comes out? Any noise from the speakers?

(From: Steve Loboyko (sloboyko@mindspring.com).)

Automotive CD players are more susceptible to smoke on lens. Also, highly variable temperatures make servo "center" adjustments tougher and critical on a car in-dash CD player. For example, I am starting to have problems reading gold/green CD-R's in my car if the interior of the car is hot. Gold/blue CD-Rs won't work at all. All work 100% fine in home audio or CD mechanisms. It will be a pain in the butt to fix, with a hair drier simulating the "normal operating temperature" on a 90 degree day.

Who says CDROM drives are fragile?

The average person thinks that a CD player or CDROM drive is a delicate piece of precision equipment that will die given the least excuse. Well, chalk at least one up for the good guys!

(From: Joseph E. Fealkovich (jef812@ix.netcom.com).)

My best friend calls me up, he works at a computer outlet in Cleveland, OH (figure it had to be Cleveland! :-) --- sam), to tell me he has a Teac CDROM he 'accidentally' ran over with a pallet truck loaded with about 850 pounds of DOS and Windows (who says software isn't a tangible asset! :-) --- sam).

The CDROM drive is crushed a little bit in the rear, the faceplate popped off and skittered across the floor. Upon obtaining this CDROM drive, I look at it and yes, the back part is pretty well damaged. Me and my good friend Timmy take this poor unit apart to look at the insides. I'll be damned, there is no internal damage whatsoever. All that has to be done is straighten the main chassis of this CDROM and straighten out the outer case. While I was at work straightening out the CDROM, I hit Teac's website to get the drivers for this CDROM, and I'll be double damned, IT IS A 16X CDROM DRIVE!! COOL! The model number is CD-516E, cool, if I get this gem working, I can put it on my secondary port on my 32-Bit IDE interface. Sure enough, I straightened out the crushed case on this unit and I install it with the drivers I downloaded from Teac's website. This CDROM works like it was brand new!:-) WOW, is this damn thing fast! COOL, I got a free 16X CDROM, all I had to do is fix the damaged case and chassis!:)

Most expensive replacement part of the century award

This is right up there with $400 hammers and $20,000 toilet seats :-)

MCM Catalog #38, page 500: Original Aiwa/Sony Spindle Assembly: $94.50(ea). It is part number 32-7275 if you are eager to order one ;-).

From the picture, this is the type of spindle assembly used in the typical $70 portable CD player or cheap (by now obsolete) CDROM drive - a $1.99 Mabuchi style motor (two pin connector included!) and plastic self locking spindle platter glued or pressed to the shaft.

Do people actual pay this???? Why would anyone spend almost $100 for one of these replacements?

Yes, I know most of the answers. The question is to stimulate discussion.

Comments on Sony KSS pickup suspension problems

There seems to be some debate as to what extent weak suspension contribute to uncorrectable (by the internal adjustments) skipping and other erratic behavior. However, it is generally agreed among those who actually have to repair CD players and CDROM drives using Sony KSS pickups that such deteriorated suspensions can indeed be a cause of a variety of problems.

(From Mark Z. (zmachar780@aol.com).)

Anyone who has worked much with these units knows that the suspension can be a factor, especially where a player is somewhat finicky about which discs it likes or doesn't. This is particularly true of the D- series portables. I call attention also to the Denon DN2000 type dual players which use the KSS240A optic. Replacing the pickup seems to *always* fix these type of erratic skipping problems.

There is no way I know of to tell for sure that the focus bias or other adjustment won't get it back into nominal area of operation, other than just trying it. In fact, adjusting the focus bias (focus offset) is often done to get the player into a better operating area, and to save the expense of a new optic. With a player say, 4 to 5 years old, the actual deterioration may be quite minor, and the adjustment may be all that is needed. Of course, if if it is really that minor, why was it acting up in the first place? I disagree with Sony on the issue of deterioration. I've seen too many examples, particularly when the objective lens is 'bottomed out'. If the focus servo is really able to overcome this physical problem:

- The focus drive electronics, transistors, IC, whatever will run unnecessarily hot. These circuits are designed to have a zero average offset to lower average power dissipation.
- Why then does the RF signal look so bad on players where the disc table is installed at the wrong height by as little as 1/2 mm?

However, most skipping, sticking, repeating, and similar symptoms are still caused by feed problems and spindle motors. Sony is correct to state that many pickups get replaced unnecessarily. I attribute this to inadequate technician training, and also that CD players work by FM.... (F***ing Magic). tech humor. Ha. Ha :-).

Enhancing the sound quality of an inexpensive CD player

OK, this isn't for everyone. But, if you have the electronics experience and desire, it may be possible:

(From: Michael Widlok (widlok@uci.agh.edu.pl).)

As we all know, reading errors are NOT main problem in CDs (as I know it is not a problem at all. I checked this in my old Technics). What really making some of them sounds so bad are awful output states and analogue filters. Sound of some cheaper players can quite easily be improved by changing these crappy output states and filters. When I recognize this I went to the market and I bought old second- hand Technics (or Matsushita) SL-P550 for a rather low price. I chose this one because it had the good optical deck (linear motor and three points spring suspension) and generally was in good condition. Then, it was extremely easy to find all signals on electronics board, as most of them are marked (what an idea!) and most important ICs are "typical" and easy to find in catalogues (it does not mean that they are good). Finally I decided to change everything from digital filter to the output. I bought NPC 8x oversampling filter, Burr-Brown DACs and designed my own analogue lowpass filters and output states. I still don't know much of a problem jitter is, but I wanted to make a really HiFi CD, so I throw away the 16.9344 MHz crystal and connected XTI pin of main laser receiver/decoder to the separate low jitter oscillator. For connections from main board I used short wires soldered directly to electrical paths, and then connected to my own circuits. It is funny how a few signals were needed (Data In, Bit CLK, L/R CLK, and System Clock - all can be found directly on Yamaha digital filter on main board). I also change (upgrade) the power supply and add a display on/ off switch. I think that almost every CD (maybe not small portable units) can be upgraded in this way, but be careful - CDs are usually NOT the limiting components in stereo system. You need a really good one to hear the difference in between them.

Impress your friends with the power of your CD player

The laser output of the typical CD player optics is less than 1 mW but since the beam is focussed to a diffraction limited spot of less than 2 um the resulting power density is truly impressive:

(Portions of the following from: James Carter (jcarter@photon-sys.com).)

Intensity is related to power by the 'area' of the beam. For a Gaussian laser (as most semiconductor lasers are), the 'area' of the beam is related to the area of the intensity contour (usually an ellipse for these guys) representing 1/e^2 or approx. 13.5% of peak intensity (at the centroid).

Thus the peak intensity occurs at the centroid and equals

```
            2 * Po
   Io  =  ------------
          pi * Wx * Wy
```

Wx and Wy are the beam semi-diameters for the 1/e^2 contour.

The beam size at the facet of a semiconductor laser can be as small as 1.5 by 3.5 microns. The high power density at the facet represents the cause for most common failure modes in laser diodes. For a 5 mW laser diode, the resulting power sensity on this facet can be in excess of 600 MW (that is Megawatts) per square meter! Sounds impressive, doesn't it?

At the CD, the spot is even smaller which for the same power would result in even higher densities. However, this is more than offset by the fact that a significant fraction of the original power is lost in the optics so the the power density might be only - 300 MW per square meter. I still would not recommend hanging out at the focal point!

Note that while these numbers are impressive, conduction and other losses generally prevent any actual damage from occurring to most common materials. However, in a CD-R recorder using a laser diode with a power output of similar magnitude, the temperature rise at the disc even while spinning at 4X or greater speed is sufficient to blast holes in the intermediate (green) information layer. Watch out!

CD to VCD converter?

(From: Allen Bong (sfbong@tm.net.my).)

In Malaysia, many people convert their cd player to be able to play vcd. The whole conversion by a skilled technician including parts is only US$60.

They can convert cheap CD players selling at RM200-300. The converter just took the signal coming from the amplifier after the CD head. And the output is RF signal for the TV. I once saw one of these cards to have a 8051 uC on it and I don't really know how the thing works. They also do mods on LD players and it works well with the remote control on the LD player.

Modifying CD player to get at data stream?

(From: Bill Den Beste (billd@reprise.com).)

A couple of years ago Elector electronics magazine published several articles about add-on items for digital audio. They also published a construction article for making a CD player.

The data stream is called SPDIF (Sony Philips Digital Interchange Format). This is the same data stream format that you'll see at an internal node on every Sound Blaster card. It is not just audio waveforms encoded as numbers. It also can contain the copy bits, and perhaps other stuff. I believe that it is a 24 bit data format, even though the data on the CD itself is only 16 bits.

Philips and SGS Thomson make neat consumer IC's that process this data stream in various ways. Again see the back issues of Elector for more information. If you cannot find them, let me know by email and I'll search my archive.

Designing CDROM reader to recover data from damaged CDs, CD-Rs, or CD-RWs

A disc/k which has been cracked or some of the coating has peeled off, may be totally unreadable, especially if any of the damage is in the directory area.

In principle, you could design a CD reader that would get most of the data in the areas that are not damaged. It would have to read slowly so that focus and tracking lock could be reacquired after skipping the damaged area. Whether a normal CD reader could be modified I don't know, it might take custom circuitry to rotate the disc at a programmable slow rate and pick off the raw data. Decoding and reconstruction could be done in software. It could be a big project with questionable returns. There would still be major gaps and with data, that could be bad news. This is worse than attempting to recover data from a magnetic disk (diskette or hard drive).

Exploration and Tinkering

Interesting CD player signals

Poking around inside a working CD player makes an excellent exercise for the student. Component CD players very often have clearly marked test points for RF, focus, tracking, and audio data. With care, there is little risk of damaging anything as long as you are not tempted to try your hand at tweaking any of the internal adjustments.

If you have nothing better to do and you have your CD player open, try to locate the test points for data, fine tracking, and focus. They may be labeled something like TP.DTA (or TP.RF), TP.FO, TP.TR.

TP.DTA or TP.RF is the data coming off of the disc having gone through only the photodiode segment combiner and preamp (probably). Using a 10:1 probe set the scope for a horizontal sweep of around .5 us/div. Try a vertical sensitivity of .2 V per division to start and adjust for a full screen display. Use internal positive triggering. While playing a disc, you should see the classic 'eye' pattern used in the communication world to characterize channel quality.

The CD player 'eye' pattern

The 'eye pattern' depicted below results from the characteristics of the run length limited 8-14 modulation coding used on the CD where there are no fewer than 3 and no more than 11 clock cycles per symbol. You should be able to make out the fact that the minimum distance between channel bits is 3 with the smallest distance between bit transitions of about 3*232 ns. The readout clock is 1/(232 ns) or about 4.321 MHz.

A 'good' eye pattern will be clean, symmetric, and stable with clear visibility in the cross hatched areas. Its amplitude is typically in the .75 to 2 V range p-p when measured at the RF test point. This waveform may be viewed using an oscilloscope of at least 5 MHz bandwidth.

Some typical RF amplitude specifications:

- Aiwa: 1.3 to 1.4 V p-p.
- Sony full size: 1.2 V p-p, auto and portable: 0.85 V p-p.

This diagram shows the general form of the eye pattern present while playing a musical track or reading data from a CDROM. An actual scope trace from a typical CD player RF testpoint is shown in: CD Player Eye Pattern.

```
        ______________________________________________________
       /      \   \   \   \    \/  \/  \/  \/  \/  \/  \/  \/
      /        \   \   \   \   /\  /\  /\  /\  /\  /\  /\  /\
     /          \   \   \    \/  \/  \/  \/  \/  \/  \/  \/  \/
                 \   \   \   /\  /\  /\  /\  /\  /\  /\  /\  /\
                  \   \    \/  \/  \/  \/  \/  \/  \/  \/  \/
                   \___\__/\__/\__/\__/\__/\__/\__/\__/\__/\__

                        |<---- 1 us ---->| (approximately)
```

Examination of the eye pattern would be the first measurement that would be performed to determine the condition of the CD player optics and electronics. A good eye pattern eliminates most of the parts of the optical pickup from suspicion.

Note that the eye pattern observed while the player is accessing the following areas of the disc may not be well formed as in the diagram above:

- Disc directory (Table of Contents or TOC).
- Before the start of the first track (Track 1, time less than -0:01).
- Between tracks of distinct selections (where there is silence).
- After the end of the last track.

This is because there is no musical data at these locations on the disc (but probably a constant value like 0) and the TOC and/or time display is obtained from the Q bit. The Q bit is part of the Control and Display byte that is present once per frame (14 EFM coded bits out of 588 total bits per frame). See the section: CD (disc) construction. This funny looking eye pattern has much more low frequency content and thus does not exhibit the nice cross hatched area as will be present with the highly variable audio data.

Focus and tracking drive or error signals

TP.FO or TP.FE is the focus voice coil error signal. Monitoring this with a disc in good condition will show what looks like noise - the more or less random fluctuations in actuator current necessary to maintain proper focus within +/- .5 um of the disc surface. On a warped disc you will see the DC level of this signal varying at the disc rotation rate. On a damaged disc, you will see higher frequency variations in the level depending on what kind of defects are present. Gently tapping the optical deck should evoke a visible effect on this signal as well as the servos correct for your mischief.

TP.TR or TP.TE is the fine tracking voice coil error signal. As with TP.FE, this will show a noise waveform with a good disc. On a disc with runout, you will see a periodic level variation at the spindle rotation frequency. Note how the DC value of this signal gradually changes as the voice coil actuator maintains lock on the track while the track spirals outward.

Eventually, this error becomes great enough to trigger the coarse tracking motor to jog the pickup a fraction of a mm and recenter it on the track at which point the signal you are watching will suddenly shift its DC level.

On a disc with scratches, there will be higher frequency deviations which will be readily visible on a scope trace. Gently tap the optical deck from various points and observe the effects on this signal.

For both focus and tracking, you can actually hear the voice coil actuators as they compensate for minute defects or just the normal data pattern. This is the 'gritty' sound one hears from the CD audio or CDROM transport when it is operating correctly and is an indication that the laser and focus (at least) are most likely functioning properly. If you listen carefully, you can actually hear various defects by the effect they have on this gritty sound but there will be no corresponding effect in the audio outputs as there would be with an LP.

Focus, tracking, and error correction performance

If you have a test CD (or use your regular CD), put your scope on one of audio outputs. Put some thin pieces of tape or mark with a (water soluble) felt tipped pen radially on the bottom surface of the disc to create some 'defects'. Play some tracks which have constant pure tones or silence. For widths less than the error correcting capability of your CD's LSI chipset, there should be no detectable signal degradation. See what happens as you increase the width of your 'defects'. Put your finger on the spindle or even gently touch the disc as it is rotating. Note that unless you really press hard, the disc will continue to play normally without any change in pitch. This is due to the servo control and extensive buffering of the data - unlike an LP turntable where the instantaneous speed is what determines pitch.

Other experiments are left as exercises for the student.

IR detector circuit

This IR Detector may be used for testing of IR remote controls, CD player laser diodes, and other low level near IR emitters.

Component values are not critical. Purchase photodiode sensitive to near IR - 750-900 um or salvage from optocoupler or photosensor. Dead computer mice, not the furry kind, usually contain IR sensitive photodiodes. For convenience, use a 9V battery for power. Even a weak one will work fine. Construct so that LED does not illuminate the photodiode!

The detected signal may be monitored across the transistor with an oscilloscope.

Inexpensive laser power meter

In principle, a reverse biased photodiode and mA meter can be used to measure laser power. A silicon solar cell could also be used in zero bias current source (photovoltaic) mode. However, this is sort of difficult for CD and similar equipment which don't produce a nice compact collimated beam that can be directed at the photodiode without losing too much. The beam from the objective lens of CD, DVD, or other similar optical storage equipment is highly divergent.

The conversion factor of current to laser beam power also depends on wavelength and the way the photodiode was processed. A typical silicon photodiode has a sensitivity of 0.4 to 0.45 mA per mW at 632.8 (HeNe laser wavelength, close enough for DVD). At 780 nm, it will increase to 0.5 to 0.55 mA per mW.

More information on laser power meters can be found in Sam's Laser FAQ in the chapter: "Items of Interest".

Laser diode fundamentals

Note: This is a summary. For additional information on using laser diodes, see Sam's Laser FAQ in the chapter: "Diode Lasers".

Typical CD laser optics put out about 0.1 to 1 mW at the objective lens though the diodes themselves may be capable of up to 4 or 5 mW depending on type. The laser diodes for CD players are infra red - IR - usually at around 780 nm. Visible laser diodes are also readily available from many sources. The most common wavelength is 670 nm which is deep red but 630 nm diodes are also available - red orange and appear much brighter (and more expensive at the present time). Inexpensive (well relatively) laser pointers use visible laser diodes with power outputs up to about 5 mW. This is enough power to risk permanent retinal damage if you look into the beam especially when well collimated as is required for a pointer. Don't.

Typical currents are in the 30-100 mA range at 1.7-2.5 V. However, the power curve is extremely non-linear. There is a lasing threshold below which there will be no output. For a diode rated at a threshold of 80 mA, the maximum operating current may be as low as 85 mA. This is one reason why all actual applications of laser diodes include optical sensing (there is a built in photodiode in the same case as the laser emitter) to regulate beam power. You can easily destroy a laser diode by exceeding the safe current even for an instant. It is critical to the life of the laser diode that under no circumstances do you exceed the safe current limit even for a microsecond!

Laser diodes are also extremely sensitive to electrostatic discharge, so use appropriate precautions. Also, do not try to test them with a VOM which could on the low ohms scale exceed their safe current rating.

While only a few hundred mW at most is dissipated by the laser diode, a good heat sink is also important for long life and stability. The optical pickup is usually a metal casting partially for this reason. Remember that the active diode chip is only about .1 mm on a side. However, some optical blocks are now made of plastic so this must not be as important as in the past.

It is possible to drive laser diodes with a DC supply and resistor, but unless you know the precise value needed, you can easily exceed the ratings.

One approach that works for testing is to use a 0-10 VDC supply (preferably a linear supply - a switching supply may put out laser diode destroying pulses) with say, a 100 ohm resistor in series with the diode. Slowly bring the current up until you get a beam. Use an IR detector for this! If you get the polarity backwards or are actually measuring across the internal photodiode, the voltage across the diode will go above 3 volts or will be less than 1 V. Then, turn power off and reverse the leads. Note: some laser diodes will be destroyed by reverse voltage greater than 3 V - a spec sheet will list the reverse voltage rating. The ones I have tried out of CD players were fine to at least 5 V in the reverse direction.

Without a laser power meter, however, you will have no way of knowing when the limit on safe beam power (safe for the laser diode, that is) is reached. If you have the data sheet for your laser diode, then the best you can do is limit the current to specified maximum rating. Also, there is usually a weakly visible emission which appears red (for IR laser diodes) present when powered. Do not be fooled into thinking that the laser diode is weak as a result of this dim red light. The main beam is IR and invisible - and up to 10,000 times more intense than it appears.

The beam from the raw laser diode is emitted in a broad wedge typically 10 x 30 degrees. A convex lens is needed to collimate the beam (make it parallel). For optimal results, this needs to be anamorphic - unequal horizontal and vertical focal lengths - to correct the astigmatism of the beam. The mass produced optical pickups used in CD players include this as well as other sophisticated optics.

For an actual application, you should use the optical feedback to regulate beam power. This usually takes the form of a simple current controlled power supply with extensive capacitive filtering and a regulated reference. It is possible to modulate the beam power by tapping into the feedback circuits - as long as you guarantee that the maximum current specification will never be exceeded. Laser diodes do not behave like LEDs and cannot be pulsed for higher peak power - they turn into DEDs - Dark Emitting Diodes.

Single chips are available from a number of manufacturers for driving laser diodes in both CW and modulated modes.

For additional information, see the document: Sam's Laser FAQ.

Laser diode life

For all intents and purposes, laser diodes in properly designed circuits do not degrade significantly during use or when powered on or off. However, it doesn't take much to blow them (see the section: Laser diode fundamentals). I have seen CD players go more than 10,000 hours with no noticeable change in performance. This doesn't necessarily mean that the laser diode itself isn't gradually degrading in some way - just that the automatic power control is still able to compensate fully. However, this is a lower bound on possible laser diode life span.

Laser diodes that fail or weaken prematurely were either defective to begin with or, their driver circuitry was inadequate, or they experience some 'event' such as a power-on transient resulting in momentary overcurrent, possibly as short as a few nanoseconds in length!

As noted elsewhere, a weak laser diode is well down on the list of likely causes for CD player problems.

Of course, in the grand scheme of things, even LEDs gradually lose brightness with use.

However, this is another area where manufacturers can cut corners - see the next section.

Comments on CD player/laser life

(From: David Kuhajda (dkuhajda@locl.net).)

I did a check on several manufactures expected laser output life. Note this does not relate to the life of the mechanical parts of the optical pickup assembly itself.

The usable laser output light level is that which the electronics and light sensors can still reliably detect the rf pattern returning off the disc. A new laser in most units optimally will give 1.5 V p-p RF level, while the threshold for failure is around .95 V p-p. (This is why many CD players cannot reliably play CD-R's as they have between 60% and 80% reflectivity of a normal CD).

Non-officially acknowledged hours rating from a MAJOR CD/LD player manufacture:

A few years ago most manufactures of consumer grade cd players reduced the quality of the laser to around 7,000 hours usable output. This is a light bulb in a sense and all light sources will eventually degrade. The laser has an auto power circuit to maintain the proper calibrated light output and the laser power should NEVER be increased may already be operating near the point at which the laser is damaged. The temperature of the laser diode also increase and as the laser gets warm the light output will decrease. I have seen this many times by monitoring the RF level while playing a reference disc and heating up the unit with a hair dryer in those old units that come in saying skips and stops playing after an hour or so.

Today many el-cheapo units has rated laser light output life of between 700 and 3000 hours. Yes, really that low. Even 7,000 hours comes out to 9.5 months if the unit is playing 24 hours a day. I cannot tell you how many of these consumer grade units I have had businesses bring in that was playing music on hold all the time, then having to tell them it is not a warranty failure due to excessive use and using a consumer product in a commercial application (all warranties on consumer goods specifically exclude this type of use)

It is very possible that due to the large air vents required on boomboxes due to the heat generated by the audio output IC, that a lot of dirt gets into the inside of the optical assembly. For example, 99% of the Aiwa units we get in for repair wind up needing new optics to make the play reliably again as the dirt has caused too much internal damage to the delicate optical pickup mechanism.

Sony acknowledges that over 90% of the optics they test come out good on tests, but still replacing them fixed the 'skipping' problem in any given cd player.

The number one failure I was seeing with optics was not the laser diode output, but from the internal grating lens shifting inside the optics (usually from the glue holding the internal grating lens in place had cracked and come loose).

The second failure I would see would be an open focus coil. This was due to poor design where the combo unit would spike the focus coil with full dc b+ on power on of the unit, causing it to exceed its mechanical limits and heat up the windings.

The only case of actual worn out lasers I have seen was in a big box RCA marketed made in China combo stereo. Whenever the unit was plugged in, the laser was on, when the amplifier was turned on the laser would get spiked with large DC voltage. The unit was suppose to have been an exchange in warranty unit, but they had to make it a repair item and supply the modification entire cd mechanisms with circuit board and an auxiliary circuit board as well.

LD players due to the larger optical pickup assembly used and the higher cost design of the unit are made to last MUCH longer than the normal el-cheapo cd player.

DVD players on the other hand are currently being made so cheaply that we are commonly seeing them in for repair JUST out of warranty with weak lasers (even from major manufactures). Just look at this Oritron super junk DVD brand that is currently on the market right now. Get real: $125 for a DVD player, what kind of junk is it really. I have a friend that works at the local Best Buy service desk and asked him after seeing a pile of these units that have been returned about them, most of them actually have problems within the first week that need to be sent back to the manufacturer for repair. No actual parts or service literature is available for these units.

CW Laser Light (reverse engineered from commercial unit)

This circuit was traced from a commercial CW laser light. Errors may have been made in the transcription. The type and specifications for the laser diode assembly (LD and PD) are unknown. The available output power is unknown but the circuit should be suitable for the typical 3-5 mW visible or IR laser diode (assuming the same polarity of LD and PD or with suitable modifications for different polarity units.)

If you do build this or any other circuit for driving a laser diode, I suggest testing it first with an LED and discrete photodiode to verify current limited operation. Them with the laser diode in place, start with a low voltage supply rather than 9V until you have determined optimal settings and work up gradually. Laser diodes are very unforgiving.

Note the heavy capacitive filtering. Changes would be needed to enable this circuit to be modulated at any reasonable rate.

Notes:

1. Capacitor C4 value estimated.
2. Potentiometer R3 measured at 6K.
3. LM431 shunt regulator set up as 2.5 V zener.
4. Supply current measured at 150 mA (includes power on LED not shown).

5. Transistor types do not appear to be critical.

Use of a CD, CDROM, CD-R, or DVD disc as diffraction grating

You have no doubt been impressed by the neat and nifty rainbow patterns seen in the reflection off of a compact disc. This is due to the effect of the closely spaced rows of pits acting like a diffraction grating.

How good is it?

I tried an informal experiment with both a normal music CD and a partly recorded CD-R (using the label side of the CD-R as the green layer on the back is a great filter for 632.8 nm HeNe laser light!).

Both types worked quite well as reflection gratings with very sharply defined 1st and 2nd order beams from a collimated HeNe laser. There was a slight amount of spread in the direction parallel to the tracks of the CD and this was more pronounced with the music CD, presumably caused by the effectively random data pits.

If you can figure out a non-destructive way of removing the label, top lacquer layer, and aluminum coating, the result should be a decent transmission type grating.

Note that there is usually no truly blank area on a normal CD - the area beyond the music is usually recorded with 0s which with the coding used, are neither blank nor a nice repeating pattern. The CD-R starts out pregrooved so that the CD-writer servo systems can follow the tracks while recording. There is no noticeable change to the label-side as a result of recording on a CD-R.

The track pitch on a CD is about 1.6 um or about 625 grooves/mm, quite comparable to some of the commercial gratings from Edmund Scientific or elsewhere. (Note that this is the nominal specification but may vary somewhat and will be less on those CDs that contain more than 74 minutes if music or 650 MB of data but it is probably constant for any give CD.) For a 1 mm HeNe spot, the curvature of the tracks is totally inconsequential. However, for larger area beams, this will have to be taken into account - using outer tracks will be better.

The 'tracks' on a DVD are much closer together - .74 um compared to 1.6 um for a CD. Since this spacing is very close to the 632.8 nm wavelength of a HeNe laser, only the 0th and first order spots will be present and the first order spots will be at a large angle - 59 degrees *within* the polycarbonate substrate. This becomes an even larger angle when they exit due to the refraction from the surface. At this extreme angle, the spots are weak and distorted. The typically longer wavelength of a laser pointer (up to 670 nm or more) would be even worse. Shorter wavelengths (like that of a green HeNe laser at 543.5 nm) would result in a smaller angle and cleaner spots.

Interestingly, on my DVD demo disc (I don't even own a DVD player), the reflection from the label-side also shows a rainbow pattern but it has a track spacing consistent with the CD rather than DVD format. (The DVD is a sandwich of two .6 mm thick polycarbonate substrates with the information on their inner surfaces allowing for either a single or double-sided disc. In the case the pattern for the label-side is just there for decoration!)

Most other optical media can be used as diffraction gratings as well. DVDs (Digital Versatile Discs) in particular should be even better at this as their tracks are much closer together than those on CDs :-).

Service Information

Advanced CD troubleshooting

If the solutions to your problems have not been covered in this document, you still have some options other than surrendering your CD player to the local service center or the dumpster.

When tackling electronic faults, a service manual with schematics will prove essential. Many manufacturers will happily supply this for a modest cost - $10 to $50 typical. However, some manufacturers are not providing schematics - only mechanical and alignment info. Confirm that a schematic (not just a block diagram) is included if you need one before purchasing the manual.

Sams Technical Publishing (formerly Howard Sams) publishes Sams Photofacts service data for almost every model TV that has ever been sold but their selection of CDfacts is nearly if not totally nonexistent.

Test point locations, important signals, and power supply voltages are often clearly labeled on the electronics board. In this case, quite a bit of troubleshooting can be done without the schematic. There is a good chance that the problem can be isolated to a particular subsystem by just following the signals using this information.

Whatever the ultimate outcome, you will have learned a great deal. Have fun - don't think of this as a chore. Electronic troubleshooting represents a detective's challenge of the type hat Sherlock Holmes could not have resisted. You at least have the advantage that the electronics do not lie or attempt to deceive you (though you may beg to differ at times). So, what are you waiting for?

Web resources

Tandy (Radio Shack) has a nice web resource and fax-back service. This is mostly for their equipment but some of it applies to other brands and there are diagrams which may be useful for other manufacturers' VCRs, TVs, CD players, camcorders, remote controls, and other devices.

- Radio Shack Product Support

Since Radio Shack does not manufacture its own equipment (I can tell this doesn't particularly surprise you!) - they are other brands with Realistic, Optimus, or other Radio Shack logos - your model may actually be covered. It may just take a little searching to find it.

Suggested references

There are a variety of books dealing with all aspects of CD player repair. While not as common as books on VCR repair, there are more of these than you might think. Your local public library may have some in the electronics section - around 621.38 if your library is numbered that way. Technical bookstores, electronics distributors, and the mail order parts sources listed in this document carry a variety of these texts.

1. Troubleshooting and Repairing Compact Disc Players
   Homer L. Davidson
   TAB Books, A Division of McGraw Hill, Inc., 1989
   Blue Ridge Summit, PA 17294, USA
   ISBN 0-8306-9107-3 (hardcover), ISBN 0-8306-3107-0 (paperback)

   Includes several complete CD player schematic diagrams which are quite interesting in their own right.) There is now at least a third edition (1996).

2. Compact Disc Troubleshooting and Repair

Neil Heller and Thomas Bentz
Howard W. Sams & Company, A Division of Macmillan, Inc., 1988
4300 West 62nd Street
Indianapolis, Indiana 46268, USA
ISBN 0-672-22521-2

3. The Compact Disc Book - A Complete Guide to the Digital Sound of the Future
   Bryan Brewer and Edd Key
   Harcourt Brace Jovanovich, Publishers, 1987
   Orlando, FL 32887
   ISBN 0-15-620050-3 (paperback)

   Includes a variety of high level information but no details.

4. The Complete Guide to Digital Audio Tape Recorders including Troubleshooting TIps
   Erik S. Schetina
   P.T.R. Prentice Hall
   Englewood Cliffs, NJ 07632
   ISBN 0-13-213448-9

   Mostly directed to digital audio tape recording but also includes some information on digital sampling and CIRC coding.

5. DAT - The Complete Guide to Digital Audio Tape
   Delton T. Horn
   TAB Books, Inc., 1991
   Blue Ridge Summit, PA 17294-0214
   ISBN 0-8306-7670-8 (hardcover), ISBN 0-8306-3670-6 (paperback)

   Includes a chapter on the compact disc.

6. The Compact Disk
   Ken C. Pohlmann

7. All Thumbs Guide to Compact Disc Players
   Gene B. Williams
   TAB Books, Inc., 1993
   Blue Ridge Summit, PA 17294-0214
   ISBN 0-8306-4179-3 (paperback)

   This one is very basic but does cover the most common problems and has illustrated instructions for hookup, cleaning the lens, cleaning and lubricating the mechanism, simple electronic problems, etc.

Rubber belts in CD players

The type of belts used in CD players for drawer loading and sometimes elsewhere is nearly always a type with a square cross section. Obtaining an exact replacement belt may be difficult and not really necessary.

Measure the old belt and select one from a parts supplier like MCM Electronics which is as close as possible - equal or slightly greater thickness and an inside circumference (this is how they are measured) such that it will be tight but not so tight as to slow the motor or cause damage to the bearings. This usually means about 5 to 10 percent less than the old (stretched) belt.

Interchangeability of electronic and mechanical components

The question often arises: If I cannot obtain an exact replacement or if I have a CD, VCR, or other equipment carcass gathering dust, can I substitute a part that is not a precise match? Sometimes, this is simply desired to confirm a diagnosis and avoid the risk of ordering an expensive replacement and/or having to wait until it arrives.

For safety related items, the answer is generally NO - an exact replacement part is needed to maintain the specifications within acceptable limits with respect to line isolation, X-ray protection and to minimize fire hazards. However, these components are rare in CD players.

Although only a few manufacturers produce most of the components in CD players and CDROM drives, don't expect a lot of readily interchangeable parts other than the common electronic ones listed below. In their never ending search for cost reductions and technology improvements, manufacturers are constantly tweaking their designs. More and more circuitry is finding its way into custom VLSI chips. Fortunately, these do not fail too often.

The only parts that are fairly standardized aside from the electronic components are motors. Often, if the motor is physically interchangeable, then it will work as a replacement. Electronic components and entire circuit boards (if identical models and production run) can often be substituted without difficulty though servo alignment will probably be needed due to slight unavoidable differences between apparently identical pickups or electronic components.

For common components, whether a not quite identical substitute will work reliably or at all depends on many factors. Except for the optical pickup, non-custom components in CD players are fairly standard.

Here are some guidelines:

1. Fuses - exact same current rating and at least equal voltage rating. I have often soldered a normal 3AG size fuse onto a smaller blown 20 mm long fuse as a substitute.

2. Resistors, capacitors, inductors, diodes, switches, potentiometers, LEDs, and other common parts - except for those specifically marked as safety-critical - substitution as long as the replacement part fits and specifications should be fine. It is best to use the same type - metal film resistor, for example. But for testing, even this is not a hard and fast rule and a carbon resistor should work just fine.

3. Rectifiers - replacements should have at equal or better PRV and Imax specifications. For power supply rectifiers, 1N400x types can usually be used.

4. Transistors - substitutes will generally work as long as their specifications meet or exceed those of the original. For testing, it is usually ok to use types that do not quite meet all of these as long as the BVceo and Ic specifications are not exceeded. However, performance may not be quite as good. For power types, make sure to use a heatsink.

5. Motors - small PM motors may be substituted if they fit physically and their winding resistance are reasonably similar (say, within 25 percent of one-another).

   Brushless DC spindle motors are not usually interchangeable.

6. Sensors - many are sufficiently similar to permit substitution.

7. Power transformers - in some cases, these may be sufficiently similar that a substitute will work. However, make sure you test for compatible output voltages to avoid damage to the regulator(s) and rest of the circuitry.

8. Belts - a close match should be good enough at least to confirm a problem or to use until the replacements arrives.

9. Mechanical parts like screws, flat and split washers, C- and E-clips, and springs - these can often be salvaged from another unit.

10. Optical pickups - see the section below: "Interchangeability of components in the optical pickup".

The following are usually custom parts and substitution of something from your junk box is unlikely to be successful even for testing: microcontrollers, other custom programmed chips, display modules; and entire optical pickups, optical decks, or power supplies unless identical.

Interchangeability of components in the optical pickup

Once you have located a problem in the optical pickup, what should you do? The quick answer is: probably nothing. In the end any such attempts may simply prove too time consuming and frustrating.

For parts like laser diodes and photodiode arrays, there are probably too many variables to consider and the labor and risks involved - even for the do-it-yourselfer - would likely be unacceptably high. As an example, the laser diode, which is an expensive component you might be tempted to attempt replacing with one from another pickup (1) may not fit physically, (2) may have different polarity laser diode and photodiode inside the case, (3) may have a very different threshold current and safe operating current, and (4) may have a different optical alignment with respect to any index marks. Any of these would likely make the interchange virtually impossible. The only possibility like to have any chance of success would be to replace the laser diode with a known working device from another *identical* pickup. This is known to work for at least some models but I wouldn't guarantee its success in general.

The only breakdown below the pickup level that I would consider as having a reasonable chance of success would be to swap the lens assembly including focus and tracking coils between identical pickups. The optical alignment is not supercritical at this point. However, servo alignment might be needed after this exchange. See the section: Aligning the lens assembly after replacement.

One style of lens assembly found in many (Sony) pickups is mounted with two tiny Torx style screws from the top of the optical block. Pop the black plastic cover and you will see these at the end opposite the lens. A small straight blade screwdriver or .7 mm hex wrench may work in place of the Torx. Unsolder the four connections for the focus and tracking coils and the entire lens assembly can be removed without disturbing anything else. (Yeh, right, like anyone would actually go to all this trouble!). The lens assembly may be mounted on a platform that is fastened with three screws - two which affect optical alignment from the bottom and a spring loaded screw from the top. Once the alignment is set at the factory, the lens assembly is fixed in place with adhesive. It should not need to be touched.

Thus, interchange of these lens assemblies is possible but expect to spend a lazy afternoon or more :-(. However, you will probably wish you had that friendly unemployed Swiss Watchmaker for your assistant.

If you have narrowed the problem down to the pickup and you have an identical pickup which you believe to be functional, the best bet is to exchange the entire pickup as a unit. Only minimal servo system alignment would likely be needed after such a replacement. The only optical adjustment needed might be the setting making the beam perpendicular to the disc surface - possibly a hexagonal nut on the bottom of the deck. Be careful with respect to static discharge which could destroy the laser diode. Sometimes, the cable carrying the laser drive voltage has a pair of solder pads to short while handling the pickup not connected to the electronics board. Take care not to rip any of the fine ribbon or other electrical cables and avoid damaging the delicate lens assembly. One other risk is that the laser power adjustment may be set too high for your new pickup - especially if you had turned it up in an effort to revive a weak laser diode.

Better yet is to replace the entire optical deck as a unit. This is a lot less work and there is no risk of optical alignment problems at all. Then, only (probably minor) servo alignment may be needed.

If you are lucky, the design of your player will even permit you to twiddle the servo adjustment screws while attempting to play a disc (with all the wiring in place) - which is really handy. Also see the section: Test CDs.

Aligning the lens assembly after replacement

Should you need to remove the lens assembly from a Sony or other optical pickup, it will need to be replaced in *precisely* the same position, accurate to .1 mm or better. Unless it is keyed in place to begin with, this will require monitoring of the return beam and maximizing the amplitude of the sum of the photodiodes A,B,C,D from a mirror or disc.

First of all, hope you never have to deal with this!

Second, it may be fundamentally impossible to accomplish with a disc in place unless you are the size of a dust mite and can fit between the CD and the pickup!

Finally, a minor miracle may also be required and it is best to arrange for this ahead of time :-).

If you get mostly one type of pickup, then you can build a test device which would power the laser and and provide a test point to monitor the combined photodiode current. In principle, it is simple. In practice you will most likely need a custom device for each type of pickup.

With some CD players, you can do this in test mode and monitor the RF while adjusting the alignment.

Recommended parts suppliers

For general electronic components like resistors and capacitors, most electronics distributors will have a sufficient variety at reasonable cost. Even Radio Shack can be considered in a pinch.

However, for consumer electronic equipment repairs, places like Digikey, Allied, and Newark do not have the a variety of Japanese semiconductors like ICs and transistor or any components like flyback transformers or even degauss Posistors.

See the document: Major Service Parts Suppliers for some companies that I have used in the past and others that have been recommended. Also see the document: Troubleshooting and Repair of Consumer Electronic Equipment for additional parts sources.

DISCLAIMER

Working on optical storage equipment entails a number of personal risks: electrical, laser, mechanical, as well as the possibility of irreversible damage to the equipment and loss or corruption of data due to improper repair or adjustment.

We will not be responsible for damage to equipment, your ego, county wide power outages, spontaneously generated mini (or larger) black holes, planetary disruptions, or personal injury or worse that may result from the use of this material.

- Back to Optical Drive Repair FAQ Table of Contents.

Introduction

Scope of this document

While compact disc (CD) players and CDROM drives account for the vast majority of optical disc platforms in the known universe, there are other types in use for both entertainment and data storage applications. These include:

- LD - LaserDisc - various forms of storage of feature length movies, instructional programs, and interactive video games on (usually) 12 inch single or double sided discs.

- MD - MiniDisc - Sony's attempt at converting everyone from analog cassette tape to optical digital record/play technology. Data storage versions also available.

- DVD - Digital Versatile (or Video) Disc - Super hyped next generation in video and data storage. This *will* replace CDROM but how much further it goes remains to be seen.

- WORM - Write Once Read Many drives - Older optical data storage storage technology using a media that may be written but which may not be erased and rewritten.

- CD-R - Recordable CD. A special case of WORM technology using the CD format which may be played or read in normal CD equipment. The CD-R writers are coming down in price and becoming much more common.

- MO - Magneto optical disk drives - various incompatible or marginally compatible forms of high capacity read/write storage on optical platters, usually in either 3-1/2" or 5-1/4" form factors, single and double sided.

These all use optical technology very similar to that of the compact disc and CDROM. Thus, most problems with these cousins of the CD will be similar. See the document: "Notes on the Troubleshooting and Repair of Compact Disc Players and CDROM Drives" for an introduction to the basic technology, general maintenance procedures, and diagnosis of most common problems. This document addresses those aspects of the technology and repair that are unique to each of these other formats. Problems with Sony PlayStation PSX (and similar) CDROM-like game machines are covered there as well.

Once CD (and DVD) rewritable technology becomes more popular (and lower in price), these will be added. I currenty have little information on this equipment.

Contributions are always welcome as you will note that there really isn't that much specific information at the present time on anything other than LaserDisk players and even this is sparse. I don't expect that much interest in or offers of CD-R, WORM, or MO repair information. However, MiniDisc has some sort of a following and we are destined to be inundated with DVD problems in the near future as they replace CDs as the equipment of choice. I am still waiting to see the inside of a DVD player - working or otherwise :-).

SAFETY

In addition to the usual safety precautions outlined in the document: "Safety Guidelines for High Voltage and/or Line Powered Equipment", some of this equipment has the added risk of vision damage from the higher power lasers that may be used for disk writers or recorders.

This isn't that much of a problem with LaserDisk players since the laser power is likely (but not guaranteed!) to be similar to that of a CD player where relatively minimal precautions are adequate.

However, for the technologies which can record or write on an optical disk, the laser power may be much higher and instant irreversible damage to vision is quite possible. Furthermore, these are almost always IR (infra-red) lasers which are for all intents and purposes, invisible. Proper precautions are essential and laser-blocking goggles are definitely recommended whenever the unit is powered without a laser shield in place. Once you damage both of your original equipment eyesballs, you don't receive any replacements (even if they are still under warranty - read the fine print of your contract)!

General safety precautions:

While there are fewer potential dangers involved in servicing an LD player or MO drive compared to a TV, monitor, or microwave oven, precautions are still required when working with the cover removed. These relate to electrical connections to the AC line, getting caught in the mechanisms, and exposure to the laser beam:

- Electrical: There may be a few exposed electrically live parts from the power line, usually around the power cord entrance, power transformer, and on/off switch. If there are, tape them over or cover them somehow so you need not be concerned with a low tech shock! Unless you are troubleshooting a primary side power supply problem, there will be no need to go near the AC line.

  Some equipment such as LaserDisc players may use switching power supplies with their own set of problems. Internal drives may include their own DC-DC converters as well (which are not particularly dangerous but can be easily damaged through the careless slip of a probe). In these case, see the document: "Notes on the Troubleshooting and Repair of Switchmode Power Supplies" for more information.

  Where an older LaserDisc player uses a Helium-Neon (HeNe) laser, there will be a high voltage power supply for the HeNe laser tube. While this is probably not powerful enough to kill you, a reflex action from touching the wrong terminal can result in collateral damage like ripped flesh from sharp sheet metal parts. These terminals are usually clearly marked and insulated but make a note of their location to be safe and add several layers of plastic electrical tape if they are exposed.

- Mechanical: Some of this equipment including LaserDisc players and higher performance optical drives spin relatively heavy (at least compared to a CD) platters at 3,600 RPM or more. The motors are larger and you really do not want to catch your tie in one of these (yes, I know, you don't wear a tie!).

- Laser: A variety of types of lasers are used in this equipment. It may be a diode type - either visible or IR, or in older LaserDisc equipment, a low power helium neon tube.

  - Low power (Class II, less than 1 mW at the lens) - This power level is typically used for the play-only or read-only equipment (CD, LD) or when in play or read mode for equipment that can write or record (MD, CD-R, WORM, MO).

  - Medium power (Class IIIa, 1 to 5 mW at the lens) - This power level may be used for recording or writing in a CD-R, MD, or MO device.

  - Medium power (Class IIIb, 5 to 30 mW or more at the lens) - This power level may be found in a CD-R or WORM drive in write mode. A typical CD-R drive sets the laser power at 3 to 5 mW for read and 25 to 30 mW for write.

  ALL THE HIGHER POWER LASERS ARE LIKELY TO BE IR AND INVISIBLE! You won't be able to see a bright beam you can avoid! The laser in all these devices is infra red, near IR - around 780 nm - border of visible range but for all intents and purposes invisible. While the laser is supposed to be set to low power for playing or reading POWER CIRCUITS CAN FAIL! Don't take any chances.

  With a visible beam, it is easier to avoid exposure and LD and DVD players use low power lasers anyhow. Reflections at these power levels are not strong enough to be a serious hazard. This will change eventually as DVD recorders and writers using higher power visible lasers are introduced. As a comparison, these will likely be similar in power level (5 mW) to the brightest laser pointers currently on the market and are a definite risk to vision at close range. Still, being visible, it is easy to avoid direct exposure.

However, for an IR laser producing an invisible beam, there is no way to reliably avoid the beam visually. With the optics intact (no damage to the pickup and none of the covers on the pickup removed) and a disk in place on the spindle or the lens covered with black tape (no holes!), it should be safe to work at a reasonable distance. Don't put one of your eyeballs up to the optical block - there could always be a light leak! Proper IR blocking goggles would definitely be a good idea where exposure to these higher power lasers is possible.

CAUTION: There is usually a very low intensity (in appearance) emission from an IR laser which appears deep red. It will be visible as a spot the size of the period at the end of this sentence when the lens is viewed from an oblique angle. This is just your eye's response to the near IR energy of the main beam. (Some people apparently cannot see this at all.) Do not be mislead into thinking that the laser is weak as a result of how dim this is. The main beam is up to 10,000 times more intense than it appears! It's power output is generally around 1 mW - comparable to a laser pointer. Take care. However, the red dot is an indication that the laser is being powered and probably functional, though it is no guarantee of the later. You really need a laser power meter or at least an IR detector to confirm the existence of an IR laser beam.

For more information on CD and optical disc technology

Philips/Magnavox used to have a very nice on-line introduction to a variety of consumer electronics technologies. Although their site has disappeared - and even people who work for them have no clue - I have now recovered several of the articles including those on TVs, VCRs, camcorders, satellite reception, and connections. See the Introductory Consumer Electronics Technology Series.

Also check out:

- A Fundamental Introduction to the Compact Disc Player is a somewhat more theoretical discussion of compact disc audio technology with diagrams and even some equations. If it doesn't put you to sleep, you will find quite a bit of interesting information in this article. In either case, it may prove of value.

- Andy Poggio's relatively short article: From Plastic Pits to "Fantasia" provides a nice overview of CD technology.

- The University of Washington has a couple of on-line tutorials which both appear to be excellent resources providing easy to understand discussions with many diagrams:

  - Compact Disc Technology.
  - Audio Compact Disc - An Introduction. This is part of their Consumer Electronics Education Project.

- The How Stuff Works Web site has some really nice introductory material (with graphics) on a variety of topics relating to technology in the modern world. Of relevance to this document are articles on CD technology, motors, remote controls, power adapters, etc.

- The Cimram International, Inc Web site provides information and links on CD and DVD technology, formats, mastering, and manufacturing.

The following sites have a variety of information on CD and DVD technology:

- CD Page
- MediaWorld

A couple of sites with CD-R specific information including some repair tips is:

- Rictee's CD-R Page.
- Andy McFadden's CD-R FAQ.

An extensive amount of information on other optical disc/k technologies with many useful links can be found at:

- Leopold's LaserDisc Page.
- The MiniDisc Page.
- The DVD Page.
- DVD Central at E/Town.
- DVD Demystified (Includes the DVD FAQ).

- Back to Optical Drive Repair FAQ Table of Contents.

Technology Specific Principles of Operation

LaserDisc (LD) Players

This is actually the oldest of the optical disc technologies to be introduced to the consumer market. In fact, most of its applications are for analog video storage - feature length movies and interactive learning tools and video games.

In terms of performance, video quality from the Laserdisc medium can be far superior to even SVHS and SuperBeta when viewed on a correspondingly high quality TV/monitor. Like a CD and unlike tape, access to any scene or even frame is nearly instantaneous. This is definitely a significant advantage for the casual viewer. However, it is the enabling technology for interactive learning and games. With over 65,000 individual frames on a side, this is a potentially very powerful way to present information as combinations of stills and moving segments and permit context dependent control of access or video action.

High-end video enthusiasts swear by Laserdisc technology but this medium never caught on due to its relatively high cost of both the equipment and the software (movies), limited rental availability, and because it is a play-only media. In addition, the capacity (NTSC) of a single LaserDisc is around 1 hour total on both sides requiring frequent disc changes even if the player has dual laser pickups.

The basic eletro-optical mechanism is similar to that of a CD including the techniques used for beam generation, focusing, and tracking. However:

- Older units may use a helium neon laser instead of laser diode for the light source. All newer LD players use laser diodes similar to those found in CD players.

- There will likely be an additional servo for pickup tilt to assure that the laser beam is perfectly perpendicular to the disc surface. Since the information is analog, this is needed to minimize crosstalk between tracks.

- Most mechanical components will be larger and much more robust since spindle speeds can reach 3,600 RPM with the large mass of a 12 inch platter.

- Both CLV (Constant Linear Velocity) and CAV (Constant Angular Velocity) encoding has been used and both may be supported on one player.

- Most LD players also will play audio CDs so testing with this less demanding medium is a good way to determine if the basic optics and electronics are in working order.

(From: Mark Zenier (mzenier@netcom.com).)

The original version is covered in The "Television Engineering Handbook" edited by Benson from McGraw-Hill, 1986. Don't know about the newer version with digital sound. (Or what the newer edition of the book covers, either).

It's an analog FM system at 8 MHz that records the composite signal, with two FM audio carriers at 2.3 and 2.8 MHz.

So what about the RCA "CED" video player?

CED stood for something like "Capacitive Electronic Disc" probably with a "Selectavision" label.

It is NOT related to LaserDisc technology and does not use an optical pickup.

If you found one of these, you have a classic dinosaur! The CED system was something RCA spent $200-300 million to develop about the same time that LaserDisc technology was being perfected. Guess which won!

And, this was shortly after the same company spent a similar vast amount of money on another consumer electronics dud. It was also named Selectavision if I recall correctly and used optical scanning of 4 mm (??) movie film.

CED uses a capacitive contact sensor 'sled' running in a grooved disc.

The pickup actually rides on the disc like the stylus on a phonograph record. The sensor detects minute changes in the capacitance between the tip of the pickup and the metallized surface of the disc embossed with millions of tiny bumps and valleys.

This really isn't that bad - the system DID work but suffered from some of the same problems as records - wear, critical tracking requirements, etc.

If you are trying to resurrect a CED player, you better have the discs you want because they will not be available at your neighborhood video store!

Since it is more than 15 years old, there can be any number of problems with the equipment just from age and non-use. These are likely to be both mechanical (gummed up grease, dirt), and electronic (dried up electrolytic capacitors in the power supply, bad connections, etc.).

However, chances are good that it wasn't actually broken to begin with since consumers likely gave up on this technology before it actually failed - there just wasn't enough movies/programming available.

Start by checking the obvious, reseating all connectors, testing power supply voltages and for ripple, etc.

It certainly would be cool to get working.

MiniDisc (MD) recorders/players

The MiniDisc cartridge looks somewhat like a small (2-1/2") version of a 3-1/2" computer diskette. Both players (around) $400 and player/recorders (around $700) have been introduced with disappointing sales. Not enough prerecorded material was available and the prices were too high to lure people away from the convenience, low cost, and limitless variety of the audio cassette medium.

MDs may be pressed like CDs with the information encoded in pits and lands. This is the way prerecorded play-only MiniDiscs are made.

For recording, the MiniDisc technology uses a higher power laser beam (upped to 5 mW at the disc surface) to heat a magneto-optically active coating to above its cure point (where magnetization is lost). A writing coil in close proximity to the back of the Minidisc is used to switch the magnetic field polarity (N or S) of the coating as it cools. Thus, the laser beam may be thought of as 'softening up' the magnetic material but the actual writing is by the coil. This is not the same way most other writable magneto optical drives are implemented. See the sections: "WORM drives" and "Magneto optical drives" for more details on these other media.

For playback of this magneto-optical (MO) recording, the pickup uses what is known as the 'magneto-optic Kerr effect'. When a polarized laser beam is reflected from the disc coating, its polarization orientation is rotated slightly depending on the magnetic field polarity (N or S). This rotation is small (about 1%) but enough to permit detection. However, since it is so small, it isn't surprising that there can be problems with the optics and front-end electronics for MO readback.

Thus, the MiniDisc pickup and front-end operates in three modes: spatial (pits and lands) read, MO read, and MO write.

The basic mechanism and optical pickup is similar to that of a CD including the techniques used for beam generation, focusing, and tracking. However:

- Additional components will be present to detect the magneto-optic Kerr effect for playback of MO recordings.

- The laser can be switched between low and high power (as well as off). However, this is not a particularly high speed change as the modulation is done by the external magnetic field coil. WARNING: IR, invisible, 5 mW at the lens is enough power to be a significant risk to vision.

- The magnetic field coil will be found directly opposite the lens (and thus it may block any access to the lens unless it is removed for servicing.

- Extensive information compression techniques are used to enable roughly the same amount of audio to be stored on a MiniDisc with about 1/5th the surface area of a CD. For data storage, this is not usually possible so an MD may hold 'only' 125 MB or so of computer information.

Digital Versatile (or Video) Disc (DVD)

The DVD is destined to replace the CD as *the* optical medium of choice in the near future. This will happen if for no other reason than manufacturers will stop producing CD players (since DVD players will be able to read CDs).

The basic components are very similar and thus cost of manufacture will be similar. So, why produce old fashioned equipment?

The DVD permits storage of up to 4.5 GB per information layer with up to 2 of these on each side (one under the other) for a total of 18 GB if fully implemented. This means (per layer):

- 8 hours of CD quality audio.

- 2 hours of MPEG-II compressed LaserDisc equivalent video (Note: there is much debate as to the actual level of quality but we won't get into that here).

- Multilingual sound tracks.

- Any mixture of these.

The 8-fold increase in storage capacity per layer is accomplished through a number of incremental enhancements to the basic CD technology including:

- Use of a 635 to 650 nm red-orange laser diode instead of a 780 nm IR laser diode.

- A higher quality (actually higher NA) optical system permitting a smaller spot on the disc.

This permits:

- Closer track spacing on the disc (.8 um instead of 1.6 um).

- Higher CLV bit density.

For readout on both sides of a dual-sided DVD, dual optical pickups can be used where the user is willing to pay for this significant added expense!

From a marketing perspective, it is essential for DVD equipment to support the CD format. However, since DVDs and CDs differ in terms of feature size, track spacing, thickness, and so forth, it would not be very effective to simply shine the DVD pickup at a CD! Either of two approaches may be taken:

- Include dual optical pickups. This is probably the best way to assure total compatibility but is obviously an expensive solution.

- Provide optics that may be switched into the beam path to 'simulate' a CD pickup. The shorter 635 to 650 wavelength light is still used in both cases but the beam width and focus are adjusted with an intermediate lens or holographically generated compensator.

Are blue lasers used in DVDs?

The readout laser for DVDs is red, around 650 nm. This is similar in color to a typical red LED.

Some people seem to think blue lasers are used for DVDs. One reason may be that manufacturers are putting blue illumination on the front panels and maybe even inside the disc compartment of DVD players - solely for marketing reasons.

However, blue or UV lasers (e.g., argon or krypton ion) may be used to write the glass master for DVD (as well as CDs) where the shorter wavelength results in crisper more accurate rendition of the pits and lands of the information layer. Of course, these machines cost $250,000.

Converting to a shorter wavelength laser for readout won't help anything except the manufacturer's bottom line assuming they could charge much more for the hype than the additional cost of the laser. Currently, the only viable option is the Nichia 400 nm violet laser diode which go for about $2K each! To take advantage of a shorter wavelength laser, the entire standard would need to be revamped. I have already named the new standard: the "Digital Ultra Disc" or DUD. :) Once those violet lasers (or alternatives) come down in price, there is little doubt that the World will be treated to yet another advance in technology whether anyone wants it or not.

Will DVD be the killer format?

There has been and will continue to be a lot of hype with respect to the incredible advantages of the Digital Video (Versatile) Disc for everything from computer multimedia to HDTV.

Here is my take. My track record isn't great on predicting the future as my crystal ball has been broken for a long time, so don't buy or sell shares in any company based on these comments!

DVD will do very well for data storage since due to its much higher capacity compared to CDROMs (5 to 20 GB versus .64 GB), it will serve an important purpose in the increasingly interactive applications and games to come.

Full size DVD will be overkill for many audio applications. At the normal CD audio sampling rate of 44.1 K/second, the smaller DVD format will hold over 8 hours of music. Whether people will be willing to pay the expected price for a DVD with several hours of music is questionable. There certainly will be many good reasons to do this - full concerts or operas on a single disc, for example. I would expect the average total length of normal musical DVDs to increase beyond what is typical of CDs as well.

However, mini-DVDs are possible. A 3-1/2" format would hold about 1/3 as much as a full size DVD or over 2 hours of music. This or an even smaller format would be ideal for discman applications.

What about multilinqual sound tracks? Sure, this capability may save money by requiring pressing of only one disc to support multiple markets. But, few people will have a need to pay for this.

There are no doubt all sorts of applications that have not been identified yet for which the DVD is ideal. However, the hopes of the industry are pegged to DVD's success for video - in part, to replace the consumer (VHS) VCR. Unfortunately, It is here where I believe DVD has its greatest weaknesses.

Many of the specifications have been developed tailored to today's video standards, not HDTV. The DVD is supposed to be superior to both VHS VCR and laserdisc formats. However, this is in comparison to standards (NTSC and PAL) that are close to celebrating their 50th birthday. Even the quality advantages are questionable as so much depends on the MPEG-2 encoding used to compress the vast amount of video information onto the DVD.

Video tape and laserdiscs do not care what is recorded on them - they are equally good or equally poor for static scenes as well as explosive action shots. This is not true of DVDs. Complex images and rapid scene chances require more bits to minimize artifacts. And, the types of artifacts that are introduced are not those one expects from poor reception or bad tapes. It will take a great deal of effort on the part of the companies who will be converting original movies and other source material to the DVD to do justice to the format. It may simply be impossible for certain action sequences. The result may be 'pixelation' or momentary blockiness, erratic motion, momentary freezes, and so forth - not just slight fuzziness or snow. It is not known how the general viewer will accept these. Developers of source material will not be free to put in whatever they desire. The medium may break down when presented with too much fast complex action or rapid scene changes.

The situation gets even murkier for HDTV where the required amounts of data and data transfer rates increase dramatically. Depending on HDTV format, this could be anywhere from 2:1 or 8:1 - or more. If the DVD is marginal now, what does this say for HDTV?

Initially, DVD will not have record capability. Thus, there will be no compelling reason to switch over and throw out your VCR especially if the quality isn't dramatically better. The majority of consumers don't care that much about picture quality anyhow. Beta, S-VHS, and laserdisc, all have substantially better picture quality than normal VHS and NTSC broadcasts. It has not mattered due to various usability issues and marketing stupidity. The critical mass was never reached with respect to availability of source or rental tapes or discs. Thus, these have been relegated to niche markets and niche markets don't drive the industry.

Will DVDs turn into yet another Edsel, Selectavision, or Betamax? Only time will tell but the industry must make a deliberate effort to assure the quality of the initial releases or else DVD's future as a video media will be sealed before it gets off the ground even if the technology there.

DVD FAQ?

Well one, at least:

- alt.video.dvd FAQ

WORM drives

A large number of technologies have been introduced to provide storage of large amounts of information on optical platters with varying degrees of flexibility.

The earliest were called WORM (Write Once Read Many) drives. Writing resulted in an irreversible change in an information layer. Thus, data could be written but not erased and rewritten (though just erasing a block might be possible). Heating with the writing laser beam resulted in damage (ablating) of a coating. Reading is similar to that used for CDs and other optical technologies.

Typical capacity was 650 MB per side. Disks could be one sided or two sided.

This is somewhat similar to the technology used in CD-R drives though many variations have been developed which vary mostly in the details.

Unlike CDs, MDs, and LDs, these optical discs are formatted more like hard drives or diskettes with circular (not spiral) tracks and fixed sectors - some of which are visible to the naked eye since they are physically etched on the disk itself.

The laser power for WORM drives is typically higher than for read-only drives when in writing mode - likely in the 10s of mW range. 30 mW is one number I have heard. Modern drives all use IR emitting laser diodes.

The basic mechanism and optical pickup is similar to that of a CD including the techniques used for beam generation, focusing, and tracking. However:

- These usually spin at high speed - 3,600 RPM typical - so spindle motors and other mechanical components are more robust.
- Laser power can be switched between a fraction of a mW for reading and high power for writing (in addition to off). WARNING: IR, invisible, Class IIIB, dangerous!

Magneto-optical drives

Most modern optical drives use magneto-optical techniques in some ways similar to the MiniDisc. However, unlike the MD, the laser beam is switched at high speed to alter the magnetic properties of the coating and a write cycle is usually a two step process:

1. Energize the bias coil with the '0' polarity (e.g., N).
2. Erase a block by turning on the laser as that area of the disk passes under the pickup.
3. Reverse the polarity of the bias field to that of a '1' (e.g., S).
4. On the next revolution, write the information by selectively heating only those regions destined to become '1's in the stored pattern.

The laser power for MO drives is typically higher than for read-only drives and likely in the 10s of mW range. Modern drives all use IR emitting laser diodes.

The media is usually enclosed in a cartridge for protection with a door that opens automatically when inserted into the drive. Capacity is typically 650 MB per side for a 5-1/4" disk.

- Additional components will be present to detect the magneto-optic Kerr effect for playback of MO recordings.

- These usually spin at high speed - 3,600 RPM typical - so spindle motors and other mechanical components are more robust.

- Laser power can be switched between a fraction of a mW for reading and high power for writing (in addition to off). WARNING: IR, invisible, Class IIIB, dangerous!

- The bias coil is opposite the lens and may block access for servicing unless removed.

CD-R Recorders/Players

These use media that is the same size as the CD but can be written once and is then read-only like the WORM disk. In many ways, this technology is similar to WORM except that the format is a spiral track like that of a CD rather than circular tracks and sectors like other optical disk formats or hard and diskette drives.

Although CD-R started out being quite expensive (greater than $10,000 for a recorder), it really was designed as an inexpensive technology and to have total compatibility for reading with CDs and CDROMs. Current prices for multispin (2X, 4X) CD-R recorders are under $500 and dropping. The capacity of a CD-R is the same as a CD - about 650 MB.

Like the WORM drive, a higher power laser ablates a coating inside the CD-R media. With most, this is a blue-green polymer dye backed by a gold coating. Otherwise, construction of the CD and CD-R media are similar.

However, since the pits and lands are not as precisely formed as those of a pressed CD whose master was made on a $250,000 laser cutting lath, some CD players or CDROM drives may have tracking or other problems with CD-Rs.

CD-R recorders and high performance CDROM drives are very similar except:

- The laser in a CD-R recorder can be switched to higher power mode and modulated for writing. WARNING: IR, invisible, enough power to be a significant risk to vision.

- Tracking may need to be more robust as before the disk is recorded, there is only a guide groove rather than the pits and lands of a normal CD.

- Servo electronics must be more complex to control disk speed for recording.

- Back to Optical Drive Repair FAQ Table of Contents.

LaserDisc Players

Considerations when troubleshooting LaserDisc (LD) players

CD and LD players share much of the same optical technology. Many models will play normal audio CDs as well as LDs. If this is the case, start by determining if a CD will play properly. If it does, then you can be fairly sure that most of the optics and front-end electronics are functional.

Modern LD players use the same 780 nm laser diodes as CD players. Really old players used Helium-Neon (HeNe) gas lasers resulting in a visible beam at 632.8 nm (orange-red). CAUTION: these use a high voltage power supply. Contact with this probably won't hurt you but will not be pleasant. The high voltage terminals are probably well insulated but it is a good idea to locate them and double check.

Since most LD players also play CDs (and possibly multiple size LDs as well), there will be optical sensors - LED-photodiode pairs aimed at the disc from one or more locations beneath the drawer assembly. If you have the top off for servicing, room lighting may confuse these sensors resulting in all sorts of strange behavior such as attempting to play a CD using the LD spindle! Cover the entire unit with a piece of cardboard or just the holes in the drawer with matt black paper to eliminate the possibility of both electronic and human confusion!

LD players will generally have one additional servo system compared to CD players - tilt. This adjusts the angle of the pickup with respect to the disc to minimize interference between adjacent tracks. This would result in degradation of the analog video signal. The tilt servo is usually pretty simple using an IR LED emitter and a pair of IR photodiodes detecting the reflection from the laserdisc. If after manually rotating the tilt motor away from the balanced position, the tilt readjusts itself, there is a good chance this it is operating correctly. There is probably a tilt balance adjustment as well but don't touch it unless you have the service manual if possible.

Spindle motors in LD players are of much higher quality than typical CD players since the spindle must spin continuously at thousands of rpm with the greater mass of the LD as well. Other motors may be similar to those in CD players. Some LD players have two spindles that are selected and moved into position depending on the type of disk being played.

Due to the mass of LDs, the clamper is even more critical to proper behavior than for CDs. Any slippage and LDs may fail to be recognized.

There may still be rubber belts that degrade :-).

Naturally, a video monitor makes an excellent diagnostic tool once it is possible to obtain some output from the LD player. A service manual is almost a must for serious troubleshooting.

LaserDisc optical alignment?

As noted elsewhere, optics don't generally drift except from abuse.

The following is a further confirmation that optical alignment should not be needed under normal conditions:

(From: Dave A. Wreski (dawreski@nic.com).)

I have been servicing these since they came out. The *only* time I had to do any optical alignments is when some fool decided to mess with the alignments. They do not misalign themselves. In the past the only adjustment we had to do (on Pioneer Laserdisc players) is the 1/4 wave plate which can be done with a scope. All other alignments must be done with a Laser power meter and a polarization adjustment jig from Pioneer. Many dollars!

If the optics are clean and haven't been maladjusted, your unit is suppose to work. If not, look elsewhere in the electrical alignments or motor problems.

Replacement for Helium-Neon laser tube and power supply components

Older LaserDisc equipment used a Helium-Neon (HeNe) laser instead of a laser diode. These use a HeNe laser tube and require a high voltage power supply for operation. The tube can wear out or get broken and the power supply can fail. Obtaining an exact replacement of either is probably virtually impossible today and too costly in any case.

However, it should be possible to substitute a surplus HeNe tube and/or HeNe laser power supply. The tube will have to be of a similar power output (usually around .5 to 1 mW) and physical size. It probably also needs to produce a polarized beam (which eliminates a lot of the common barcode scanner tubes as replacements). If the beam diameter and divergence are similar, it may be possible to get by without any optical alignment as long as the tube is carefully mounted with its output in the same position and orientation as the original. However, since these parameters are probably not known, there could be problems with a swap. In that case, another tube can probably be made to work but some amount of optical alignment (possibly just resetting the position of one lens) will be needed. A service manual will be essential.

HeNe laser tubes with power supplies can be had for as little as $25 from various mail order sources but you need to confirm compatibility. It may be possible to compensate for a different beam diameter and/or divergence by adjusting the external optics. However, you can't easily get a non-polarized tube to produce a polarized beam. (It can be done with powerful magnets but this is probably not a viable option inside a cramped LaserDisc player.) I don't know if LaserDisc players do anything special with optical feedback or anything like that but if it is just a power supply, this may be an easy and inexpensive alternative.

If a suitable HeNe laser replacement is unavailable, too expensive, or just too mundane, it may be possible to use a diode laser - even a laser pointer - in its place. The beam characteristics would need to be similar with respect to divergence and polarization. A unit with adjustable focus will probably be best to match up divergence. Since, all diode lasers are polarized, that at least, shouldn't be an issue. Apparently, some people have successfully done such a transplant without major problems. The most difficulty may arise from devising a suitable mounting arrangement and providing the stable low voltage power needed for the diode laser or pointer. I'd still recommend staying with an HeNe laser if possible but at least, there is an alternative that will keep your prized 1979 LaserDisc player going strong. :)

Kenwood LaserDisc clamping problems

With the larger mass of a LaserDisc compared to a CD, clamping is even more critical. Slipping belts are a common cause of clamping problems.

(From: dwb@rell.com).

I had a problem with my Kenwood machine not locking the disc in place correctly. The drive belt was slipping to bad (couldn't hear it though). The replacement was a NEW mechanism that regeared the assembly for slower feed but more more clamping force.

Philips Laser disk problems and discussion

> "A friend of mine has a Phillips Laserdisc player that is acting up. What it does is the player will just stop playing in the middle of the movie, usually in the same spot."

(From: Douglas W. Jefferys (dougj@freenet.hamilton.on.ca).)

How old is the player? I've worked on the Philips 22VP931 and seen similar things. This is an ancient (ca. 1982) industrial player with a tendency for the radial and tangential mirrors to jam in their servos. (The glue that holds the magnets behind the mirrors weakens with age. If a magnet detaches, the mirror jams solid, but the magnets can also migrate outwards and cause sticky behavior).

If it's an older player, it's *possible* that it's in the early stages of the same failure mode. (That said, all the 22VP931s I've seen that have this failure have had *solid* jams on at least one of the mirrors, so I think it's an all-or-nothing thing.)

Anyways, after fixing the servos (a nightmare - it's a good thing I had help from a knowledgeable source about what to expect when I went into the guts of the thing :-), I did an eyeball alignment (power *OFF*, machine unplugged, a double-check that the power is off and the machine unplugged, and look down through the objective and see if you can see down the entire beam path) and got the same results you did. Worked fine on the early portion of the disk, but slowly screws up later on. High-speed seeks worked marginally early on, and not at all on later portions of the disk.

An examination of the player while playing showed that one of the mirrors was near the limit of its range of movement at the point when the video started freezing up.

NOTE: I'd strongly recommend *against* looking at the mirrors in operation unless it's either a visible-beam system or you have goggles opaque to the laser's frequency. I was willing to be somewhat stupid because it was a visible-beam system, and I still used a piece of paper to ensure my head was nowhere near the areas where bits of beam were leaking from the player. I wouldn't have even fantasized about attempting this with an IR beam.

About three hours and umpteen incremental adjustments of the optical head's alignment screws (which I had to remove and thereby misalign when fixing the servos), and the thing was working fine.

Summary:

1. Check to ensure the tangential/radial mirrors move freely.

2. Check optical alignment on early portion of disk and 'stuck' portion of disk. Preferably with an optical alignment tool, but if you've got goggles or a visible-beam system and more balls than brains, you can *carefully* look at the mirrors when the disk is playing and use that as a guess as to which way to tweak the mirrors.

One final note: Some of the alignment things can be "one-way" adjustments, and anything on the optical path is vulnerable to scratches. I'd strongly advise trying to find the service manual before attempting any modifications.

If you have contacts with professional fixers, I'd also suggest you bounce your ideas off of them before proceeding. When hacking LD players, you're always one mistake away from owning a very expensive pile of spare parts.

Pioneer Laserdisc RS-232 commands

(From: Jim Jackson (jim@aviendha.demon.co.uk).)

Here is a list of commands I have for controlling Pioneer players via the RS-232C jack. Hope it helps. I have also heard that there is supposedly a MCI driver for Windows but I haven't personally seen it. I tried these codes on a Pioneer machine I have at work using the Windows terminal program and was able to control the player. This file is from a public domain file for the amiga. I think I also have a C program (also for the amiga) somewhere if you need it.

Communication protocol:

- Computer activates CTS (pin 5) of RS232 port, (amiga 7-line handshake).
- Then sends a command sequence and expects 'R' and carriage return (CR).
- ASCII digits used for addresses, etc. Returns frame# as ASCII digits.
- Player is string oriented and reverse-polish (arg then verb).

COMMANDS	CHARS	HEX	DECIMAL	COMMENT
Door Open	OP			open the door
Reject	RJ			stop disc rotation
Start	SA			start disc rotation
Play	PL			(address)PL
Pause	PA			
Still	ST			still frame
Step Forward	SF			
Step Reverse	SR			
Scan Forward	NF			
Scan Reverse	NR			
MultiSpeed FWD	MF			(address)MF
MultiSpeed REV	MR			(address)MR
Speed	SP			integer SP
Search	SE			address SE
Stop Marker	SM			address SM
Frame	FR			set frame mode
Time	TM			set time code mode
Chapter	CH			set chapter mode
Audio Control	AD			integer AD 0=off,1=Ch1,2=Ch2,3=stereo
Video Control	VD			integer VD 0=off,1=on
Display Control	DS			integer DS 0=off,1=on
Clear	CL			clear entry or mode
Frame #	?F			get frame number
Time code #	?T			get time code number

```
Chapter #        ?C                                        get chapter number
Player active?   ?P                                        P00=door
open,P01=park,P05=still
Disc status      ?D                                        5 bytes and CR returned
(and a few others....)

SERIAL PORT CONNECTION:

  Computer      Player
 ----------    --------
   TxD 2        3 RxD
   RxD 3        2 TxD
   CTS 5        4 DTR
   GND 7        1 GND
```

```

Pioneer LaserDisc player test program

From: Colin Kraft (ckraft@airmail.net).)

I have just found a RS-232 test program for all Pioneer LaserDisc players on Pioneer's web page. The URL is:

- Pioneer Drivers

It's called testprog.exe and it's quite impressive and handles just about every Pioneer player that has the RS-232 port. It also comes with a nice doc file that cover dip settings for various players and more.

I tried it with my newly acquired LDV4200 and found that it did not work. Right now I am fearing that my player has a problem with the control port. The data seems to be coming through the cable as I get a flashing logic probe when I hook it up but the player does not respond.

I'm not sure about the codes as they are not covered in the otherwise excellent doc file (they always leave something out it seems). However, I think you can get codes for your player through Pioneer.

Comments on Pioneer 8210

(Portions from: Dave A. Wreski (dawreski@nic.com).)

The 8210 service manual is 120 pages long. This is not an easy unit to work on. It is the very first industrial video disk player that Pioneer made. All of the GM dealers had them when they first came out and I have seen them for sale in most flee markets for around $50.00.

These are built like a tank and use a HeNe laser tube and a bunch of discrete optics that are very hard to align properly without the manual.

Pioneer '90' series LaserDisc player doesn't play older LDs

> "Check those discs you are playing. My 1090 won't play some older Image Discs including my (BOO HOO!) Bride Of Re-Animator disc."

(From: Steven B (lasers@netrus.net).)

The 90 series of laser player had a fault that was fixed by Pioneer at no cost. It also caused a whole new series designation. Call Pioneer!

Pioneer CD/LD Player Model CLD-S104 with shorted power supply

(From Mark Z. (zmachar780@aol.com).)

Your Pioneer LD has a shorted protective device, a V1B24 or similar. Looks like a diode and is located near the main AC input to the board. Clip it out, replace the fuse, and normal operation will resume. You STILL NEED to replace it; it protects some very expensive chips. Get the reference number off the board and call Pioneer at 800-457-2881.

Pioneer 503 LD player sled slews to one end after service

(From: illusion@pqc.com).

I have seen that before. The Sled runs on a differential op-amp. This uses +15V and -15V. One of these supplies is out. There are two fuses in power supply for this. Most likely u blew one when changing spindle motor. This will throw loading motor and sled motor, and maybe even the tilt motor (if it isn't also the loading motor) into overdrive in 1 direction. Loss of either supply will shift the differential one way.

Pioneer CLD-D701 tray locking problem?

> "I've owned a Pioneer 701 laserdisc player for many years. Other than its tendency to drift out of alignment slowly and steadily over the years, it has been a good LD player. However, within the last year the tray has developed a strange problem. Each time I turn the 701 on and press the eject button to load a LD it takes about 6 seconds of gear grinding before the tray finally decides to come out. Just a couple of years ago the response was almost immediate.
>
> Once the tray has finally opened, thereafter it behaves normally and responds immediately for as long as the player is left on. Even if it's turned off briefly and back on, the tray behaves OK. However, if I wait to the next day the tray goes back to its nearly 6 second wait again.

There appear to be several opinions as to the cause

First suggests it is a sticky rubber problem:

(From: Jeff Boettler (boettler@us.ibm.com).)

Eject the LD drawer and disconnect from the mains. Then remove the cover. On the 2950 there is a mechanism that clamps the disc that is suspended by metal bars running over the top of the drawer. Remove this, around four screws and locate the motor. There will be a rubber mat that grabs the disc. Clean this with meths and nothing else. Allow to dry and reassemble.

Apparently this problem is accelerated by dirty labels on the LD and BBFC logos that have been removed, which leave a nasty deposit that rubs off on the mat.

(From: Bruce Esquibel (bje@ripco.com).)

I somewhat have a clue - but haven't came up with a 100% fix yet.

The trouble appears to be the upper 'track' that hub/laser assembly uses when it returns from the side 2 position.

This track floats within the metal sleeve on the upper left hand side as you look at the player from the rear (front away from you). It appears the last inch or so is warped or slightly deformed, probably because of age.

If you examine the construction the track is pulled upward via a pair of springs and held in by a couple L-tabs or ears from the track. When the laser is returning from side 2 to stop you can see the track slightly move as the motor on the hub assembly runs on it.

When it just about hits the end, that is when the grinding noise is heard, the gear on the shaft of the motor is spinning, but not meshing with that part of the track. It appears that after so much time the player detects the error and starts 'slapping' the hub around and eventually it grabs and does its flip.

Odd part about this is that even the slightest pressure on either the track or hub will allow it to cycle without missing a beat.

What I did, which reduced the grinding, but did not fix the trouble completely was to modify the rear spring to be tighter by carefully cutting the loop off and unwinding one turn, making into another loop. I suppose you can find another similar spring which has less turns also. The other bit that helped was kind of cheesy, the rear L-tab from the track seemed to have too much play when the motor ran near it. All I did was stick a small piece of electrical tape under it, on the metal housing which also tightened the track.

I'm pretty sure the track itself is the problem, but it looks like a son-of-a-bitch to replace, even if it is a replaceable part. Another possibility is the gear on the motor shaft getting worn down but being the problem is only at that one end, I really don't think so.

If you aren't into repair (just a joe consumer), I really don't recommend trying either the spring mod or tape bit, the spring can be easily malformed or the L-tab can break off, which either happening will put you in a world of hurt.

All I can add is don't bother greasing the track, was the first thing I tried and it didn't help a bit. Also there was no indication of it needing lubrication anyway. This is a tolerance issue between the gear and track.

The grinding noise, although sounding nasty, isn't really. It's not chewing up anything and I didn't even notice nylon dust around the area where the teeth are grinding. It's more of an annoyance problem than a major malfunction.

Pioneer LD-3090 turn over problem

(From: Kurtis Bahr (kbahr@erols.com).)

I once fixed a 3090 that had a problem when stopping the LD and the pickup tried to turn back over to side A. It actually made a grinding sound for awhile then finally grabbed into the turning assembly and turned over.

The fix was to lubricate the metal guide shaft where it transfers from the playing shaft to the shaft on the turn mechanism. After this was done it has worked flawlessly.

Sony LDP-1450 problems and discussion

> "I'm the proud owner of a very confused LDP-1450 from a Mad Dog McRee machine. It's got six option DIP switches, all are "off" (down), and>it's set for 1200 baud."

(From: Ruben Panossian (malcor@ozemail.com.au).)

The Extended Function dip switches are for just that, extended functions, which change certain characteristics of the player's operation. There are only three extended functions, using switches 1, 2, and 4 only. The other DIP switches are not used. Factory default is for all of the DIP switches to be set in the "off" position.

The baud rate setting would not matter if you have nothing connected to the interface. BTW, it should be set for 9600 for ALG games.

> "Power-Up: Disc rotates 10-30 degrees in random directions, changing directions erratically every half-second or so, and the head makes a weird squeaking sound periodically as it tries to seek (maybe it's making physical contact with the disc??)"

The objective is unable to find focus when this occurs. (usually) The disc will not spin-up to speed, rather, a slower turn and often in reverse. To determine if the player is finding focus you will need to get access to the lower PCB's. Turn the player on its *side* and remove the bottom cover. (Do *not* try to eject the disc in this position!) This is the servicing position.

The large board you will see, behind the lower cover, is called MB-40. You will need to pull this board out a bit so you can work on it. Locate IC313, it is an HA11529. This IC controls the focus (coils), tracking (coils) and communicates to the main system control.

Looking at the schematics, you can see that pin 36 of IC313 drives the focus coils. Pin 26 of IC313 is an output to the system control, which signals when focus is locked. By using a CRO, connect one channel to pin 26 and the other to pin 36. Adjust the display so that you can see the two signal but not on top of each other. You will need a CRO (or DSO, whatever) as the signals are about 3Vpp.

Turn on the LD player (with a disc already loaded) and watch the signals. (the disc should be moving and sounds from the player) You should get a ramping (triangular) signal on pin 36 for a moment then a steady line (0V), indicating that focus has occurred. The signal on pin 26 (focus lock) is high, when focus is not locked, and low when locked. When the focus is locked the player should spin-up and go in to playback mode.

Now, if you are finding that focus locks then searches then locks, in a peculiar way then you will have to do some more checking to determine the problem. This can be caused by many things.

If focus is not locking and the signal on pin 36 is a constant triangular wave then the problem is more than likely in the optical block or the laser not turning on.

Check to see if the objective is free. Next, check the continuity of the focus coils from the connector on the MB-40 board.

You can check if the laser diode is turning on by checking the test point TP302 on the MB-40 board. It is located near IC312 which is a three pin -5V voltage regulator. When there is -5V on this test point the laser should be on. If there is no -5V there then check for -8 to -10V on R334 (any side) If there is no voltage there then there is a voltage rail supply problem. (like you hadn't guessed)

If there is around -10V, then check the base on Q314. This is the right pin if the flat side is facing you, the right way around. It should have 0V on it to turn the laser on. Hmm... I will try again. One pin is connected to the +5V rail (collector), another pin, the emitter, drives the base of Q313 (which then supplies -10V to IC312) which should have +5V on it when the remaining pin (base) is at 0V. The base is connected to the LD "ON" or LD "OFF" signal. It is an active low signal, so a low signal will turn "on" transistor Q314 and in turn eventually turn on the laser diode. The laser diode also has an APC which complicates things, but don't worry about that at the moment.

If the of base of Q314 is 0V and the collector is +5V then the emitter should have almost +5V on it. If not then the transistor must be real hot or dead. If it is hot, Q313 would be faulty. BTW, this transistor, Q314, is a pre-biased "digital" transistor. It is either fully on or off.

I had a laser power problem like this, on a player out of a TT, which I had previously repaired. This time it turned out that the laser was not turning on all the time. Some times it would be ok for a couple of hours then it wouldn't work properly. By the time I had taken the covers off it was OK again. (Grrrr)

To make a long and frustrating story short, I found that the laser wasn't being turned on when it should all the time. Turned out to be a bad connection on IC902, which is a 80 pin quad flat pack (SMD) and *only* pin 31 had a poor connection. This pin controls the laser diode "on" and "off" signal. I think I may have caused this poor connection when I was poking around previously.

Also be careful when probing around a SMD like IC902. If you inadvertently short out a couple of pins, the slide motor may move (turbo) the optical block towards the spindle and not stop, causing a nice gear jumping noise that brings on a sudden panic attack. Which may cause you to knock over your LD player while trying to find the "OFF" button while still holding a cro probe. Although, I wouldn't admit to doing such a stupid thing, especially publicly. :-)

Now, back to IC 313 on the M-40 PCB.

If you are not getting a triangular wave or steady line on pin 36, but a wavy (sinus) signal then check the soldered joints on pins 38, 41 on IC313 and on R384, R382, R381, C337, C338. These are for phase compensation for the focus coil. If the signal looks strange on pin 36 of IC313 or the laser is turned on and IC313 is not working then IC313 or the serial control input signals may be your problem. I have only seen a couple of poor soldered connections on these, otherwise A+, players but you never know...

If you find that focus is locking in say 10ms intervals (on and off) then the problem may be in the focus loop, which is initiated right when focus is locked. This loop controls the current supplied to the focus coil to maintain a constant current which is proportional to the focus error, so the focal point is maintained as the disc turns. Keep in mind that the focal length is not constant, as the disc is rotating.

Or the problem could get interesting. In other words, *could* end-up being a "dog" of a problem, unless you have a manual. Either way a manual is essential. If you can read and understand the circuit diagrams then you shouldn't have any problems, other than the faults that were devised in hell.

> "Self Test: Removing the front cover revealed a "self test" jumper. Shorting the two pins together forced the player to spin up. The player correctly displays video for a few seconds (overlaid on the video is a frame number of approximately 7000), but quality, which starts off great, deteriorates rapidly, and the player then jumps back 100 frames or so and repeats the cycle. The words "NTSC 12" appear underneath the frame number whenever the self test jumper is shorted.
>
> The frames played are identical for any given disc. Mad Dog McRee gave me 7000ish, and Star Rider gave me 6900ish.
>
> When the player is in this mode, pressing the eject button causes the video to mute and the player to spin down. When the disc has stopped rotating, a further press of the eject button will eject the disc correctly, and a further pressing will reload the player."

Yes, this is normal. Even if the focus error is greater than it's cut-off point the player will spin-up and try to display video. How good the video is will depend on how great the focus error is, I guess. I have done this myself, however, have found the video to be very jumpy and poor if any at all. When the focus error gets to it's cut-off point it re-initiates focus search..

If the video is clear and stable then your problem sounds like it is not with the optical block, focus, etc. (with the test jumper closed)

The test jumper you found is *only* meant for adjusting the "inner" and "outer" frame limits for the disc sizes, hence the displayed frame numbers.

> "Theories:
>
> 1. The player works but is still configured for a video game; it has to have something useful coming in on the RS-232 port in order for it to work."

No. There were different LDP1450 software revisions though.

With the Extended Function Dip switches all set to the "off" position the player will "spin-up" a disc and go to playback mode, when a disc is loaded.

> "2. This might be changeable (or I might get a different set of diagnostic information) if I knew what to do with the six option DIP switches."

Yes and no. This is not your problem, though,.

> "3. The player is malfunctioning, probably something to do with alignment of the slide on which the optical head moves, and this accounts for the weird looping behavior I get in the self-test mode."

Possible and no.

> "Questions:
>
> 1. Am I doing something boneheaded?

No, considering the lack of information you have for this player. You could have done worse...by poking around IC902. I don't think that you will get very far without a service manual. The Sony service manual is relatively expensive, however, it is essential, It is also well detailed and clear, unlike some early player manuals.

> "2. Anyone know where I can get a service manual?"

Yes, from Sony :-). Because it is not a real old LD player, they will have the manual.

> "3. I have yet to hook it up to a computer. I have a utility that purports to be able to talk to an LD player; would this help, or should I concentrate on getting it to work correctly in stand-alone mode before trying to talk to it?"

This wouldn't help you with repairing the player, rather the opposite.

Also, I forgot to mention one of the first things you should check for. Check the power supply voltages. Obviously +5V is ok. You should have an idea of which voltages are ok by what is working in the player as a start, anyway. There are around 10 voltage supplies or more including at least 5 different voltage rails.

Disclaimer:

If anyone goes blind, destroys their LD player, decapitates their dog Fluffy, etc, by following my suggestions , it is not my fault. Only work on a LD player if you have an idea of what you are doing and understand what the dangers are. i.e., take blame for your own actions.

Replacing a laserdisc player spindle motor

With a CD player, all you have to get correct is the spindle height.

Unfortunately, for a typical LD player, this is just the beginning.

(From: Jack (jackh35785@aol.com).)

Replacing a spindle motor is a "can of worms". I used to build these things!! You have a VERY critical height that is adjustable by three pylons with screws, etc. You need a special disc which had a "constant pitch" from inside to outside. There is also a method of doing this using a mirror disc (as the CD folks know about). You absolutely must have the LD player service manual!

MinDisc Equipment

MiniDisc record/write problems

(From: David Vlack (cptvdeo@ainil.com).)

To write a MD, a magnetic head is brought in contact with the top of the disk with the writing laser below. Without the magnetic head in place, no recording takes place. I have seen a few of these (mostly SHARP) where the actuator motor binds up. Taking it apart and freeing it up usually fixes the problem.

Sony MiniDisk player/recorder considerations

The Sony MiniDisk system was supposed to replace cassette tape as the preferred medium for portable music (and data). Yeh, well, I am not holding my breath but it may yet come to pass. The disks are about 2-1/2 inches in diameter and enclosed in a protective case like a 1.44 MB diskette. Thus, dirty disks, at least, should not be much of a problem. A MiniDisk (MD) holds approximately 1/5th as much raw data as a full size CD. Compression techniques are used to achieve the same maximum time for audio - about 74 minutes - supposedly with negligible loss in audio quality. (I won't get into that argument either).

For playback of prerecorded discs, the optics and servo systems are operating in modes which are very similar to those in CD players and thus suffer from most of the afflictions and remedies described elsewhere in this document. The digital decoding and error correction including an advanced form of the CIRC may be substantially more sophisticated for MD players and MD data drives (if you can imagine that being possible) but the circuitry involved should be very reliable.

However, for playback of MiniDisks recorded on MO (magneto-optical) media, there can be many other problems as the optics/electronics are sensing the different polarization of reflected light from the N and S magnetized spots rather than pits and lands. The signal-to-noise ratio of the MO effect may be lower than that of a stamped disc. Thus, prerecorded media with the normal pits and lands on the information layer may work fine but MO media may suffer from tracking, audio noise, or uncorrectable data errors. Servo adjustments for tracking and CLV spindle control may be even more critical than for CD players.

Note that some MDs may include both prerecorded (stamped) and MO sections so that it is possible that only certain portions of these disks will play reliably.

MiniDisk recording requires that the laser diode be operated at higher power (around 4.5 mW optical output compared with less than 1 mW for reading) and that an electromagnetic head in contact with the back of the MD is driven with the EFM coded data pattern. This is not really a write head such as that used in a computer disk drive - the laser beam does the actual writing by heating the MO layer but the magnetic field determines the polarity (e.g., 1 or 0, N or S) of the written spots. Therefore, the actual position of the head is not critical - there is no servo for it! Note that this approach contrasts with that used in many other MO drives where the laser power is modulated to write 1s and 0s. The 'Magnetic Field Modulation' approach used with the MiniDisk claims many advantages in terms of robustness when confronted with less than perfect optical alignment and control of laser power, among others.

CLV servo lock during recording is determined by a signal derived be impressing a reference modulation (wiggle) on the premastered groove wall position - yet another possible area for failure or need for servo adjustments!

CAUTION: the higher power laser output required for recording is substantially more hazardous than that of CD players. However, since under normal conditions even with the case disassembled, the disk and electromagnet will be blocking the lens, there is little danger. However, if you remove the electromagnet and there is no disk in place, this optical power must be treated with respect.

Sony MDS 302 Minidisc optical blocks

This likely pertains to other Sony models as well.

(From: Shawn (slin01@mail.orion.org).)

These is a very common problem with Sony MD/CD players. I'll bet it is skipping and/or ruining your recordable MD's, right? It causes far more "disasters" with MD because an MD deck that has trouble reading a recordable MD will think it is corrupt and try to write a new TOC, which can ruin the contents of the disc! When this occurs, press the STOP button until the "TOC" indicator disappears (may take up to 10 seconds) and eject your disc, it will come out unharmed.

Anyhow, on to the optical block problems. I will bet your MDS302 will work fine if turned on its side or upside-down. I have seen this problem many times with Sony MD/CD equipment. I have MD players from Sharp which are much older and have suffered great abuses (like being run over by a car) which don't suffer this problem.

My only guess is that it's either a problem with the lens suspension or the focusing coil. It is definitely a problem with the focusing system in the optical block because: A) replacing the block fixes the problem B) sometimes adjusting Focus Bias on the deck will compensate and reduce or eliminate the problem. C) I have fooled around under the cover of the optical block and have experimented using pieces of tape to suspend the lens suspension. I suspect this compensates for either a poorly functioning suspension or a screwy focus coil. I have been able to regain 100% perfect operation using this fudge-fix method!

Unfortunately, to fix this problem properly, you will need the new optical block. We can only hope that Sony will correct this problem! BTW, you could always use your deck upside-down or sideways. :(

DVD Equipment

CD and DVD support on same drive

Digital Versatile (or Video) Disc players should be hitting the streets by now or at least very soon. What this means is that DVD players will need repair just like CD players.

While much of the basic construction of CD and DVD players is similar, in order for a single player to work with both CDs and DVDs requires some fancy footwork to avoid the costs of dual laser pickups. This comes about from the change in the laser wavelength (780 nm for CDs, 632 nm for DVDs) and thickness of the disc (1.2 mm for CDs, .6 mm for DVDs). This requires differences in the optics to produce the proper spot size and readback image on the photodiode array.

(From: Bill Studenmund (wrstuden@macro.stanford.edu).)

I saw an overview in a journal on what they're doing, and it's pretty cool. They have a variable aperture in the beam (maybe it's on a hinge and snaps into the beam path?). In one setting, the beam is the right diameter to fill an inner area of the objective, and focuses to a spot the right diameter for reading normal CD's. The spot has correction for the spherical aberration from 1.2 mm of disk.

When the aperture is not in the beam, it fills the full aperture of the lens. There's a holographic grating on the lens so the the combination of the inner and outer areas is diffraction limited for 635 and compensates for 0.6 mm of disk.

Though the signal to noise ratio will be lower as the 1/4 wavelength's a bit off, I doubt it'll be a problem. The electronics have gotten so good that they can read a disk w/o metal backing! That's how the Sony dual-layer disk technique works. There are two surfaces with data, and the one in the disk has no aluminum backing. They get enough S/N to read that layer. It's about 50 um above the "normal" layer, so not much of a defocus.

Could DVD discs be made with compatible CD tracks?

CDs are 1.2 mm thick. DVDs consist of two bonded .6 mm substrates. In principle, the DVD layer could be made partially transparent permitting a CD player's laser beam to focus through it to some tracks of CD information pressed in their normal position 1.2 mm from the bottom surface.

As a practical matter, it is very unlikely that any existing CD player could be made to work with such a scheme. It would be like viewing the pits through a frosted plastic screen - theoretically possible but substantially reducing the signal to noise ratio. Furthermore, the CD focus servo would very likely lock onto the DVD rather than the CD layer as it goes through its focus search routine.

It might be possible to design such a CD player but why would anyone want one? By the time this matters, DVD players will either be mainstream (CD-only players may not even be available any more) or will have been superseded by something even more wonderful. Why would you pay a premium for a DVD pressing and then only want to play portions of it on a CD player anyhow?

WORM Drives

WORM drive Laser Diodes

(From: Alan Shinn (alshinn@sirius.com).)

Well, I bought a few of those WORM drives I wrote about. The LD puts out at 30mW at 110mA, As measured by using it to heat up a surface mount transistor hooked up as a thermometer with a surface mount resistor glued onto it for calibration.. I wish I had gotten more. Not that I know what I will do with them (the LDs) The drives also have several rare earth magnets so they were quite a fun deal.

CD-R Equipment

Differences between CD and CD-R media

(From: Michael Portmann (mikep@adelaide.on.net).)

I have a flyer on Mitsui CD-R media. I quote from this:

The difference between a CD-R and a CD-ROM lies in the structural layers between the polycarbonate substrate and the protective lacquer surface that both discs possess.

The CD-R has one long groove stamped in the polycarbonate substrate to guide the laser. This groove is covered with an organic dye lyer, which, when written upon by the heat of a higher powered laser light from the recorder, will deform to produce the 'pits' and 'lands' of information. The dye is protected by a non-corrosive, highly reflective thin layer of gold. One the CD-R layer is recorded, the deformations in the dye become permanent.

The Mitsui gold CD uses a patented Phthalocyanine Dye & Data shield surface.

They then go on to mention how unlike Cyanine based CD-R, theirs shows less degeneration from continuous exposure to light and heat.

HP 4020i/Philips CDD2000 Spring Fix for Write Append Errors

(From: Rick Richardson (rick@dgii.com).)

Here is the fix I applied to my two year old HP 4020i CD-R recorder when I started to get Write Append errors when writing CD's larger than about 550 MBs.

I got a tip that this problem was due to a "spring" wearing out or of insufficient strength from David Neal on the cdwrite@pixar.com mailing list (Unix CD-R software mailing list).

Armed with this clue, I searched DejaNews on the subject of CDD2000 & Spring. Here I found basically two theories for the problem - the spring theory and another one that said it is dust on the laser lens that needs to be blown off with compressed air (*not* wiped).

Since my HP 4020i drive is over two years old, I figured I had nothing to lose by opening it up and seeing if I couldn't apply the "spring fix". Also, at the same time I blew off the laser lens with compressed air.

After applying the "spring fix" and blowing the lens with air, the drive now works 100% again. I cannot say with confidence which of the these actually fixed the drive.

I attach the approximate procedure I used for applying the "spring fix" below. I disclaim any responsibility for the correctness or incorrectness of this fix. Apply the fix will void your warranty. You should not attempt the fix unless you have the proper tools and ability.

Tools Needed:

- Torx T-10 screwdriver
- Torx T-? screwdriver (even smaller than above). I did not have this small a Torx screwdriver, so I used a regular slotted screwdriver with about a 1/8" blade from a jewelers screwdriver kit. I was able to wedge the slotted screwdriver into two of the Torx slots and get enough friction to remove the screws
- Very very small philips screwdriver. Again, I did not have this size screwdriver, but was able to use another of the slotted screwdrivers from a jewelers kit. (A jeweler's screwdriver set with Philips types will probably have the correct size. --- sam)
- Two pair of small needle nosed pliers.
- Pair of dikes (cutters) used for electronic work

Parts Needed:

- About 1.25" long straight but springy wire. I found a suitable wire in an old 5.25" floppy drive that was used to apply pressure to the spindle.

Skills Needed:

- Good eye-hand coordination.
- Good eyesight.
- Steady hands.
- Patience.

The first step is to remove the case. Remove two screws with the T-10 screwdriver and four screws with the T-? screwdriver. Remove metal case. Gently release the top circuit board from two plastic alignment posts -- this may require gradual rocking of the circuit board but do not stress the circuit board as it is very thin.

The next step is to remove the main circuit board by disconnecting three ribbon cables and two sets of two pin connectors. The larger ribbon cables are released by moving two pieces of plastic at each end of the cable connector away from the connector body by about 1/8". The cables should then easily slide out of the connector. The smaller cable has a slightly different release mechanism, but again just move it about 1/8" away from the connector body. Slowly rock the two pin cables from their sockets.

You should now be able to see 4 more T-10 screws. Remove these to free the drive mechanism from the other part of the metal case.

The next step is to remove the smaller circuit board on the laser transport assembly. Remove 4 philips head screws. Pull the board up and lay it over - you will not be able to fully remove the board because two wires are soldered to the motor.

If you look at the transport now, you will see a worm gear which drives a regular gear which drives a rack gear. The rack gear is spring loaded to press up against the regular gear. According to theory, the spring which causes this pressure is worn out and/or not designed to be strong enough.

The spring itself is a straight length of springy wire, about 1" in length and rumored to be about .012" in diameter. Since I don't own calipers, I couldn't verify this.

The spring is held in place only by its springiness. Each end fits into a slot and the middle is bowed down an under a notch in the plastic rack gear.

What you want to do is add a *second* spring wire. You should not need to remove the original spring wire. I found a suitable wire in a 5.25" floppy drive I had laying around. I removed the wire from the floppy drive and straightened out a couple of bends that were in it and ended up with a straight piece of springy wire about 1.25" long, which is longer than the spring in the CD-R drive. You want it longer for now because it is easier to install it that way. It will be cut to length later. Use the two pairs of needle nose pliers to straighten the spring wire.

With your finger, rotate the worm gear on the shaft of the motor to move the transport carriage so that the center of the spring is under the center of the regular gear. You should be able to see the notches that hold both end of the spring now.

Lay your new spring on top of these notches. Using the blade of a small screwdriver perpendicular to the length of the spring, press the spring down in the middle until it is underneath the slot in the black rack gear. This bows the spring about 1/8" in the middle. The spring should now be in place.

Using your smallest dikes, cut the ends of the spring wire off so that they are the proper length. Wear eye protection when doing this, and if possible grasp the end being cut off with needle nose pliers so that the wire won't fly around the room or worse into the drive mechanism.

With the drive still opened up, use a can of compressed air to blow off the dust on the laser lens. DO NOT touch the laser lens as it is magnetically floating in its holder.

Now, reassemble the drive by reversing the disassembly instructions.

DISCLAIMER

Although working on small audio and related electronic equipment is generally less risky than dealing with equipment like microwave ovens, TVs, and computer monitors, devices that plug into the wall can still produce a very lethal electric shock as well cause a fire from incorrect or careless repairs both during servicing or later on. It is essential that you read, understand, and follow all safety guidelines contained in this document and in the document: Safety Guidelines for High Voltage and/or Line Powered Equipment.

Improper repair of battery operated devices can also result in bad consequences for you, the device, and any equipment attached to it.

We will not be responsible for damage to equipment, your ego, county wide power outages, spontaneously generated mini (or larger) black holes, planetary disruptions, or personal injury or worse that may result from the use of this material.

Introduction

Note: Information on AC adapters, power supplies, batteries, and electronic flash units has been relocated to other documents (with what should be obvious titles) in this same directory.

Why is all that junk in your attic?

If you have ever tried to get a piece of consumer electronic equipment repaired, you understand why so much dead stuff is likely to be gathering dust in your attic or basement closet or junk box. It does not pay! This may be partially by design. However, to be fair, it may take just as much time to diagnose and repair a problem with a $20 Walkman as a $300 VCR and time is money for a repair shop. It is often not even economical to repair the more expensive equipment let alone a $40 answering machine. The cost of the estimate alone would probably buy at least one new unit and possibly many more.

However, if you can do the repair yourself, the equation changes dramatically as your parts costs will be 1/2 to 1/4 of what a professional will charge and of course your time is free. The educational aspects may also be appealing. You will learn a lot in the process. Many problems can be solved quickly and inexpensively. Fixing an old boombox to take take to the beach may just make sense after all.

This document provides maintenance and repair information for a variety of consumer electronic devices not covered by other documents in the "Notes on the Troubleshooting and Repair of..." series. Suggestions for additions (and, of course, correction) are always welcome.

You will be able to diagnose problems and in most cases, correct them as well. As most difficulties encountered with this type of equipment are mechanical, there is significant emphasis on dirt, lubrication, deteriorated rubber parts, broken doohickies, and so forth. With minor exceptions, specific manufacturers and models will not be covered as there are so many variations that such a treatment would require a huge and very detailed text. Rather, the most common problems will be addressed and enough basic principles of operation will be provided to enable you to narrow the problem down and likely determine a course of action for repair - or decide that replacement is indeed the better option. However, in many cases, you will be able to do what is required to repair a piece of equipment for a fraction of what would be charged by a repair center. Perhaps, you will even be able to revive something that would otherwise have gone into the dumpster - or remained in that closet until you moved out of your house (or longer)!

Should you still not be able to find a solution, you will have learned a great deal and be able to ask appropriate questions and supply relevant information if you decide to post to sci.electronics.repair. It will also be easier to do further research using a repair book or guide. In any case, you will have the satisfaction of knowing you did as much as you could before finally giving up or (if it is worthwhile cost-wise) taking it in for professional repair. With your new-found knowledge, you will have the upper hand and will not easily be snowed by a dishonest or incompetent technician.

If you are just getting started, you should refer to "Repair Briefs, an Introduction" for additional troubleshooting tips, recommended test equipment, suggested parts inventory, and other general information.

Information on consumer electronics technology

Your local public library (621.384 if your library is numbered that way) or technical bookstore represents a valuable resource for books on both the technology and repair of a large variety of consumer electronics devices.

For general troubleshooting techniques, see the section: Some general references.

The How Stuff Works Web site has some really nice introductory material (with graphics) on a variety of topics relating to technology in the modern world. Of relevance to this document are articles on motors, power adapters, relays, batteries, etc.

Check out "Sam's Neat, Nifty, and Handy Bookmarks" (at this site) in the "Education and Tutorials" area for links to basic introductory material on electronics and other related fields.

Web sites dealing with low voltage wiring

These sites deal with non-power wiring information: phones, audio, video, home automation, etc. Since much of the content of this document relates to home electronics that may involve such wiring, these sites may be of interest. The first also has a pile of links to other related sites.

Maintenance and Troubleshooting Guide

SAFETY

The only danger to you in most audio equipment and the other devices covered in this document is from the AC line connection (if any) and getting sucked into any mechanical people traps. Before you plug in the unit with any covers removed, make note and cover up any exposed AC line connections. The rest of the circuitry is low voltage and while you can destroy your equipment by your actions, you should be fairly safe. Exceptions to this are noted where appropriate.

- Don't wear any jewelry or other articles that could accidentally contact circuitry and conduct current, or get caught in moving parts (protect long hair as well).

- If circuit boards need to be removed from their mountings, put insulating material between the boards and anything they may short to. Hold them in place with string or electrical tape. Prop them up with insulation sticks - plastic or wood.

- Connect/disconnect any test leads with the equipment unpowered and unplugged. Use clip leads or solder temporary wires to reach cramped locations or difficult to access locations.

- If you must probe live, put electrical tape over all but the last 1/16" of the test probes to avoid the possibility of an accidental short which could cause damage to various components. Clip the reference end of the meter or scope to the appropriate ground return.

- Perform as many tests as possible with power off and the equipment unplugged. For example, the semiconductors in the power supply of an audio amplifier can be tested for shorts and the fusable resistors can be tested for opens.

- If you need to probe, solder, or otherwise touch circuits in a switching power supply with the power off, discharge (across) large power supply filter capacitors with a 2 W or greater 20-100K resistor and then verify with your voltmeter.

- The use of GFCI (Ground Fault Circuit Interrupter) protected outlet is a good idea but will not protect you from shock from many points in a line connected power supply. A circuit breaker is too slow and insensitive to provide any protection for you or in many cases, your equipment. A GFCI may prevent your scope probe ground from melting should you accidentally connect it to a live circuit, however.

- Don't attempt repair work when you are tired. Not only will you be more careless, but your primary diagnostic tool - deductive reasoning - will not be operating at full capacity.

- Finally, never assume anything without checking it out for yourself! Don't take shortcuts!

Getting zapped from a piece of audio (or other A/V) equipment

A slight (or not so slight) tingle when touching cabinet parts, or even a sort of vibration not due to actual physical movement as you run a finger over the metal may be an indication of some electrical leakage. Usually, this is harmless but can probably be eliminated.

Check with a multimeter on the AC volts range between any combination of user accessible parts - cases, antenna jacks, etc., and an earth ground like the third hole of a properly grounded outlets.

- If you measure an AC voltage up to about 1/2 the line voltage where you live (110 VAC or 220 VAC), it may just be due to the various capacitors inside the equipment coupling to a live chassis.

- However, if you measure the full line voltage, you may have a serious fault somewhere that requires immediate attention. Modern equipment must be designed in such a way that no matter how it is plugged in, no user accessible parts can be live. (Some really old AC/DC sets may indeed have one side of the line connected to an uninsulated chassis.) However, a short circuit somewhere inside can produce such a fault - a very hazardous situation.

  For the slight tingle case:

- Check outlet wiring - check H-N polarity, and for 3-prong outlets, that there is a proper ground. Plug everything into a single circuit if possible.

- Make sure each piece of equipment is plugged into its outlet properly with its polarized plug.

- Check the case and connectors of each piece of equipment between a known ground for voltage. Also check the cable itself. If you read a high voltage on it, have your cable company check it out.

- Reversing a two prong plug in the outlet may help if it isn't polarized. If it is, the outlet or the equipment itself might be improperly wired.

Troubleshooting tips

Many problems have simple solutions. Don't immediately assume that your problem is some combination of esoteric complex convoluted failures. For a tape deck, it may just be a bad belt or a bad tape. Try to remember that the problems with the most catastrophic impact on operation (a dead AC adapter) have the simplest solutions (repair the wires broken due to flexing in the power cable).

If you get stuck, sleep on it. Sometimes, just letting the problem bounce around in your head will lead to a different more successful approach or solution. Don't work when you are really tired - it is both dangerous and mostly non-productive (or possibly destructive).

Whenever working on precision equipment, make copious notes and diagrams. You will be eternally grateful when the time comes to reassemble the unit. Most connectors are keyed against incorrect insertion or interchange of cables, but not always. Apparently identical screws may be of differing lengths or have slightly different thread types. Little parts may fit in more than one place or orientation. Etc. Etc.

Pill bottles, film canisters, and plastic ice cube trays come in handy for sorting and storing screws and other small parts after disassembly.

Select a work area which is well lighted and where dropped parts can be located - not on a deep pile shag rug. Something like a large plastic tray with a slight lip may come in handy as it prevents small parts from rolling off of the work table. The best location will also be relatively dust free and allow you to suspend your troubleshooting to eat or sleep or think without having to pile everything into a cardboard box for storage.

Another consideration is ESD - Electro-Static Discharge. The electronic components in a some devices like cassette decks, Walkmen, and portable phones, are vulnerable to ESD. There is no need to go overboard but taking reasonable precautions like not wearing clothing made of wool that tends to generate static. When working on larger devices like cassette decks, get into the habit of touching a ground like the metal chassis before touching any circuit components.

A basic set of precision hand tools will be all you need to disassemble and perform adjustments on most consumer electronic equipment. These do not need to be really expensive but poor quality tools are worse than useless and can cause damage. Needed tools include a selection of Philips and straight blade screwdrivers, needlenose pliers, wire cutters, tweezers, and dental picks. A jeweler's screwdriver set is a must particularly if you are working on compact equipment. For adjustments, a miniature (1/16" blade) screwdriver with a non-metallic tip is desirable both to prevent the presence of metal from altering the electrical properties of the circuit and to minimize the possibility of shorting something from accidental contact with the circuitry.

For thermal or warmup problems, a can of 'cold spray' or 'circuit chiller' (they are the same) and a heat gun or blow dryer come in handy to identify components whose characteristics may be drifting with temperature. Using the extension tube of the spray can or making a cardboard nozzle for the heat gun can provide very precise control of which components you are affecting.

Basic cleaning supplies include Q-tips (you may know them as cotton buds) for everything BUT the video heads on VCRs and other helical scan tape transports, chamois covered cleaning sticks (for video heads), lint free cloths or paper towels, water, and isopropyl alcohol (preferably 91 percent medicinal grade or better).

For info on useful chemicals, adhesives, and lubricants, see "Repair Briefs, an Introduction" as well as other documents available at this site.

Soldering equipment

The ease and quality of your work will depend both on proper soldering as well as desoldering (often called rework) equipment.

- A low wattage (25 W) iron for delicate components including discrete semiconductors, ICs, other small parts).
- A medium wattage (40-50W) iron for heavy duty circuit board work including power components, power plane connections, and large transformers).
- A 100-140 W soldering gun for chassis connections.

Three wire grounded soldering equipment is recommended but I do not consider it essential for this type of repair work. However, a temperature regulated soldering station is a really nice piece of equipment if you can afford it or happen on a really good deal.

I consider fine gauge rosin core solder (.030 or less) to be best for most applications (e.g., Ersin Multicore).

- Desoldering pump - SoldaPullit or similar 'solder sucker' for removing components easily and usually nondestructively. SolderWick is also handy for cleaning up desoldered connections.

  A vacuum rework station is not needed unless you are removing your soldered in 1,500 pin Intel P8!

CAUTION: You can easily turn a simple repair (e.g., bad solder connections) into an expensive mess if you use inappropriate soldering equipment and/or lack the soldering skills to go along with it. If in doubt, find someone else to do the soldering or at least practice, practice, practice, soldering and desoldering on a junk circuit board first!

Soldering techniques

Soldering is a skill that is handy to know for many types of construction and repair. For modern small appliances, it is less important than it once was as solderless connectors have virtually replaced solder for internal wiring.

However, there are times where soldering is more convenient. Use of the proper technique is critical to reliability and safety. A good solder connection is not just a bunch of wires and terminals with solder dribbled over them. When done correctly, the solder actually bonds to the surface of the metal (usually copper) parts.

Effective soldering is by no means difficult but some practice may be needed to perfect your technique.

The following guidelines will assure reliable solder joints:

- Only use rosin core solder (e.g., 60/40 tin/lead) for electronics work. A 1 pound spool will last a long time and costs about $10. Suggested diameter is .030 to .060 inches for appliances. The smaller size is preferred as it will be useful for other types of precision electronics repairs or construction as well. The rosin is used as a flux to clean the metal surface to assure a secure bond. NEVER use acid core solder or the stuff used to sweat copper pipes! The flux is corrosive and it is not possible to adequately clean up the connections afterward to remove all residue.

- Keep the tip of the soldering iron or gun clean and tinned. Buy tips that are permanently tinned - they are coated and will outlast countless normal copper tips. A quick wipe on a wet sponge when hot and a bit of solder and they will be as good as new for a long time. (These should never be filed or sanded).

- Make sure every part to be soldered - terminal, wire, component leads - is free of any surface film, insulation, or oxidation. Fine sandpaper or an Xacto knife may be used, for example, to clean the surfaces. The secret to a good solder joint is to make sure everything is perfectly clean and shiny and not depend on the flux alone to accomplish this. Just make sure the scrapings are cleared away so they don't cause short circuits.

- Start with a strong mechanical joint. Don't depend on the solder to hold the connection together. If possible, loop each wire or component lead through the hole in the terminal. If there is no hole, wrap them once around the terminal. Gently anchor them with a pair of needlenose pliers.

- Use a properly sized soldering iron or gun: 20-25 W iron for fine circuit board work; 25-50 W iron for general soldering of terminals and wires and power circuit boards; 100-200 W soldering gun for chassis and large area circuit planes. With a properly sized iron or gun, the task will be fast - 1 to 2 seconds for a typical connection - and will result in little or no damage to the circuit board, plastic switch housings, insulation, etc. Large soldering jobs will take longer but no more than 5 to 10 seconds for a large expanse of copper. If it is taking too long, your iron is undersized for the task, is dirty, or has not reached operating temperature. For appliance work there is no need for a fancy soldering station - a less than $10 soldering iron or $25 soldering gun as appropriate will be all that is required.

- Heat the parts to be soldered, not the solder. Touch the end of the solder to the parts, not the soldering iron or gun. Once the terminal, wires, or component leads are hot, the solder will flow via capillary action, fill all voids, and make a secure mechanical and electrical bond. Sometimes, applying a little from each side will more effectively reach all nooks and crannies.

- Don't overdo it. Only enough solder is needed to fill all voids. The resulting surface should be concave between the wires and terminal, not bulging with excess solder.

- Keep everything absolutely still for the few seconds it takes the solder to solidify. Otherwise, you will end up with a bad connection - what is called a 'cold solder joint'.

- A good solder connection will be quite shiny - not dull gray or granular. If your result is less than perfect reheat it and add a bit of new solder with flux to help it reflow.

Practice on some scrap wire and electronic parts. It should take you about 3 minutes to master the technique!

Desoldering techniques

Occasionally, it will be necessary to remove solder - either excess or to replace wires or components. A variety of tools are available for this purpose. The one I recommend is a vacuum solder pump called 'SoldaPullet' (about $20). Cock the pump, heat the joint to be cleared, and press the trigger. Molten solder is sucked up into the barrel of the device leaving the terminal nearly free of solder. Then use a pair of needlenose pliers and a dental pick to gently free the wires or component. Other approaches that may be used in place of or in addition to this: Solder Wick which is a copper braid that absorbs solder via capillary action; rubber bulb type solder pumps, and motor driven vacuum solder rework stations (pricey).

See the document: Troubleshooting and Repair of Consumer Electronics Equipment for additional info on desoldering of electronic components.

Soldering pins in plastic connectors

The thermoplastic used to mold many common cheap connectors softens or melts at relatively low temperatures. This can result in the pins popping out or shifting position (even shorting) as you attempt to solder to them to replace a bad connection, for example.

One approach that works in some cases is to use the mating socket to stabilize the pins so they remain in position as you solder. The plastic will still melt - not as much if you use an adequately sized iron since the socket will act as a heat sink - but will not move.

An important consideration is using the proper soldering iron. In some cases, a larger iron is better - you get in and out more quickly without heating up everything in the neighborhood.

Test equipment

Don't start with the electronic test equipment, start with some analytical thinking. Many problems associated with consumer electronic equipment do not require a schematic (though one may be useful). The majority of problems with consumer electronic equipment are mechanical and can be dealt with using nothing more than a good set of precision hand tools; some alcohol, degreaser, contact cleaner, light oil and grease; and your powers of observation (and a little experience). Your built in senses and that stuff between your ears represents the most important test equipment you have.

A DMM or VOM is necessary for checking of power supply voltages and testing of sensors, LEDs, switches, and other small components. This does not need to be expensive but since you will be depending on its readings, reliability is important. Even a relatively inexpensive DMM from Radio Shack will be fine for most repair work. You will wonder how you ever lived without one! Cost: $25-50.

Unless you get deep into electronic repair, a high bandwidth oscilloscope is not required. However, a relatively inexpensive 5 or 10 MHz dual trace scope is very handy and you will find all kinds of uses for it. Such a scope should cost less than $150 on the used market.

There are several specific pieces of test equipment that you may already own which are required depending on the devices being fixed.

Audio equipment:

- Stereo tuner or other audio signal source. An audio signal generator is nice but not really essential.
- An audio amp connected to a loudspeaker. The input should be selectable between line level and mic level and be brought out through a shielded cable to a test probe and ground clip. This is useful for tracing an audio circuit to determine where a signal is getting lost. Inexpensive signal tracers are also available but this option is likely free.

  If you intend to test phonograph (e.g., vinyl) or low level signals from tape heads, the amp should have magnetic phono level (average of 2 to 5 mV which is equivalent to -54 dBV to -46 dBV) in addition to line level (CD, DVD, tape, etc., average of 250 mV, peak of 2 V) inputs.
- Prerecorded and garbage cassettes or tapes for testing of component and walkman tape transports.

Video games, cable boxes, and other video sources:

- A TV (preferably color) with RF (antenna) inputs connected to a VCR with a working tuner and RF modulator or a TV with both RF and A/V (RCA jacks) inputs.
- A known good game cartridge to confirm that the problem is in the game console.

Telephone equipment:

- A working tone dialing phone. If I had a choice, it would be a good old reliable ATT Touch Tone desk phone.
- A working rotary dialing phone. If I had a choice, it would be a good old reliable ATT rotary dial desk phone. (This is really only needed if you are doing repairs where tone dialing isn't available.)
- A dual connector phone jack. Two independent phone lines are desirable for answering machine or modem testing.
- A PC or laptop with a fax-modem (for modem and fax machine testing).
- A low voltage DC power supply or wall wart to perform certain tests without a telephone connection or phone line simulator.
- A handy-dandy phone line tester. The inexpensive variety is just a pair of LEDs in series with a resistor for each line attached to an RJ11 connector. However, this is much more convenient than fumbling with a multimeter! You can buy one at Radio Shack (about $7) or easily build your own. See the section: Handy-dandy phone line tester for details.

Handy-dandy phone line tester

This simple device (total cost about $3) will show at a glance the status of all of the phone lines connected to a modular jack.

Parts list:

- Surface mount RJ11 modular jack.
- RJ11 extension cord.

For each phone line:

- 2 LEDs (red and green).
- 10K resistor.

Construct the following circuit for each line and attach to the appropriate color terminals/wires of the modular jack:

```
                          10K             Green LED
Line 1:     (Green) o------/\/\-----+--------|>|-------+------o (Red
Line 2:     (Black)                 |  Wiring Correct  |        (Yellow)
Line 3:     (White)                 |                  |        (Blue)
                                    |      Red LED     |
                                    +--------|<|-------+
                                     Reverse Polarity
```

Note: Polarity of Tip and Ring are reversed with respect to the wire colors because of swap that occurs using the RJ11 extension cord.

Mount the LEDs in holes drilled in the plastic cover of the modular jack (making sure they clear the base when the cover is screwed down).

To test old style 4 prong phone jacks, use an adapter on the end of the RJ11 extension cord.

Correctly wired lines will light up green, reverse polarity will be red, dead line will be dark, line-in-use will be dark or nearly dark. If you catch a line that is ringing. both LEDs will flicker.

Putting just the LED portion (leave out the resistor) of this circuit in *series* with the phone line will implement an off-hook (in use) indicator.

Getting inside consumer electronic equipment

Yes, you will void the warranty, but you knew this already.

Note: the sections on loudspeakers, cameras, and watches have additional 'getting inside' info.

Manufacturers seem to take great pride in being very mysterious as to how to open their equipment. Not always, but this is too common to just be a coincidence.

A variety of techniques are used to secure the covers on consumer electronic equipment:

1. Screws. Yes, many still use this somewhat antiquated technique. Sometimes, there are even embossed arrows on the case indicating which screws need to be removed to get at the guts. In addition to obvious screw holes, there may be some that are only accessible when a battery or cassette compartment is opened or a trim panel is popped off.

   These will often be of the Philips variety. (Strictly speaking, many of these are not actual Philips head screws but a slight variation. Nonetheless, a Philips screwdriver of suitable size will work on them.) A precision jeweler's screwdriver set including miniature Philips head drivers is a must for repair of miniature portable devices.

   Sometimes, you will find Torx or a variety of security type fasteners. Suitable driver bits are available. Sometimes, you can improvise using regular tools. In the case of security Torx, the center post can usually be broken off with a pair of needlenose pliers allowing a normal Torx driver to be used. In a pinch, a suitable size hex wrench can substitute for a Torx driver. Places like MCM Electronics carry a variety of security bits.

2. Hidden screws. These will require prying up a plug or peeling off a decorative decal. It will be obvious that you were tinkering - it is virtually impossible to put a decal back in an undetectable way. Sometimes the rubber feet can be pryed out revealing screw holes. For a stick-on label, rubbing your finger over it may permit you to locate a hidden screw hole. Just puncture the label to access the screw as this may be less messy then attempting to peel it off.

3. Snaps. Look around the seam between the two halves. You may (if you are lucky) see points at which gently (or forcibly) pressing with a screwdriver will unlock the covers. Sometimes, just going around the seam with a butter knife will pop the cover at one location which will then reveal the locations of the other snaps.

4. Glue. Or more likely, the plastic is fused together. This is particularly common with AC adapters (wall warts). In this case, I usually carefully go around the seam with a hacksaw blade taking extreme care not to go through and damage internal components. Reassemble with plastic electrical tape.

5. It isn't designed for repair. Don't laugh. I feel we will see more and more of this in our disposable society. Some devices are totally potted in Epoxy and are throwaways. With others, the only way to open them non-destructively is from the inside.

Don't force anything unless you are sure there is no alternative - most of the time, once you determine the method of fastening, covers will come apart easily. If they get hung up, there may be an undetected screw or snap still in place.

The most annoying (to be polite) situation is when after removing the 18 screws holding the case together (losing 3 of them entirely and mangling the heads on 2 others), removing three subassemblies, and two other circuit boards, you find that the adjustment you wanted was accessible through a hole in the case just by partially peeling back a rubber hand grip!

When reassembling the equipment make sure to route cables and other wiring such that they will not get pinched or snagged and possibly broken or have their insulation nicked or pierced and that they will not get caught in moving parts. Replace any cable ties that were cut or removed during disassembly and add additional ones of your own if needed. Some electrical tape may sometimes come in handy to provide insulation insurance as well.

Getting built up dust and dirt out of a equipment

This should be the first step in any inspection and cleaning procedure.

Do not be tempted to use compressed air!

I would quicker use a soft brush to carefully dust off the circuit boards and power supply. Work in such a way that the resulting dust does not fall on the mechanical parts.

For intricate mechanisms, using compressed air could dislodge dirt and dust which may then settle on lubricated parts contaminating them. High pressure air could move oil or grease from where it is to where it should not be. If you are talking about a shop air line, the pressure may be much much too high and there may be contaminants as well.

A Q-tip (cotton swab) moistened with politically correct alcohol can be used to remove dust and dirt from various surfaces of the deck (in addition to the normal proper cleaning procedures for the guides, rollers, heads, wheels, belts, etc.)

What to do if a tiny tiny part falls inside

We have all done this: a tiny washer or spring pops off and disappears from sight inside the guts of the unit. Don't panic. First - unplug it if AC powered. Remove the battery pack if possible from a portable device.

Try to locate the part with a bright light without moving anything. You may have gotten lucky (yeh, right). Next, over an area where a dropped part will be visible (not a shag carpet!), try any reasonable means to shake it loose - upside down, a little gently tapping and shaking, etc. A hard surface is better in some ways as you might hear the part drop. On the other hand it may bounce into the great beyond.

If this does not work, you have two options:

1. Assume that the part has landed in a place that will not cause future problems. There could be electrical problems if it is metallic and shorts out some circuitry or there could be mechanical problems if it jams some part of the mechanism. There is an excellent chance that the part will never cause any harm. What chance? I don't know, maybe 99%. It is not worth taking the unit to pieces to locate the part. You are more likely to damage something else in the process. Obtain a replacement and get on with your life. The exception is, of course, if you now begin experiencing problems you **know** were not there before.

2. Take the unit to pieces in an attempt to locate the part. For all you know, it may be clear across the room and you will never find it inside. If all the gymnastics have not knocked it loose, then it may be really

wedged somewhere and will stay there - forever. If the unit behaves normally, then in all likelihood it will continue to do so.

To prevent this sort of thing from happening in the future you will no doubt be much more careful. Sure you will! Some suggestions to prevent ejection of an E-clip, split washer, or spring into the great beyond:

1. Construct a paper dam around the area.

2. Tie a thread or fine wire around the part before attempting to remove it. Keep this 'safety line' on until after it has been reinstalled, then just pull it free.

3. Keep one finger on the part as you attempt to pop it free.

4. Hold onto the part with a pair of needlenose pliers or tweezers while prying with a small screwdriver.

Audio Cassette and Open Reel Tape Equipment

Parts of an audio tape transport

The following description applies to most cassette and open reel tape transports including those used in portable and microcassette recorders, Walkmen, and telephone answering machines.

Looking at the top of the deck such that the tape heads are at the bottom:

- Supply reel table - left hand side platform on which the supply tape reel sits. Edge which contacts idler tire (if used) should be cleaned.

- Takeup reel table - right hand side platform on which the takeup tape reel sits. Edge which contacts idler tire (if used) should be cleaned.

- Idler - assembly which swings between supply and takeup reels and transfers power to the appropriate reel to wind the tape up during play and record and often to drive FF and REW. In some designs, this uses gears or some other type of mechanism. In very expensive decks, individual motors are used for each reel and there is no intermediate drive.

- Idler tire - the black rubber ring on the outside of one part of the idler which actually contacts the reel edges. This is not as common in audio tape decks as VCRs. If one is used, it should be cleaned and inspected for deterioration, dirt, and wear.

- Capstan - right side after tape exits from area of record/playback/erase heads. The capstan is a shaft (about 1/16" diameter in cassette decks, recorders, and Walkmen, 3/16" or larger diameter in open reel machines) which during play and record modes precisely controls tape movement when the pinch roller is pressed against it. For autoreverse transports, there will be two capstans - one on each side of the head assembly so that the tape is always pulled across the heads as this is most precise. (In a VCR, there is only one capstan and it is also used for reverse play or search modes.) Clean to assure proper tape movement during play and record modes.

- Pinch Roller - black rubber roller which spins freely and is pressed against the capstan during play, record, and search modes. For autoreverse decks, there will be two pinch rollers, one for each capstan. A hard, shiny, cracked, or dried out pinch roller can lead to tape edge munching and erratic or wavering sound. Clean thoroughly (until no more black stuff comes off). Inspect for cracked or deteriorated rubber.

- Tape heads. Most low to mid priced tape decks have two - an erase head and a combined record/playback head. High-end decks will have separate record and playback heads supporting sound-on-sound mixing to the same track and allowing recording quality to be monitored off of the tape. These may be physically independent assemblies or combined into a single unit. Autoreverse decks often have a head assembly that rotates 180 degrees depending on tape direction. This is less expensive than having two erase heads and two record/playback heads or a single record/playback head that shifted position to align with the appropriate tracks and electronic switching of the record and playback signals.

  Play-only transports such as found in car cassette decks and Walkmen do not need an erase head. Autoreverse play-only decks often do just shift the position of the playback head a fraction of a mm depending on playback direction to line up with the tracks and interchanges the connections for L and R channels.

  Clean the polished surfaces thoroughly (DO NOT use anything abrasive!).

- Various other guide posts - vertical stationary metal posts which tape contacts. Should be cleaned but rarely need adjustment.

- Belts - various size black rubber bands - a typical transport will have between 0 and 4 belts, usually below decks. These will require replacement after a few years. Clean and inspect.

General guide to tape deck cleaning and rubber parts replacement

The following procedures apply to boom boxes, cassette decks, microcassette and other portable tape recorders, open reel tape decks, and telephone answering machines. While the tape transports used in these devices are less complex than those used in VCRs and other helical scan recording equipment, some routine maintenance can go a long way towards preventing future problems. All the guideposts, wheels, and rubber parts should be inspected and cleaned periodically - how often depends on usage. Of course, no one really does this unless something goes wrong.

Qtips and alcohol (91% medicinal is ok, pure isopropyl is better. Avoid rubbing alcohol especially if it contains any additives) can be used everywhere EXCEPT on the rotating heads of VCRs and camcorders (and other helical scan devices like 8mm and 4mm (DAT) storage drives) - see the document: Notes on the Troubleshooting and Repair of Video Cassette Recorders for detailed procedures on cleaning of video heads - you can destroy the most expensive part of your VCR by improper cleaning techniques. Dry quickly to avoid leaving residue behind. Sometimes good old fashioned water (just a damp cloth) will work better on sugar based gunk and other kids' grime.

Cleaning may get your machine going well enough to get by until any replacement rubber parts arrive.

Things to clean:

(Some of these components may not be present in your particular equipment).

- Capstan and pinch roller. These collect a lot of crud mostly oxide which flakes off of (old) tapes. Use as many Q-tips (wet but not dripping with alcohol) as necessary to remove all foreign matter from the capstan (the shiny shaft that pulls the tape through the unit for play and record). Just don't get impatient and use something sharp - the crud will come off with the Qtips and maybe some help from a fingernail. On autoreverse decks, there will usually be two capstans and pinch rollers.

  Clean the pinch roller (presses against the capstan in play and record) until no more black stuff comes off. Use as many Qtips as necessary.

  If the pinch roller is still hard and/or shiny or has a cracked surface, it will probably need replacement. Many are available from the sources listed in the section: Recommended parts suppliers.

- Various guideposts that the tape contacts. Clean like the capstan.

- Idler tire (idler swings between reels and transfers motor power to reels - clean until no more black stuff comes off. A dirty or worn idler tire may prevent the takeup reel from turning resulting in spilled tape.

  Also, the idler assembly includes a slip clutch. If this weakens, the idler may not have enough force to press on the reel table edges.

- Reel table edges - surface on the reel tables where the idler contacts.

- Audio head(s) and erase head. Q-tips and alcohol are ok for these. Do not use anything sharp or abrasive!

- Anything else that the tape contacts on its exciting journey through your machine.

- Rubber belts. Access to some of these may require the services of a Swiss watchmaker (if any still exist). Some boomboxes seem to be designed specifically to be difficult to service. After noting where each belt goes, remove them individually (if possible) and clean with alcohol and Qtips or a lint free cloth. Dry quickly to avoid degrading the rubber from contact with the alcohol. If a belt is trapped by some assembly and not easy to remove, use the Qtip on the belt and/or pulley in place. However, if it is stretched, flabby, or damaged, you will need to figure out how to free it.

  Note that on some equipment like dual cassette boomboxes and telephone answering machines, the belt(s) may follow a highly circuitous path - make a detailed diagram!

  Any belts that appear loose, flabby or do not return instantly to their relaxed size when stretched by 25%

or so will need to be replaced and may be the cause of your problems. Belts cost about $.30-$2.00. Meanwhile, the belts will function better once they are cleaned, maybe just enough to get by until your replacements arrive.

Lubrication of electronic equipment

The short recommendation is: Don't add any oil or grease unless you are positively sure it is needed. Most parts are lubricated at the factory and do not need any further lubrication over their lifetime. Too much lubrication is worse then too little. It is easy to add a drop of oil but difficult and time consuming to restore a tape deck that has taken a swim.

NEVER, ever, use WD40! WD40 is not a good lubricant despite the claims on the label. Legend has it that the WD stands for Water Displacer - which is one of the functions of WD40 when used to coat tools for rust prevention. WD40 is much too thin to do any good as a general lubricant and will quickly collect dirt and dry up. It is also quite flammable and a pretty good solvent - there is no telling what will be affected by this.

A light machine oil like electric motor or sewing machine oil should be used for gear or wheel shafts. A plastic safe grease like silicone grease or Molylube is suitable for gears, cams, or mechanical (piano key) type mode selectors. Never use oil or grease on electrical contacts.

Unless the unit was not properly lubricated at the factory (which is quite possible), don't add any unless your inspection reveals the specific need. Sometimes you will find a dry capstan, motor, lever, or gear shaft. If possible, disassemble and clean out the old lubricant before adding fresh oil or grease.

Note that in most cases, oil is for plain bearings (not ball or roller) and pivots while grease is used on sliding parts and gear teeth.

In general, do not lubricate anything unless you know there is a need. Never 'shotgun' a problem by lubricating everything in sight! You might as well literally use a shotgun on the equipment!

Tape head demagnetizing

With audio tape decks, demagnetizing is often recommended to improve sound quality and frequency response. There is some debate as to how much benefit there is to this practice but if done properly, there is little risk. Demagnetizing removes the residual magnetic fields that can build up on ferrous pole pieces of the tape heads and various guideposts and other parts in the tape path which may affect frequency response.

Use a small demagnetizer designed for a tape deck or cassette deck. See the section: Homemade audio tape head demagnetizer if you don't have one or don't want to buy one. However, do not use anything that might be too powerful or a bulk tape eraser which would certainly be too powerful.

Make sure the tip is covered with a soft material to prevent damage to the finely polished surfaces in the tape transport.

The tape deck should be off (unpowered) during this process. (Strictly speaking, this doesn't really matter but it's just safer that way.)

Turn power on to the demagnetizer when a couple of feet away from the unit. Then, slowly bring it in close and slowly go over all surfaces of anything that the tape contacts or comes close to in the tape path. The key word here is **slowly**. Move fast, and you will make the magnetic fields stronger. When finished, slowly draw the demagnetizer away to a distance of a couple of feet before turning it off.

Homemade audio tape head demagnetizer

A perfectly serviceable tape head demagnetizer can be easily constructed using a large nail, 100 turns of insulated wire (just guessing here) and an AC wall adapter (from an obsolete modem, for example). Grind down the end of the nail so that it is not sharp and coat it with a soft material or cover the end with electrical tape to protect the finely polished heads from scratches.

Adjust the number of turns and input voltage for desired strength. How strong should it be? A direct comparison with a commercial unit would be best but when in close proximity to a steel surface, you should be able to feel the 120 Hz attraction but it shouldn't jump out of your hand! Sort of like "Use a pinch of salt you will know how much" :-)

Building a bulk tape eraser

A variety of approaches work for this - all based on strong magnetic fields. These will erase floppy diskettes, audio and video tapes, and all your credit cards and Turnpike passes!

- Magnets removed from large loudspeakers (including the pole pieces where the voice coil went) and microwave oven magnetrons.
- Some motors, transformers, the butt-end of some soldering guns, etc.

(From: Steven L. Bender (buqu35d@prodigy.com).)

You need a power transformer about 3" in each direction, can be like a low voltage 12 volt / 3 Amp unit or rated higher. Remove end bells if any, remove all the metal laminations (break the first one, yank it, and the rest will come easier). Re-insert all the metal laminations facing in the same direction, with the "E" all pointed the same, re-glue, varnish, or whatever. Connect AC Plug to the Primary, then insulate the whole works with Plastic tape and outre layer of Duct tape. After insulating it with several layers of tape - Instant Bulk Eraser.

WARNING: Do not apply power for more than 60 seconds at a time! (It will get hot and burn your hand after two minutes.)

I had one of those for some years, but accidentally left it plugged in, (pulled the wrong wire out of the 6 to 1 outlet box) and after a few minutes, it smelled and was too hot to touch, and made a nasty noise as the copper started to melt... (Sounds Effects of Liquid Krell Metal in the distance...., Forbidden Planet - Paramount, 1956).

Luckily I didn't walk out, another few minutes and it would have caught fire..

I am not liable for any personal, profession, or consequential damages from use of this information !!!

(From: Steve Walz (rstevew@armory.com).)

Use a transformer and remove the EI core pieces and replace all the E's only in the same direction. Current limit it with a wire-wound resistor so it doesn't overheat and put a momentary pushbutton on it and a power cord to wall AC and insulate it so you don't shock yourself. Then place it so the open face of the E core pieces faces the tape or disk or whatever to be erased and push the button. Run it all over both sides of the tape or disk and pull the tape or disk away before letting up on the button if you wish to erase it. If you wish to magnetize a tool or such, simply let up on the button while the object or tool is still in contact with it. That's how that works! (You may have to do it a couple times before you catch the AC cycle at the peak! --- Sam.)

(From: Pat Swayne (me@patswayne.com).)

Here's a safety tip for your homemade bulk tape eraser: Use a small length of very thin solder as a fusable link. Place this as close to, but insulated from, the primary windings as possible, and pass the current through it. If the thing gets too hot, it will melt the solder and break the connection.

(From: Sam.)

It would have to get mighty hot for that to be effective but it's cheap enough. Of course, a thermal fuse or thermostat would be a more well controlled alternative.

Splicing of audio tapes

If a tape is broken or seriously crinkled, cutting out the bad section and joining the remaining ends will be necessary. There are special splicing kits for this. I don't know if a place like Radio Shack carries these but an audio dealer or electronics distributor should have one. In a pinch, you could very carefully use a razor blade or Xacto knife to cut the tape an a 45 degree angle and ordinary transparent to mend it. Then, it is best to copy the tape to a new one. At least with an audio deck, you don't really have to worry about ruining the heads with an improperly made splice though you do want to avoid depositing adhesive from the mending tape onto parts of the transport!

Tape or cassette deck, recorder, or Walkman transport problems

The following are common problems with audio tape transports:

1. No movement in PLAY or REC - most likely capstan is not turning or not engaged. If the motor is not working (listen for a hum from inside the transport), refer to the chapter: "Motors and Relays". Otherwise, see the list below.

2. Tape eating - the capstan is turning but the takeup reel is stationary or not turning rapidly enough to take up the tape as it feeds from the capstan/pinch roller.

3. FF and/or REW are inoperative or sluggish - assuming the motor is working, the driven reel is not being powered at all or does not have sufficient torque to overcome the tape friction. The driven reel alone must pull the tape through the transport.

Note that the required torque for the driven reel is much less for PLAY and REC compared to FF and REW as the capstan in contact with the pinch roller pulls the tape from the supply reel.

The most likely causes are similar for all of these symptoms. The driven reel and/or capstan is not turning due to:

- A broken or stretched belt, an old and deteriorated, dirty, or worn idler tire. Refer to the section: General guide to tape deck cleaning and rubber parts replacement.
- Worn or broken. For example, a spring may have popped off an idler clutch or a press-fit gear or pulley may have split.
- Gummed up lubrication which is preventing the idler gear or tire that operates the takeup reel from engaging. See the section Lubrication of electronic equipment.
- A solenoid that is not engaging properly due to a weak spring, insufficient drive, lubrication problems, or broken parts.

If the cause is not immediately evident once the bottom of the transport is visible, try to observe exactly what is happening when you play a garbage tape or run the deck with no tape present. Look for broken parts or bits of parts that may have failed off.

If the transport shuts down shortly after entering any mode, check for a missing or stretched tape counter drive belt or a defective reel rotation sensor. The tape eating protection circuits are shutting down the unit improperly due to a lack of reel sensor pulses. A related symptom will be that the tape counter (mechanical or electronic) does not change during the period when the tape is moving.

If the logic is not properly controlling the various solenoids or other actuators in a 'soft touch deck', then a service manual will be needed to proceed much further.

Tape transport azimith adjustment 1 (single REC/PLAY head)

When prerecorded tapes or tapes recorded on another deck sound muddy, the azimith alignment of the suspect deck may have shifted or be misadjusted. Azimith refers to the angle that the record/playback head gap makes with respect to recorded audio tracks. This angle should be exactly 90 degrees. If it is not, than high frequencies will tend to be reduced in amplitude during playback of a tape not recorded on this machine. Similarly, a tape recorded on a transport with an improper azimith setting will sound muddy on a properly adjusted deck.

A simple test to determine if azimith alignment is your problem is to record some music on your machine and immediately play it back. If this recording sounds fine but it sounds muddy on another deck, then improper azimith alignment is the likely cause.

If the recording is still muddy, your deck may have electronic problems like excessive bias (check to make sure you have selected the proper type of tape or bias setting), a worn record/playback head, or the heads or other parts may be magnetized (see the section: Tape head demagnetizing. However, dirty heads as well other mechanical problems can also result in weak muddy sound. See the section: General guide to tape deck cleaning and rubber parts replacement.

The best way to adjust azimith is while playing a recording that was made on a known good deck - commercial tapes are usually (but not always) a good choice.

WARNING: once you adjust the azimith, any tapes previously recorded on this transport may sound muddy. If you only record and play your own tapes on this deck, you may want to just leave it alone.

The azimith adjustment is usually a screw that pivots the record/playback head. It may be spring loaded and possibly fixed in place with a some Loctite or varnish. Often it will be accessible through a hole without removing any covers but not always. Look for it while in play or record mode in back of any holes (which you had no idea had a purpose until now). If there are no access holes, you will have to remove the loading door, cover, or front panel. Be sure you have the correct screw before turning wildly - others may affect critical height or simply be mounting screws.

Play a tape with lots of good highs - classical instrumental music or jazz are excellent. Now, simply set the azimith adjustment for best sounding and strongest high frequencies which should result in most natural sound. Go slow - a 1/16 of a turn is significant. Turn the screw back and forth and leave it in the best sounding position. Carefully put a dab of Loctite or nail polish on the screw to prevent it from moving.

Tape transport azimith adjustment 2 (separate REC/PLAY heads)

This applies to 3 head decks where there are separate record, playback, and erase heads. First, read the section: Tape transport azimith adjustment 1 (single REC/PLAY head). Once you have located the correct adjustment screws:

1. Using a known good tape (a commercial tape perhaps), adjust your Playback (PB) head azimuth for best high frequency (treble) response.

2. While recording from a source with lots of high frequency (e.g., a string quartet or composition for brass) and monitoring using the PB head, adjust the REC head azimuth for best treble response. Note: do the adjustments a bit at a time since there will be slight delay until they take effect due to the spacing of the REC and PB heads.

Walkman/Discman power or sound intermittent

Note: for actual tape speed, operation, or sound quality issues, start with the section: General guide to tape deck cleaning and rubber parts replacement.

The socket that the AC adapter or headphones plug into is often quite abused during normal operation. This can lead to broken solder connections where it joins the circuit board inside the unit. Test for this possibility by wiggling the plug without moving or flexing the cable itself. If the sound cuts in and out or the tape player starts and stops or the radio goes on and off, or the CD player resets or stops, then there is likely a bad connection here. Note: eliminate the alternate possibility that the AC adapter or headphone cable is bad by wiggling and tugging on the cable while holding the plug steady. Further verify that it is not simply a matter of dirt or grime interfering with a good connection.

The connections can be easily resoldered but you will need to open up the case using. Hopefully this will only require jeweler's screwdrivers and great care. (However, some Walkmen are constructed such that access to the interior is virtually impossible without a hand-grenade.) To repair the connections, use a low wattage iron and fine rosin core solder. Make sure you do not introduce any solder bridges. Try not to lose any of the microscrews.

Cassette or tape playback - one channel dead

This could be a bad playback head, bad connections, or a bad component in the playback electronics.

First, confirm that the problem is not in your headphones, patch cables, or the remainder of your audio system - try an alternate audio source where possible.

To determine if the playback circuitry is working, gain access to the terminals on the playback head - a metal cased little cube near the center of the tape side of the cassette. There should be four wires coming from it. While the machine is supposed to be playing, touch the end of a jeweler's screwdriver gently to each of the four terminals in turn. When you touch the good channel, you should hear a buzz from the appropriate speaker. If you touch one terminal and get a buzz from the 'dead' channel, then it is possible that the head is bad for that channel. If you can touch two different terminals and get a buzz in the bad channel for both, the it is likely that the ground connection to the input preamp has fallen off. If you do not get anything from the bad channel, then there is likely an electronic problem in that channel. Bad connections aside, the most common problem area would be the audio amplifier - bad IC or capacitor.

Distorted or erratic recording

First determine if it is a record or playback problem - play a tape recorded on another machine or a commercial prerecorded tape. Try a tape from this machine on another known working tape player.

If record is the problem and it has very distorted sound, this may be a sign of a bad bias oscillator or switching circuit or record switch. The bias is an ultrasonic signal that is impressed on the tape along with the input signal. Without it, the sound will be highly distorted. In effect, it is a linearizing signal.

Check that the record select switch is clean - it may have many contacts and may have collected a lot of crud. If behavior changes with each activation of the record switch, get some contact or tuner cleaner spray and use the extension tube to spray inside the switch (with the power off), put the switch through its paces several times and allow to dry before powering it up.

If it is a portable subject to abuse, check for bad connections as well, especially if, say, one channel comes and goes.

Beyond this, you can try to measure the signal going to the record heads while in record mode. You should be able to see a high frequency signal in addition to the input signal. If the either of these is absent, then you need to trace back to its source and at this point will probably need a schematic.

Previous recording not erased

In this case both the original and new audio appear on the tape. The most likely cause (assuming your deck doesn't have some fancy sound-with-sound or sound-on-sound modes that may be engaged) is a faulty erase head or its driving signal.

The erase head precedes the record head and probably uses the same high frequency signal as that for record bias to totally wipe the previous recording. (However, on really really cheap tape recorders, erase may just be performed by a permanent magnet.) If the new recordings are really distorted, the bias oscillator itself may not be working. The erase head is either part of the REC/PLAY head assembly or a totally separate head. Check for broken wires to this head as well. If you have an oscilloscope, monitor the signal during record. The erase head could also be defective or really dirty.

Cassette player erratic autoreverse

Some of the autoreverse decks use a rotating magnet under or part of the each reel and a reed switch or hall effect device to detect lack of motion and do the autoreverse thing.

I had one from a Toyota where the plastic drive gear which included the magnet and was part of the reel split and was getting stuck at the broken tooth causing a reverse and eventually eating the tape. It was $9 for that little plastic gear.

Others are entirely mechanical and if there is a lack of lubrication, dirt, tired belts or idlers, or broken parts they may start acting erratically.

Although there could be an electronic fault, carefully examine the mechanism for obvious or subtle problems before breaking out the 'scope.

The following methods are use for autoreverse:

1. Optical sensor detecting the clear leader on the cassette. Better tape decks use this for sensing at the end so that the reverse occurs just quickly at the end of the tape rather than waiting for the leader to go by and a second or two for the tape to stop.

2. Totally mechanical where a lever arm presses against the tape and when the tension increases with the reel stopped, it trips a mechanism to reverse.

3. Optical sensors on reel rotation.

4. Magnetic sensors on reel rotation - either hall effect devices or simple reed switches.

If the transport will run without a tape in place, see if the takeup reel is rotating properly and whether the reverse still occurs. If reel rotation is normal but it still reverses, the either you have the optical tape end sensor or there is some fault in the sensors for the reel rotation. If the takeup reel does not rotate, then as suggested above, check for bad belts or idler tire.

Belts and idler tires are readily available from places like MCM Electronics.

Autoreverse audio not correct for either or both directions

This may mean that one or both directions is weak or erratic or that both sets of tracks are playing simultaneously (one in reverse).

There are three common ways of implementing autoreverse with respect to the tape heads:

1. Locate both the record/play heads and erase head on an assembly that can rotate (flip) 180 degrees depending on the direction. Mechanical stops determine the precise position.

2. Locate both the record/play heads and erase head on an assembly that can shift transversely across the tape by one track distance depending on direction. The connections to the L and R channels must be interchanged electronically in this case for one of the directions.

3. Provide a complete set of heads for both directions. Selection is then done electronically or via a set of switch contacts controlled by the direction reversing mechanism. (This would require duplicating 6 heads for a full record/play deck so it is more likely with a simple player which would then only require a total of 4 heads.)

Problems may be mechanical or electronic. However, it is probably not what you would consider head alignment.

In either design, the mechanism could be gummed up and not being properly positioned in one or both directions. There could be broken cables or bad connections since (particularly with (1) and (2).)there could be significant cable movement.

Check, clean, and lubricate the mechanics first before considering electronic faults. However, since all of these must select channels based on direction, electronic or switching problems are quite possible.

Walkman plays both sides of tape at once

One set of tracks will be playing backwards which may make for interesting conversation! There are two possibilities:

- Where a single pair of heads is used, the head assembly is misaligned and straddling both sets of tracks. This would be the case with a non-autoreverse player or with an autoreverse player that shifts head position when it reverses direction.

  This is a mechanical problem with head alignment (height) or the shifting mechanism (autoreverse).

- For an autoreverse unit where the heads do not shift position (there are four heads gaps - one for each track but only 2 get selected for each direction), the head selection circuitry or switch is routing both sets of head signals to the amp.

  This is an electronic or switch contact problem.

General tape speed problems - slow, fast, or dead

Are the speed problems sudden or gradual? Over what period of time? Seconds, minutes? For portable devices, are you using a good set of their recommended type of batteries? If the error in speed is significant, then there is something wrong. It isn't a matter of an adjustment!

Did this problem start suddenly or was this a tape recorder you found buried under an inch thick layer of dust in an attic?

If the latter, then there could very well be multiple mechanical problems due to deteriorated rubber parts - replace then or toss it.

Fast play could be an indication of a hard deteriorated pinch roller. Or, you could have forgotten to turn off a 'fast dub' or 'quick copy' switch!

Clean and lubricate the mechanism. Check for dry or tight bearings.

Is there any pattern to the problems - like with respect to the start and end of cassettes?

Where the tape speed has suddenly become excessive, here are some possibilities:

1. Mechanical. If you had a recent tape eating episode, there may be a wad of tape wrapped around the capstan. Remove it. Alternatively, the pinch roller may not be fully engaging against the capstan and the takeup reel is simply pulling the tape through without any speed control. Clean the mechanism, check for tired belts and springs.

2. Electrical. The motor speed control is not working. This may be either a mechanical governor inside the motor or a voltage regulator or other electronic control often also inside the motor. In the latter case, you may be able to disassemble the motor and repair it. One possibility is that the series regulator has decided to turn into a short circuit. This may be external or internal to the motor.

3. Cockpit error. Some tape recorders and tape decks have various features (which you no doubt never use) that may have been inadvertently turned on or twiddled (perhaps by your 3 year old). These include high speed dub as well as selectable and/or adjustable record or playback speed.

Slight tape speed error may simply mean that an internal adjustment is needed. There may be an access hole on the motor or an external pot. (Use a plastic tool to avoid shorting out something!) However, keep in mind that any tapes you recorded on this machine (assuming it can record) recently will play at an incorrect speed once you adjust the speed.

Is it slow and steady - no more wow and flutter than normal? Or slow and erratic indicating that (1) the speed regulator is faulty, (2) some bearings may need oil, (3) the pinch roller is glazed.

If the mechanics seem ok, then check for electronic problems with the motor or regulator. Sometimes there is a trimpot for speed adjustment inside or external to the motor. A faulty regulator or even a bad connection may be the cause.

A variety of techniques are used to regulate the record/playback speed:

1. Mechanical governor inside motor - centrifugal contacts open at correct speed reducing current to motor. If speed is too low, than springs could have weakened or contacts could be bad - open. If speed is too high, contacts may be welded closed. There may be a resistor and/or capacitor across the contacts. An open resistor could conceivably cause unstable speed fluctuations. A capacitor may be present to reduce electrical noise.

2. Voltage regulator inside motor case or external to motor. The regulator or transistor may be faulty. If power for the motor seems to come directly from an unregulated supply, check across the motor terminals with an ohmmeter. A low reading which is identical in both directions would indicate a direct connection to the motor brushes with no internal regulator (or perhaps a shorted regulator). A high reading or one that is different in each direction indicates an internal electronic regulator - or you could just use your eyeballs to determine if there are any electronics inside the motor. These can be disassembled and bad parts replaced. There may be an access hole on the motor for an adjustment. (Use a plastic screwdriver for the adjustment to avoid the possibility of shorting something inside the motor!) Alternatively, you could remove the guts and install an external regulator using an LM317 or similar part.

3. Active regulator with tachometer feedback from motor winding - there would be 4 wires instead of two coming out of the motor - 2 for power and 2 for tach. Control circuitry could be bad or the tach output could be dead (speed too high).

4. If an optical strobe disk is located on the motor shaft, then it may be part of a speed control circuit. If it is on one of the reels - probably the takeup reel - then it simply operates the (electronic) tape counter or signals the controller that the takeup reel is turning - to catch tape spills.

Tape speed problems on older equipment

Older reel-to-reel decks (maybe even some cassette decks) likely use an AC induction or synchronous motor driven from the power line. Speed selection is usually done by switching in different sets of motor windings and the use of slip-on capstan/pinch roller sleeves.

Speed problems are most likely a result of

- Decayed rubber parts - belts, idler tires, pinch roller.
- Gummed up lubrication or worn bearings.
- Dried up or otherwise faulty capacitors in the motor circuitry.
- Faulty switches or wiring in associated with speed selection.
- An actual bad motor is possible but not that common.

See the appropriate sections in the chapters: "Turntables" and "Motors and Relays" for specific information on these types of problems.

Tape speed adjustment made easy

OK, you have found the magic screw, but how to set the speed accurately? Sometimes, there will be strobe disks on tape decks which will appear stationary under fluorescent lighting (magnetic ballasts only - electronic ballasts are usually high frequency and do not modulate the light intensity at the power line frequency) but not usually. So, you do it by ear:

Make a recording of a single tone on a tape recorder you trust - one with accurate speed.

Suitable sources include: a signal generator, electronic instrument, Touch-Tone phone tone, PC sound card output or PC speaker, etc. A frequency around 400-1000 Hz should work well.

Then, adjust the speed while listening to this same source simultaneously with the tape being played back on the unit to be adjusted. As you adjust the speed, you will hear the pitch change. As it approaches the correct setting, you will hear the tones beat against each other. When you are set correctly, the pitches will be equal and the beat frequency will go to zero. Even if you are tone deaf, you will easily be able to adjust pitch accuracy to better than 1/10 of a semitone using this method.

Recording the 60 or 50 Hz power line (through a suitable isolated attenuator) and using this as a test tone will work if you have an oscilloscope. Trigger on 'line' and adjust playback speed to stop the trace from drifting. However, this is too low a frequency to be used accurately with your Mark I ears!

Some alternatives:

(From: Helling Bernie (helling@uwindsor.ca).)

A while ago I hit upon a way to set the speed on old cassette decks that have gone out of speed.

Use an electronic guitar tuner

They cost about $40, can be borrowed, etc... Find a pro cassette deck that is in speed, (the local campus radio station had a nice one) and record a tape full of A tone. My guitar tuner puts out tones too, so that was easy....

Play the tape in the suspect deck, while adjusting the motor trim to replay a A tone perfectly on the tuner meter...

Tadah....

I never did have the patience to learn to play the guitar, so I got some use off the tuning meter....

(From: Paul Temple" (mri@earthlink.net).)

Get a song on CD and a tape of the same album. Play both at the same time and adjust away!

Sudden increase in flutter on tape decks or Walkmen

If your prized Walkman suddenly develops a severe case of warbling sound check:

1. Batteries (where appropriate). Almost dead batteries will greatly increase flutter. Use of Nickel-Cadmium rechargeable batteries in place of alkalines may result in problems due to their lower voltage (1.2 V vs, 1.5 V per cell).

2. Tired belts - loose flabby deteriorated belts will produce varying, probably slow, speed as well.

3. Dirt or goo on pulleys. Sometimes a glob of stuff gets stuck to a pulley and produces a periodic variation in speed. I picked one up at a garage sale that had this problem. I thought it was a bad motor until a careful examination revealed that the belt was jumping a mm or so on each rotation of an idler pulley.

4. Lack of lubrication - a dry or worn bearing may result in a variety of speed problems.

5. Bad speed regulator - either mechanical or electronic including bad solder connections or cracks in circuit board traces.

6. Bad power supply.

7. Bad tape. Don't overlook this obvious possibility, try another one.

Annoying tick every 30 seconds or so from audio output

This may be an almost inaudible tick, click, or pop which occurs fairly regularly. Its frequency may be dependent on many factors including temperature, humidity, even whether you are at the start or end of a cassette! I may occur even if no cassette is present but the motors are running.

The tick is probably due to a static discharge though other causes are possible including mechanical problems and bad capacitors in the power supply.

(From: Paul Grohe (grohe@galaxy.nsc.com).)

The problem is with a plastic or nylon gear, in contact with a rubber belt or tire, generating a charge and discharging to some nearby metal. (It acts just like a miniature Van De Graff generator --- sam.)

You have to listen around for it. Murphy sez it will probably be buried deep in the "guts" of the machine ;^)

I found it by touching a small wire to each of the pulleys until it stopped "snapping" (actually, I got a little "snap" when I found it).

My "cure" was to use some stranded wire to create a "brush" that lightly brushed against the pulley to bleed off the charge to the chassis.

I would first check the two big capstan flywheels and anything powered by the main motor belt. Look for any plastic, or metal with plastic bushings and parts in contact with belts or tires.

(From: Ylo Mets (ylo@mango.mef.ki.se).)

I have experienced similar ticking in an old two-motor deck. There was some dust collected between the takeup/wind motor shaft end and the metal chassis, which evidently generated static electricity. Cleaning the dust did the trick, although at first I thought the shaft was too close to the metal chassis. You can check for the static by breathing slowly into the mechanism. The damp air should discharge the static and the frequency of ticks decreases. Such ticking is especially annoying because it is not exactly regular.

Reel-to-reel tape deck problems

> "I have a Teac 2300S reel to reel. 7" reel capacity, 1/4" tape. Two problems. First, right channel doesn't play back. Second, pinch roller doesn't come up to the capstan unless it's gently pushed."

(From: Davetech (dnesbitt@mindspring.com).)

I've repaired a few reel-to-reels in the past and generally find that they all need three main things done:

- They need all the rubber parts - belts, tires, rollers - replaced. Also the brake pads.
- They need all the controls and switches cleaned with a de-oxy type cleaner. (This may be the cause of your right channel problem).
- They need all the mechanical pivot points cleaned and re-lubed. (This may be the problem with your pinch roller).

The last one I did, the old grease had hardened up so much that the heads would not come up to contact the tape - and the grease was so hardened that I could not get the linkage pulled off even using pliers and pulling as hard as I could. I had to heat the post with a propane torch before the old grease would soften enough that I could separate the parts.

I put enough time in the last unit that I could have fixed 3 or 4 VCR's, so I'm not real big on taking them in. They are generally very time consuming to disassemble and reassemble and overhaul. But not usually technically difficult to fix.

Tape creeps off capstan

> "I have a Sony reel-to-reel tape recorder. When I play a tape, after a few seconds or minutes of playback, I can watch the tape creeping up the capstan between the rubber roller until it comes out the top and off the capstan."

The first thing to check - as with a VCR with similar symptoms - is the condition of the rubber parts, in particular, the pinch roller. Next, would be tape path alignment and wear:

(From: Jack Schidt (dbutler@airmail.net).)

Check the reel height as well. Capstans are upset if the reel tables have shifted. Use a straight edge between the two reel tables. There are set screws that sometimes get loose on some of these machines.

Check for a worn capstan bushing. Disconnect the drive belt (if any) and see it there is lateral play in the capstan. If so, perhaps you can shim it (either the motor [if equipped] or the idler).

Also make sure the tension is simply not too high. You should be unable to pull the tape through, but ridiculous force (as in something is BENT) will cause this problem as well.

8-track player problems

These compete with turntables for classification in the Jurassic era. 8-track equipment uses a cartridge with a single reel and enless loop tape (tape is pulled from the center and returned to the outside). The tape can only move in the forward direction - rewind is not possible.

There were also similar competing but incompatible 4-track systems as well as quadraphonic 8-track (when quad was all the rage).

Four pairs of channels allow for many hours of stereo playback without changing cartridges. A pair of playback heads is mechanically shifted among the 4 possible sets of tracks when a metallic strip on the tape passes over a set of contacts which operate a solenoid.

Most common problems are - you guessed it - mechanical with the cartridge or in the drive or head shifting mechanism. General comments with respect to cassette decks apply here as well.

If you are really interested in resurrecting that 8-track player found under the steamer trunk in your aunt's attic, there are many links to information on 8-track equipment, books, history, dealers, collecting, and everything else 8-track related that most people probably don't care much about anymore at the following web site:

- 8 Track Heaven

There may be links for specific 8-track player repair information but I could not locate them at this site.

However, this one seems to be the place to go for step-by-step 8-track cartridge repair:

- Jeremy Larsen's Web Page

Repairing a cassette tape

(From: Filip "I'll buy a vowel" Gieszczykiewicz (filipg@repairfaq.org).)

This will be either easy or very hard. Question: do both of these have SCREWS holding the tape together? If yes, EASY, if not, very HARD!

See what I'm getting at? Go to the store and get a quality tape that ALSO has screws holding it together... you will transplant the insides into the new cases. Take off the screws from both (old and new tape, do it one tape at a time). Remove both top covers - make sure you don't lose the thin plastic "lubricant" sheet (if any). Swap the tape reels - BE VERY SURE the old one doesn't go flying off or it's more or less toast. Put the old tape reels into the new case, make sure the tape follows the same path as the one you took out did - so it doesn't get trapped by the case when you replace the top. Put the "lubricant" sheet back on top of the two reels of old tape and replace the top. Put in all 5 screws. There you go. I'd say that this is 100% successful every time I've tried it.

If your tapes don't use screws but are, rather, glued together, you're on your own. I suggest a VERY sharp utility knife but tape damage is, alas, a very REAL possibility.

Another way you can do this if you want to also replace the REELs (or if it's a sealed unit) is to rewind the old tape, cut the tape LEADER and attach it to the new cassette that you have already gutted. Put the new tape together (2 screws will do) and attach a small motor to the takeup reel. When the tape has been transfereed to the new reel, cut it off the old one (the old cassette is now empty) and open the new one again, attach the tape to the reel and put it back together using all screws. Other than the leader being 2" shorter, you have the old SOUL in a new BODY.

Of course, watch out that you wind the tape EXACTLY as it was and not on the other side... etc. etc. I have done this twice. Grrrr.

It's a pain in the rear... so do it only if you have to... I wouldn't do this for money..... if that tells you anything.

Turntables

Turntable (record changer) maintenance

Here are general comments on oiling dinosaurs, oops sorry, turntables.

Usually there is a 'C-clip' or 'E-clip' which holds the platter (the thing that rotates) onto the spindle. It may be covered with a decorative piece which can be easily removed. The clip can be pryed off (gently) with a small screwdriver (just don't lose it, though even this is not a biggie so long as you never turn the thing up-side-down).

The platter can then be lifted straight up and off the spindle. You will see several things (this will vary depending on your particular unit):

1. A flat washer, sitting on a ball bearing race sitting on another flat washer (one or both of these washers may be missing. Also, the top one may stick to the platter when it is removed.) The ball bearings, shaft, washers, etc. should all be cleaned with degreaser and then lubed with a light grease. If either the steel balls or the flat washers are corroded, replacement will be necessary or else there will be terrible audible rumble. For now, it will at least work well enough to determine what else, if anything, needs attention. Also clean and lubricate the platter bushing (center hole) and shaft (vertical post on which it rotates).

2. Changer gears etc. These will have varying amounts of grease on them if it is not gummed up, leave them alone. Put a drop or two of light oil on the shafts. Inspect other linkages as well. If the grease is gummed up on the gears or sliding linkages, you will need to clean it off thoroughly with degreaser and

then use a small amount of high quality grease suitable for delicate mechanisms. One cause of a changer failing to activate at the end of a record is gummed up grease.

3. Motor. Check to see if the motor shaft turns freely and smoothly even if spun quickly between your fingers. If it does - without squealing, don't do anything else. If it is tight or makes noise, then you will need to carefully disassemble the motor and clean and lubricate the bearings at each end with light oil. Don't lose any of the various washers/spacers that may be present on the shaft as it is removed from the end pieces and make sure to lubricate and return them to exactly the location and the same order they were in originally.

4. Clean the rubber parts with isopropyl alcohol and Q-tips or a lint free cloth until no more black stuff comes off and then dry thoroughly. Now, inspect the belts (if any). If belts are flabby or cracked or if they don't instantly return to their relaxed length if stretched 25% and released, they will need replacing. Check the idler tire (if present). If hard or cracked, it will need replacing as well.

Note: Light oil here means electric motor oil or even 3-In-One but NOT WD40. Light grease means something that is suitable for fine mechanisms and is safe for plastics. Automotive bearing grease may not qualify.

Where the drive belt is found to be bad, an exact replacement is best. Though something close will work, there may be a very slight change in speed which may or may not bother you (probably not if you either don't have perfect pitch or aren't playing an instrument along with the records). For turntables with servo lock circuitry or a drive motor with a speed adjustment, correction may be possible.

Speed control in turntables

Most inexpensive turntables/changers will use a synchronous motor or even just an induction motor. The only maintenance for the motor is cleaning and lubrication. A deteriorated drive belt can result in reduced, probably erratic speed or inability to start altogether.

Servo controlled turntables utilize a feedback technique which locks the platter speed to a stable reference - either the power line (50/60 Hz) or more commonly a crystal oscillator. Here is one example:

A Sony turntable I repaired used a magnetic stripe pattern on the inside of the platter which was sensed by a magnetic pickup. The resulting signal was phase locked to a stable reference and used to control a brushless DC direct drive motor. Speed would become erratic if (1) the magnetic pattern were damaged, (2) the pickup position was moved too far from the surface of the platter, (3) the Hall-effect sensors in the motor were bad, or (4) the control electronics went bad. In one case, it turned out that one of the Hall effect sensors had failed in the motor. This required disassembling the motor and replacing the sensor - $4 from Sony.

To determine whether the turntable is running at the proper speed or for adjusting it, many turntables came with a "strobe disk" built in that used the 60 Hz (or 50 Hz) power line frequency as a reference driving a neon indicator lamp. When the appropriate set of lines on the disc appear stationary under the neon illumination, the speed is correct. In the good old days, such a disc could be purchased at any record store. :) In the modern age, go to Nauck's Vintage Turntable Stroboscope Disc Page and download a program to print your own. Or, if you have a graphics program that will generate equally spaced radial lines, the relevant numbers are (for 60 Hz power): 432 (16-2/3 rpm), 216 (33-1/3 rpm), 160 (45 rpm), 92 (78.26 rpm).

Turntable runs slow or fast after being moved

This is likely to be a mechanical problem - a belt that has worked loose and is riding on the rim of the motor pulley or the wrong surface of the platter.

For an AC line driven motor (no electronics between the AC line and motor except possible for a power transformer), it is virtually impossible for any fault to result in a motor running faster than normal. A motor may run slow due to dirt, lubrication, or bearing problems.

Of course, check to see that any speed selector has not been accidentally moved to the '16' or '78' position!

For a servo-locked turntable, a misalignment of the sensor used for speed feedback could result in an incorrect - probably higher than normal (and uncontrolled) speed.

Servo locked turntables

The basic direct drive turntable consists of a DC brushless motor, some type of platter speed/position feedback, and an electronic control loop - a phase locked loop to regulate speed. Otherwise similar units may use a rubber belt to couple the motor to the platter.

A variety of faults can occur with these units resulting in incorrect or erratic speed, excessive wow and flutter, or no rotation at all:

- Mechanical problems like gummed up lubrication, deteriorated belt, or bad bearings. Note that any of these will not likely result in a constant slow speed but rather erratic or uneven operation (since the servo will be fighting with the mechanical resistance or slip).

- Inoperative or weak feedback sensor. This may be a magnetic pickup in close proximity to a magnetic pattern laid down on the inside of the perimeter of the platter. Check to make sure the pickup is positioned properly, as close as possible but making sure there is no chance of contact (which could scrape off the magnetic coating and pattern - impossible to restore).

- Defective power supply, especially for dried out filter capacitors in older units. Check voltages with a DMM. If you have a scope, check for excessive ripple. On a turntable more than, say, 10 years old, defective capacitors are quite likely.

- Bad connections and dirty speed select or other switches and/or pots. Inspect and resolder as needed and use contact cleaner if necessary on switches and pots. Just cycling the switches and rotating the pot(s) back and forth a few times may clean them up well enough for another thousand LPs. :) (However, mark their original position exactly unless you are able to do a complete calibration!)

- Defective components in the motor (Hall effect sensors), its driving circuits, or the controller. This will require a bit of low level troubleshooting but should be possible given the relative simplicity of the circuitry.

Wow, flutter, and rumble in a turntable

Wow and flutter refer to undesirable periodic variations in pitch caused by changes in turntable (or tape deck) speed. Wow would be a slow variation (e.g., once per rotation) while flutter would be rapid (e.g., a motor pulley with a bump). Even if very slight, these faults will be all too obvious with music but may go undetected at much higher levels for voice recordings.

Rumble is a very low frequency noise added to the audio caused by vibration due to cheap, worn, dirty, or dry spindle bearings or by vibrations coupled in from some other motor driven component or even from loudspeakers if the volume is turned way up. If really bad, rumble may sound like a freight train in the next room. Also see the section: Comments on turntable rumble.

Note that rumble should not be confused with hum - 50 or 60 Hz pickup from the power line. Hum can be virtually eliminated by the use of decent shielded cables (not that expensive, just decent), and making sure that the turntable frame is jumpered to the ground terminal of the amp or receiver. Hum can also result from mechanical causes - the vibration of an inexpensive motor or improperly mounted power transformer in the turntable (or almost anywhere else in the HiFi system). It may not be possible to eliminate some of these sources of hum except by redesign or other major modifications to the equipment.

For anyone only used to listening to CDs, even very small amounts of and of these will prove very obvious and extremely objectionable. Wow, flutter, and rumble are undetectable - for all intents and purposes nonexistent - with even the cheapest junkiest CD player.

For a common motor driven turntable, the following are likely causes:

1. Bad belt or idler. Rubber 'rusts'. If it is old, then almost certainly the rubber parts have deteriorated and will need replacement. Unfortunately, replacement parts are not as readily available as they once were. The places listed at the end of this document may have some and there are many other sources but it is not as easy as one would like.

2. Dirty or worn spindle bearing. This will cause rumble. The thrust ball bearing can be cleaned and lubricated or replaced. The platter bushing can be cleaned and lubricated.

3. Lump of crud stuck to motor pulley or idler, usually of unknown origin.

4. Dried up lubrication in motor, idler, or other rotating part. These can be cleaned and lubricated.

5. Bad motor (not that likely) except for lubrication in which case the motor can be disassembled, cleaned, and lubed.

6. Physical damage to platter - something heavy was dropped on it upsetting the delicate balance.

If you are attempting to restore a 20 year old turntable from Aunt Annie's attic, don't even bother to power it up before replacing all the rubber parts and cleaning and lubricating the motor, idler, and spindle bearing.

Comments on turntable rumble

Rumble is a low frequency, almost sub-sonic sound that is inevitable with most turntables. A turntable that doesn't rumble is possible but expect to pay about as much as for a small car. Buzz words like 'magnetic suspension and 'dynamically stabilized' drive will probably accompany the stratospheric price tag. :)

(From: JURB6005 (jurb6005@aol.comtere).)

A turntable that doesn't rumble may be purchased for a few thousand bucks, but for the rest of us.....

You failed to mention the type of drive, belt rim (idler) and I doubt it's direct. A rim drive, while it's off should be silent when you whip that platter up to about 200 rpm with your hand. A light platter should keep spinning for at least 2 minutes. The old 12 pound platter should spin for about 5 to 8 minutes. When you first spin it up, listen, in a quiet room to the turntable. You should hear NOTHING. If you hear anything, check those platter bearings and/ or any automatic linkage it may have.

Note: If it's a belt drive REMOVE THE BELT FIRST!! If it's a rim drive make sure the motor spindle is unscrupulously clean and the idler isn't hardened or out of round. If the rumble only occurs when you turn it loud (like feedback) you need to isolate the turntable from the speakers. This type of feedback rumble can sometimes be reduced by reversing the phase of ALL the speakers. i.e. they are still in phase with each other, but now reversed with respect to the input.

(From: Philip Nasadowski (nasadowsk@mail.hartford.edu).)

Also realize - these things aren't silent!!! Try seeing if your amp has a rumble filter (that's what it's there for!) Make sure the motor is clean, the drive wheel is good, etc. Oh yeah, and experiment with various greases on the bearings too. And make sure the order of the washer / bearing washer/ is right.

I have had the pleasure of enjoying several excellent turntables, the ones that you can put right on top of the speakers and track almost as well as a Zero One Hundred. They've included a Dual 1229, a couple of Elac Miracords and even a transcription grade BSR 810. My favorite was the 1229. And yes, with an Audio Technica AT13 ea (10-30,000Hz) >cartridge, they can sound better than a CD. Good luck.

Ever try a Grado cartridge? They're nice...

(From: Jerry Greenberg (jerryg50@hotmail.com).)

If I can remember correctly, is this the old direct drive turntable with a rubber wheel between the motor shaft and the platter?

If it is, putting on a new fresh rubber drive wheel will help it out a bit. But, because of the design of this table, there will always be some mechanical hum pickup. It starts at the motor...

Erratic sound from turntable

Sound that varies randomly in intensity or where one channel drops out will usually be due to bad connections in the various units. This could be:

1. At the pickup itself. There may be small press fit connectors at the cartridge. These sometimes become

loose. Gently remove each one (one at a time! so that you do not mix up the wiring) and squeeze with a pair of tweezers or needlenose pliers. Snap in cartridges may have dirty contacts the springiness may have disappeared.

2. At the RCA plugs under the turntable which connect to the tonearm. Depending on your design and problem, you may need to simply clean with contact cleaner or squeeze the metal shell or center contact.

3. At the receiver, preamp, or amplifier. Same as (2) above.

4. Sometimes the cables themselves will develop broken wires at one end or the other. Easiest is to try a different set of cables.

Turntable tracking and skating force adjustment

Tracking force keeps the stylus in the record's groove. Too little is as bad as too much. It is best to follow the recommendations of the cartridge/stylus manufacturer. If you do not have this information, start low and increase until you eliminate skipping or excessive distortion, buzzing, or stuttering. If too low, the stylus will make only partial contact with the groove during high amplitude segments - it will jump from peak to peak (or other portion) of the wave rather than smoothly and continuously following it. If too high, it will gouge the vinyl (or the shellac or whatever depending on the vintage of your records) or in extreme cases, bottom out on the cartridge's suspension.

Skating force compensation is applied to compensate for the fact that except at one distance from the spindle (or with a linear drive tone arm where this does not apply), the tone arm is not tangential to the groove. Imagine a perfectly flat record without any grooves. If you 'play' this, the tone arm will be stable at only one position somewhere in the middle - where a line drawn through its pivot point and the stylus is just tangential to a circle at that distance from the spindle. The skating is usually a simple spring which attempts to compensate for this in such a way that the side force tending to move the stylus is minimized at all positions. Otherwise, the inner and outer walls of the groove will experience a different force which will add distortion and affect stereo separate and balance.

Skating force compensation is usually set based on the tracking force.

Note that if you are used to CDs or high quality cassettes, all the horrors of records will be all to obvious unless you are using high-end equipment (the kind that likely costs as much as your automobile) and meticulously maintain your vinyl record collection. Sonic defects like wow, flutter, rumble, distortion, noise, imperfect stereo separation, skipping, and limited frequency response are all facts of life for this technology which has not changed in any fundamental way since Edison's time.

Turntable tracking/skating problems

(From: Bill Turner (wrt@eskimo.com).)

You're bringing back memories. I used to work for the leading Magnavox warranty repair station in Los Angeles and I've repaired hundreds of the good 'ol Micromatics.

Assuming there isn't something actually *pulling* the arm across the record (in other words it's just sort of sliding across on it's own) the problem is almost always the needle. Either the tip is worn out, broken, missing, etc or it could have just been dislodged from it's holder. Lift up the arm and look carefully at the needle. The actual diamond tip is on the end of a short shaft which in turn rests in a fork-shaped rubber holder. This shaft is easily knocked out of the holder, and if that's the case, just carefully put it back.

Hope this helps. The Micromatic was a fine record player in it's time. Good luck, and let me know if I can help some other way.

About stylus wear

So you still have one of those modified potters' wheels on which you place a pre-formed piece of plastic that looks like a flattened dinner plate with a hole in the middle and drag a needle over its surface to produce sound. How can you tell when the needle, err, stylus, has worn to the point (no pun...) of requiring replacement?

It used to be that you could take it to any record store. They would look at the stylus under a microscope, and after a few choice utterances of "Oh my!" followed by "This will strip the music right off your LPs", and would then tell you that your stylus required replacement IMMEDIATELY whether it did or not :-). Of course, record stores don't exist anymore.

If you have a semi-decent microscope, you can do the same and get an honest answer ;-). 100X should be more than sufficient, though getting the stylus into position to view it may prove to be challenge.

The tip of a good stylus looks smooth and is spherical or ellipsoidal in shape. A worn stylus will exhibit edges/corners due to the wear of the tip. Yes, even diamond will wear down if you drag it over thousands of miles of vinyl. Some of your LP record jackets may even have typical photos of good and worn styli so check these out as well.

If the stylus is visibly worn:

1. The physical result will be that it will grind away at the grooves in your records.

2. The audible result of a bad needle will be excessive distortion and loss of high frequencies from (1).

After you replace it, your old records will still never sound as good as they did before because of (1) :-(.

Changer won't cycle automatically

If it is a basic old fully mechanical record changer, this is usually due to gummed up grease. There is a large gear which gets activated to operate the lift-and-place mechanism. Attached to this gear is a small swinging segment that gets jogged by the tone arm reaching the proper position. The grease gets gummy and prevents this. You have to remove the platter.

If it is a fancier changer with fully electronic controls, then it may be a sensor or something in the circuitry.

Of course, there was this one I recently worked on where some previous repair person (I am using this term generously) had glued the moving parts of the changer mechanism together so it could not possibly ever have worked again (until I unglued them all).

Loudspeakers

Loudspeaker anatomy

In this document, we use the terms 'loudspeaker' or 'speaker system' to denote a unit consisting of one or more drivers in an acoustic enclosure perhaps along with a frequency selective crossover, tone controls and switches, fuses or circuit breakers. Connections to the amplifier or receiver are via terminals on the rear. The front is covered with an (optically) opaque or semitransparent grille which provides protection and improves the appearance (depending on your point of view).

A 'driver' is the actual unit that converts electrical energy into sound energy. Most drivers use voice coil technology: a very low mass coil wound on a light rigid tube is suspended within a powerful magnetic field and attached to a paper, plastic, or composite cone. The audio signal causes the coil to move back and forth and this motion causes the cone to move which causes the air to move which we perceive as sound.

The typical driver consists of several parts:

- Frame - a rigid steel or composite structure on which the driver is constructed. The frame holds the magnet and core, cone suspension, and connection terminals.

- Magnet - this includes a powerful (usually ceramic, AlNiCo, or rare earth) magnet including a core structure provide a very narrow cylindrical air gap. This accounts for most of the mass of a driver.

- Voice coil - a one or two layer coil of fine wire wound on a light rigid cardboard, plastic, or composite tube suspended within the air gap of the magnet and connected via flexible wires to the electrical terminals.

- Cone - a roughly cone shaped very light and rigid structure that does the actual work of moving air molecules. The cone in a woofer may be 12 or more inches across. The cone in a tweeter may only be an inch in diameter. This is the part of the driver you actually see from the front of the speaker system with the grille removed. The center is usually protected with a small plastic dome.

- Suspension - a corrugated flexible mounting for the voice coil called a 'spider' and outer ring of very soft plastic or foam. Together, these allow the voice coil/cone combination to move readily in and out as a unit without tilting or or rubbing. For most designs, there is a certain amount of springiness to this suspension. Acoustic suspension loudspeaker, however, use the trapped air in a totally sealed speaker enclosure to provide the restoring force.

Inexpensive 'LoFi' devices like portable and clock radios, many TVs, intercoms, and so forth use a single, cheap driver. Some have a coaxial pair of cones but this does little to improve the frequency response.

HiFi speakers systems will divide the audio frequency spectrum into several bands and use drivers optimized for each. The reason is that it is not possible to design a single driver that has a uniform response for the entire audio frequency spectrum. A 'woofer' is large and massive and handles the low base notes. A 'tweeter' has a very low mass structure and is used for the high frequencies. A 'mid-range' handles the mid frequencies. There may also be 'sub-woofers' for the very very low notes that we feel more than hear. Some systems may include 'super-tweeters' for the very highest frequencies (which few people can hear. This may make for some impressive specifications but perhaps little else.)

A 'crossover' network - a set of inductors and capacitors - implements a set of filters to direct the electrical signal (mostly) to the proper drivers.

Various controls or switches may be provided to allow for the adjustment of low, mid, and high frequency response to match the room acoustics more faithfully or to taste. Fuses or circuit breakers may be included to protect the speaker system from intentional (high volume levels) or accidental (amplifier output stage blows) abuse.

Loudspeaker problems

If you have a high quality and expensive set of loudspeaker, then the cost of professional repair may be justified. However, if the problem is with speaker systems you might not write home about, then read on.

Playing your music system at very high volume levels, especially CDs which may have peaks that way exceed the ratings of your loudspeakers is asking for trouble - but you knew that! CDs can be deceiving because the noise floor is so low that you are tempted to turn up the volume. A peak comes along and your speaker cones are clear across the county (remember the movie 'Back to the Future'?). Loudspeaker systems are generally pretty robust but continuous abuse can take its toll.

Problems with loudspeakers:

1. An entire speaker system is dead.

   Verify that the connections both at the speaker system and at the source are secure. Check circuit breakers or fuses in the speaker system. Reset or replace as needed.

   Make sure it is not the amplifier or other source that is defective by swapping channels if that is possible. Alternatively, test for output using a speaker from another system or even a set of headphones (but keep the volume turned way down). Assuming that these tests confirm that the speaker system is indeed not responding, you will need to get inside.

   It would take quite a blast of power to kill an entire speaker system. Therefore, it is likely that there is a simple bad connection inside, perhaps right at the terminal block. You should be able to easily trace the circuitry - this is not a missile guidance system after all - to locate the bad connection. If nothing is found, then proceed to test the individual drivers as outlined below.

2. One or more drivers (the name for the individual speakers in a loudspeaker enclosure) is dead - no sound

at all even when you place you ear right up to it. The cause may be a bad driver, a bad component or bad connection in the crossover network. Test these components as outlined below.

3. One or more drivers produces distorted or weak sound. Distorted may mean fuzzy, buzzing, or scratchy a various volume levels. Most likely this is due to a bad driver but it could also be a defective component in the crossover - a capacitor for example or even a marginal connection.

Getting inside a speaker system usually means removing the decorative grille if it snaps off or unscrewing the backpanel and/or terminal block. Use your judgement. With the grille removed, you will be able to unscrew the individual drivers one at a time. With the back off, you will have access to all the internal components. If sealing putty is used, don't lose it or expect to obtain some replacement putty (non-hardening window caulking like Mortite is suitable).

Test the components in the crossover network with a multimeter. These are simple parts like capacitors, inductors, and potentiometers or reostats. Confirm that any circuit breakers or fuse holders have continuity.

Test the drivers on the low ohms scale of your multimeter. Disconnect one wire so that the crossover components will not influence the reading. Woofers and midrange drivers should measure a few ohms. If their impedance is marked, the reading you get will probably be somewhat lower but not 0. If possible compare your readings with the same driver in the good speaker system (if this is a stereo setup). Some tweeters (very small high frequency drivers) may have a series capacitor built in which will result in an infinite ohms measurement. Other than these, a high reading indicates an open voice coil which means a bad driver. In a comparison with an identical unit, a very low reading would mean a partially or totally shorted voice coil, again meaning a bad driver. Except for expensive systems with removable voice coil assemblies, either of these usually mean that a replacement will be required for the entire driver. Sometimes an open voice coil can be repaired if the break can be found.

To confirm these tests, use an audio source to power just the suspect driver. Your stereo system, a small amplifier attached to an audio source, or even a pocket radio (use its speaker output if the headphone output does not have enough power) will suffice. The resulting sound will not be of high quality because you do not have the enclosure sealed and it is only one of the drivers in the system, but it should give you some idea of its condition. Again, comparing with an identical unit would be another confirmation.

Electrical causes for loudspeaker damage

These are not going to be covered by any warranty! Of course, not mentioned below are: fire, flood, falling from a tenth story window, getting run over by a bulldozer, or being plugged into the wall outlet instead of the stereo, etc. :-).

(Portions from: Lasse Langwadt Christensen (fuz@control.auc.dk).)

1. DC bias across speaker will cause the voice coil to overheat. Windings may short out or open up. Also see (3), below. This usually results from an amplifier output stage failure - shorted capacitor, for example.

2. High power clipped signal:

- A clipped signal contains a lot of high frequency energy and that could burn a tweeter, because the voice coil overheats.

- The clipped signal could have a amplitude so large that the voice coil hits the magnet and is bent. It's a permanent damage but not always terminal, because the might still work, but make a scraping noise. If you play loud with it for a long time (and it doesn't burn out - see (3), the part scraping against the magnet might wear off.

3. If the speaker is overheated, because of high power for a long period of time, the voice coil could expand and scrape against the magnet, and perhaps short some of the turns. This is not always permanent, and some manufacturers use Teflon on the magnet, so that it's less likely to cause damage.

Repairing loudspeaker drivers

As noted above, if you are dealing with a high quality system, leave these repairs to professionals or obtain an entire replacement as some reduction in audio quality may result from the abuse you are about to inflict on the poor defenseless driver.

We will address two types of repairs: physical damage to a speaker driver cone and an open voice coil (actually, wiring outside the voice coil). However, serious damage to the cone or just plain deterioration of the suspension components may require replacement of the entire driver unless a close enough match can be found.

For more information on loudspeaker repair, see: "Speakers (big, small, in between)" also at this site.

(From: Roy J. Tellason (rtellason@pa.net).)

I've worked with a lot of both Musical Instrument stuff (guitar amps and such) and also pro sound gear (a whole 'nother world, really) and this stuff gets used pretty hard. It's not uncommon to find a driver failure, either from the high levels at which this stuff is commonly used, or the abuse it takes getting hauled around on the road, etc.

I noted with interest the comments in one section regarding the voice coil rubbing. In the type of thing I'm talking about above, any such rubbing means a bad driver, no ifs ands or buts about it. The test for it is easy -- just push on the cone, from the front side. In some enclosures you may have to remove the driver for this. If there's a problem, you'll hear a rubbing sound, and the driver is a candidate for replacement or re-coning. It should move freely, in both directions, with no rubbing at all. But you need to press evenly with both hands on either side of the middle!

I also ran across one that had me going for a bit. I'd play audio through it (my stereo supplied the test signal, but through a little box with a pot in it to avoid overdriving the amp), and it sounded okay to me, but the musician who owned it (a piano and organ player) wasn't happy with the way it sounded for him. Piano is some of the most demanding music, with the high transients...

Anyway, he told me that the unit had been "funny" for him ever since one occasion when the amp had fallen on its face.

I pulled the speaker out, and was I surprised when I tried the "push test" - that cone didn't seem to want to move _at all_. It apparently moved enough to play the audio I was feeding through it, but not near enough for his use.

Not the first time me being a tech but not a musician has given me a bit of trouble...

One other comment that I can offer is that both MI and Pro Audio folks do a *lot* of re-coning, the prices on a lot of their hardware make it more practical than in most home equipment. These guys can also supply replacement drivers in some pretty hefty configurations, both size-wise and in terms of power-handling capability. I wouldn't recommend putting an MI-type (guitar amp, say) speaker into a pro audio application, though I don't see why the other way around wouldn't work, even if it would be a bit more expensive.

Repairing speaker driver cones

Minor damage to the cone can be repaired using a flexible adhesive like weatherstrip cement and a piece of thick paper to reinforce the seam or hole if necessary. Since this will not totally perfect match with the original paper cone, there could be audible distortion at certain frequencies particularly at higher volume levels. However, such a repair will be better than nothing. Cut the paper in a shape and size to just overlap both sides of the torn area or completely cover the puncture. Use just the smallest amount of adhesive to fasten your 'splint' to the cone. The less material you add, the more likely that the audio effects will be minimal.

Note: Almost any general purpose adhesive can be used. However, it is advised to avoid RTV silicone (bathtub caulk, etc.) since wherever this stuff goes, nothing else will every stick again. For a little hole, this probably doesn't matter but you definitely don't want to replace the surround with it!

(From: M. Przytarski (m.r.p.@ix.netcom.com).)

I have repaired many field-coil speakers, and there is one sure proof way my grandfather showed me (and several Tube Radio rebuilding mags suggest the same).

Take a milk glue (Elmers or such), and rub it around the crack. Then take a piece of brown lunch bag and rub it with glue. Place it over the crack, and rub some glue on it, pressing it in place. The glue should by now soak the paper of the cone and bag. When dried you cant tell the difference in sound and its as sturdy as ever. This also works for those units that a animal (or kid) has put a hole in. I repaired a speaker that was missing almost half of the cone from mice. It sounds great and was cheap to do.

Recommended adhesives and solvents

(From: Greg (EB) Danner (gdanner@prairienet.org).)

I've been using surrounds from MAT and also from Dalbani. They are MUCH cheaper than some of the other sources, but appear to be of good quality. What I've been using for glue is:

1. "Elmer's Craft Bond Tacky Glue". A 4 oz. bottle is about $3.00 from local OSCO drug store, found it in their school and office supply aisle. Nice and thick, stays where you put it, dries quickly, and stays flexible (unlike some white glues which dry hard and brittle and might crack when vibrated in a speaker).

2. "Weldwood Universal Space Age Adhesive (concentrated)", 4 oz. bottle was about $4.00 at a local hardware store. Thinner and runnier than (1), but also dries flexible, and it supposedly bonds more

materials than (1). If you check some of the pictures on the DECWARE speaker repair pages, you will see a bottle of this glue next to the speaker.

For cleaning off the old glue and bits of old surround, as well as for softening the glue around the dust-cap so it can be non-destructively removed for cleaning the voice coil gap and shimming the voice coil while replacing the surround, the following solvent works great:

3. "Oatey Cleaner for CPVC or PVC or ABS - Clear", 16 oz can, white and yellow label. Available in plumbing department at local hardware stores. This is a solvent (MEK and acetone) based cleaner, so be sure to follow label directions, as it is flammable and you don't want to inhale the vapors. Just brush it on with a small paint brush, wait 30-60 seconds, and it will soften the old glue so you can peel it off.

(Portions from: rbeez99@aol.com)

If you are actually rebuilding the voice coil on a large driver, you really need a high temperature adhesive. Much of that power becomes heat! JB Weld is a good two part Epoxy for this application.

Some sources for loudspeaker repair parts and services

(I have not dealt with any of these places personally - these are all based on recommendations of others.)

- Simply Speakers, 11203 49th St. N., Clearwater, FL 34622, Voice phone: (813) 571-1245, Fax: (813) 571-4041, http://www.simply-speakers.com, provides speaker repair services and also sells do-it-yourself refoaming kits for repairing foam edge surrounds on most round 4" to 15" and oval 6" x 9" speakers.

- Stepp Audio Technologies, P.O. Box 1088, Flat Rock, NC 28731, 1-704-697-9001.

- The Circuit Shop, 3716 28th Street, Kentwood, MI 49512, 1-800-593-0869 or 1-616-285-1144.

- (From: Raymond Carlsen (rrcc@u.washington.edu).)

  Various sizes of paper cones and foam-edge replacements are available from MAT Electronics @ 1-800-628-1118. They range in price from less than a dollar to about $5 for the largest (15") drivers. The downside is there is a $25 minimum. However, they also sell electronic components like flybacks, video heads and belts, ICs and transistors, etc. So coming up with a minimum order may not be too difficult.

- (From: Johnion (johnion@aol.com).)

  I was given a pair of infinity speakers and ordered replacement cones from "The Speaker Place". As long as the problem is just the cones, the kit is great (and cheap).

  These are the numbers I used around a 1-1/2 years ago:

  The Speaker Place - NEW FOAM, 3047 West Henrietta Road, Rochester, NY 14623, Phone: 1-800-NEWFOAM (1-800-639-3626), Fax: 1-800-2FXFOAM (1-800-239-3626), Voice Mail: 1-800-

FOAMMAIL (1-800-362-6624). Email NEWFOAM@msn.com, Web: http://www.NEWFOAM.com.

- (From: T Schwartz (toschwartz@worldnet.att.net).)

  I've had excellent results sending drivers to Millersound Labs:

  Millersound Labs, 1422 Taylor Road, Lansdale, PA 19446, Phone 215-412-7700, Fax 215-412-0542

  They can re-foam or re-cone depending on what is needed, they are fast, easy to deal with, and IMHO, reasonably priced. Call them for a quote.

- (From: jl (jlager@tir.com).)

  Orange County Speaker, 12141 Mariners Way, Garden Grove, California, 714-554-8520.

- (From: Aan Jerig (ajerig@gate.net).)

  Lakes Loudspeaker, 4400 W. Hillsboro Blvd., Coconut Creek, FL 33073, 1-800-367-7757.

Repairing an open driver

An open driver can sometimes be rescued by tracing the input wires through the cone and under the center protective dome. The most likely places for these wires to break are right at the place where they pass through the cone and just after they pass under the dome. Note: some drivers have replaceable voice coil units. If this is the case, you should probably just replace the entire unit.

First, scrape away the insulating varnish on the front of the cone where the wires emerge and head toward the center. Use your ohmmeter to test for continuity here. If you find that you now are measuring a reasonable resistance - a few ohms, then trace back to determine which of the two wires is broken or has had the solder connection come loose. If it is still infinite, you will have to go under the dome.

Use an Xacto knife to carefully remove the dome. Use a shallow angle and cut as near the edge as you can. Take care not to puncture the paper cone which may continue under the dome as the voice coil may be of a smaller diameter than the dome. The shallow cut will also provide a base to reattach the dome if you are successful. Carefully scrape off a bit of the enamel insulation as near to the voice coil as possible and test with your ohmmeter once again. If the resistance is still infinite, there is nothing more you can do but salvage the magnet for fun experiments or erasing floppy disks. There is essentially no way to replace just the voice coil unless your driver has a removable voice coil unit (in which case you would not be reading this).

If the resistance now measures normal - a few ohms, trace back to determine which wire is broken and use some fine (e.g., #30 gauge) wire to bridge the break. You will have to scrape off the enamel insulation to permit the solder to adhere. Make sure it is secure mechanically first - a speaker cone is a rather violent environment for soldered connections. Finally, use some flexible adhesive to protect and reinforce the solder connections, to glue down your new wire along its entire length, to protect and reinforce the place where the wire passes through the cone, and finally, to reattach the central dome. Let the adhesive dry thoroughly before playing the finale to the 1812 Overture.

Loudspeakers - repair or replace?

Assuming that the cabinet is in reasonable condition, the question arises: is it worth replacing broken, damaged, or worn out drivers or faulty crossover components that are not repairable rather than just dumping the speaker systems?

It is very straightforward to swap drivers as long as you get ones with similar characteristics. It all depends on what you want out of a loudspeaker. If you are basically happy with them, then it will be a lot cheaper than replacing the entire speaker system(s). However, speaker system quality has improved considerably in the last 15 years so now may be the time to upgrade.

As far as crossover components are concerned, these are basically common electronic parts and replacement is probably worthwhile.

However, if one driver has a deteriorated suspension, it is likely that its mate does as well and that other drivers may not far behind. Replacing **all** the internal components of a loudspeaker may not be worth it.

Radio Shack as well as places like MCM Electronics and Dalbani have a variety of replacement drivers, and crossovers and parts.

Speakers wired in series?

(From: Frank Fendley (frank.fendley@datacom.iglou.com).)

Wiring speakers in series increases the impedance of the load, generally allowing less expensive output chips and smaller heatsinks, due to reduced current. It also decreases the amount of output audio power in most cases, since power is inversely proportional to impedance for a given voltage.

Many cheaper home stereo receiver and power amps are configured in a similar manner. If you have a switch and output connectors for "A" and "B" speakers, in some cases when you turn the switch to "A+B", the two left speakers and the two right speakers are wired in series. To find out if this is the case on your stereo, hook up only one set of speakers to the "A" jacks. Turn the speaker select switch to "A+B". If you have no audio through the speakers, then your receiver or power amp is configured to place the speakers in series with both sets of speakers are connected. On better stereo equipment, if you have only one set of speakers and select the "A+B" switch setting, your speakers will still function, indicating that the speakers are wired in parallel in the "both" position.

Bottom line - the answer is money (isn't the answer always money?). It's cheaper for the manufacturers to design for speakers in series.

Comments on speaker shielding

When loudspeakers - even those little speakers that came with your PC - are near TVs or monitors, there may be problems with the fringe fields of the powerful magnets affecting color purity, convergence, or geometry. Speakers designed to be used with PCs in close proximity to their monitor will likely include some internal shielding. This may even be effective. However, the large powerful loudspeakers used with high performance stereo systems will likely not have such shielding. The best solution where display problems have been traced to the loudspeakers is to move them further away from the TV or monitor (and then degauss the CRT to remove the residual magnetism. Where this is not possible, shielding of the speakers may be possible:

(Also see the document: [TV and Monitor CRT (Picture Tube) Information](#).)

(From: Lionel Wagner (ck508@freenet.carleton.ca).)

Put a Tin can over the magnet. This will reduce the external field by about 50%. If more shielding is desired, put additional cans over the first, in layers, like Russian dolls. (Note: a Tin can is actually made nearly entirely of steel - the term 'Tin' is historical. --- sam)

(From: Nicholas Bodley (nbodley@tiac.net).)

While both electrostatic and electromagnetic (E/M) fields can affect the paths of the electron beams in a CRT, only E/M fields are likely to be strong enough to be a problem.

Magnetic shields have existed for about a century at least. Some decades ago, a tradenamed alloy called Mu-Metal became famous, but it lost its effectiveness when bent or otherwise stressed. Restoring it to usefulness required hydrogen annealing, something rarely done in a home shop (maybe one or two in the USA).

More-recent alloys are much less fussy; tradenames are Netic and Co-Netic.

Magnetic shields don't block lines of force; they have high permeability, vastly more than air, and they guide the magnetism around what they are shielding; they make it bypass the protected items.

I have been around some shielded speakers recently, but never saw any disassembled. They looked conventional, must have had the "giant thick washer" (my term) magnet, and seemed to have a larger front polepiece than usual.

They had a shielding can around the magnet; there was a gap between the front edge of the can and the polepiece. I suspect that a second internal magnet was placed between the rear of the main magnet and the rear (bottom) of the can, so there would be minimal flux at the gap between the can and the front polepiece. Holding pieces of steel close to the gap between the can and the polepiece showed very little flux there.

Modern magnets are not easy to demagnetize, in general.

(From: Dave Roberts (dave@aasl.demon.co.uk).)

The *good* so-called magnetically screened speakers rely on two means of controlling stray flux. The static field from the magnet on the speaker (which would cause colour purity problems) is minimized by the design of the magnet. This is often at the expense of gap field linearity, leading to greater distortion - not that most users seem to worry about that...

The mains varying field is minimized by use of a toroidal mains transformer, but the more recent mains powered speakers seem to be coming with *plug top* PSUs, which take the problem further away.

His need is for loudspeakers already mounted in a wall, not the individual drivers. The assumption is that the woofer/tweeter/whatever are correctly wired inside the enclosure.

Loudspeaker phasing

Multiple speakers need to be driven so that they are in phase - positive peaks result in the cones of all drivers moving in the same direction. All drivers are marked in some way with + and -/red and black/etc. This results in the best base response, uniformity of sounds, and stereo imaging.

(Where you are actually constructing a loudspeaker system from individual drivers, this must be done inside the speaker enclosure as well matching the markings on each of the drivers.)

If the front cover (grill cloth) is removable or relatively transparent, than it is a simple matter to observe or feel which way the woofer cone moves when a 1.5 V battery is attached to the speaker wires. Make sure both speakers are wired to the amplifier outputs with the same polarity.

However, once a loudspeaker is mounted in the wall, for example, access to see the markings may not be possible. There may be no markings so it must be an acoustic method I would think - even observing the woofer cone may not be possible.

One can do this by feeding the same low frequency signal (say 60 Hz) to both channels and positioning a microphone about midway between them (and away from the wall). Then, the correct polarity will have greater amplitude. The acoustic wavelength of a 60 Hz signal is more than 18 feet so precise position shouldn't be critical. This is basically the same way one does phasing by ear except that a scope or sound level meter will be more precise!

(From: Robert Kesler (kesler@eunet.yu).)

Such a 'gadget' is available as a commercial instrument for 'synchronizing the polarity' of the speakers, microphones and/or cable polarity in a system, where many microphones amplifiers and speakers are used in each others fields.

There are two separate units:

- The first part is a generator, supplying an asymmetrical signal (e.g., short repetitive pulses with long pauses). The generator has an electrical output, to be fed in the speaker, amplifier or the cable to be tested and an audio output (small speaker) to be fed in the microphone.

- The receiver part, similarly, has two inputs: a microphone for checking the polarity of the speaker and an electrical input to be used for checking the amplifiers, cables etc. to be tested.

One possible simple way to make the receiver could be to amplify the peak-to-peak value of the received signal to drive a CMOS chip, and feed it in the input of an inverter and in a buffer, the inverter should feed a red LED, the buffer a green LED.

(From: Jim Coe (jimcoe@ix.netcom.com).)

1. If you have 2 speakers and you want them in same phase (but you don't care about absolute phase - i.e. whether a positive air pressure at the recording microphone reproduces as a positive air pressure at you ear, not negative) than the idea about measuring by interference 1/2 way between is OK. Except that:

   - If you measure with a microphone and the speakers are in a wall, DO put it against the wall - to get a purer pressure response and to get away from high frequency reflections.

   - Instead of looking for a summation of the pressure waves from the 2 drivers, look for a null zone when one driver is out of phase. A summation cannot be more than +6dB SPL (a "doubling"), but the null can be (theoretically infinite) much more (maybe -12 dBSPL to -30 dBSPL in practice). Once you know the drivers are out of phase, you know how to get them in phase.

2. If dealing with 1 driver and you can't access the leads and see the cone to use a battery, inject a positive waveform (diode across a sine, triangle or square wave generator? Look at the acoustic wave with a microphone driving an oscilloscope. You can use a small bare speaker, previously tested with a battery while observing the cone, to calibrate your setup. In this way, you can get the absolute phase.

Should you care about absolute phase? Yes - if you want the best 3-D sound effects. Also, with close microphone recording techniques, some sound sources do not produce symmetrical air pressure waves - so listening in the same phase as the recording can give more realism. That is, if the audio processing between you and the recorded signal doesn't mess things up too much.

Don't ever trust the markings on speaker terminals from the speaker manufacturers. I was once required to test many drivers from a famous American manufacturer, using a high quality phase tester, and found more than 20% of them mislabeled! They weren't testing them on their assembly line - just marking them by visual inspection of the driver wiring. They later became a customer for the same phase testers I was using (some friends of mine invented it and I was one of their beta testers).

Electrostatic Loudspeakers and Headphones

While the vast majority of sound producing devices utilize a moving coil (or at least are magnetically actuated), there are also some that are both very expensive and which supposedly provide very accurate sound reproduction based on electrostatic principles. Basically, a conductive membrane or diaphragm is charged to a high DC voltage with respect to a fixed plate - several hundred volts for a headphone driver but several thousand volts for a wall-size loudspeaker. This sets up a bias field that draws the diaphragms together and keeps them tight. The audio signal is boosted to a high AC voltage and added to the DC bias. The resulting change in force results in the movement of the diaphragm and thus the production of sound. The claimed advantages of such an approach is that the sound emitting area can be very large and the movement very small minimizing various types of distortions.

The DC bias voltage can be supplied by any number of means - directly from the AC line via a transformer and/or voltage multiplier or using a high frequency inverter. The current requirement is essentially 0.

(Note: There are also some 'planar magnetic' loudspeakers in existence which may look similar to electrostatic types but have no external power source and special circuitry inside. The planar voice coil is etched onto a thin diaphragm suspended within the magnetic structure.)

The audio signal from the output of a normal amplifier may be boosted to a higher voltage by another special amplifier which is part of the electrostatic loudspeaker 'energizer' before being further boosted by a transformer to drive the speakers themselves.

The energizer schematic below is for a pair of Radio Shack electrostatic headphones. A room-size set of Thunderblasters would require a somewhat more sophisticated set of electronics - probably including its own amplifier as well as operating at much higher voltage and higher power - but the basic idea will be the same.

The 3.3 ohm PTC (Positive Temperature Coefficient) thermistors are supposed to provide some sort of protection for the transformer and its circuitry in case the unit is fed with too much power. Now how could that happen? :) However, if abused too much, they can fail as well. Problems may occur in the voltage doubler and high value resistors sometimes just go bad on their own.

Trying to find replacements can be a treat but it appears that some PolySwitch protectors fit the description and should be available from major electronics distributors. For example, the 3.3 ohm device has a hold current spec of 0.17 A (.1 W) and a trip current of 0.34 A (.4 W). However, I don't know if this is adequate for the headphones described above.

Comments on electrostatic headphone operation and repair

(From: bill_h (bill_h@sunsouthwest.com).)

I have a couple pair of the Radio Shack electrostatics that I've used from time to time over the years (about thirty, I think!)

When they were closing them out, I ordered a couple spare 'replacement elements', and from looking them over, I think I have some ideas about repairing them, if it ever becomes necessary.

You'd have to come up with a frame to stretch the mylar. Then you would glue the plastic 'element' frame to it. Don't know how much tension you'd need, but I'm sure it can't have any slack whatever.

I was thinking about looking for one of those metal silk screen frames that used to be pretty common around circuit board houses. A nice size would be maybe 8" or 10" square, so a 'standard' mylar (Saran wrap? (I don't think so, but it might work --- Sam) would fit. Lay a piece onto the frame, clamp it, then tighten the screws to put some tension on the film and make sure it's even (use a torque wrench) and flat.

After the glue dries, just trim away the excess film. Put the spacer rings and metal plates back and basically you have a new 'element'.

I'm assuming everybody knows the way these things work - a mylar film is pushed and pulled between a couple highly charged (maybe 300vdc) metal plates, with a lot of holes in them. The mylar moves the air, so you get sound, which has to pass through the metal plates.

There is one other thing I've noticed. Probably for protection, there's a VERY high value resistor in series with the DC supply, and when the 'phones have been sitting un-energized for a while (weeks/months) they can take a DAY or more to become fully charged. And until they charge, the sound output is VERY LOW.

In other words, you can't plug Realistic electrostatics in, send audio into them, and tell anything about whether they work or not, for HOURS, at least.

Over the years I've tried every type of earphone that's come along. While there are some positive things that have come along, for my money nothing has yet equaled a good electrostatic for super clean mid/upper frequencies from the large area (planar) radiator.

I've long suspected small radiators, trying to move large amounts of air by extreme motion, run into the adiabatic characteristics of air whereby some of that extreme motion is turned into HEAT instead of sound. And that may account for some unpleasant distortion.

A large area radiator doesn't impart as much force to the air molecules nearest its surface, and doesn't run as much risk of this non-linear effect.

Might explain the superior sound from large planar speakers like Magnapans.

With headphones, you don't have a limited 'sweet spot' to worry about.

Repairing Acoustic Research (AR) Speakers

The following will also apply to many other brands of loudspeaker systems.

(From: Jim Adney (jadney@vwtype3.org).)

You must go in through the front hole that the woofer mounts in. The hard part is removing the grill cloth and its frame without damaging it. Mine have all been glued in place so you have to use a thin piece of metal that you can work around the side and in back and then pull out carefully. Do this carefully all around until you have broken all the glue bonds; the grill cloth frames are usually plastic, so you have to be careful not to break them. You should probably inspect the face of the cloth for staples first, as AR used staples on the AR-2ax's that I have taken apart. If you have staples, just carefully pull them all out from the front and then the grill cloth/frame will come out easily.

Then you can see all the speakers and you will notice that the woofer is just held in place with a ring of screws. Remove the screws and pry the speaker up (it is sealed in place with a compound that will still be somewhat soft and that you should just reuse when you're done.

Once the woofer is out, mark which color wire goes to which terminal on the woofer and then unsolder them. They MUST be put back the same way!

Inside you will find the speaker packed with fiberglass insulation. Carefully pull all this out and pack it in a box or paper bag for reuse later. Note how it is placed so you can do it the same way. I think there was also some kind of paper which was used to keep the fiberglass from rubbing against the backside of the speaker cones. Some kind of disposable gloves might be nice for handling the fiberglass.

Now you can see the crossover attached to the inside back of the cabinet. Make yourself a sketch of the wiring so that you can put it back the way you found it, and then unsolder the leads to the 2 pots and remove the pots. These disassemble easily, so clean/scrape until they work properly again. You can carefully clean the heavy oxidation off the slider and the wire with a dental tool or a small screwdriver; work slowly and carefully Reassemble and install.

Put everything back in reverse order. The crossover components all age well, so there is no point in just replacing things because they are old, but if something was obviously burned you might have to think about replacing it. I have never seen anything damaged there.

When I put these back together I use velcro to hold the grill cloth/frames in place. You can buy velcro by the yard at fabric stores and glue the pieces in place. This makes future repairs MUCH easier.

I've done about 4 pairs of old AR speakers (2s and 3s) this way so far, and they have all fixed up nicely. My current set of AR-3s needed this when I found them, and they have worked nicely ever since they were repaired, about 8 years ago. Takes an afternoon, no parts required.

Telephone Equipment

Web resources for telephone information

In the old days, before dinosaurs and indoor plumbing, there were telephones. You rented your dial phone from the PHONE COMPANY and it came in two styles: desk phone or wall phone. You could have any color as long as it was black. A great advance was the introduction of decorator colors, which was emphasized when you ordered your telephone service. Then came Touch Tone phones but these still looked like phones! And for the most part, all of these were very reliable. A 50 year old phone is very likely to be in perfect operating condition today having never required repair despite long faithful service and much abuse (the PHONE COMPANY made mucho profits from those rentals year in and year out with no expenses!) and only their equipment could be plugged into the phone line. Now with deregulation we have almost every shape, style, color, and quality. Phones are throwaway items given away in cereal boxes. And all types of other equipment gets connected including modems, fax machines, intruder alarms, and college senior projects. Amazingly, the phone system remains very reliable.

There is a Telephone FAQ under development. While this is not an official document, the information in it seems to be accurate. I don't know that it has a lot more than what is covered in this chapter but might be worth checking out nonethless:

- Skip's Telephone FAQ

There are some additional Telephone related Web links in my bookmark file at Sam's Neat, Nifty, and Handy Bookmarks.

Telephone basics

- Connections to 'Plain Old Telephone Service (POTS)' is via two wires. POTS is the type nearly everyone currently has to their residence. Newer ISDN or fiber lines use different techniques.

- The wires are called 'Tip' and 'Ring'. This terminology has nothing to do with telephone ringing but is historical; Tip and Ring were connected to the tip and ring respectively of the plug used on manual switchboards.

- Tip and Ring color codes are as follows - this is not always adhered to!

```
                          Type A              Type B
     Phone line          Tip,Ring            Tip,Ring
  ------------------------------------------------------------
```

```
First line (Pair 1)       Green,Red               White,Blue
Second line (Pair 2)      Black,Yellow            White,Orange
Third line (Pair 3)       White,Blue              White,Green
```

Type A is often simply called 'quad' and is the most inexpensive cable. However, the conductors are usually not twisted and type A should not be employed in new installations especially where computer modems or fax machines are to be used on any of the lines as crosstalk between multiple phone circuits in the same cable may result in excessive transmission errors and interference with normal phone conversations.

For type B, the colors refer to the dominant one if the wires are striped. Each pair is twisted together which greatly reduces crosstalk.

- On RJ11 type connectors, Pair 1 is the central two wires, Pair 2 is the next two, and Pair 3 are the outer wires if there are 6 conductors - many RJ11 cables only have 2 or 4.
- Tip will be approximately +50 VDC with respect to Ring when phones (or computer modems or fax machines) are on-hook. Test with a multimeter.
- Ringing voltage is about 90 VAC. A neon light bulb (NE2) can be used to test for this if a multimeter is not available.
- When off-hook (dialing or talking), there will be a DC voltage of approximately 5 to 15 V between Tip and Ring. This is needed for the phone circuit and also is used to power the dialing in phones without a separate AC supply or adapter.
- The on-hook and ringing voltages can give you a shock but are probably not particularly dangerous to healthy people. Still, it is best to work on phone wiring with it disconnected from the telephone company's feed or with another phone on the same circuit off-hook.
- Some phones will work with only one of the two possible polarities of Tip and Ring while others incorporate a bridge rectifier (for power) and will work either way - test both ways if a phone does not dial or work at all.
- DTMF refers to the Dual Tone Multi-Frequency dialing touch tone codes. Each number, *, and #, are represented by a pair of audio frequencies. (You can hear the individual ones by holding down multiple buttons on an old style ATT Touch Tone phone). See the section: DTMF codes.

DTMF codes

DTMF (Dual Tone Multi-Frequency) are the tones that phones use. The frequencies are as follows:

```
  Hz      1209    1336   1477    1633
-----------------------------------
 697        1       2       3      A
 770        4       5       6      B
 852        7       8       9      C
```

```
941       *      0      #     D
```

Follow the rows and columns to the number you want to know the frequencies of and this table will show you. The column of letters at the right is on some Ham radios.

Where an old style ATT Touch Tone phone's DTMF frequencies need to be adjusted, accuracy of better than 1 Hz is easily obtained without fancy equipment - just another working tone dialing phone. See the section: Classic ATT Touch Tone phone will not dial properly.

For more information on DTMF coding, decoding, equipment, chips, etc., see the:

- DTMF FAQ

Phone jack or extension installation or repair

The phone companies would have you believe that installing or repairing phone wiring is somewhere between rocket science and nuclear physics in complexity. In fact:

- Installing new jacks consists of two parts: running the wires and hooking them up. The only difficulty with running the wires is getting between floors. Connecting them is a matter of matching the colors of the insulation, stripping, wrapping around screws, and tightening the screws. Even if you are color blind, this is not difficult.

- Unless you disturb it, phone wiring rarely goes bad - even in old houses. Thus, if you have any amount of handyperson ability, paying the $2 a month inside wiring insurance is throwing away $24 a year.

- Unlike electrical wiring, phone wiring does not have serious safety issues associated with it. However, you could get a mild shock from touching the two wires of an active phone line. The on-hook voltage is about 50 VDC and if someone were to try calling your number at the same time, the ringing voltage is around 90 VAC. Both of these are easily dealt with: put a jumper between the two phone wires where they enter your house while you are working on the wiring. This will result in an 'off hook' condition and outside callers will get a busy signal.

Telephone interference from local radio station

(From: Robert Myers (rmyers7@ibm.net).)

See the:

- RF Elimination Technical Bulletin

for an explanation of this problem.

(From: Gray Frierson Haertig (gfh@haertig.com).)

AM interference to telephones is very common. Most modern telephones are full of transistors and diodes which make splendid demodulators for the AM signal. Some of these semiconductors are in the part of the circuit that drives the earpiece, which might explain why only you hear the radio. We assume that there is really an 880 AM in your town so we can rule out psychosis. If the radio starts telling you to kill people, get help immediately.

The AM is probably coming in on the phone lines. The reason phones have this problem in particular, is because they are connected to really long antennas - the phone lines. Bet the 880 transmitter is pretty near your house.

The susceptibility of different kinds of phones is very different. And, depending on where in the circuit the detection is happening, one susceptible phone can put the AM audio on the phone line so all the phones will have problems. First thing to do is unplug all your phones. Then plug phones in one a time in their normal locations and see which phones are susceptible.

Check out Mike Sandman's Telecom and Cable Installation Products. These folks make a wide range of interference filters that frequently will help with the problem. It may be cheaper to replace seriously affected phones with phones that are not so susceptible. And remember, the price of the phone has absolutely nothing to do with it's susceptibility.

(From: Lord Valve (detritus@ix.netcom.com).)

Your phone wiring has a local ground, usually attached to a water pipe. Chances are better than even that this connection is oxidized. Remove the clamp and clean the copper pipe with a piece of Scotch-Brite. Clean the clamp, too, and the incoming ground wire. Put it all back together and cover the whole assembly with grease. (The grease will block moisture and prevent re-oxidation.)

(From: Michael Bell (mbell72398@aol.com).)

I find your post a common problem to an everyday experience to me. I work with a local telco and this is very much a problem. Some phones are more prone to this than others. Believe it or not, the electronic ringing (this is any phone that does not have the plain old bell in it) ones are more likely due to the circuits in them. The phone company will (at no charge to you) put a AM coil that will greatly lessen the interference in the protector outside your home. They should have a that blocks your local AM station's frequency before it comes in your home. However, this will not help if certain phones are acting as the antenae for your interference. Call your local telco first. Why pay if they can solve it.

Remember that they cannot charge you for work up to the protector.

(From: Anthony Falvo (afalvo@borg.com).)

I am the Chief Engineer of an AM radio station. We put out a measly 1000 watts of power but it has the same effect on all of our studio gear. What you need to do is open the affected phone and place a 40 mH coil in line with about .01 uf cap in series across the phone line values may very ans get a coil that is tunable slug like from an old TV IF section wire in series and tune the coil for best rejection of the offending signal you may completly eliminate it sometimes you need 2 of these FILTERS to ground from bolth sides of the phone line depending hoe bad the interfereing signal is what you are essentialy creating is a crude NOTCH filter that will

NOTCH out the offending freq according to the Tuning of the coil.

If I can eliminate the noise from our studio lines wich are no more the 20 feet from the Tower, then I'm sure this will work for you.

(From: Robert Blackshaw (blackshaw@erols.com).)

I spent 33 years with Bell Canada and have seen this phenomena in rural areas with open wire lines. The splice connectors would become oxidized (copper oxide) and treat every subscriber to "free" radio.

(From: Jim Muehlberg (muehlber@plains.nodak.edu)..

I'm currently in studying EE and took a course in electromagnetic compatibility (EMC) This is a huge field with many employment opportunities.

We conducted a lab experiment that simulated this problem. It is a fine example of what is called common mode currents. The idea to install the chokes as described above is likely to cure the problem. Perhaps a simpler quick check is to take the phone cord from the wall and wrap as many turns as possible around an IRON bar or big bolt or if you can find one surplus, a big ferrite toroid. It is important that each conductor be wrapped in the same direction. This constitutes a common mode choke. This will be "invisible" to the differential signal (desired) and be a large reactance to the common mode currents. If it works, install the whole shebang at the wire entrance.

Answering machine comments

Most answering machines still use one or two tape decks. Most problems are mechanical. Refer to the sections on the relevant tape player/recorder problems. The newest ones are fully digital electronic - forget repairs unless obvious bad connections, physical damage, power supply, or phone line side failure.

- Many non-mechanical problems with answering machines are related to the circuitry connected to the phone line. This is subject to the high on-hook and ringing voltage and possible voltage spikes due to lightning, etc.

  Testing of the components on the phone line side of the coupling transformer is a worthwhile exercise and may reveal a shorted semiconductor or capacitor.

  See the section: Checking phones and answering machines for electronic problems.

- If the outgoing message (OGM) or phone messages do not record or playback, check for broken wires at the appropriate tape heads and clean the mode selector switches.

- With endless loops outgoing message cassettes, the metal strip that is used to sense the beginning can wear or become dirty. Try a new cassette or clean it.

- Like VCRs, there may be various 'mode switches' or position sensors. Where these are physical switches, they may have dirty or worn contacts. Optical sensors can fail as well though it is unusual.

- Mechanical problems unique to answering machine tape transports are also possible. Some very clever engineering is often used to share parts where two tape transports are used. Parts may have popped off or broken. Springs may have sprung or weakened. Sliding parts may have jammed. Look for loose parts or broken pieces when the unit is disassembled. Careful inspection during operation may reveal whether it is getting stuck due to a mechanical failure.

- On erratic behavior where two phone lines share a common untwisted (e.g., "quad") cable, activity on one line may result in the answering machine picking up or otherwise messing up the other line, at least with some models. Solution: Separate the lines or use better cable.

Answering machine delays after playing OGM

This may be one of those machines where it has to go through the entire outgoing message (OGM) tape before allowing recording of the phone conversation - If it is, then just get yourself the shortest outgoing message tape you can find and time your OGM to nearly fill it.

Also, if you are trying to use an OGM tape recorded on another answering machine, even if the tape is compatible, the frequency or coding of the control tones - the beeps - may not be the same. Try re-recording it on the machine in question.

If these are not the problems, the machine may not be sensing the beep code put on the tape when you record the OGM or the beep is not being recorded properly. This is likely an electronic or logic problem requiring the schematic unless you get lucky with bad connections or a broken wire at the tape head.

Answering machine picks up then hangs up

- If it has a 'telco' and a 'phone' connector verify that you are plugged into the 'telco'. Otherwise, it may hang itself up. Who knows. If someone else attempted a repair, these jacks could even have been replaced interchanged.

- Measure voltage on the relay coil. If it actually disappears when the relay cuts out, then something is telling the relay to turn off. If it is just reduced, then there may be a power problem. If it is relatively stable, then the relay may be bad.

- Test components near the telephone connection for shorts/opens. Parts connected to the telephone line get abused by the ringing voltage and other transients. Maybe you will get lucky and find a fried part.

- If you can identify the power supply outputs, verify their voltages if possible. Check the 'wall wart' if it uses one for proper output.

- Make sure that the tape mechanisms have completed their cycles. While unlikely, it is possible that the logic gets confused if one of the tape units has not reset itself due to a mechanical fault like a bad belt.

- As usual with cheaply made consumer stuff (as well as cheaply made expensive industrial stuff), check for bad connections.

Beyond this, circuit diagrams would be a definite plus.

Answering machine does not complete cycle

This is often a mechanical problem. As it goes through the cycle, see if the mechanism is perhaps getting hung up at a certain point do to a weak spring or motor. A cam may get stuck or a solenoid may fail to engage. Gently prodding the uncooperative part (or any likely parts if the appropriate one is not obvious) may convince it to continue and allow you to make a diagnosis.

For endless loop outgoing cassettes make sure that the metal sense strip is not worn off and that the sensor is making good contact. Try a new outgoing message cassette or manually short the sensor contacts to see if it will then shut down.

Answering machine has weak outgoing message

You probably have no way of knowing since you probably never listen to the outgoing message, but did the problem happen suddenly?

Does playback of the outgoing message directly to the speaker appear to be at normal volume?

Do incoming messaged get recorded at normal volume?

First, confirm that the unit is in good mechanical condition. See the section: General guide to tape deck cleaning and rubber parts replacement. Clean the tape head and inspect for anything that may be interfering with good tape-head contact. Clean the internal record/play selector switches. Dirty contacts can result in any number of symptoms.

Assuming that none of this helps significantly, you are left with a problem in the electronics.

If local record and playback of the the outgoing message works normally, the problem is not a bad tape head. It is probably in the interface to the phone line.

If local record and/or playback do not work correctly, then there are likely problems with that circuitry.

One other slight possibility is that you have so much equipment (phones, modems, fax machines, etc.) on the phone line that in your house that the answering machine is not able to drive the line properly and reduced outgoing message volume is the result.

Newly installed phone will not tone dial

If a Touch Tone phone that was previously working now does not tone dial from a new jack or new residence (the button presses are totally ignored, but all other functions are unaffected), the red and green wires are probably interchanged at the new jack, or the phone itself is miswired (the wires inside the phone may have been interchanged to compensate for an incorrectly wired jack at the old location).

Newer electronic phones will utilize either polarity. The older ATT battlewagons will only dial when hooked up with the correct polarity. This does not affect conversation, ring, or rotary phones.

Cordless phone problems

There are several types of problems with cordless phones that can be diagnosed and repaired without sophisticated test equipment. Anything involving problems with the RF or digital circuitry is not likely to be within the scope of your capabilities, at least not without complete schematics (yeh, right), test equipment, and a miracle or two.

1. Bad rechargeable battery - dead, shorted cell(s), or reduced capacity. The NiCd battery packs in cordless phones are usually easily replaced for around $5-10. This really is the best solution. The problem is almost never in the charging circuits. Replacing individual cells is not recommended. Battery packs can be built up from individual NiCd cells with solder tabs for a modest cost savings. Reuse the old battery pack connector (you may need to do this with a replacement pack as well if the new connector is not identical to the old one), double check polarity, and tape and insulate your homemade pack after soldering to prevent shorts.

   A NiCd battery pack with shorted cells will either prevent operation totally or keep the 'battery low' light resulting in a weak, noisy, or intermittent connection. If the voltage measured on the battery pack after 24 hours of charging is less than 1.2 V times the number of cells in the pack, it is most likely bad.

2. Dirty keypad - resulting in intermittent, incorrect, or no operation of buttons on handset. This may be due to internal migration of some unidentified substance (how else to describe disgusting sticky gunk that has no right being there on multiple samples of the same model phone) or from external spills. If you are lucky, the keypad can be disassembled without resorting to drastic measures. There may be screws or it may snap apart once access is gained to the inside of the handset. Clean contact surfaces on both the rubber button panel (or plastic keys) and the circuit board first with soap and water and then with isopropyl alcohol. Dry thoroughly.

   If the keypad is assembled with 'upset' plastic (fancy term for little melted plastic posts), then you should probably try contact cleaner sprayed as best as possible through any openings before attempting to cut these away since reassembling the keypad without the plastic posts will be difficult. However, I have successfully repaired these by breaking off the tops of the posts to remove the circuit board and rubber keys, and then using a dab of windshield sealer on each post as an adhesive to hold the thing together after cleaning. However, I much prefer screws :-).

3. Bad AC adapter on base station - see the docuemnt: Notes on the Troubleshooting and Repair of AC Adapters, Power Supplies, and Battery Packs. This will likely result in a dead base station. If you have replaced the AC adapter or are using a universal type, double check the voltage setting AND polarity.

4. Bad phone line connection - don't ignore this possibility - test with another phone.

5. Bad circuitry on phone line side of interface (coupling transformer) - inspect for blown or shorted components.

6. Bad connections or broken circuit board - if the handset has seen violent service, these are likely

possibilities. See the section on: "Equipment dropped or abused".

7. You forgot the code number - some phones use a multidigit code number as a marginal security feature which must match on handset and base station. If the battery goes dead in the handset or the AC adapter is pulled on the base station, this code may be forgotten. You do have the user's manual, right?

   BTW, do set this code to a non-default value. I was once able to dial out on my neighbor's cordless phone using my phone from my house as a result, I suspect, of their phone being set to its default code!

8. Base station and handset out of sync - some models require that the base station initialize the handset before any communication is possible between them. Put the handset on the base station for a few seconds to reset. This can happen at any time due to circumstances beyond human control but will almost certainly happen if you replace or disconnect the battery in the handset of these model phones.

Cordless phone keypads

(From: Martin Sniedze (MSniedze@STRNNTS1.telecom.com.au).)

I found that the keypad was always getting wet/oily somehow. Cleaning with alcohol only fixed the dialing problem for about a week. A bit of asking at phone repairer revealed that sanyo has a 'possible' problem with the keypads absorbing/emitting the oily substance. The repairer sold me a membrane that goes between the silicon keypad and the PCB, it has carbon pads on the back. It stops the moisture getting through. It has completely fixed the problem in my phone (it was done 6 months ago). They should be free.

(From: Steve Lenaghan (tamerica@prairie.ca).)

We do a ton of cordless phones and I have never had to repair a conductive pad in my career (35 years). We soak them in scalding water and dish soap for 30 minutes. I clean the PC boards with alcohol and a rough cloth. Works every time.

Erratic or noisy telephone equipment

The following applies to normal desk or wall phones, cordless phones, modems, answering machines, fax machines - essentially anything plugged or wired into the phone system.

Always check the cords first - especially the one between the handset and the desk or wall phone itself since it gets a lot of abuse. Noisy, intermittent, or totally dead behavior is possible. In some cases, even the (electronics) ringer will not work if a wire in this cord is broken as the ringing signal is generated in the handset and sent back to the ringer unit. Try jiggling the cord at both ends to see if noise is generated or behavior changes. Even permanently wired in cords are replaceable - just take care to draw a diagram and/or label all the wires before disconnecting the old one.

Bad connections are relatively rare in original ATT dial or Touch Tone telephones. These old phones also used very high quality contacts for the on-hook, dial, and button switches which rarely resulted in problems. However, with the multitude of modern equipment of all degrees of quality, bad connections and dirty or degraded switches and relays are very common.

The various microswitches and/or relays for on-hook and other functions seem to be particularly prone to degredation if not properly specified in the design. If phone line pickup or mode switching is noisy or erratic, this is a likely cause. Most of these swiches and relays are replaceable although creativity may be required as an exact match may not be easy to locate.

To assure that the problem is actually with the particular piece of equipment, disconnect other devices on the same telephone line. Aside from the obvious oversight of a phone that has not been hung up, modems or fax machines that are not powered on may load the phone lines excessively. For example, if you have two PCs with modem connections to the same phone line, the signal quality on one of them may degrade to the point of reducing the effective transmission speed, producing an excessive error rate, or not successfully connecting at all if the other is turned off. (They may also behave strangely if the Originate/Answer settings of the modem are set incorrectly - but that is another matter.)

Checking phones and answering machines for electronic problems

Most signal problems will be related to failed components on the telephone line side of the coupling transformer including components in the phone line derived power supply (if used). Phone lines are subject to all kinds of abuse including lightning strikes (although something significant may do extensive damage beyond reasonably hope of repair).

- Test all the components on the telephone line side of the coupling transformer when line connect, detect, or dial problems are encountered. There may be shorted semiconductors due to a voltage spike or just bad luck.

- Some units extract power from the phone line and the rectifiers or other related components can go bad. This can result in either power problems (telephone is totally dead) or dialing problems.

- Make sure you are using the proper AC adapter and test it for correct output.

- There could be a defective power supply inside the phone - the regulator could be shorted or a filter capacitor could be dried up. See the chapter: "Equipment Power Supplies".

- Check for loose or broken connections - phones get dropped.

- For erratic dialing problems, inspect and clean the keypad and other switch contacts. Also see the section: Cordless phone problems.

Modem problems

First, confirm that your modem settings are correct - reset the modem to factory defaults using the Hayes AT commands (e.g., AT&F1) or dip switch settings. Confirm that your software is set up correctly and that there are no IRQ or IO address conflicts.

If the modem starts to dial but aborts and hangs up, confirm that you do not have the wiring of the 'telco' and 'phone' connectors interchanges.

Also see the section: Erratic or noisy telephone equipment.

Since the phone line is subject to all kinds of abuse, most actual problems (that are not software related), will be on the phone line side of the coupling transformer.

- There will be various resistors, diodes, transistors, capacitors, opto-isolators, and relays for routing the incoming and outgoing signals, or for protection and these can fail shorted or open, or change value.

  On one U.S. Robotics 56K modem, I found a pair of 10 ohm surface mount resistors that failed due to a storm related surge - one had changed value to about 20 ohms and the other had opened. The difference between 10 and 20 ohms made no difference (I left it that way though it could be less reliable and fail eventually) but the open resistor resulted in a "No Dial Tone" error. More below as this is a common occurrance with modest surges.

- There may be an actual fuse (or more than one) as well - but it will probably not look like a common fuse but may be very tiny - more like a resistor - or even a surface mount part. Hopefully, the circuit board will be marked 'F1' or 'PR1' or something similar. Check fuses for opens.

- A lightning strike is likely to obliterate components in the modem beyond even your abilities to salvage it. If it arcs over the coupling transformer or just induces a large enough voltage spike, the logic circuitry will be history. However, in many cases, damage is minor.

If you have signal problems - a modem will try to dial out but not make its way to the phone line, testing on each side of the couping transformer with a scope or Hi-Z headphones should be able to determine if the problem is on the logic or phone line side of the device.

Check that the proper AC adapter is being used (if relevant) and that is is putting out the proper voltage. Check the internal power supply components for proper output. They are often common IC regulators like the 7805 and are easily tested. Replacements are inexpensive and plentiful.

(From: Rick Miller (wizkid@mv.mv.com).)

First thing to check: almost all modems have a pair of low-value resistors (10-20 ohm) between the phone line and their line transformer.

I got a 2400 baud voicemail modem for free this way! Repaired an "unrepairable" modem (according to the ACER computer technician! :))

Replaced a "booger resister" with a real 1/2 job.... had to work hard to get the leads soldered onto the SMT pads!:)

(From: Jordan Hazen (jnh@aardvark.cen.ufl.edu).)

Yes, in my experience you're much more likely to sustain damage from a phone-line surge than anything on the power grid. Modem electronics tend to be more delicate than the stuff in your power supply.

First thing to check: almost all modems have a pair of low-value resistors (10-20 ohm) between the phone line and their line transformer. These are intended to take the brunt of a lightning hit and protect the electronics upstream. Traditionally, these have been large, high-current resistors (like 1/2 watt), but sometimes now they try to get away with little 1/16-watt surface mount ones that are much more likely to blow. Sometimes it's obvious when the resistors have died, with visible singe marks, pieces blown away(!), etc. Usually these fail as an open, resulting in "NO DIALTONE" on trying to connect.

Other vulnerable stuff includes the zener diodes intended to clip down incoming ring voltage, on the transformer "primary" (telco) side. These may fail as a short-circuit. The ring-detect optoisolator may also blow, and it can simply be removed if you don't need to take incoming calls.

One of my modems actually had the line relay's contacts welded together by a lightning hit, so it stayed off-hook constantly! Check the isolation transformer for a open coil on either side. If it's a high-speed modem, be sure to replace blown transformers with one of about the same type & quality... the ones on 2400-baud modems usually had poor frequency response/linearity.

Any damage beyond the transformer will be hard to repair w/o a schematic, since the surface-mount diodes, transistors, etc. damaged may be hard to ID for replacement on a surface-mount board. Something blown in this area may cause slow/error-prone connections, rather than complete failure. It happened to be with a particularly nasty strike (the one welding the line relay closed), transforming a 33.6k modem into a 4800 :-(

Oh, and if the modem's completely dead - no response to AT commands-- you're probably out of luck... this means there's damage to the digital logic, and it's invariably the 200-pin custom ASICs that blow rather that 74xxx buffers.

(From: jlager@tir.com).

My experiences with the front end of answering machines are welded relay contacts mostly. The symptom is usually holding down the line.

Testing a Fax machine without a second phone line

Note: This was written for phone systems in the UK but should apply elsewhere.

(From: Peter Duck (pduck@zetnet.co.uk).)

All you need is another fax machine or a computer w/faxmodem and fax software plus a small circuit to simulate the phone-system.

(This doesn't provide/check 'ringing', so one must tell the receiving end when to Answer/Start, but I use this for modems and/or fax machines.)

```
                        33 ohms        E      C     LED
         o---------+----/\/\----------.      .----|<|-----+-----o(+)
          To        |                  _\___/_             |
        two-way     |                      |               |
        adaptor     +----|<|--|<|---------+-------/\/\----+   PP3 (9V)
```

```
    for both      2 X 1N4148-ish       B        3.3k       Battery
     modems
       o-----------------------------------------------------o (-)
```

The current is approximately 20 ma, so almost any small transistor is OK. Shown for NPN: adapt if you only have a PNP. The LED is optional, but reminds you to unplug things instead of having to buy a new battery each time. :-)

If you're trying to figure out how it works, the 'constant' current will be such that the (voltage drop across 33 ohms) + Vbe = (2 * (Vf of a diode))

Though a phone-line would be fed from a 50 V source (in the UK, anyway), all that's needed to keep the modems happy (or fax machine) is some excess over the Vfs of the diode bridges that enable them to cope with either polarity of line-voltage.

Calculators, Clocks, and Watches

Web site for clock and watch information and repair

The following Web site has links to lots of clock repair informaion including a repair FAQ, clock/watch companies, and more:

- Mike's Clock Clinic's Web and FTP Pages.

Problems with calculators

Small hand held and desk calculators share many of the same afflictions as hand held IR remote controls. In particular, battery and keypad problems are common.

Caution: many devices using LCD displays utilize a printed flex cable to interconnect the electronics and the display. Often, this is simply glued to the LCD panel and possibly to the logic board as well. The cables are quite fragile and easily torn. They are also easily ripped from the adhesive on the LCD panel or logic board. If the unit is fairly old, this adhesive may be very weak and brittle. Repair or replacement should this occur is virtually impossible. The material used for the conductors is a type of conductive paint that cannot be soldered. It may be possible to use a similar material like the conductive Epoxy used to repair printed circuit boards but this would be extremely tedious painstaking work. Be extremely careful when moving any of the internal components - LCD, logic board, keyboard, battery holder/pack, and printer.

The following problems are likely:

1. Batteries - one or more cells are dead, weak, or have leaked. Try a new set if normal primary cells (e.g., alkaline) are used. Clean the battery contacts. Where rechargeable (usually NiCd) batteries are used, one

or more cells may have shorted resulting in a dead calculator or dim display, or printer that doesn't work reliably. See the chapter: "Batteries". Test each cell after charging for the recommended time or overnight. NiCd cells should be about 1.2 V when fully charged. If any are 0 V, the cell is shorted. This is particularly likely with a unit that has been left in a closet unused for an extended period of time. It is generally recommended that the entire battery pack be replaced rather than a single cell as the others are probably on their way out and the capacities will not be equalized anyhow. Rechargeable batteries may be the cause of a calculator that does not work properly on AC power as well since they are usually used like a large filter capacitor and shorted cells will prevent the required DC voltage from being provided to the electronics. Open cells or bad battery connections will prevent this filtering as well and may result in erratic operation or other symptoms. For this reason, it may not be possible to run a unit of this type reliably or at all with the rechargeable batteries removed.

 Some calculators that use rechargeable batteries like older HPs and TIs have a battery pack of 24.4 to 3.6 V with a DC-DC inverter to obtain the 9 V or so that the NMOS chipset required. These rarely fail except possibly due to leakage of neglected dead batteries. However, good batteries need to be in place for the calculator to work properly. If you are not interested in using these types of calculators on batteries, disconnect the DC=DC convertor and substitute a suitable AC adapter. Check the voltage and current requirements for your particular model.

2. Keypad - dirt, gunk, and wear may result in one or more keys that are intermittent or bounce (result in multiple entries). Disassemble, clean and restore the conductive coating if necessary. See the document: Notes on the Troubleshooting and Repair of Hand Held Remote Controls.

3. Printer (where applicable) - in addition to replacing the ribbon when the print quality deteriorates, cleaning and lubrication may be needed periodically. Dust, dirt, and paper particles collect and gum up the works. Clean and then relube with light machine oil or grease as appropriate. Sometimes, gears or other parts break resulting in erratic operation or paper or other jams. Locating service parts is virtually impossible.

4. AC adapter - if the calculator does not work when plugged into the AC line, this may be defective - broken wires at either end of the cord are very common. However, shorted cells in an internal NiCd battery will likely prevent the proper voltage from being supplied to the electronics even when using AC power since the battery is often used like a large filter capacitor at the same time it is being charged. Open cells or bad connections to the battery pack may result in erratic operation or other symptoms as well.

 Don't overlook the obvious: are you using the proper adapter and if it is a universal type, is the polarity and voltage set correctly? Check the specifications. With the proliferation of AC adapters, it is all to easy to accidentally substitute one from another device.

Repairing a calculator (or other device) with a fried power transformer

There may be a thermal fuse (under the outer layers of insulation, between the bobbin and core, or molded into the bobbin) which is the only casualty and it may be replaceable but don't just bypass it (except for testing), so this is worth checking out. Also see the document: Notes on the Troubleshooting and Repair of AC Adapters, Power Supplies, and Battery Packs.

(The specific example below is for a Sharp desktop calculator, model CS-1608. It has a power transformer with 6 wires on the secondary: 2 red, 2 yellow, 1 orange, and 1 brown.)

Power surges, overheating, or connecting a 115 V device to a 220 V line can all blow the primary. An overload could also but is likely not the problem. In my experience, it seems that the transformers in these things are designed so close to core saturation that excess voltage will not be transferred to the secondary and even plugging a 115 transformer device like a digital clock into a 220 line will not kill the logic, but just melts the transformer primary. I have a bag full of the things (including a cordless phone) which were damaged in this manner when someone decided to do a little house rewiring. You can guess the rest.

As far as the calculator goes, there are probably 2 sets of secondary windings probably with centertaps - check it with a multimeter. I would guess that the brown is the centertap for the reds and the orange is the centertap for the yellows but simple tests will confirm or refute this. One may be for the logic and the other for the printer motors, LCD, who knows?

Obviously, if you can obtain an exact replacement, **this** is truly the best solution. Short of this, try to find someone who can measure the secondary voltages on a working model of this calculator. Then, you could replace the transformer with a pair of readily available transformers with suitable ratings.

If you feel on the lucky side and can at least determine which wires go with which windings, you could carefully bring up power on one output and see if there is any response. It will be at least 5 V. Examining the regulation circuitry and filter capacitors could also provide a clue. Also, you could determine the ratio of the secondaries by powering one from a low voltage AC source and measuring the output of the other (assuming the primary isn't so messed up as to load down the transformer due to shorts).

There are many options besides giving up.

Getting inside calculators

Many will have a couple of screws (possibly hidden under rubber feet or inside the battery compartment) or snaps which will permit the two halves of the case to be separated. However, some very popular models are apparently not designed to be repaired at all:

Note: I have heard that there is a somewhat less destructive (but not any easier) procedure for getting inside HP48s than that given below but have not seen it.

(From: A.R. Duell (ard12@eng.cam.ac.uk).)

Have you ever tried to open up an HP48 (or just about any HP calculator later than the 71B)? It's non-trivial to do non-destructively - these darn things are held together by pegs that were melted over after the case was assembled.

From memory (and I've never actually done a 48, just the smaller ones) you have to:

1. Remove batteries, cards, etc.

2. Carefully peel off the metal overlay on the keyboard. This can be done without putting a fold in it, but it

takes practice.

3. Use a 4 mm (I think) drill held in the fingers to remove the tops of the moulded studs holding the case together

4. Pull off the back part of the case.

You can now see the circuit board. It's held down by twisted metal tabs. The keyboard is under it, and is held together by a lot more of those infernal moulded studs.

Battery powered digital clock problems

First, try a fresh battery and clean the battery contacts if necessary. If the battery is very low or dead, well.... When the battery is low or the connections are bad, the countdown logic may run erratically - fast as well as slow. Give it a week and then see if the problem still exists.

If it does - and the error is only a few minutes a week - then an adjustment may be all that is needed. If the error is much worse - like it is running at half speed - then there is a problem in the logic - time for new clock (or at least a new movement).

There should be a recessed screw for fine speed adjustment accessible from the back - possibly after a sticker or outer cover is removed. It may be marked with a couple of arrows and if you are lucky, with the proper direction for speed increase and decrease.

Without test equipment, the best you can do is a trial and error approach. Turn the screw just the tiniest bit in the appropriate direction. If this is not marked, use counterclockwise to slow it down and vice-versa.

Wait a week, then readjust if necessary.

If you have frequency counter with a time period mode, you can try putting it across the solenoid terminals and adjusting for exactly 1.000000 second. Hopefully the load of the counter will not affect the oscillator frequency.

With sensitive equipment, it may even be possible to do this without any connections by detecting the fundamental frequency radiation of the quartz crystal oscillator and adjusting it for exactly 32,768 Hz (most common).

However, keep in mind that the clock's quartz crystal accuracy required to gain or lose less than 1 minute a month is about +/- 1 part in 43,000 which may be better than that of your frequency counter's timebase. One alternative is to perform the same measurement on a clock that is known to be accurate and then match the one you are adjusting to that.

AC powered digital clock problems

Common problems include totally dead, missing segments in display, running at the wrong rate, switches or buttons do not work. (Also applies to the clock portions of clock radios.)

Note that these is often a battery - possibly just an 9V alkaline type for backup in the event of a power failure. If this is missing or dead, any momentary power interruption will reset the clock.

Although a totally dead clock could be caused by a logic failure, the most likely problem is in the power supply. The power transformer may have an open winding or there may a bad connection elsewhere. A diode may be defective or a capacitor may be dried up.

Often, the secondary of the power transformer is center tapped - test both sides with a multimeter on its AC scale. Typical values are 6-15 VRMS. If both sides are dead, then the primary is likely open. There may be a blown fusable resistor under the coil wrappings but a burnt out primary is likely. Although generic replacement transformers are available you will have two problems: determining the exact voltage and current requirements (though these are not usually critical) and obtaining a suitable regulatory (UL. CE, etc) approved transformer - required for fire safety reasons.

If the transformer checks out, trace the circuit to locate the DC outputs. These power supplies are usually pretty simple and it should be easy to locate any problems.

Missing segments in the display are most likely caused by bad connections. Try prodding and twisting the circuit board and inspect for cold solder joints.

A clock that runs slow on 50 Hz power or fast on 60 Hz power may not be compatible with the local line frequency since these clocks usually use the power line for timing rather than a quartz crystal. This is actually a more precise (as well as less expensive) approach as the power line frequency long term accuracy is nearly perfect. Sometimes there is a switch or jumper to select the line frequency.

Dirty switches and buttons can be cleaned using a spray contact cleaner.

Analog AC Motor Driven Clock Doesn't Run

The most common type uses a sealed rotor/gearbox inside a AC line powered coil. After 40+ years, even these reliable devices may stop running, often following a power interruption.

It's most likely gummed up lubricant but probably in good condition otherwise. The best option short of replacement (which may or may not be possible given its age) is to disassemble the gearbox and clean the gear-train and rotor bearings with degreaser, then lubricate the rotor bearings and gears with light oil. To get inside, file along the edge where it's joined, then glue back together.

Another option if you're lazy, which may not work as well, is to drill a tiny hole in from the side so it just breaks through, and squirt in some degreaser. Let it do its thing, blow it out, repeat a couple times. Then add some light oil and seal the hole. The problem with this approach is that it may not get to the rotor bearings - which are likely the main source of the problem.

In any case, DO NOT USE WD40 for the lube!!!! You'll just be doing it again in 6 months.

See Timepiece Workshop Tips and specifically Comments on Telechron Rotor Repair for some specific notes on dealing with the most popular types of movements.

The following sounds easy enough but I'm a bit skeptical as to it's chances of success and long term reliability:

(From: Jim Adney (jadney@vwtype3.org).)

The best cure for sticky electric clockworks that I've heard came from the USENET newsgroup for antiques. One person there suggested putting some rather heavy oil in a container and heating it up on the stove.

Drop the sealed clockworks in the hot oil and let it come up to temp. As it does, the air inside it will expand and bubble out. Wait for the bubbles to stop.

Remove the container from the heat and let it cool down with the clockworks still in it. As everything cools, the air in the clockworks will contract, pulling oil inside. Let it cool overnight and them pull out the works and wipe it off. Power it up and see if it wants to run.

Most of the time this will fix things, but you may want to let the works sit on a rag for a week to let excess oil seep out before you reinstall it.

Once you've oiled it this way, it's a good idea to run it for awhile in various positions other than the one where it spent most of its life.

Why is my $2 LED clock so much more accurate than the clock in my $2,000 PC?

Computer clocks use a crystal and are not tied to the AC line - after all, they have to keep time even when the computer is unplugged. Cheap digital clocks that plug into the AC line are extremely accurate - better than anything else you are likely to have access to short of the broadcast time signal.

The reason for this is that the power line frequency is referenced to an atomic clock somewhere and its long term accuracy is therefore maintained to great precision. Even the short term frequency stability is very good, changing by at most a small fraction of 1 percent due to variations in electric load affecting generator speed (U.S national power grid - isolated areas with local power generators could see much much wider swings).

These clocks may not keep good time if (1) the power line is very noisy, (2) there is a power outage, or (3) they are broken. Power line noise on the same circuit might confuse some clocks, however. This might happen with light dimmers or universal motors (e.g., vacuum cleaners, electric drills, etc.) on the same circuit.

Replacing batteries in digital watches

About the only type of service you can expect to perform is battery replacement but even this can save a few dollars compared to taking the watch to a jeweler. The typical watch battery will last anywhere from a year (alkaline) to 5 years (lithium). The most likely cause of a watch that has a dead or weak display, or has stopped or is not keeping proper time is a weak or dead battery.

The batteries (actually single cells) used in most modern watches (they used to be called electric watches, remember the Accutron?) are either alkaline or lithium button cells. Some are quite tiny. You will need to open up the watch to identify the type so that a replacement can be obtained.

How you go about doing this will depend on the watch:

1. Screws. If there are visible screws on either the front or rear, then removing these will probably enable the cover to be popped off. These will be teeny tiny star (sort of Philips) head type - use a precision jeweler's screwdriver with a Philips head tip. Immediately put the screws into a pill bottle or film canister - they seem to evaporate on their own.

   Note the orientation of the back: The piezo transducer of the audible alarm may make contact via tiny springs in a specific location. Take care not to lose the springs (or put them in a safe place) if they are not secured inside the watch.

2. Snap off back. This is probably most common. Look for an indentation around the edge. Using a penknife or other similar relatively sharp edged tool in this indentation or at any convenient spot if there is none. It is best to use the wristband mounting rod as a lever fulcrum if possible. The back should pop off. Note the orientation of the back before you set it aside so that you can get it back the same way.

   Same precautions as above.

3. Cover unscrews. The entire back may be mounted in a screw thread around its edge in which case you will have to somehow grab the entire back and rotate counter clockwise. An adjustable wrench with some tape to protect the finish on the watch may work.

If there is an O-ring seal (like on the space shuttle), be careful not to nick or otherwise damage it (you know what happens when these are damaged!).

Once the back is off, you will see a lot of precision stuff - though not nearly as much as in an old fashioned mechanical watch. DON'T TOUCH! You are interested in only one thing - the battery. Sometimes, once the back is off, the button cell will simply drop out as there is no other fastener. In other cases, one or two more teeny tiny screws will hold it in places. Carefully remove these and the button cell. Replace the screws so you will not loose them. Make a note of the orientation of the button cell - it is almost always smooth side out but perhaps not in every case.

Test the battery with a multimeter. The voltage of a fresh battery will be about 1.5 V for an alkaline cell and as high as 3 V for a lithium cell. A watch will typically still work with a battery that has gone down to as little as half its rated voltage.

Replacement batteries can be obtained from Radio Shack, some supermarkets, large drug outlets, electronic distributors, or mail order parts suppliers. Most likely, you will need to cross reference the teeny tiny markings on the old battery - places that sell batteries usually have a replacement guide.

Cost should be about $2.00 for a typical alkaline cell and slightly more for the longer lived lithium variety.

Note: some watches bury the battery inside the works requiring further disassembly. This is usually straightforward but will require additional steps and some added risk of totally screwing it up.

Install and secure the replacement battery and immediately confirm that the display is alive or the second hand is moving. If it is not, double check polarity. Sometimes, the back will need to be in place for proper contact to be made.

Replace the contact springs for the piezo beeper (if present). Where the back can be secured in more than one orientation, make sure it is the same as it was originally. If not, the audible alarm may not work as noted above. There is usually an obvious correct orientation based on labeling or some other means.

Repairing a watch electromagnet coil?

This is somewhat unlikely unless you touch or breath on the coil while changing the battery (almost - the wire is VERY thin) but I couldn't resist including it!

> "I have a 70's sonic oscillator watch (Omega 720) that has a bad magnet coil. The leads from the coil are apparently severed from the board. Is there anyone out there that could possibly repair it? (I don't know of any available spare parts."

(From: Jack Schidt (jack@wintel.net).)

I collect old Accutrons, and have seen this before. If you genuinely believe the coil itself is OK you can remove the coil, and under a magnifying glass attach a fine strand of wire to the fractured lead near the bobbin.

You can get this wire from an old ferrite loopstick, etc., Try to find the copper foil Litz type WITHOUT fabric inside- fabric burns easily.

Do both leads while you are at it. Prior to soldering, wind the new wire around a pin, to give it a small coil. This prevents breakage from happening again. Likely Omega forgot to do this when they manufactured the watch.

A light touch with a hot iron will remove the insulation on the existing magnet wire. Put a dot of epoxy at the solder joints to prevent more breakage. Tack the new wire to the coil body.

This is delicate surgery. If you cannot get at enough wire to solder, unwind a turn [if the break is on the outside wire]. If the break is on the inside lead- you may be screwed.

Lastly, these things are wound with #40 [sometimes smaller- check with gauge] wire, which is fragile, but obtainable. You can rewind the coil- but this takes time. Count the turns while unwinding.

I do not know of anyone who has a jig to rewind these things. Perhaps a search of the web would turn up something. Have you sent Mike Murray (www.accutronman.com) an e-mail? He may be able to help you. He regularly posts on the alt.horology newsgroup, and those people could help you as well. Perhaps rec.antiques.radio+phono could help. Old radios have IF coils that need to be repaired, and someone there may have a jig.

Photographic Equipment

Note: For information on electronic flash operation and problems, refer to Electronic Flash Units and Strobe Lights.

Light meters

First check the batteries (if any). Self powered meters like the old Westons and their clones could also cause damage to the delicate meter movement if the light regulating lid was left open in bright light. Bad connections were also common. I have repaired the meter movements on these but it is not much fun. See the sections starting with: Analog Panel Meters for repair information.

Hand held light meters are subject to damage from being dropped.

Problems with internal light meters include bad batteries and corroded battery contacts, dirty or worn potentiometers.

Pocket camera repair

It seems that in the last few years, the amount of circuitry crammed into a compact 35 mm camera has grown exponentially. Auto-film-advance, auto- exposure, auto-film speed detection and loading, auto focus, auto-flash selection, auto-red-eye reduction - just about everything that could be put under computer control has been. Next thing you know, the photographer will be replaced with a auto-robot!

For the most part, modern cameras are very reliable. However, when something goes wrong, it is virtually impossible to attempt repair for two reasons:

1. The circuitry is so crammed into a tiny case that access is difficult and convoluted. Many connections are made with relatively fragile flexible printed cables and getting at certain parts means removing a whole bunch of other stuff.

2. Much of the circuitry is surface mount and many custom parts are used. Schematics are nearly impossible to obtain and with all the computer control, probably not that useful in any case. Most parts are not available except from the manufacturer and then possibly only to authorized service centers.

However, some problems can be addressed without resorting to the camera repair shop or dumpster.

If the camera is still under warranty, don't even think about attempting any kind of repair unless it is just a bad battery. Almost certainly, evidence of your efforts will be all too visible - mangled miniature screw heads and damaged plastic seams - at the very least. There are no easy repair solutions. Let the professionals deal with it.

If out of warranty and/or you don't care about it and/or you want an excuse to buy a new camera, then you may be able to fix certain (very limited) types of problems.

Getting inside a pocket camera

For anything beyond the battery, you will need to get inside. However, before you expend a lot of effort on a hopeless cause consider that unless you see something obvious - a broken connection, bent or dirty switch contact, or a motor or other mechanical part that is stuck, binding, or in need of cleaning and lubrication - there is not a lot you will likely be able to do. One exception is with respect to the electronic flash which is usually relatively self contained and simple enough to be successfully repaired without a schematic.

As with other consumer electronic equipment, getting inside may be a challenge worthy of Sherlock Holmes. In addition to many obvious very tiny screws around the periphery, there may be hidden screws inside the battery compartment and under the hand grip (carefully peel it back if that area is the last holdout). Also see the section: Getting inside consumer electronic equipment.

This is the time to make careful notes and put all the tiny parts in storage containers as soon as they are removed. If you never follow any of these recommendations for other types of equipment, at least do so for pocket cameras!

Caution: the energy storage capacitor for the electronic flash may be located in an unexpected spot way on the other side of the camera. Accidentally touching its terminals when charged will be unpleasant to say the least. Even if the camera is 'off', some designs maintain this capacitor at full charge. In addition, it may retain a painful charge for days - with the battery removed. Once you get the skins off of the camera (if you ever succeed), identify this capacitor - it will be about the size of a AA battery - and put electrical tape over its terminals.

Pocket camera problems

The following malfunctions may sometimes be successfully dealt with without an army of camera repair technicians at your disposal:

Caution: never open the back of a 35 mm camera anywhere there is light of any kind if there is a chance that there is film inside. If the camera is dead, there may be no way of knowing. Doing this even for an instant may ruin all of the film that has been exposed and two (usually) additional pictures. Opening the back of any other kind of roll film camera will only expose a few frames as the exposed film usually has a backing (120) or is inside a cartridge (110).

If a 35 mm camera failed with a roll of film on which you have taken irreplaceable photographs inside, the pictures can still be saved even if the camera never works again. First, wash your hands thoroughly to remove skin oils. Use a closet with a tightly fitting door (at night is better or stuff something in any cracks to block all light - it must be pitch black) for a darkroom. Open the back of the camera and carefully remove the film cassette. Gently pull the exposed film from the takeup spool (on the shutter release side of the camera). It should unwind easily. Avoid touching the film surface itself with your fingers (the edges are ok). Then, turn the plastic shaft sticking out of the film cassette clockwise to wind the exposed film entirely into the cassette.

(For items (2)-(4), you will need to get inside of the camera. See the section below: "Getting inside a pocket camera".)

1. General erratic or sluggish operation, weak display, camera pooped out during film advance or rewind. Most likely cause: the battery died.

Test the battery and/or try a new one. It is possible that the battery simply decided to go flat at an inconvenient time or that a replacement was defective. If possible, check the voltage on the battery while it is in the camera and the affected operations are performed. If the voltage drops substantially, there could be an overload - a motor that is binding or a shorted component. If the camera had been dropped, a mechanical problem is likely.

2. Flash inoperative or excess current drain - runs down batteries. Other functions may or may not work correctly. Most likely cause: a shorted inverter transistor. The electronic flash or strobe is usually a self contained module near the actual flash window but the energy storage capacitor may be mounted elsewhere - like the opposite side of the case. See the warning below - you could be in for a surprise!

3. Mechanical problems with focus, exposure, film advance, or rewind. Likely causes: binding due to damage from being bumped or dropped, bad or erratic motor operation, gummed up lubrication or dirt, or defective driver or control logic. Locate the motor for each function (right, good luck) and confirm that they spin freely and move the appropriate gears, levers, cogs, wheels, or whatever. If there is any significant resistance to movement, attempt to determine if it is simply a lubrication problem or if something is stuck. Test the motors - see the section: Small motors in consumer electronic equipment.

4. Auto-film-loading, film advance, or rewind do not operate at all or do not terminate. Most likely cause: defective motor or mechanical problems, dirty, corroded, or faulty sensor switches or bad controller. If there is no action or something seems to get stuck or sounds like it is struggling, check the battery and motor (see (1) and (3) above). Inspect the various microswitches for broken actuators, bent or deformed contacts, or something stuck in them like a bit of film that broke away from the roll. Dirt may be preventing a key contact closure. Sometimes, improper cable routing during manufacture can interfere with the free movement of a leaf type contact.

5. Exposure too light or too dark. Check the film speed setting and/or clean the contact fingers under the cassette that sense the film (ASA or ISO) speed. Clean the light meter sensor. Check the batteries, Look for evidence of problems with the lens iris and/or shutter mechanism. If the shutter speed can be set manually, see the section: Testing of camera shutter speed.

6. Automatic camera not responding to adjustments. Changing the diaphragm or shutter speed usually moves a variable resistor which is part of the exposure computer. If a single control has an erratic effect or no effect, its variable resistor is likely dirty or broken. If none of the controls behave as expected, there may be a problem in the actual circuitry that computes the exposure. There is little chance that you could repair such a fault. First, replace the batteries. Some of these systems will behave strangely if the batteries are weak.

Unless there is something obvious - the diaphragm control is not engaging the lever of the variable resistor, for example, and you care about the future health of your camera, my recommendation would be to take it in for professional service.

To successfully repair modern sophisticated compact cameras requires that you be really really experienced working on teeny tiny mechanisms, have the proper precision tools (e.g., good quality jeweler's screwdrivers, not just the $2 K-Mart assortment), bright light and a good magnifier, and a great deal of patience and attention to detail.

Testing of camera shutter speed

If you suspect shutter speed problems, there are several easy ways to measure this for your camera. The most accurate require some test equipment but you can get a pretty good idea with little or no equipment beyond a stopwatch (for slow shutter speeds - above 1/2 to 1 second and a TV (for fast shutter speeds - below about 1/60 of a second (NTSC 525/60).

Some of these approaches assume that you have access to the film plane of the camera - this may be tough with many highly automated compact cameras which will be unhappy unless a roll of film is properly loaded with the back door closed.

Note that the behavior of focal plane and leaf (in-the-lens) shutters is significantly different at high shutter speeds and this affects the the interpretation of measurements.

Some simple homemade equipment will enable testing of the intermediate shutter speeds.

1. Testing slow to medium shutter speeds - the use of a stopwatch is self evident for really long times (greater than .5 second or so). However, viewing or photographing the sweep hand of a mechanical stop watch or a homemade motor driven rotating white spot or LED can provide quite accurate results. Accurate timing motors are inexpensive and readily available. Mount a black disk with a single small white spot at its edge on the motor shaft and mark some graduations around its perimeter on a stationary back board. For a high tech look, use an LED instead. Use your creativity.

   Making measurements from the photographic images of the arcs formed by the spot as it rotates while the shutter is open should result in accuracies better than 1 or 2% for shutter speeds comparable to or slower than the rotation frequency of the motor. In other words, shutter speeds down to 1/10th of a second for a 600 rpm (10 rps) motor or down to 1/60th of a second for a 3600 rpm (60 rps) motor.

   At these speeds, focal plane and leaf shutters should result in similar results since the open and close times are small compared to the total exposure time.

2. Testing fast shutter speeds - view a TV (B/W is fine) screen on a piece of ground glass at the focal plane or take a series of snapshots of a TV screen (a well adjusted B/W TV is best as the individual scan lines will be visible).

   Note: If your camera has a focal plane shutter (e.g., 35 mm SLRs), orient the camera so that the shutter curtain travels across - horizontally (rather than up or down).

   If you are photographing the screen, take a few shots at each speed in case the timing of your trigger finger is not quite precise and you cross the vertical blanking period with some of them. This will also allow you to identify and quantify any variations in shutter speed that may be present from shot-to-shot.

   - For a focal plane shutter, you will see a bright diagonal bar. (The angle of the bar can be used to estimate the speed of the shutter curtain's traversal.)

   - For a leaf (in-the-lens) shutter, you will see a bright horizontal bar. but the start and end of the exposure (top and bottom of the bar) will be somewhat fuzzy due to the non-zero time it takes to open and close the shutter leaves. You will have to estimate the locations of the 'full width half maximum' for each speed.

In both cases, there will some additional smearing at the bottom of the bar due to the persistence of the CRT phosphors.

The effective exposure time can then be calculated by multiplying the number of scan lines in the bar at any given horizontal position by 63.5 uS (the NTSC horizontal scan time).

If you cannot resolve individual scan lines, figure that a typical over- scanned (NTSC) TV screen has 420-440 visible lines. If you can adjust your TV (remember this can be an old B/W set when knobs were knobs!) for underscan, about 488 or so active video lines will be visible.

If you have an oscilloscope or electronic counter/timer, fairly accurate measurements can be made at all shutter speeds using a bright light and a photodetector circuit.

3. Using an electronic counter/timer or oscilloscope. A gated 24 bit counter clocked at 1 MHz would permit (ideally) testing shutter speeds from 1/2000th second to 16 seconds with an accuracy of better than .2 percent. Of course in practice, the finite size of any photodiode and/or the finite open/close time of any shutter will limit this at high shutter speeds. Any resonably well calibrated oscilloscope will be accurate enough for shutter speed determination.

   Construct the IR detector circuit described in the document: Notes on the Troubleshooting and Repair of Hand Held Remote Controls. (Note that the fact that it is called an IR detector is irrelevant since the typical photodiode is sensitive to visible wavelengths of light as well.) Connect its output to the minus gate of your counter or the vertical input of your scope. Put a diffuse light source (i.e., light bulb) close to the lens so that it is not in focus. Position the detector photodiode in the center of the focal plane - mount it on a little piece of cardboard that fits on the film guide rails. Using this setup, it should be a simple matter to measure the shutter timing. Take multiple 'exposures' to identify and quantify any variations in shutter speed that may be present from shot-to-shot.

   - For a focal plane shutter, the time response will be the convolution of the photodetector area and the slit in the shutter curtain. The smaller the aperture of the photodiode, the less this will be a factor. Masking it with black tape may be desirable when testing fast shutter speeds. In simple terms, make the photodiode aperture narrow.

   - For between-the-lens shutters, the finite open and close times of the leaves will show up on the oscilloscope in the rise and fall times of the trace. The measurement on the electronic timer will be affected by its trigger level setting for this reason. However, since this photodetector is not linearly calibrated, the open and close times cannot be accurately determined from the waveform.

Here's an approach that finally represents a good use for your sound card:

(From: Jim Busse (busseja@yahoo.com).)

I thought I'd share a very easy way to measure the speed of a camera shutter using your computer.

1. Go down to your friendly parts store and get a photodiode. It really doesn't matter which one so long as it is small.

2. Put a current limiting resistor in series with the diode (100 to 500 ohms should work fine.

3. Paste the diode on a thin strip of cardboard sized so that the cardboard fits where your film is within the camera. The diode should be placed about in the center as seen from the front of the camera looking through the lens opening. This is not critical but the diode must be placed somewhere the film is exposed to the light when the lens activates.

4. Use thin wires and connect them to your microphone input on your sound card.

5. Close the camera, cock the shutter and point the camera at a light source.

6. If you have Wave Studio (comes with Sound Blaster), start to record the mic input and simply take a picture.

7. Look at the waveform of the picture. You can set the recording to 44 kB/s so you can easily measure 1/1000s, or 1/2000s exposure.

The whole setup costs a couple of dollars and gives you instant information. Of course it is difficult to adjust the exposure time for a camera but you can easily compensate using the exposure f-stop, (slow speed, larger opening, etc.).

Darkroom timers

Developing timers only provide a display or clock face (possibly with an alarm) while enlarging timers include a pair of switched outlets - one for the enlarger and the other for the safe light. These are usually self resetting to permit multiple prints to be made at the same exposure time setting.

Where the device plugged into a controlled outlet does not come on, first make sure these units are operational (i.e., the bulbs of the enlarger and/or safelight are not burned out and that their power switches are in the 'on' position. The problem could also be that one of these devices is defective as well.

Two types of designs are common:

1. Electromechanical - using an AC timing motor and gear train with cam operated switches controlling the output circuits directly or via relays.

   If the hands fail to move or it does not reset properly, the timing motor or other mechanical parts may require cleaning and lubrication. The motor may be inoperative due to open or shorted windings. See the section: Small motors in consumer electronic equipment. Where the timer appears to work but the controlled outlets (e.g., enlarger and safe light) do not go on oroff, check for a loose cam or bent linkages and dirty or worn switch or relay contacts. If the dial fails to reset after the cycle completes, it may be binding or require cleaning and lubrication or a spring may have come loose or broken.

2. Electronic - digital countdown circuits and logic controlling mechanical or solid state relays or triacs.

   Where the unit appears dead, test as with AC line powered digital clocks (see the section: AC powered digital clock problems). If the buttons have the proper effect and the digits count properly but the external circuits are not switching, then test for problems in the power control circuits. If the unit is erratic or does not properly count or reset, there could be power supply or logic problems.

Weird exposure meter problem of the year

Here is one for the photo album:

> "Ever since I bought the Mamiya 645 Pro 2 months ago, I've had exposure problems. I usually bring any new eqpt up to Twin Peaks (in SF) to test for lens sharpness, and overall function. Well my first shots from there were 2 stops overexposed, and the meter was reading wrong, so I returned the camera for repair, assuming it was broken out of the box. Mamiya went over it with a fine tooth comb, and could find nothing wrong with it. I got it back on Monday, and went up to Twin Peaks again. Same problem as before! The meter read 2 stops over! I cursed the techies at Mamiya, I cursed the product, I cursed MF, and then I decided to get scientific about it. So I took the camera off the tripod, and pointed it around at various things: all normal readings.
>
> I pointed the camera back at the scene I had just metered on the tripod...normal reading. I remounted the camera on the tripod ... 2 stops over. I removed the camera ... normal reading. I remounted the camera ... 2 stops over. Unbelievable. So that's when I started thinking about the RF and TV signals being transmitted from the big tower there, and how the tripod might act as an antenna, and cause a small current to enter through the ground socket and perhaps change the ground reference voltage. But it's a carbon fiber tripod! Still, I was on a quest.
>
> So I borrowed another 645 Pro from the store, and I took my 3 tripods up the hill. They were the Gitzo 1228, a Slik U212, and a Tiltall. All 3 tripods and both cameras exhibited this phenomenon, but to varying degrees. The Gitzo was off the most, anywhere from 1-3 stops. The other 2 did not affect the meter as much, at the most 1-2 stops. Funny thing is, the cameras did not even have to *touch* the tripod to have their readings affected! As I moved the camera closer, the meter would start overexposing by up to a stop, then jump even more once mounted.
>
> As a control, I then went halfway down the hill, and repeated the test. The effect was less, with the Gitzo giving 1-2 stops. I then went downtown, and tested again. No difference between on/off camera. I tested again when I got home. Again, no difference."

What you have described could indeed be due to RF interference. Metal and carbon fiber are both conductors so the construction of the tripods may not make that much difference.

How is it happening? This is anyone's guess but enough of a current could be induced in the sensitive electronic circuitry to throw off the meter. The ICs are full of diode junctions which can be rectifying (detecting) the relatively weak RF signal resulting in a DC offset. If this were the case and you happened to adjust the tripod height to be around 1/4 wavelength of one of the transmitters you *would* know it! :-)

Common problems with Kodak slide projectors

For service manuals and parts lists of newer/current model projectors, believe it or not, Kodak actually has a Web page at [Kodak: Slide Projectors Family Service Manuals](). (Though I don't know if they sell repair parts.) One source for some of the more common replacement parts in Kodak Equipment is [Micro-Tools (Kodak Parts)]().

(From: Olen Burkholder (burkhood@jmu.edu).)

I have worked on lots of these. Here is the likely problem.

If the advance/rev buttons do not work on either the remote or the projector but the select button cycles the mechanism, the probable cause is the nylon link is broken on the change solenoid plunger. If the mechanism doesn't cycle when pressing the select button, I expect the mechanism drive belt is broken. It is separate from the fan belt. The way to tell is to look and see if the main worm gear at the motor end of the mechanism is turning when the motor is running. If it is not, the belt is the culprit.

A note of caution. If you elect to disassemble the projector, Wrap the heat filter in a cloth. (The flat green lens in front of the lamp). If it is bare and laid on a flat surface, it can shatter spontaneously from internal thermal stresses. I know, I lost some this way. Also, Do not run the projector with the lamp burning and the case bottom removed. If you do, the thermal fuse will open within a minute or two and you will need to replace it as well (not an easy task and don't leave it out!). Also see the document: [Notes on the Troubleshooting and Repair of AC Adapters, Power Supplies, and Battery Packs]().

If you have never disassembled one of these, you might want to consider whether a 20 year old projector is worth the trouble. These things can be a real bear to work on without previous experience with this design.

(From: Johntneal (johntneal@aol.com).)

One source for plastic gears and parts for Kodak Carousel projectors is:

- [Fargo Enterprises, Inc.](), Vacaville, CA 95696.

Fil's notes on Kodak Carousel repair

In response to:

> "My IIIe slide projector does not advance the tray. When I push the switch the movement works, and I see the actuators moving (tray removed) but the tray doesn't advance. I just got this projector am I using it the wrong way or is it broken? Can someone tell me how to fix the advance mechanism."

(From: Filip "I'll buy a vowel" Gieszczykiewicz (filipg@repairfaq.org).)

I would try another tray first. Then, make sure you have aligned the tray and give it another try. Try both directions. Also, put a slide all by itself into the slot and see if the mechanism works from there.

I have fixed a few of the "Carousel custom 7xx/8xx[H]" series and they were most DEFINITELY *NOT* fun to work on. I would clean and lubricate first. Then, observe a *working* projector to see what moves where when. Timing is just about everything. At least in the 7/8xx series, there were broken plastic parts. Also, the AF gears break. I have yet to find a source for those.

Still, I get a feeling of accomplishment getting working an AF projector after paying $7.95 at a thrift store :-) They're worth just a *bit* more. :)

Screws hold the bottom of the case. Take them out and you should be able to lift the cover. Some of them have one slotted screw to change bulbs which also takes bottom off. Some have further assemblies that brace each-other - to take one out you have to take apart 1/2 of the projector. ARGH!

Avoid taking it apart. If you're not familiar and don't have similar models you can study, you'll most likely end up "screwed". I got lucky. The following week found another 800H in the store for $12.95. Bad bulb socket. Clean the optics in the AF versions! >

Slide projector autofocus

These systems are considerably simpler than their counterparts for cameras due to the very constrained nature of the problem. In fact, as far as I know, few if any actually do any more than attempting to maintain the lens at a constant distance from the surface of the film in the slide.

One way is to reflect a spot of light off the slide and adjust the lens so a photodetector coupled to the lens motion has that spot centered. It is really open-loop with respect to the actual focus of the lens - just maintains the position of the lens relative to the surface of the slide constant. In other words, it will maintain the wrong focus just as accurately if you don't set it properly to begin with!

On the projectors I have seen, slides covered with glass may not work properly since there is a strong reflection from the glass itself. They assume all your slides will be of the same construction. The idea is that the film itself may bow out or in and that is what it cares about. The older ones, at least, were far from perfect.

Where an autofocus slide projector doesn't autofocus, due to their simplicity, it should be possible to identify the faulty component. However, getting a replacement part for a 20 year old projector may be another matter. With non-use (how often do people use their slide projectors anymore?), gummed up lubrication in the motor that moves the lens or its drive train may be the most likely problem! However, there can always be bad connections and bad capacitors, photodetector, or something else. Of course, if an incandescent lamp is used to project the spot, it may just be burnt out!

If you were to implement an autofocus system today, there would be many options including maximizing edge or even film grain sharpness with a little scanner inside the projector! The displaced spot type systems were very simple and cheap using only a few components and no fancy processors.

Motors and Relays

Small motors in consumer electronic equipment

A variety of motor types are found in audio and other electronic equipment. For the additional information on the specific types of motors used in VCRs and CD players, see the documents: "Notes on the Troubleshooting and Repair of Video Cassette Recorders" and "Notes on the Troubleshooting and Repair of Compact Disc Players and CDROM Drives".

Types of motors:

1. Small brush-type permanent magnet (PM) DC motors similar to those found in battery operated appliances. Such motors are used in cassette decks and boomboxes, answering machines, motorized toys, CD players and CDROM drives, and VCRs. Where speed is critical, these may include an internal mechanical governor or electronic regulator. In some cases there will be an auxiliary tachometer winding for speed control feedback.

   These are usually quite reliable but can develop shorted or open windings, a dirty commutator, gummed up lubrication, or dry or worn bearings. Replacement is best but mechanical repair (lubrication, cleaning) is sometimes possible.

   Also see the section: General tape speed problems - slow, fast, or dead.

   Additional info on these types of motors can be found in "Notes on the Troubleshooting and Repair of Compact Disc Players and CDROM Drives".

2. A low profile or 'pancake' brushless DC motor may provide power for a in some Walkman type tape players, direct drive capstans and general power in VCRs or tape decks. Since these are electronically controlled, any non-mechanical failures are difficult to diagnose. In some cases, electronic component malfunction can be identified and remedied.

3. AC induction motors - shaded pole or synchronous type used in inexpensive turntables. These motors are extremely reliable and are easy to disassemble, clean, and lubricate. Just do not lose any of the spacer washers on each end of the shaft and make notes to assure proper reassembly.

4. Miniature synchronous motors used in mechanical clock drives as found in older clock radios or electric clocks powered from the AC line, appliance controllers, and refrigerator defrost timers. These assemblies include a gear train either sealed inside the motor or external to it. If the motor does not start up, it is probably due to dried gummed up lubrication. Getting inside can be a joy but it is usually possible to pop the cover and get at the rotor shaft (which is usually where the lubrication is needed). However, the tiny pinion gear may need to be removed to get at both ends of the rotor shaft and bearings.

Motor noise in audio equipment

Of course you expect your audio equipment to be absolutely silent unless told to perform. Motor noise should not be objectionable. However, what if it is? There are several kinds of noise: rotating noise, vibration, and electrical interference:

If the noise is related to the rotating motor shaft, try lubricating the motor (or other suspect) bearings - a single drop of electric motor oil, sewing machine oil, or other light oil (NOT WD40 - it is not a suitable lubricant), to the bearings (at each end for the motor). This may help at least as a temporary fix. In some cases, using a slightly heavier oil will help with a worn bearing. See the section: Lubrication of electronic equipment.

For AC motors and transformers, steel laminations or the motor's mounting may be loose resulting in a buzz or hum. Tightening a screw or two may quiet it down. Painting the laminations with varnish suitable for electrical equipment may be needed in extreme cases. Sometimes, the noise may actually be a result of a nearby metal shield or other chassis hardware that is being vibrated by the motor's magnetic field. A strategically placed shim or piece of masking tape may work wonders.

If the noise - a buzz or whine - is actually coming from the audio output but only occurs with the motor running, the interference filter on the motor power supply may have failed. This is often just a capacitor across the motor terminals and it may be defective or there may be a bad connection.

Finding a replacement motor

In many cases, motors are fairly standardized and you may be able to find a generic replacement much more cheaply than the original manufacturer's part. However, the replacement must match the following:

1. Mechanical - you must be able to mount it. In most cases, this really does mean an exact drop-in. Sometimes, a slightly longer shaft or mounting hole out of place can be tolerated. The pulley or other drive bushing, if any, must be able to be mounted on the new motor's shaft. If this is a press fit on the old motor, take extreme care so as not to damage this part when removing it (even if this means destroying the old motor in the process - it is garbage anyway).

2. Electrical - the voltage and current ratings must be similar.

3. Rotation direction - with conventional DC motors, this may be reversible by changing polarity of the voltage source. With AC motors, turning the stator around with respect to the rotor will reverse rotation direction. However, some motors have a fixed direction of rotation which cannot be altered.

4. Speed - for tape players and turntables - this may not be feedback controlled. With a little care you should be able to determine the normal rpms of the motor. For example, with a cassette deck, knowing the tape speed (1-7/8" inches per second is standard), it is straightforward calculate the motor shaft speed based on simple measurements of pulley and capstan diameter ratios.

MCM Electronics, Dalbani, and Premium Parts stock a variety of generic replacement motors for tape decks, Walkmen, boomboxes, and CD players.

Relay basics

The ubiquitous electromechanical relay is a device that is used in a large variety of applications to switch power as well as signals in electrical and electronic equipment. Operation is quite simple: An electromagnet powered by an AC or DC coil pulls on an armature having a set of moving contacts which make or break a connection with a set of stationary contacts.

Most common relays can be characterized by three sets of parameters:

1. Coil - voltage; resistance, current, or power consumption; and whether it is AC or DC. For AC coils only, the VA (volt-amps) rating may be used instead of or in addition to power consumption due to the inductive coil. Typical coil voltages range from 5 V to 480 V (AC or DC) - and beyond. Current and power consumption depend on the size of the relay.

2. Contact configuration - number of sets of contacts and whether they are their type. The designation will be something like SPST-NO, DPDT, 4PST-NC, 6PDT, etc. The first two letters refers to the number of sets of simultaneously activated contacts (S=1, D=2, numbers are usually used for more than 2 sets of contacts). The second two letters refers to the contact configuration (ST=NO or NC but no common terminal, DT will have a common - there will be both an NO and NC terminal). Where contacts are ST, the last two letters indicate NO or NC. An almost unlimited number of variations are possible. Typical relays have anywhere from 1 to 6 or more separate sets of ST or DT contacts or a mixture of the two.

3. Contact ratings - this may be specified for a number of types of applications. For example: in amperes at a particular voltage for DC resistive loads, or in horsepower at various voltages for AC inductive loads. Like fuse ratings, these are maximum ratings and lower values are almost always acceptable. Small relays may be able to switch only a few hundred mA at 32 V while large industrial contactors can switch 1000s of A at 1000s of V. Even the contactor in your automobile's starter must control hundreds of amps to the starter motor.

The common (C) contacts connect to the normally closed (NC) contacts when the coil is unpowered and to the normally open (NO) contacts when the coil is powered.

Miniature and subminiature relays are used to switch phone line signals in modems, fax machines, and telephone answering machines; audio amplifier speaker protection circuits; multiscan monitor deflection components; and many other places.

Small relays control power in lighting equipment, TVs and other home appliances, automotive systems and accessories, and the like.

Large relays (often called contactors) are used for the control of central air conditioning systems (compressor and blower motors), all types and sizes of industrial machinery - as well as in the starter of your automobile.

Relay identification

A relay without a pin connection diagram can usually be identified with a multimeter and variable power supply - or by eye. Many have the critical information printed on the cover. However, for detailed specifications, referring to the manufacturer's databook (or WEB page) really is best!

(The following assumes a subminiature (DIP) relay. Lower coil resistances, higher coil voltages, and other variations may exist for larger relays.)

1. If the case of the relay is transparent or you can pop the top, examine the pole piece of the electromagnet. If there is a (copper) ring around half the pole piece, the relay coil is designed for AC (usually line frequency - 50 or 60 Hz) operation. An AC relay operated on DC will overheat very quickly but can be tested on DC.

2. Determine the coil pins. Use your eyeball if possible or your multimeter on the low resistance scale. For a small relay, the coil will most likely be a few hundred ohms. All other combinations of pins will be zero or infinity. If the resistance is under, say, 100 ohms, you may have an AC coil rather than a DC coil.

3. Power the relay from a variable DC supply (I am assuming it has a DC coil which is likely for a DIP relay. You can still do this with an AC coil but it will heat up quickly). Start at zero and increase the voltage until you hear the contacts close. This will probably be at around 3 volts (for a 5 V coil) or 8 volts for a 12 V coil - this will be roughly 60% of nominal coil voltage. If you do not hear anything, reverse the polarity of the coil and try again - you may have a latching relay. Alternatively, put your multimeter on the resistance scale across one of the pairs of pins that measured zero ohms as it is likely to be a NC set of contacts. This will change to infinity ohms when the relay switches.

4. Now that you can switch the relay on and off, you can use your multimeter on the resistance scale to determine which contacts are normally open (NO) and which contacts are normally closed (NC). (Normally here means unpowered.)

5. The power rating of the contacts can be estimated by their diameter (if they are visible). Rough current estimates (resistive loads): 20 A - 5 mm, 10 A - 3 mm, 5 A - 2 mm, 1 A - 1 mm. These must be derated substantially for inductive loads.

For latching relays, the polarity of the coil voltage determines whether the relay is switched on or off. In other words, to switch to the opposite state requires the polarity of the voltage to the coil to be reversed. Other types are possible but not very common.

Relay testing and repair

If the relay is totally inoperative, test for voltage to the coil. If the voltage is correct, the relay may have an open coil. If the voltage is low or zero, the coil may be shorted or the driving circuit may be defective. If the relay makes a normal switching sound but does not correctly control its output connections, the contacts may be corroded, dirty, worn, welded closed, binding, or there may be other mechanical problems.

Remove the relay from the circuit (if possible) and measure the coil resistance. Compare your reading with the marked or specified value and/or compare with a known working relay of the same type. An open coil is obviously defective but sometimes the break is right at the terminal connections and can be repaired easily. If you can gain access by removing the cover, a visual examination will confirm this. If the resistance is too low, some of the windings are probably shorted. This will result in overheating as well as no or erratic operation. Replacement will be required.

Relay contacts start out bright and shiny. As they are used, arcing, dirt, and wear take their toll. A sealed relay used at well below its rated current with a resistive load may work reliably for millions of cycles. However, this will be significantly reduced when switching high currents - especially with inductive loads which results in contact arcing. One speck of dirt can prevent a contact from closing so cleanliness is important. Excessive arcing can result in the contacts getting welded together as well.

The resistance of closed contacts on a relay that is in good condition should be very low - probably below the measurable limits on a typical multimeter - a few milliohms. If you measure significant or erratic resistance for the closed contacts as the relay is switched or if very gentle tapping results in erratic resistance changes, the contacts are probably dirty, corroded, or worn. If you can get at the contacts, the use of contact cleaner first and a piece of paper pulled back and forth through the closed contacts may help. Superfine sandpaper may be used as a last resort but this is only a short term fix. The relay will most likely need to be replaced if the contacts are switching any substantial power.

Electromechanical Systems

This chapter deals with some of the specific issues relating to the types of electromechanical systems found in items ranging from high-tech toys like the Furby(tm) - the craze a year or so ago, (see Furby Autopsy for a most interesting look into how much can be done with a little bit of technology) to more traditional low cost robots. While similar in principle, the details of high quality industrial robots are quite different are beyond the scope of this document.

Electromechanical systems require a broad range of skills to troubleshoot because of the interaction of the software, electronics, and mechanics. While some problems like damaged mechanical parts after a mobile robot went down a flight of stairs will be obvious, others like the lack of response of a sensor could be due to many causes and a systematic approach must be taken to rule out each potential cause.

An electromechanical system consists of: motors and actuators, sensors, mechanical components (linkages, gears, belts and pulleys, etc), controller (microprocessor, program, and data memory, and its interfaces), power drivers, and power supplies - and software or firmware.

Motors and actuators

Two types of motors are commonly used in small robots: DC permanent magnet (PM) motors and stepper motors:

- Small PM motors are similar to high quality servo motors in how they work but are built as cheaply as possible. Direction of rotation and torque/speed are determined by the polarity and magnitude of the average voltage applied to them. Rotation is continuous (unlike stepper motors, see below). Speed can be quite high - 10s of thousands of rpm (revolutions per minute). Position feedback is needed where a system needs to move to a particular spot.

  They are found in all sorts of consumer electronic equipment, toys, and hand power tools. They are fairly reliable if run well within their ratings.

Problems with PM motors include:

  - Dirt or 'gunk' collecting on the commutator causing erratic operation or partially shorting the motor. Test with a multimeter.
  - Wear of the brushes if they are made of metal. This will result in erratic operation or a totally open motor.

  For typical toys and small robots, motor failures are probably less common than for motors used in applications like VCRs which may run for hours continuously.

- Stepper motors rotate in discrete steps as determined by the application of a multiphase waveform to their sets of field coils. They will hold their position with power removed (though with less torque then when power is on). Since movement is in discrete increments, except for an initial 'home' position reference, no feedback is required since movement to any position can be programmed by a known number of steps (assuming the rest of the mechanism has no slip). Common electronic equipment like printers and diskette drives used stepper motors as well.

  Problems with stepper motors include:

  - Open or shorted windings - check with a multimeter. However, a few shorted turns may not show up but result in overheating or speed problems.
  - Dry or worn bearing - shaft should rotate without binding though magnetic detents will be felt.
  - Demagnetized rotor - this may happen if the motor is disassembled or if it is driven with a much higher input than expected. Compare with a known good sample of the same motor. Weak or no evidence of detents compared to an identical good unit is one sign of this.

  CAUTION: Disassembling a stepper motor may result in demagnetization of the rotor when it is removed from the stator assembly. This is for all intents and purposes, irreversible at home. Low cost PM motors are generally not prone to this but some high quality servo motors may be rendered useless from disassembly.

- Solenoids are used where only 2 positions of some mechanism are needed as with a robot gripper. While motors require lubrication, many solenoids do not.

  Problems with solenoids include:

  - pen or shorted coil.
  - Dirt, damage, or gummed up grease from improper lubrication causing binding.

Sensors

Anything that detects some physical condition can be classified as a sensor. These include:

- Proximity and distance. These may be based on physical, optical, or sonic effects. A simple probe activating a microswitch will detect contact with a wall or obstruction. Optical proximity sensors send a beam out (typically from an IR LED) and detect any return reflections with a photodiode or phototransistor. Optical triangulation (which is used in many camcorders) and the Polaroid sonar module (used on their cameras for focusing) and sold separately can measure distance to 10s of feet with moderate accuracy.

  Problems can range from a crunched microswitch, dirt on an optical lens, electronic, interface, and buggy software.

- Angle. The most common type are probably variable resistors (pots or rheostats) for inexpensive devices like toys. Optical encoders or electromagnetic types are often used on higher quality equipment. Most computer mice (ironically, not the ones called optical mice!) use optical encoders.

  Problems include defective LEDs or photodiodes in the encoder (optical types) or bad coils or drivers (electromagnetic type).

- Speed. For the rotation of a motor or wheel, optical encoders are common with the actual speed calculated by software. A very simple 1 pulse per revolution may be sufficient for some purposes but more commonly, the A and B (quadrature) outputs of an optical encoder are interpreted to provide both angular position and speed.

- 1, 2, and 3-D imagers. These typically use CCD or CMOS camera with software to analyze the resulting data. A single line CCD array is sufficient for 1-D detecting contours or slowly scanning a scene to acquire a 2-D image. A pair of cameras can be used to acquire a 3-D information in the form of a stereo pair. Or, a laser line scanner in conjunction with a single camera to acquire 3-D information directly.

  Problems with any of these devices can range from a bad sensor (e.g., dead pixels, complete lines or, worse), control electronics, interface, or software problems.

Detailed testing is beyond the scope of this article but the basic procedure should be to attempt to localize the fault to the sensor, interface, or elsewhere by substitution if possible since that is easiest, or measurements of the sensor inputs and outputs. For example, for an optical encoder, check that power input is correct and then look at the A and B outputs to determine if they are good solid logic levels (where appropriate) as the shaft or wheel is rotated slowly by hand. Note that in many cases, problems with erratic counts from an optical or mechanical sensor producing A/B quadrature outputs is due to incorrect software or logic - there are many ways to get it correct enough to work under continuous rotation in one direction or the other but it takes more effort (a state machine approach) to work under conditions where the shaft is jiggling back and forth.

Testing of camera type devices can be much more complex requiring details documentation on the sensor and its electronics, a scope or logic analyzer, and a certain amount of luck!

Controllers

The intelligence in these systems is generally provided by a some form of programmable device. The simplest may use PICs - Programmable Interface Controllers - single chip micros with built in memory and interfaces.

More capable systems may use a higher performance microprocessor or multiple processors in a distributed architecture. There is no way to cover these in this article except to emphasize the importance of recognizing that the software/firmware bugs can manifest themselves in very peculiar ways. Also, note that motors and other electromechanical actuators result in an electrically noisy environment which is shared by the controller. Unless this is taken into consideration in the design of the system, problems like random lockups or reboots or just plain unreliable operation are almost assured. More below.

Power supplies

Almost all of the toys and small robot type devices are (or can be) powered by some form of batteries, possibly with DC-DC converters to generate multiple voltages from a single battery pack. Weak, dead, or improperly selected batteries must be near the top of the list of common problems with these and other portable systems.

Mechanics

Robots almost by definition include movement. Bearings and sliding parts can become worn, gummed up, or damaged. Rule number one has to be: Never force anything. If rotation of a shaft doesn't result in the expected movement, determine why. Perhaps you're turning it in the wrong direction and it's already at one end of its travel. Or, maybe something has jammed between gears.

Realize, however, that with many inexpensive devices like toys, everything is constructed as cheaply as possible - repair may simply not be possible if some key component has broken.

Fortunately, if properly lubricated when constructed and operated in clean environments, additional attention may never be needed. However, water, dust, dirt, and sand can require the need for frequent cleaning and lubrication. Rule number two is: "NEVER use WD40 as a lubricant!

- Sealed ball bearings should be replaced if they become excessively noisy or rough when rotated by hand. Disassembly, cleaning, and repacking may be possible but irreversible damage to the bearing surfaces (races) may already have occurred.

- Sleeve bearings (bushings) in motors may be lubricated for life or may need a periodic application of a couple of drops of light machine or electric motor oil. If dry or dirty, complete disassembly, cleaning, lubrication, and reassembly is advised if possible. Where excessively worn, replacement is the only option.

- Slow speed rotating and sliding parts should be lubricated with a light grease. If dry or tight, disassemble to permit the old gummed up grease and dirt.

Obviously, inspect for damage such as bent shafts or linkages, missing screws or cotter pins, etc.

Troubleshooting approach

Where a commercial product suddenly refuses to cooperate, mechanical or electrical problems are most likely. However, if you are attempting to troubleshoot a system you have built - and it uses a programmable processor - software/firmware problems must be near the top of the possibilities list, especially if it had worked before. Ask yourself: "What changed?" Has the broken function been tested since the last software change or download?

Some items to check when dealing with robotic systems:

- Test the power supply voltages. The most common problem is likely to be dead or weak batteries! Make sure the voltages hold up under load. Many types of motors draw a high current when starting and it decreases as the speed picks up. Thus, just checking the voltages while at idle isn't a sufficient test. In addition to unreliable movement, a dip in a critical power supply voltage may cause the system to reboot!

- Determine if the controller is booting properly. If you are designing a system, adding some diagnostic LEDs or a diagnostic terminal port will help emmensely. An in circuit software debugging facility is even better.

- Where only certain operations aren't working, attempt to determine what they have in common such as shared power supply voltages, an interface bus, or a block of program code. Power the relevant motors or actuators from an external source (AFTER DISCONNECTING THEM!) and see if the expect motion takes place. And/or activate them manually to assure there is no binding of parts or other mechanical problems.

- If you have spare parts or if parts like similar motors can be swapped, doing so can quickly confirm or rule out possible causes.

- With moving parts, bad connections due to flexing of cables or loosening of solder joints are quite likely. Problems may only appear when something is in a particular range of positions, or be more erratic.

- Erratic problems can also be caused by electrical interference between electromechanical actuators and sensitive logic or analog circuitry. For a commercial system, shields on cables may have become disconnected, cable routing may have changed, and power supplies may be marginal. When building your own robot, use separate power supplies for analog circuitry, digital circuitry, and actuators. Provide adequate bypassing (e.g., 0.1 uF ceramic caps on every chip as well as 22 uF electrolytic caps scattered around each circuit board. Add series L-C filters on next to the actuators. Use twisted pair or shielded cable for low level sensor and similar signals. And, not all commercial products: are designed properly!

- Don't jump to conclusions. With the combination of electronics, mechanics, and software, a trivial fault in one subsystem can result in a change in behavior in unexpected places.

Robotic and other electromechanical systems make great projects. In addition to the appear of seeing something other than electrons move and interact with its environment, the interdisciplinary nature of these devices result in an fun and rewarding educational experience, whether designing a robot from scratch, or repairing a high tech toy like a Furby(tm).

Analog Panel Meters

Problems with Analog Panel Meters

While much new equipment uses digital readouts, there is still a lot of equipment out there with analog meters. And, for some applications, the continuously moving needle of an analog meter is superior to rapidly changing digits.

The actual mechanism of an analog panel meter is most often the "D'Arsonval moving coil meter movement". Meter Movement from Classic Simpson 260 VOM shows the assembly from a very popular series of analog volt-ohm-milliammeters (VOMs) with models dating from the 1950s and still being manufactured today. A closeup with parts labeled can be found in D'Arsonval Meter Movement Anatomy. A coil of fine wire wound on an aluminum or plastic frame is mounted on precision bearings within a strong magnetic field. The needle or pointer is attached to frame along with small balance weights at each 90 degree position. Some type of restoring force keeps the needle at the zero point when no current is applied. There are two common types of bearings: jeweled bearings with hair-springs (fine spiral wire springs similar to those in mechanical clocks and watches if you remember those) and taut-band suspension (the latter becoming more common in high quality movements). In general, if no hair-springs (or their remains) are visible, the unit uses a taut-band suspension.

With a DC current, a torque is produced which rotates the coil, frame, and needle to indicate the measured value. With a uniform magnetic field, the response is close to linear over 90 degrees. DC current is measured directly by passing it through the coil. Low resistance shunts may be used to increase the current range. DC Voltage is measured by putting a current limiting resistance in series with the meter. AC measurements are made by first rectifying the input. Where very low values are to be measured, a precision op-amp rectifier may be used.

More information can be found at: Integrated Publishing's Pemanent Magnet Moving Coil Movement Page.

Typical problems with these devices include:

- Burnt out coil from excessive overload.

  This usually is a terminal condition since disassembling and rewinding the coil is not really a home project. However, for some types, it's not totally impossible if there is no alternative.

- Bent pointer due to modest overload. Up to several times the full scale current, the wire of the coil may not be damaged but the point will whack into the end stop with such force that it may get bent - possibly quite significantly.

  It's usually possible to carefully bend it back in shape. Should the needle break off, a dab of Superglue(tm) may work for reattachment but the movement will need to be rebalanced. Or, replacement with a broom straw or other very thin, light, pointer. Avoid placing any stress on the frame/coil or bearings.

- Movement unbalanced. There are usually little wire coils used as weights at three 90 degree locations around the frame. These are designed to be rotated on their mounting pins to permit the movement to be balanced for all orientations. The "weights" may be gently pushed or pulled to change their position relative to the center of rotation.

Step 1: Set the zero with the meter sitting so the shaft of the movement if precisely vertical (so the weights have no effect). Then orient the meter so the pointer is horizontal with the two side-weights vertical (so they will have no effect) and adjust the bottom weight for zero. Go back and forth to fine tune.

Step 2: Adjust the side weights so changing orientation from horizontal to vertical doesn't change the position of the pointer. If the imbalance was caused by the reattachment or replacement of the needle, it should be sufficient to adjust the two side weights by the same amount as the bottom weight.

There is a more detailed description below.

- Sticky pointer - mechanical. The needle gets stuck at very specific locations as though it's hitting something. This is very often due to dust, dirt, flaking paint or rust, ferrous particles, or other debris that have found their way between the coil/frame and magnet yoke. However, first check that is isn't simply due to a static charge that has been built up on the glass or plastic faceplate from rubbing when cleaning or whatever. (See the next item.)

  It's usually possible to use a fine NON-MAGNETIC "probe" like a piece of nylon fishing line to sweep the area between the coil, magnet, and central core, of 'stuff'. If it's coated to be slightly sticky, total removal of the debris may be possible. But just moving it out of the path of the coil/frame - particularly the ferrous particles since they will stay put - may be enough. Take special care not to bend the hair spring (if used) or put any stress on the frame/coil assembly and bearings. In severe cases, it may be necessary to remove the magnet entirely and clean it separately. However, the most likely outcome of this would be damage to the pointer or hairsprings so it should be avoided if possible.

- Sticky pointer - static buildup. The pointer may get stuck or have trouble moving to certain locations and this may change over time. A static charge has built up on the faceplate either from rubbing or for other unknown reasons like a nuclear bomb going off in the vicinity. :) In most cases, careful cleaning of just the outside with liquid detergent, antistatic spray, or a clothes dryer anti-cling sheet should cure it. Even gently blowing on the faceplate with your breath to fog it may be enough to dissipate the charge. However, in severe cases, the faceplate will have to be removed and treated on the inside in a similar manner.

- Broken bearing pivot or hair spring (jeweled bearing). The tip of the shaft is ground to a very fine point and a severe physical shock cam break off the tip. The meter may still work but will be somewhat sticky.

  Carefully adjusting the bearings to be slightly closer together may help but there is no total solution.

- Bent hair spring. It's unlikely this would happen on its own but might occur during repair.

  These can usually be bent back into reasonable position.

- Broken hair spring. Again, not something likely to happen on its own.

  Careful resoldering may work but it's not easy. Note: Since the current passes through the spring, non-conductive adhesives can't be used.

- Broken taut band between frame/coil and suspension.

  No practical repair is possible.

- Broken taut band suspension.

  It may be possible to reconstruct or replace the piece to which the band is soldered assuming the band itself hasn't broken. More details below.

- Damaged or deteriorated meter scale.

  Some artistic talent may be needed, but these can be restored to at least be legible. Alternatively, a new scale may be hand or computer printed on a sheet of thin paper or plastic and glued on top of the old one. Clearance may need to be adjusted if there isn't enough space between the pointer and original scale.

- Corroded mirror on mirror scale meter.

  The scale can be removed so the mirror itself can be replaced or moved so a good section is exposed. If replacement is needed, a piece of aluminum foil may be adequate for anyone who isn't a real purist.

- Non-functioning backlight.

  These are either tiny incandescent lamps or LEDs. They are usually accessible but some disassembly may be required. But first make sure the driving circuit/power supply is working.

- Broken or cracked faceplate.

  For meters with glass plates, it is usually possible to remove the old glass and replace it with window or picture frame glass. If the original mounting clips or tabs don't work, use some small dabs of Epoxy or other adhesive to hold it in place. Rectangular meters are definitely easier to deal with in this regard than round ones - all that is needed is a good glass cutter (about $2).

  For plastic meters, a replacement is probably best but if there is no choice, it may be possible to "graft" on a new piece of plastic depending on how much is damaged.

When all else fails, replacing the entire meter or just the movement may be the only option. Many types of analog meters are still available new from electronics distributors. Older style and/or discontinued models may be found at surplus places, particularly those catering to amateur radio. Where a suitable meter can be found but it's scale is not appropriate, a new one can be drawn or painted, or created via software. One such program can be found under "Software" at: Jim Tonne's (WB6BLD) Web Site.

It's not impossible to rebuild a meter - just extremely difficult and time consuming. Here's a link to the Web site of someone who must have had way too much time on their hands and completely restored a TV-7 tube tester, meter and all. It's in german but the Altavista Universal Translator can do a good enough job to read it in

English and it's the pictures that really matter anyhow: TV-7 Tube Tester Restoration.

Balancing a Meter Movement

(From: Dave M. (dgmason@att.net).)

Pretty simple thing to do if you have deft fingers and a steady hand. If you have nervous hands, then it's dangerous to the meter for you to attempt it. It helps if you have a balance weight tool that fits the weight springs. This tool looks like a wire-wrap tool and make life much simpler with meter weights. A good, nonmagnetic tweezer with a knurled inner surface is a good alternative. If you resort to using needle nosed pliers, you risk permanent damage to the pivot and jewels. Be extremely gentle with the tool you use. And STAY AWAY from the hairspring. If you kink it or otherwise bend it out of shape, accuracy of the movement will suffer terribly.

OK, the caveats are out of the way.

First thing to do is to open the movement to allow easy access to the weights on the pointer. The typical D'Arsonval movement looks something like this:

```
      |
      |
      |
      |
      |
      |
   ---+---   <-- Side weights
      |
      |    <--  Tail weight
```

Each arm of the pointer, except for the pointer itself, normally has a weight screwed onto it. It will look like a coil of wire wound around the pointer arm. To balance the pointer, you adjust these weights in and out so that the pointer remains in the same place regardless of the position of the meter.

Balancing is done in two planes. First with the pointer vertical and again with the pointer horizontal. With the meter flat on the bench, adjust the meter's zero screw until it is exactly on the scale's zero marking. Next, with the pointer horizontal, adjust the weight on the tail (opposite the pointer) until the pointer remains in exactly the same position as when the meter is flat. Turn the meter so that the pointer is vertical. Twist the weights on the side arms so that the pointer is at exactly the same position as when the meter is flat. Repeat until the pointer remains in the same position regardless of position.

(From: Jim Adney (jadney@vwtype3.org).)

There are balance weights which look like little bent coil springs slipped over "spokes" which radiate out from the pivot point. These springs just have to be slipped in or out to change the balance. If, for example, the needle was shortened, you need to take the spring/weight that is 180 deg from the needle and either push it closer to center, or pull it completely off and shorten it.

You check your work by holding the meter AXIS horizontal and then rotating it about that axis. Examine it when the needle is horizontal and again when it is vertical.

The side-to-side balance is correct when the meter reads the same with the needle pointing straight up or down. The other axis is balanced when the meter reads the same with the needle pointing to either the left or the right.

Once this works, the meter should also read the same as when facing up.

Work carefully, and avoid putting any strain on the actual pivot.

Repairing a Taut Band Suspension

I was forced to attempt this repair after damaging the suspension in a Hastings CVT-16 thermocouple vacuum gauge controller. OK, I really didn't have to do it as replacements for the entire unit could be found relatively inexpensively on eBay but I considered it a challenge. Also, if I bought a replacement for the entire unit, I'd then have yet another set of electronics without a meter! (The meters used in these instruments are special low impedance devices so stock replacements would not work.)

The broken meter looks like the meter portion of TC Vacuum Gauge and Pump Protector. The adjustment knob is used to move the red set-point pointer (which is mechanically and electrically independent of the meter movement itself).

The problem occurred when I obtained a unit (not the one in the photo) that had a broken adjustment knob. In attempting to confirm that the set-point adjustment worked, I foolishly tried using a tool to turn what remained of the shaft behind the knob. Unfortunately, I didn't notice that the suspension for the front taut band is located behind the knob and unprotected. So, it basically got shredded. Can you spell "stupid design"?. :(If the knob's shaft was solid instead of hollow, there would have been no problem.

I normally consider damage to meter movement bearings to be non-repairable but as I said, this was a challenge. :) The first step was to confirm that enough of the band remained to attach to a new suspension. After removing the front cover and set-point mechanism, the extent of the damage could be seen. The suspension was just a formed piece of metal - something springy and the band was still soldered to its twisted remains. A quick touch of a hot soldering iron and the band was free. While it was completely intact, there wasn't much of it - perhaps 1/16 inch sticking up though the "cup" where the suspension was located. And, the band is extremely thin - perhaps 1 mil x 5 mils (1 mil = 0.001 inch).

To replace the suspension, I cut a piece of thin copper sheet into a shape that when folded over would fit in the cup. Thus, there was a top and bottom. An off-center hole was drilled and tapped for an 0-80 screw that would adjust the separation of the two "leaves". A 0.01" hole was drilled in the center of the top for the band to fit through with a larger clearance hole in the bottom. This contraption was filed so it would fit loosely in the cup.

My original plan was to mount an XYZ micropositioner above the meter with a gripper to hold the band to enable adjustment before soldering it to the new suspension. I even fabricated a wonderful little screw clamp to use as a gripper. However, the band tip is so darn short and thin that this proved to be unworkable. So, the folded suspension almost flat was placed in the cup with the band tip poking through its hole. This affair was held down with a piece of wire fastened to a convenient screw (to prevent the surface tension of hot solder from lifting it), and the band was soldered to the suspension. Next, the 0-80 screw was installed and tightened until the meter frame/coil came free, and then some to provide clearance. The suspension was then adjusted in position to center the frame/coil and in angle to set the zero on the scale with the zero lever centered.

This replacement is not as robust as the original since it's not very resilient. Any good whack in the direction toward the back of the meter would probably cause it to fail due to the inertia of the frame/coil but it does seem to work. Also, since the length of the free part of the band and its tension have changed, it is likely that the calibration will be slightly different.

General Equipment

IC and hybrid power audio amplifiers

Note: troubleshooting of large audio amplifiers constructed with discrete output stages is left to a separate document. See: BIG Audio Power Amps.

The audio amplifiers found in small radios, Walkmen, portable cassette recorders, and other low power devices are often single chips with few external components. Obtain a pin diagram, test inputs and output(s) with an audio signal tracer and/or oscilloscope. A dead output where inputs and power are present usually indicate a defective IC - as does one that becomes excessively hot - assuming that the output is not overloaded.

Larger audio amplifiers may use ICs (up to 10 or 20 W) or hybrid modules (up to 100 W per channel and beyond). Purists may argue about the quality of the sound from these compared to discrete component designs but they are being used in many designs - at most price points (except perhaps the stratosphere of audiophile land).

Hybrids modules (called 'blocks' or 'bricks' by some) may be totally self contained requiring just power and line level inputs or may be just the final stage in an overall system including external amplifier circuitry which is effectively a power op amp - high gain with negative feedback. Failure of these bricks is quite common.

Note that testing of these op amp designs - whether discrete or brick based - can be very confusing due to the high gain and feedback. Intermediate signals in a working channel may look like power supply ripple and noise. In a dead channel these same points may appear to be normal or highly distorted audio depending on which stage you test. In addition, since extensive negative feedback is used, power supply ripple and noise is much less important significant and there may be substantial amounts of both in a normally operating amplifier.

One of the bricks may be shorted resulting in a blown fuse or overheating of other components. It is usually safe to unsolder each of the hybrids to determine if the other channel or at least other portions of the unit come back to life and without blowing fuses.

With stereo amplifiers, it is normally safe - and most effective - to swap components between the working and dead channels as long as you are sure there is no short circuit on the output. This is by far the quickest way to confirm a dead brick. (I would be a lot more reluctant to make this recommendation for a large audio amplifier constructed with discrete transistors in the final power stage as multiple cascade failures are possibly and likely if **all** defective parts are not located before power is reapplied.)

Amplifier noise caused by bad hybrid bricks?

There can be all sorts of sources for low level noise or static including bad connections almost anywhere, defective semiconductors, and erratic power amp modules. These are usually hybrid circuits - multiple devices mounted on a common substrate and interconnected via a variety of technologies. Think of them as entire subsystems encased in plastic.

Thus, hybrid bricks may have problems with noise especially considering that they may run hot and be abused by poor tastes in music (or at least high volume levels). Thermal cycling can take its toll on this kind of device. If you have eliminated other likely causes, replacing the brick would be the next step if the module is not that expensive - how much do you value your time and hair? Of course, if there are separate bricks for each channel, one channel is most affected, and the volume control does not affect the level of the noise, the choice is clear - swap. This will be relatively low risk in most cases. A hot air gun used carefully on the final modules might also be a good way of inducing or changing symptoms resulting from marginal connections or components.

Troubleshooting blown audio amps

(From: Andy Cuffe (baltimora@psu.edu).)

If it has IC's for the audio output you can just remove one of them. If the fuse still blows try removing the other one. If the fuse blows with both output ICs out you know there are problems in an other part of the unit, probably the power supply.

If it uses transistors instead of ICs you just need to check them with an ohmmeter. The bad ones almost always measure close to 0 ohms between at least 2 of the three pins. Once you find the bad pair try the stereo with them removed. You should get normal sound from the channel with the good transistors. To determine if there is more damage to the amplifier you can swap the good transistors into the damaged channel. Before you remove anything WRITE DOWN where they go because it's easy to get them mixed up. I strongly recommend that you don't bypass the fuse unless you don't want to fix it very much. I have seen a lot of repairable electronics ruined by this type of troubleshooting.

(From: Dakuhajda (dakuhajda@aol.com).)

Where one channel still works, on old amplifiers we commonly remove output transistors from both channels, place a 5 watt 100 ohm resistor across the base to emitter connection of every output transistor. Then bring the power supply up on a variac and measure all the voltages on each channel. With a working channel it should be a simple matter of making DC measurements to find the area of the problem.

(From: Wild Bill (kwag98@tcis.net).)

A lot of the diagnosis can be accomplished with a DMM. Either the diode check test or the ohmmeter will give you a direction to proceed in. Most of these comments are related to units with through-hole (components with leads) circuit boards.. not to boards which have lots of surface mount components on the foil side.

If you don't possess the skills, equipment and safe working habits required to perform the procedures, take the faulty equipment to someone that does. If you read the rest, you'll discover (and maybe understand) why technicians charge fees for their work.

For almost any bipolar-transistor-output-type amplifier testing, it's a progressive process. A good starting place is checking key components for opens and shorts:

- Bias resistors for open (infinite ohms).

- Transistors for shorts with the diode test.

- Ohms checks for the power transformer, standby transformer windings, and relay coils.

- Diode check for rectifiers, full wave bridge rectifiers and transistors.

- Capacitor testing should also be part of the diagnosis stage, particularly the large caps, but almost any one of them could prevent the amp from working, even partly.

Make notes of defective components, you can offer some help to someone else some day.

Before proceeding to the stage of disassembly, check for circuit board mounting screws that are intended to ground the board to the metal chassis. When these get loose, this can cause a lot of weird symptoms.

It's often necessary to start unsoldering parts since a 0.33 ohm bias resistor with a shorted transistor across it may appear to be normal. In most cases where there is no output, or the protection circuits are preventing the amp from powering up, you'll find several faulty components. Since the unit isn't powering up (or it keeps blowing fuses), you can find faults quicker (in my opinion) by checking key components without power applied. This method is also more economical since parts won't be repeatedly destroyed until eventually all of the faulty ones are replaced at once.

Many manufacturers utilize fusible and/or flameproof small wattage resistors to prevent catastrophic damage, and all of them should be checked. They might be blue, green or tan colored.. and often have values of less than 1 ohm, but when you see this type, check all of them.

When damaged output transistors are discovered, check the driver stage for that output.. it's often damaged too. Some driver stages use linear ICs.. if the pinout is known, compare resistance or diode check tests between all of them.

After a thorough check of key components, and faulty devices have been replaced, remove the line fuse and replace it with a 60 watt lamp.. everyone has a well-insulated lamp with alligator clips on it, right? The lamp will usually prevent destruction of components.

Instead of attaching speakers to the outputs (main or front L & R), use dummy load resistors. high power non-inductive (or no connections at all). The unit should be powered with an isolated variac. 40 VAC will probably be a good place to start making initial voltage measurements. You could also have an ammeter in series with the lamp, but the lamp gives a good visual indication.. brief light output followed by a barely visible glowing filament. If the lamp shows continuous light output (at this low variac setting), there is a major short somewhere near the power transformer. In that case, disconnect everything and resume ohmmeter tests. Check for components which may have gotten warm or hot.

If a dim glow is visible, don't rush to put a fuse in and attach speakers to power it up at full line voltage yet.. but instead, start making AC (transformer outputs) and DC voltage checks (full wave bridge rectifiers, plus and minus and branch circuit supplies). Check the individual supplies DC filtering and check for the presence of AC at all of the amp's outputs with a scope.

If all appears to be normal at reduced line volts, turn the unit off and increase the variac output to 60, make previous checks.. same for 80, 100 then 120. If dummy loads haven't been attached to the output terminals yet, turn the variac back down and repeat the previous procedure.. and check for heat at the dummy loads. With the volume control set low, there should be little heat.

For amps with rear and center channels, check the main channel L and R first, then turn down the variac and attach dummy loads to the other channels as you repeat the previous steps.

This seems like a lot of backing up and rechecking, but it is an economical method of accomplishing a thorough amplifier repair. Before connecting a repaired amp to the original speaker system, check the speakers and wiring.

Audio amplifier that blows one channel's output components

The situation is that after finding and replacing output transistors and other blown parts, the same thing happens again almost immediately or sooner.

(From: Mike Ross (mike.ross@juxta.mnet.pubnix.ten).)

Before you blow up any more parts insert some temporary current limiting resistors (i.e. 330 ohms 10W is okay) in series with each individual output transistor collector lead. If the transistors saturate then there is either a bias idle current or still yet an offset voltage problem.

Blown diodes and resistors in the bias voltage reference circuit could easily cause the outputs to self destruct. One common design problem is seen with the adjustment trimmer pot, in that if the wiper opens then it results in maximum idle current. Of course they should always be designed so that if the wiper opens then the idle current goes to minimum. This could be one cause. Good luck.

If all else fails, hurl it across the room a few times! :)

(From: Dave (gravman@idirect.com).)

Where one channel blows outputs, check the zobel network components. This is a capacitor (usually green mylar with values of .047 to .1 uF) connected in series with a low ohm resistor (2.7 to 8.2 ohm) BETWEEN the speaker line and common ground. I have seen a few amps with the same symptom and the cause was that capacitor blown OPEN! Cranking up the treble full at very high volume levels can cause this to occur. Even a nearby CB or HAM transmitter with lots of watts can inject into your unshielded speaker leads and blow that cap!

When that cap goes open circuit, the amp will oscillate at a high frequency beyond hearing range. I've scoped as high as 80 KHZ!

If those two components are OK, and you have definitely confirmed that all others are OK, leave the output transistors out, install a 100 ohm 5W speaker load resistor and power up the amp with a DC voltmeter in place. You should measure much less than +/- .6 volts DC across that dummy load. If the voltage is more, you've got a improperly installed transistor, bad bias pot, defective front end differential pair transistor(s), leaky/damaged bias diodes, etc. Check, double check, and re-check your components.

If the voltage is within proper range, connect a scope across the dummy load resistor, slowly increase input music or sine-wave. If you see a extremely blurred signal, shut down the amp and search for possible defective small pF value compensation capacitors in other parts of the circuit. You may have to pull each one and check/replace until you find the culprit. You may simply have a leaky/flakey transistor in there somewhere. You may also have a corroded/loose ground connection or bad solder joints too!

Do these tests, and see what you find. ALWAYS CHECK YOUR OWN WORK THREE TIMES BEFORE CURSING!!!

Audio amplifier that seems to have reduced power

(From: Jerry Greenberg (jerryg50@hotmail.com).)

The first step is to verify the voltages in the power supply for both the preamp and output stages.

I would also start by changing the main filter caps in the power supply to start. This is the only true way to test these...

The best way to test for such a problem is to feed an audio generator into the amp and put an 8 ohm dummy load for the speakers. Use a scope and go through it to see what is happening. Set the audio generator to a 40 or 50 Hz tone.

The test for the output stage is to turn up the volume with the scope across the dummy load to start. See and measure the amplitude of the waveform to determine the voltage P-P output. You should see where it is starting to distort the waveform, and back off about 5 to 10%. From that calculate the RMS, and then calculate the actual Power. If it is more than than the rated output of the amp you are overdriving it anyways...

Don't leave high volume tone into the dummy load for more than a few minutes at at time. This is hard on the unit for long periods of time...

Note* I have found many consumer amplifiers can only put out their rated power at 1kHz. Only the high quality ones can do it at all frequencies... At about 50 to 80 Hz most consumer amps will only put out about 50 to 70% of their rated power...

Comments on recurring audio amplifier failures

(From: Mark Kinsler (kinsler@adenine.frognet.net).)

The classic failure of output transistors in audio equipment is the collector-emitter short, which is typically caused by overcurrent, which is typically caused by someone short-circuiting the speaker wires together in an attempt to add or move the speakers, which is typically caused by someone being at a party and drunk.

(From: Tom MacIntyre)

Whenever someone brings an amp in for what looks like blown outputs, we try to talk them into bringing the speaker cables in, so the ends can be tinned properly. No extra charge, and maybe save them a few bucks from a few strands doing the short-circuit thing.

The only way to prevent a recurrence of the problem is to install fast-blow fuses in series with the speaker lines deep inside the receiver where the owner cannot find them.

They'll find them if they want to, but your point is well-taken.

(From: Phillip R. Cline (pcline@iquest.net).)

I used to work on high end audio stuff and when properly designed an amp can take a direct short at full power or any other level the volume may be set. Having said this I must qualify my statement. I did say I worked on high end stuff. This would not include the systems that appear to be a rack or component system but is in fact one big front panel molded to look like a group of individual components stacked on each other. This also doesn't include the vast majority of Japanese mid-fi stuff made and sold since about 1980 to the present. Most of that stuff use DC coupled amps and no speaker protection circuits or they use the infamous STK or SVI series of hybrid amp modules. These tend to be very unreliable and the output stages fail in these on a regular basis. Another problem is that often times there is now where near enough heat sink on the output devices and they overheat and fail. On one JVC amp that would be considered high end the engineers in their infinite wisdom decided to power one half of the bipolar supply going to the preamp op-amps through a panel lamp on the front panel. Guess what happens when the lamp opens up? Catastrophic failure of nearly all the semiconductors occurred when the lamp burnt out. This caused the speaker protection circuit to be effectively disabled and all the main power supply current fried everything including the woofers in the speakers due to a severe offset voltage present due to the lamp failure removing one side of the bipolar supply of the preamp section. Nice work on the engineers part.

When we got an amp with suspicious failure mode we always wanted to see the speakers to make sure that the owner didn't crank the amp up until it was clipping which would in some cases fry the crossover caps as well as the tweeters and mids and in more severe cases the woofers also thus rendering the speaker a very low value resistor which would in turn fry the amp. To prevent this we would sometimes have to increase the crossover caps voltage rating and we might even through a fuse in the speaker cabinet somewhere. That way when the fuse blew the customer had no choice but to tell the reason for the failure after being confronted with the evidence.

This kind of stuff is the primary reason for me leaving the repair business after the fact that most consumer audio and video stuff except TVs are made disposable.

Substituting Darlington transistors in audio amplifiers

(From Daan van der Veer (D.J.C.vanderVeer@stm.tudelft.nl).)

I have good experiences with the use of Darlingtons instead of normal output transistors in audio power amplifiers. The only problem is that you have to readjust the bias current of the bases of the drivers. Furthermore, reduced or increased frequency response is almost always corrected by the amplifier's feedback.

Readjusting the bias current is very simple with a scope and a sine wave generator, but could also be done with a simple voltmeter. And a computer is a very handy tool in diagnosing amps, if you have a soundcard, you can (mis)use it to measure a frequency response of any everyday amp (frequency response of most soundblaster compatible soundcards is 44 kHz). And with a very precisely tuned high quality notch filter you can even measure the THD of any amp, *real-time*. (This is very handy if you want to adjust output transistor bias current, to a minimum of crossover distortion).

Comments on power supply regulation in audio amps

(From: DangerDave (dangerdav@earthlink.net).)

I can't speak for all audio designers, but here are a few things I consider:

1. Differential output stages cancel in-phase sag/ripple

2. Regulation can add noise

3. Regulation adds complexity/reliability problems

4. Regulation adds cost

5. Other things are often more important than regulation to a predetermined voltage - e.g.; sag, ripple, stiffness, Zout. Letting the power supply DC output go as the mains voltage is usually good to within 5% or so, thus absolute regulation to a set-point voltage doesn't buy you much power headroom, and does create the possibility series regulators will overheat if the mains voltage rises. If the output stage is high power, the PS must supply high current, thus the overheating concerns under conditions of high mains voltage.

6. A little more complex argument - distortion products are determined by the order of the transfer functions of the subcircuits. The lower the order of transfer function, the lower the order of distortion artifacts. Under NFB conditions, the situation is more complex, as phase, gain, and bandwidth constraints interact with the PS's transfer function, to create multiplicative artifacts, leading to IM, TIM, and other spectral artifacts. You can easily create "loop within a loop" problems using servo'd voltage regulation. This topic really deserves more discussion. IIRC, Norman Crowhurst originally worked out multiplicative distortion mechanisms graphically in the 1950s and published them in Audio. Since that time TIM and other spectral distortion mechanisms have been further analyzed in AES and IEEE.

   Basically, a simple, low order PS transfer function may create fewer and lower order multiplicative artifacts (less objectionable distortion). The main thing is to keep the PS high in equivalent capacitance and low in Zout - e.g., an "ideal" voltage source. You don't need set-point regulation to accomplish this, and elimination of closed loop feedback voltage regulation usually makes the PS's transfer function lower order.

The simplest way to do this is giant caps in the PS. This is a popular approach among high end audio companies at this time. Some advertise "X uF of Capacitance" or "X Joules of Energy" A better approach is to use the new generation FET's, IGBT's, and other extremely low series resistance pass elements. Referenced to a stable voltage, the equivalent series output resistance of PS's so designed can be < 1 ohm, 20-20kHz, and no need to fill the box with giant (and expensive) caps. Reduces in-rush problems as well, so you don't add complexity/reliability problems with controlled ramp-up circuits, timed power-up schemes, and the host of ancillary circuitry required to keep breakers from triping. :) Equivalent transfer function and parts complexity can both be low, relative to servo'd NFB voltage regulation schemes.

Big topic. Interesting question. Hope I gave you a few insights.

Noisy or intermittent switches and controls

Symptoms include audible noise when rotating knobs, erratic operation of mode selectors, random changes in volume, switches, or controls that need to be jiggled or tapped to make them cooperate.

The causes are likely to be either dirt or wear.

First, try a spray control/contact cleaner - even the stuff from Radio Shack may make a remarkable difference iff (1) dirt is the problem and (2) you can get the cleaner inside the troublesome part.

DO NOT use WD40 or a similar product because aside from the flammability issues their use may result in rapid failure even if you get the immediate gratification often provided by these sprays. See the section: Why NOT to use WD40 on noisy controls.

Some types of contact and control cleaners can be used safely with low voltage circuits while they are powered but not always - read the label directions. Select a product that specifically states that is it safe for switches and controls.

Use the extension tube that comes with the spray can and snake it into or near any visible access holes. Operate the control or switch to help the cleaning action. Don't overdoe it - if you get to the right spot, a little is all that is needed.

Resist the urge to use sandpaper or steelwool (ack!) on switch or connector contacts. However, pulling a piece paper through a set of contacts or the occasional gentle use of a soft pencil eraser (e.g., Pink Pearl) may be helpful.

If this does not help - or only helps short term - the part may be worn. Sometimes, repair is possible (a slide switch with contacts that have loosened with use, for example) but replacement is better - if you can find an exact or suitably close match. See the section: Interchangeability of components.

Note that capacitor type frequency select controls may also be subject to noise as they are rotated. This may also be due to dirt/oxidation between the rotating part and the stationary connector. Some contact cleaner should help. For large variable capacitors with air between the plates, there may also be conductive slivers or dust that has found their way in between the plates - use a brush to remove these. Some plates may also have gotten bent somehow (e.g., if you were doing some other work in the area).

Why NOT to use WD40 on noisy controls

This may not apply to the resistive elements in all/many/most controls but why risk it?:

(From: Richardson (rchvid7@flash.net).)

Here are some facts after seeing the results first hand in an environment where Pro TV editors were using up controls in audio mixers manufactured by Shure Brothers. WD40 when used for the first time resulted in good operation for 5 days. After that time the controls started to deteriorate very quickly and were junk the next week.

The situation was clear after opening up the pots afterward. The carbon material was bonded to itself and to the phenol substrate by some chemical which became soft after being exposed to the hydrocarbon base of the WD40. It soon deteriorated to mush.

The use of LPS 1 did not cause such a dramatic failure of the surfaces but did not provide any improvement that lasted.

In the past we could get good results with Freon cleaning spray, but it is getting harder to get than the replacement controls.

In test pots the only way to get an improvement was to carefully remove residue and relubricate with a lubricant like Radio Shack "Gel Lube" or the latest Sony grease available for broadcast and pro use.

Resuscitating potentiometers

(From: Rene Zuidema (cps_rjz@cistron.nl).)

Often, pots are not really dirty, but the pot wiper just worn out the resistive layer. No amount of cleaning will solve the problem.

Just carefully re-bend the wiper contacts to follow another track alongside the damaged resistive material. If done well, the wiper will now track intact resistive material again. As new!

This specially works for servo's as used in RC cars / planes etc. In these applications the resistive track around the servo neutral position is worn out after some seasons of use.

(From: Paul Weber (webpa@aol.com).)

Disassemble the pot by carefully bending the tabs that hold the cover on (assuming this is a cheap consumer type pot). Inspect the works with a magnifying glass; find the fingers on the rotor that touch the resistor material. Using a needle or dental pick carefully bend the fingers out of the furrow they've worn in the resistor material. Objective is to make contact with an unworn area on the resistor material. Clean the whole thing with spray cleaner and re-assemble.

Overall resistance may be slightly changed due to the lost resistance material, but this is usually not a problem in consumer applications. Good luck!

General intermittent or erratic behavior

Any intermittent problems that cause random sudden changes in performance are likely due to bad connections, internal connectors that need to be cleaned and reseated, or dirty switches and controls. First, see the section: Noisy or intermittent switches and controls.

Bad solder joints are very common in consumer electronic equipment due both to poor quality manufacturing where cost reduction may be the most important consideration. In addition solder connections deteriorate after numerous thermal cycles, vibration, and physical abuse. Circuit board connections to large hot parts or parts that may have mechanical stress applied to them are most likely be suffer from hairline solder fractures (often called 'cold solder joints' when they result from poor quality soldering at the time of manufacture). However, since the solder is often the only thing anchoring these components, mechanical stress can eventually crack the solder bond as well.

To locate cold solder joints, use a strong light and magnifier and examine the pins of large components and components that are subject to physical stress (like headphone jacks and power connectors) for hairline cracks in the solder around the pin. Gently wiggle the component if possible (with the power off). Any detectable movement at the joint indicates a problem. A just perceptible hairline crack around the pin is also an indication of a defective solder connection. With the power on, gently prod the circuit board and suspect components with an insulated tool to see if the problem can be effected.

When in doubt, resolder any suspicious connections. Some device may use double sided circuit boards which do not have plated through holes. In these cases, solder both top and bottom to be sure that the connections are solid. Use a large enough soldering iron to assure that your solder connection is solid. Put a bit of new solder with flux on every connection you touch up even if there was plenty of solder there before.

In addition to soldering problems, check for loose or corroded screw type ground (or other) terminals, and internal connectors that need to be cleaned and reseated.

Need to turn up volume to get sound to come on

If at times, it is necessary to turn the volume way up or possibly to tap or whack the unit to get the sound in one or both channels to come on when the unit is first powered up, the speaker protection relay could be faulty. Receivers and audio amplifiers often include a set of relay contacts in series with each output to protect the loudspeakers from power-on and power-off transients as well as damage due to a fault in the audio circuits. However, these contacts may deteriorate after awhile resulting in intermittent sound.

While this set of symptoms could be the result of general bad connections or even dirty controls or switches, the relay is often at fault. This is exacerbated by switching the unit on and off at high volume levels as well as this may cause contact arcing.

To determine if the relay is at fault, either test it as outlined in the section: Relay testing and repair or with the unit on, very gently tap the relay to see if the sound comes as goes. If the relay is bad, you can try cleaning its contacts or replace with one that has similar electrical specifications as long as you can mount is somehow. Don't be tempted to bypass the relay as it serves a very important protective function for both the amplifier and your loudspeakers.

If it is not the relay, see the sections: "General intermittent or erratic behavior" as well as "Noisy or intermittent switches and controls".

Speakers take a while to come on

You turn on your stereo receiver and everything appears normal - display, tuning, signal strength, etc., but there is no sound. A few minutes later, just when you had entirely given up any hope, there is a click and everything is normal - until the next time you power down. The amplifier is taunting you - hehe, I will come on when I feel like it!

(Note that if it never comes on, then there could be a real problem that the protection circuitry is catching such as shorted components in one of the power amplifiers.)

This sounds like the signal to power the speaker relays is not being generated. The underlying cause could be a fault in the time delay or fault protection (overload) circuit.

It could be as simple as a bad capacitor. A first test might be to check for an audio signal at the input to the speaker relay. If there is signal almost as soon as you power it up, then trace back from the relay coil to see what type of circuitry is there. A schematic will probably be needed unless you find an obvious bad connection or dried up capacitor.

Amplifier clicking and shutting down on music peaks

(From: Frank Fendley (frank.fendley@datacom.iglou.com).)

It sounds like the protection circuit (usually a relay) is cutting in during louder music passages. This is caused by an imbalance in the amplifier circuitry, generally resulting in a DC offset voltage appearing on the output. The usual cause is a defective transistor(s), probably in the earlier stages in this case.

Of course, it could also be that you have 10 sets of speakers connected to the amplifier and all the volume levels turned to the stops - it is simply protecting itself from abuse! :-) --- sam.

Speaker outputs do not come on or shut off immediately

(From: Ronald Dozier (dozier@strauss2.udel.edu).)

The protection relay usually detects DC offset at the speaker terminals and then open's the speaker leads. Check for a DC offset > 100 mV or so before at the output, before the protection relays.

Leaky outputs are the first to suspect.

In most PP drivers the voltage between the bases of the output transistors should be about 2 Vbe or around 1.2 volts. 0V is definitely a problem. I have only seen one amp (mine) that used 4 Vbe. or about 3.2 volts. The voltage across the emitter resistors without a load are in the 0 to 20 mV range. This voltage should not increase appreciably over time and is set with the bias adjustment. Careless playing with the bias pot will result in output transistor destruction. It is best set with the aid of a distortion analyzer.

All resistors/transistors in the driver and output stage and in some cases the pre-amp are all suspect. The small valued ones like to change value. Compare with functioning channel.

Speaker thump - $2,000 amps versus PCs

(From: (filipg@repairfaq.org).)

Your stereo doesn't do this because it has a relay that doesn't turn on the speakers to the amp until AFTER it "thumps"! So, even a $2000 amp "thumps" it's just that there is a *provision* for that in the design. Altec has to compete with crappy brands that offer "200W" for $9.95... they can't afford to put in a $0.55 relay (*2 million units, you do the math for their total cost).

The reason they use the relay on the "speaker" side and not the "volume" side is so they can also have a "speaker protection" in the same deal - if you exceed some volume for too long, the relay will disengage the speakers, preventing their demise. You have not such worries so I suggest a small relay in the volume side of the speaker.

A 555 timer set for ~1 second will do nicely. Power it off the amp's power and set it to energize the relay after 1 second. The "thump" will still happen, but the volume will be "0". Put the relay in line with the wires to the volume control such that when it is not energized (i.e., amp off) it sets the volume at 0 and when energized (1 second after amp on) the pot controls the volume.

Problem solved.

BTW, your amp isn't technically "broken" - it's just designed that way. :-)

Determining power output of amplifier

You need a load resistor of a value equal to the ohms rating of the speakers you intend to use and a power rating sufficient to handle the maximum you expect the amp to put out for a short time at least. Then, all you need to do is drive it until just below clipping and measure the voltage. P=V^2/R. This really requires an audio signal generator but some music with a sustained high level might be sufficient to make measurements. Of course, unless you have an oscilloscope, you will have a hard time determining when clipping occurs without destroying a set of speakers in the process. :(

Strictly speaking, you need to do this simultaneously on both (all) channels as a weak power supply can also limit power output but that is for the advanced course!

Dead channels on front-end audio components

Unlike big amplifiers, these are not normally failures caused by abuse or high power components. This type of equipment includes preamps, cassette decks, CD players, tuners, etc.

First, eliminate the audio patch cables by trying a different set or swapping left and right at both ends. In addition, confirm that your amplifier is operating on all cylinders (or channels).

Assuming this does not turn up anything:

For a tuner, the problem is almost certainly very near the output - probably a bad connection, bad jack, or bad final IC or transistor stage. There isn't much between the demodulator and the line output.

For a tape deck, much more can be involved. First, clean any mechanical REC/PLAY mode and other switches with contact cleaner as dirty contacts may result in one channel dropping out. If this does not help, determine if the output of the tape head is making it to the toutput by touching the terminals on the playback head with a tiny screwdriver when in play mode - you should get a hum when you are on the appropriate signal wire. If there is none for the bad channel, then you will have to either trace forward from the head or backward from the output. If you do hear a hum in the defective channel, the tape head itself may be bad - shorted or open - very dirty.

Older tuners, receivers, premaps, tape decks, etc. used discrete transistors and circuit tracing was possible. Modern equipment relies on ICs but pinouts, at least, are generally available by checking a cross reference guide such as those put out by ECG, NTE, or SK.

Again, first eliminate bad jacks or cables -- and with tape decks - clean the REC/PLAY (and other) mode selector switches.

Repairing stereo headphone plugs/cables

This is only worth the time, effort, and expense if the original cost was substantial. It hardly makes sense to pay $2 for a replacement plug and an hour of labor to repair a Dollar Store set of headphones!

The most common location for broken wires is at the plug end due to repeated stress. Sometimes these can be repaired by pealing back the rubber boot, cutting, stripping, and soldering the broken wires end-to-end. However, in most cases, you will grow old attempting to do this successfully and replacing the plug is the desirable solution. Radio Shack or any real electronics distributor will have the required "1/8 inch stereo phone plug". If you don't want to solder, they are available with teeny tiny screw terminals.

Note: Sometimes the wires break at other locations so replacing the plug may not help!

There are a pair of shielded wires which need to be cut back to well beyond where the break took place (to expose undamaged wire), stripped carefully to expose the inner conductor and separate the outer braid/shield. This wire is really really thin and fragile so if you have trouble opening a zip-lock bag, leave the repairs to someone else. :)

```
    ----.__________ ____ __
         __________ ____ __>
    ----'
           Collar  Ring Tip
            Gnd   Right Left
```

- The Tip is the left channel (probably a color other than red like green, blue, or white. Check for continuity to the old plug if you can locate the broken end of the appropriate wire. Or momentarily touch a 1.5 V battery (NOT a 9 V - you could damage the headphones) between the inner wire and shield. You should get a click in the appropriate headphone.

- The ring is right (check as above or just assume it is the other one).

- The collar is common (both braids).

Equipment hums or buzzes

Assuming there are no other symptoms and the sound is coming from inside the unit and not the loudspeakers, this is probably simply due to vibrating laminations in the power transformer or motor(s) or nearby sheetmetal that is affected by the magnetic fields from the power transformer or motor(s). Most of the time, this is harmless but can definitely be quite annoying especially when one expects total silence from their audio equipment. If the noise is coming from any motors or their vicinity, refer to the section: Motor noise in audio equipment.

Sometimes, simply tightening the screws that hold the transformer or motor together or the mounting screws will be all that is needed. Placing a toothpick or piece of plastic in a strategic location may help. It is also possible to coat the offending component with a varnish or sealer suitable for electronic equipment but be careful not to use so much that cooling is compromised or getting any in bearings or locations that would interfere with rotating parts.

Dirty power - a light dimmer on the same circuit - may also result in increased magnetic noise. See the section: Dirty power and buzz from equipment.

If the hum or buzz is in the audio, there could be a bad filter capacitor in the power supply, other power supply problems, bad grounds inside the unit or general ground problems with external equipment, or other bad connections. Disconnect all external devices (except the speakers if you do not have a pair of headphones) and determine if the problem still exists. Proceed accordingly. Some Sony receivers are known to develop bad grounds internally and just tightening the circuit board mounting screws and/or resoldering ground connections will cure these.

Overloads can also cause a hum or buzz but would generally result in other symptoms like a totally or partially dead amplifier, severe distortion, smoke, six foot flames, etc.

If the problem is only annoying when the equipment is not in use, as a last resort (where no memory or clock functions run off the AC line), putting in an AC line switch may not be such a bad idea.

Dirty power and buzz from equipment

Power line waveforms that are not sinusoidal can cause buzz. Multiple devices on the same circuit (or even different circuits) can interact. A TV or other equipment may add to the problem since its switching power supply draws current only on part of each cycle.

Excessive voltage can also increase the 'magnetic noise' from motors and power transformers. This sound is a result of core or winding vibrations.

You need to check for both of these possibilities - a calibrated scope is best. DMMs and VOMs may not read correctly with non-sinusoidal waveforms.

Will line voltage fluctuations affect A/V equipment

When large applicances like air conditioners, refrigerators, and heaters kick in, there is often a momentary dip in line voltage (especially if they are on the same branch circuit) which is very visible on incandescent lamps but is it actually harmful to electronic equipment?

It really depends on many factors but a couple percent variation in voltage (which is probably what you are seeing) probably isn't going to affect your A/V equipment in any way. Most modern equipment includes internal voltage regulation so there could indeed be no detectable effects.

Note that the volt or two drop in the wiring isn't in itself dangerous since it is distributed over a large length of wire. For example, a 2 V drop with a 10 A load is only 20 W lost in the wiring which over 50 or 100 feet is negligible heating. However, if this just started happening with no changes or additions to the wiring - especially if it is erratic - it could be due to a bad connection which is potentially dangerous and should be checked out.

A line filter might be of some value if you are actually seeing or hearing interference when the offending equipment kicks in. However, if you can't detect it, don't worry about.

Note that a surge suppressor is basically useless for this sort of voltage fluctuation as it only kicks in with a very significant *increase* in voltage.

WARNING: If you are actually seeing your lights *brighten* when that equipment starts up, get your electric wiring checked out. This could indicate a loose Neutral connection and that can result in expensive damage to anything plugged into your residence's electrical system and a safety and fire hazard. See the document: Notes on the Troubleshooting and Repair of Small Appliances and Power Tools for more information on this and other wiring problems.

Identifying and correcting sources of interference

Although this is a rather special application, similar problems and solutions apply to other interference problems. Also see the section: Interference on AM radio band.

> "I am using a 12V DC to 110 VAC converter in my car, to run a small TV/VCR. It works fine. But the TV speaker is not very good.

> So I got one of those cassette adapters that has an audio cassette on one end, and a headphone jack on the other. I plug that into the TV, and the cassette slot on my car stereo. So then I can hear the TV sound on the car speakers, which are much better speakers.
>
> But now there is a lot of high frequency noise that way, on the car speakers. It is very irritating. A high frequency buzz of some kind. How can I reduce or eliminate that noise?"

(From Duncan (duncan@punk.net).)

First we have to figure out where it is coming from. The inverter is certainly a noise source, and without spending a large sum for a well filtered inverter you have to deal with the noise somehow.

One possibility is that the noise is on the 12 volt power supply going to your car stereo. To test for this, play a blank tape while running the TV and listen for the same noise. Fix with filters on the power leads of stereo and/or inverter, wire to a solid clean rail very close to the battery.

Another possibility is capacitive coupling between the TV, connected to the higher voltage side of your inverter, and the tape deck's playback heads. This might be alleviated by using a different, more isolated inverter or by using another method of getting the audio into the stereo system. FM modulators intended for portable CD players might work.

Another possibility is that the power supply of the television is not rejecting the higher frequency components of the inverter's signal. The fix here would be to add more capacitors and perhaps resistive or inductive filter elements inside the television. Check this by plugging headphones into the same jack and listening for the noise.

Still another possibility is that the noise you hear is part of the horizontal sync signal, which is not rejected well by all televisions. This causes a high pitched continuous squeal which is inaudible to some people. The only easy work-arounds here would be to try a different television or to turn down the treble or select Dolby-B on your car stereo. To test for this effect, try the same hookup in your house with your home stereo, cassette deck, adaptor cassette, and television.

Or just hook up your HiFi stereo VCR to the home stereo, move the whole mess into the car, and ignore the car stereo. Four of Radio Shack's little Pro-7 speakers with a Marantz 25 watt by four channel amplifier worked quite well for me, especially when combined with a hand-held LCD monitor :-).

Interference on AM radio band

This sort of problem is usually in the form of a buzz or hum at 60 Hz or 120 Hz (or 50 Hz or 100 Hz if your power is at 50 Hz). There may be a little of this on a small portion of the AM band but if it is excessive and interferes with even strong stations, then a remedy is needed! The following approach should serve to locate the source if it isn't obvious:

(From: Doug (dslosty@pipeline.com).)

First, turn off the main house breakers and listen on AM with a battery operated portable radio.

If the noise has disappeared, then you are generating the interference in your own home and its time to check out things like light dimmers, fluorescent lamps, touch-control incandescent lamps, motors, even cordless phones, etc.

If the interference is still present on the portable AM radio, with the breakers off, walk around the perimeter of the house and see if it's loudest near the electric service entrance.

If it is, walk up and down the street and try to see if the intensity varies (your neighbors will think you're weird - but what the heck!).

If the interference comes from outside of your home, it's time to call the electric utility company and ask to speak with one of their engineers. The electric industry is required by the U.S. FCC. to keep radio interference (RFI) to a minimum. They may try to stonewall you but if you persist, they will sent out an engineer with radio direction finding equipment to locate the source of the interference. If the source is a piece of equipment on a non-cooperative neighbor's property, you may have another problem - but - one step at a time.

I've been through this procedure several times. Last time, the electric company engineer tracked it to a broken and arching pole insulator.

As a former AM broadcast engineer (and current HAM radio operator), I've experienced this problem enough to know that while challenging, the interference source can always be found.

(From: Mr Fixit (mrfixit@cyberhighway.net).)

Radio Shack sells RF chokes. Label says "SNAP-ON FILTER CHOKES (2) cat. no. 273-104"

They open up and snap together over your wires. Very simple to install and come with comprehensive instructions.

With a little experimentation you can see if you need it on your power cord, on the speaker wires or both. (these wires can act as antennas for certain frequencies of RFI)

I use them all over my house on phones, TV's, stereos, computer speakers etc to block out RFI from my CB base station and vis-versa.

BTW: if you happen to have any unneeded computer monitor cables laying around, the oversize collar near the end is a RF choke. I had a couple so I cut the covering and slid them off the cable. I put them onto our cordless phone base unit antenna as an experiment to see if it would reduce the ever-present buzz it had. To my surprise, the buzz disappeared with no loss of signal strength.

(From: Dan Hicks (danhicks@millcomm.com).)

An even better idea is to put these chokes on the RF **generators** in your house. I'm not sure if it's "code" to install them on permanent wiring, but it should be safe to do so so long as you are reasonably careful. And it's easy to install them on any plug-in devices that appear to cause problems.

Internal fuse blew during lightning storm (or elephant hit power pole)

Power surges or nearby lightning strikes can destroy electronic equipment. However, most of the time, damage is minimal or at least easily repaired. With a direct hit, you may not recognize what is left of it!

Ideally, electronic equipment should be unplugged (both AC line and phone line!) during electrical storms if possible. Modern TVs, VCRs, microwave ovens, and even stereo equipment is particularly susceptible to lightning and surge damage because some parts of the circuitry are always alive and therefore have a connection to the AC line. Telephones, modems, and fax machine are directly connected to the phone lines. Better designs include filtering and surge suppression components built in. With a near-miss, the only thing that may happen is for the internal fuse to blow or for the microcontroller to go bonkers and just require power cycling. (Unplug the unit from the wall for a couple minutes and see if that will reset it.) There is no possible protection against a direct strike. However, devices with power switches that totally break the line connection are more robust since it takes much more voltage to jump the gap in the switch than to fry electronic parts. Monitors and TVs may also have their CRTs magnetized due to the electromagnetic fields associated with a lightning strike - similar but on a smaller scale to the EMP of a nuclear detonation.

Was the unit operating or on standby at the time? If was switched off using an actual power switch (not a logic pushbutton), then either a component in front of the switch has blown, the surge was enough to jump the gap between the switch contacts, or it was just a coincidence (yeh, right).

If it was operating or on standby or has no actual power switch, then a number of parts could be fried.

Many devices have their own internal surge protection devices like MOVs (Metal Oxide Varistors) after the fuse. So it is possible that all that is wrong is that the line fuse has blown. Remove the case (unplug it!) and start at the line connector. If you find a blown fuse, remove it and measure across the in-board side of fuse holder and the other (should be the neutral) side of the line. With the power switch off, this reading should be very high. With the switch on, it may be quite low if the unit uses a large power transformer (a few ohms or less). For example (assuming power transformer operated supply):

- Small AC adapter - 100 to 500 ohms.
- Large AC adapter - 10 to 100 ohms.
- VCR - 15 to 30 ohms.
- Cassette deck or CD player - 25 to 100 ohms.
- Stereo receiver or amplifier - .5 to 10 ohms.

Some may be outside these ranges but if the reading is extremely low, the power transformer could have a partially or totally shorted primary. If it is very high (greater than 1 K ohms), then the primary of the power transformer may be open or there may be blown thermal fuse under the outer insulation wrappings of the transformer windings. This may be replaceable but don't just bypass it (except for testing). See the document: Notes on the Troubleshooting and Repair of AC Adapters, Power Supplies, and Battery Packs.

If the unit has a switching power supply (the AC input doesn't go to a power transformer but gets rectified and filtered first), see the document: Notes on the Troubleshooting and Repair of Small Switchmode Power Supplies.

If the resistance checks out, replace the fuse and try powering the unit. There will be 3 possibilities:

1. It will work fine, problem solved.

2. It will immediately blow the fuse. This means there is at least one component shorted - possibilities include an MOV, line filter capacitor, transformer primary.

3. It will not work properly or still appear dead. This could mean there are blown fuses or fusable resistors or other defective parts in the power supply or other circuitry. In this case further testing will be needed and at some point you may require the schematic.

Use of surge suppressors and line filters

Should you always use a surge suppressor outlet strip or line circuit? Sure, it shouldn't hurt. Just don't depend on these to provide protection under all circumstances. Some are better than others and the marketing blurb is at best of little help in making an informed selection. Product literature - unless it is backed up by testing from a reputable lab - is usually pretty useless and often confusing.

Line filters can also be useful if power in you area is noisy or prone to spikes or dips.

However, keep in mind that most well designed electronic equipment already includes both surge suppressors like MOVs as well as L-C line filters. More is not necessarily better but may move the point of failure to a readily accessible outlet strip rather than the innards of your equipment if damage occurs.

It is still best to unplug everything if the air raid sirens go off or you see an elephant wearing thick glasses running through the neighborhood (or an impending lightning storm).

Surge Suppressor/UPS cascading

(From: Fred Noble (f-noble@suttondesigns.com).)

A large number of users still seem confused about the use of a Surge Suppressor in line with a UPS. The general rule is, do NOT plug a surge suppressor INTO the OUTPUT of a UPS that produces a non-sinewave output that exceeds 5% Total Harmonic Distortion (or THD) when the UPS operates from battery supporting any load under any ambient conditions. Do NOT plug a Line Conditioner or other type of filter into the UPS either.

You can plug a UPS into a well grounded surge suppressor, but this is not always a good idea, especially when we are talking about various 'low cost' surge suppressors of questionable electrical integrity. We constantly hear of low-end surge suppressor recalls for safety reasons, with several recent recalls ordered by the U.S. Consumer Product Safety Commission, for example, http://cpsc.gov/cpscpub/prerel/prhtml97/97078.html. A cursory search using the keywords 'surge arrester consumer recalls' with the Excite engine reveals several such recalls.

If the surge suppressor you plug the UPS *into* is electrically 'safe' you are still extending the ground path with such a cascading arrangement, which, on balance, may not be wise. The UPS should provide Surge Suppression energy ratings of 480 Joules or more. Then, you probably wouldn't require the additional upstream surge suppressor at all. This does not mean that you shouldn't also have a surge suppressor installed at the MAINS or the branch panel, however. We are only talking about the extra, stand-alone, AC protection devices.

This is also not to say that you should not provide additional surge suppression for your modem or UTP connections!. This you must do, and a low cost device that is also a *high quality* device, should be used. These devices are designed specifically for the protection of DC electrical surges and they are not used in series with a UPS anyway.

Lightning, surge supressors, and telephone equipment

(From: aa-2@deltanet.com@deltanet.com)

Nothing will stop a good lightning strike, but there are things you can do to put the odds more in your favor.

For telephone line protection, the place to start is where the phone line comes into your house. Locate the protector and verify you have a good ground close to it. Next, replace the standard carbon protector elements with gas tubes. These often look like large brass hex bolts with no wires attached, but the exact design will vary. Carbon protectors operate rather slowly; gas tubes ionize very quickly and carry large amounts of current. You may have to shop around your local telco supplier to find these. Strictly speaking, these are on the telco side of the demarc and you're not supposed to fool with them, but if you won't tell, I won't either. Or you could call your local telco and ask for the gas tubes...

Then add your store-bought protector inside. Make sure it has a good ground, too. It can't hurt, and it might help. But the best place to try and stop the lightning is before it enters your house.

Paul's Notes on Power Line Connected Devices

The most common of these are so-called "wireless" intercoms and X10 appliance controllers.

(From: Paul Grohe (grohe@galaxy.nsc.com).)

The "Wireless" intercoms actually send 220 to 250 kHz signals across the power line. They pump about a volt or two into the line - then receive in the millivolt range. Obviously - the power line is NOT a good transmission medium.

They worked fine years ago when most loads were mostly inductive (lamps, motors, transformers, etc).

Nowadays, there are loads that essentially place small value capacitors across the line - most notably power strips and newer electronic equipment with switching supplies (Computers, TVs, VCRs, compact fluorescent lamps, etc). These "small" caps essentially short out any high-frequency noise on the power line. To make things worse, switching supplies and CFL bulbs run in the 40 to 80 kHz range, and can spray harmonics well into the 200 kHz range. Some channels will get knocked out by poorly filtered switching supplies or CFLs.

Also, both intercoms need to be on the same service "leg". The majority of (US) homes are fed by a 120-0-120 feed. Half the home is on one leg, and the other half is on the other leg to "balance" the load. Even two outlets in the same room may be on different legs. The kitchen usually has the most of these "mixed" outlets.

If the intercoms are on opposite legs, the signal has to traverse the transformer to get to the other leg. Obviously, with the inductance of the pole transformer and long power feed, the signal rarely makes it back.

BTW: If the intercoms work better if a 220 VAC load, such as an oven, drier or stove is turned on - then they are defiantly on separate legs.

X-10 remote controls also face a similar problem. Do a search on X-10 wireless controllers - there are many FAQs about signal problems and what causes them. There are devices that allow the X-10 signal to "bridge" between the two lines. Essentially a high-voltage, low value capacitor that must be professionally installed at the breaker box.

One thing I have found is to NOT plug the Intercom/X10 device into the *same* outlet as a filtered outlet strip or TV/VCR/Computer/CFL. Instead, pick an outlet *between* the sending unit and the electronic loads.

Think of "loads" as capacitive, and power line as slightly inductive - and you'll see why.

As an alternative to power-line carrier - Radio Shack sells intercoms that use the phone line as the carrier - RS# 430-0483. Of course, they need a phone line too - but the performance is *much*, *much*, *much* better than the power line units.

I originally tried the usual 'power line" intercoms - but encountered many problems with noise/interference from the computer and compact fluorescent lamps. I happened across a pile of some older-model phone-line intercoms at Goodwill and gave them a try - they worked perfectly with NO interference at all (although if you have DSL using "Microfilters" at each phone - you cannot use these intercoms or you must split off DSL at the phone box).

The best they can do is to try other outlets - even if it means extension cords. Otherwise, they will have to switch to an "alternate" means since the power line is unusable. I have seen RF "intercoms" somewhere (900 mHz?) - so there are some available. But if phone lines are available at the locations they wish to use - then I would highly recommend the phone-line intercoms.

Equipment dropped or abused

I have heard of someone fighting off a would-be mugger with a tape deck but this is generally not a recommended practice. However, once it happens - your cassette deck fell off its shelf or you prized walkman fell from your hang glider (ok, maybe that will be too much even for miracles) - what should you do?

Overall, electronic equipment - especially portable devices - are quite tough. However, falling or being beaten in just the wrong way can do substantial and possibly not immediately visible damage.

If you take it in for service, the estimate you get may make the national debt look like pocket change in comparison. Attempting to repair anything that has been dropped is a very uncertain challenge - and since time is money for a professional, spending an unknown amount of time on a single repair is very risky. There is no harm is getting an estimate (though many shops charge for just agreeing that what you are holding was once a - say - tapedeck!)

This doesn't mean you should not tackle it yourself. There may be nothing wrong or very minor problems that can easily be remedied.

First, unplug the unit even if it looks fine. Until you do a thorough internal inspection, there is no telling what may have been knocked out of whack or broken. Electrical parts may be shorting due to a broken circuit board or one that has just popped free. Don't be tempted to apply power even if there are no obvious signs of damage - turning it on may blow something due to a shorting circuit board. If it is a portable, remove the batteries.

Then, inspect the exterior for cracking, chipping, or dents. In addition to identifying cosmetic problems, this will help to locate possible areas to check for internal damage once the covers are removed.

Next, remove the covers and check for mechanical problems like a bent or deformed brackets, cracked plastic parts, and anything that may have shifted position or jumped from its mountings.

Carefully straighten any bent metal parts. Replace parts that were knocked loose, glue and possibly reinforce cracked or broken plastic. Plastics, in particular, are troublesome because most glues - even plastic cement - do not work very well. Using a splint (medical term) or sistering (construction term) to reinforce a broken plastic part is often a good idea. Use multiple layers of Duco Cement or clear windshield sealer and screws (sheetmetal or machine screws may be best depending on the thickness and type of plastic). Wood glue and Epoxy do not work well on plastic. Some brands of superglue, PVC pipe cement, or plastic hobby cement may work depending on the type of plastic.

Cycle the the mechanism and check for free movement of the various moving parts.

Inspect for any broken electronic components - these will need to be replaced. Check for blown fuses - the initial impact may have shorted something momentarily which then blew a fuse.

There is always a slight risk that the initial impact has already fried electronic parts as a result of a momentary short or from broken circuit traces and there will still be problems even after repairing the visible damage and/or replacing the broken components.

Examine the circuit boards for any visible breaks or cracks. These will be especially likely at the corners where the stress may have been greatest. If you find **any** cracks, no matter how small in the circuit board, you will need to carefully inspect to determine if any circuit traces run across these cracks. If they do, then there are certainly breaks in the circuitry which will need to be repaired. Circuit boards in consumer equipment are almost never more than two layers so repair is possible but if any substantial number of traces are broken, it will take a great deal of painstaking work to jumper across these traces with fine wire - you cannot just run over them with solder as this will not last. Use a fine tipped low wattage soldering iron under a magnifying lens and run #28 to 30 gauge insulated wires between convenient endpoints - these don't need to be directly on either side of the break. Double check each connection after soldering for correct wiring and that there are no shorts before proceeding to the next. Also see the section: Repair of printed circuit board traces.

If the circuit board is beyond hope or you do not feel you would be able to repair it in finite time, replacements may be available but their cost is likely to be more than the equipment is worth. Locating a junk unit of the same model to cannibalize for parts may be a more realistic option.

Once all visible damage has been repaired and broken parts have been replaced, power it up and see what happens. Be prepared to pull the plug if there are serious problems (billowing smoke would qualify). Determine if it appears to initialize correctly - without shutting down. Play a garbage tape to determine if there are any problems that might damage the tape. Listen carefully for any evidence of poor tracking, tape speed instability, or weak or muddy audio that might indicate that tape path alignment requires further attention. Listen as well for any unexpected mechanical sounds that were not there before.

Very likely, the unit will be fine, you can replace the covers, and now find a more secure spot for it to prevent this sort of event in the future. Maybe hang gliding is just not for you!

Decayed glue in electronic equipment

Larger components like electrolytic capacitors are often secured to the circuit board with some sort of adhesive. Originally, it is white and inert. However, with heat and age, some types decay to a brown, conductive and/or corrosive material which can cause all sorts of problems including the creation of high leakage paths or dead shorts and eating away at nearby wiring traces.

The bottom line: Most of the time, this stuff serves no essential purpose anyhow and should be removed. A non-corrosive RTV or hot-melt glue can be used in its place if structural support is needed.

(From: Richard Rasker (r.e.rasker@student.utwente.nl).)

Are you repairing somewhat older Japanese (Yamaha, Nikko, etc.) equipment, but the problem seems very obscure? Then maybe this may interest you:

In some amplifiers and other equipment, the supply capacitors and other large pcb-mounted devices are secured in place by a type of gluelike substance, that after several years causes corrosion to all metal parts that it touches; eventually, the metal connections (like component wire leads and wire bridges) will fail.

The substance in question is a dark yellow rubber-like compound, coloring brown and turning rather hard on the places where damage is done to other components. The only solution is to scratch it away completely and replace all components affected.

I've already repaired five amps where this turned out to be the cause of trouble - with very vague symptoms, like a missing ground reference to an endstage, an on-board controller that wouldn't start up, etc. The first time it took me forever to find, so if this posting will make even one repair easier for someone, I'm already happy.

Hope this makes life a (little) bit easier for all those people out there trying to repair stuff, instead of throwing it away :)

P.S. My theory about this process: I think that the substance used is a rubber compound with an excess of sulfur, which will very slowly react with oxygen and moisture to form corroding chemicals (like sulfites). If anyone has a better theory (or the correct explanation), please let me know.

(From: Jake Gray (jake79@hotmail.com).)

I have found in a lot of electronical gear and more recently in my monitor. The glue has been designed mainly to hold leads and wires in place, also to hold capacitors in place.

It eventually soaks up the moisture from the air, giving it a conductive effect and the places that it is located don't like having a conductor across them. And, as time goes on, the glue seems to carbonize and become an even better conductor.

Just keep and eye out for it, it is like a creamy colour and remove it ASAP.

With many appliances, especially those with many IC's, I have found that with the removal of the glue, they work fine.

Repair of printed circuit board traces

In most cases, a functional repair - using wire to bridge the breaks soldered to conveniently located pads - is all that is needed. This will be at least as reliable as the original foil wiring if done properly. However, there are those times when a complete restoration is desired:

Note: If the original cause was chemical corrosion rather than mechanical, ALL of the offending material must be removed and/or neutralized before any sort of reliable repair can be attempted!

(From: MKILGORE (mkilgore@aol.com).)

Yes, you can repair damaged/lifted conductors and pads on circuit boards. If you would like to repair the damaged area professionally, track repair kits are available from sources such as Pace. These repairs once completed are almost undistinguishable from the original work. Damaged pad replacement - Using a scalple or Xacto knife follow the run attached to the pad back to a point where it is still firmly secured, at a 45 degree angle, cut the trace loose and remove it from the board and discard. Scrape any solder mask from the end of the trace back about 3 trace widths, and clean the area with an ink eraser, then tin the area. Select a pad with trace from the kit (various sizes are included) position it in place of the damaged run and form it so it follows the contour of the board to the 45 degree angle cut and rests on top of the original trace by about 2 trace widths. Now prepare a small amount of two part epoxy and flow it on the board where the replacement conductor will lie, do not get any on the tinned conductor. Lay the replacement conductor in place and allow the epoxy to dry, this can be speeded up with a heat lamp. Once dry simply apply flux to the joint and solder the two pieces together. If this was a plated through hole, or strength is an issue, the kit contains eyelets which can be installed through the board. --- However, if the trace you wish to repair is merely lifted you can simply use the epoxy and secure it back in place.

Circuit repair where a pad has been lifted due to mechanical stress

This might be the case where someone tripped over the AC adapter cord of a walkman or laptop computer thus ripping the jack from the circuit board.

(From: KIRTO (Kholson@cris.com).)

As you will see in the following, I recommend using something other than the pad to get that strength.

I suggest you provide mechanical connection between the jack and the board so that the jack can't move with respect to the board.

Techniques include a wire strap over the component near the back and soldered to the board like you see on crystals or adhesive under the jack like you see on large caps in midboard.

Another possibility is to put a rubber bumper atop the jack so that the front cannot tip inward when it's in the case. A stick-on foot might be a start, with whatever 'foot surgery' is needed to fit.

If the jack has a rim near the front (like a std keyboard connector) you might be able to put triangular braces on either side of it with adhesive and some stiff rubber or plastic.

I have seen this problem happen when someone trips on a cord and thus pulls the connected jack at a sharp angle with high force. Warn the customer about this possibility, and suggest using an extension cord on the power adaptor.

(From: Hank Sievers (textax@aol.com).)

The best way that I can think of is to bend down whatever part of the leg extends through the board and bridge with a heavy bare wire and plenty of solder to as much of the nearest part of the trace (scraped to the copper, of course) as you can. Then, for good measure put a drop of magic glue or some silcone sealant where the leg comes through the hole. Should be stronger than the original.

I am a charter member of the the 'down-to-the-component-troubleshooting fraternity', since I am naturally curious and fortunate enough to have the time, since I am retired. However, I can see where it is often important to the bottom money line, not to spend too much time on a repair and so replace the entire unit. Time is money also!

Boombox or other equipment went to the beach (sand and/or surf)

A (former) relative took your boombox to the beach this summer and now it has sand or perhaps salt in it. Or, maybe you could not resist "sing'n in the rain" and a big bus went by without slowing. Now neither of the tape decks will play. Can this possibly be fixed? Will it be worth the effort?

Unless this is a really expensive sophisticated unit, I doubt whether it will pay you to take it anywhere for repair. Furthermore, as with equipment that has been dropped or physically abused, few repair shops will be inclined to touch the job. They really don't like challenges of this sort.

That leaves you!

If saltwater was involved in a significant way, you can probably forget it. Without immediate attention, saltwater corrosion can set in very quickly and attacks electronic components, circuit board traces, cable wiring, and mechanical parts. The only thing worse is damage caused by forgotten, leaky batteries.

Although it is probably too late, the first thing to do when electronic equipment gets wet is to remove the power source - switch it off and pull the plug or remove the batteries if possible. Don't be tempted to apply power until you have determined that it is completely dried out. If power was on when the 'incident' took place, then electronic damage may have already resulted which will not be apparent until after cleaning, drying, and lubrication.

The following description assumes a dual cassette boombox. Adjust as appropriate for your patient:

If the tape decks are totally dead, you may have serious electronic or corrosion which will make any salvage unlikely. If they sort of move (or even twitch a bit) but the sound is erratic, weak, fluttery, etc. then there may be hope. (Of course, if it got wet, you should not have done this test until everything was cleaned and dried!)

NEVER use strong solvents for any cleaning. These may attack plastic parts or cause internal damage to electronic components.

Mechanical intensive care:

1. Remove the tape decks. This will be a pain but otherwise you will not be able to get at everything. Make as many as drawings as needed so you will be able to reassemble.

2. Make a drawing of the belt routing, remove the belt(s), wash and dry them, label and set them aside.

3. Use a soft brush (like a paintbrush) to dust out as much sand as possible. Hopefully, you can get it all this way. A vacuum cleaner with a wand attachment may prove handy to suck out sand. Don't use high pressure compressed air - it will just spread the sand around. Any grease or oil on which sand has collected will need to be totally removed and replaced with fresh lubrication.

4. If there is evidence of salt (remember, I said forget it...but), you will need to wash it off. Yes, wash it. Keep water out of the motors. Use low pressure compressed air (a blow dryer on low heat should be fine) to dry so that it does not rust. Ditto if it is still wet with contaminated liquid (we won't say where this came from), wash with fresh water to remove all traces of it as quickly as possible. A final rinse with 91% or pure isopropyl alcohol will decrease drying time and should not damage mechanical assemblies. Degreaser may be used if it is safe for plastic and rubber parts.

   Lubricate all bearing points with a drop of light machine oil - electric motor oil, sewing machine oil, etc. (Never never never WD40). Lubricate gears, cams, and sliding parts with a light plastic safe grease.

5. Replace the belts and reinstall the tape decks.

Electronic intensive care:

1. Remove the circuit boards and label the connectors if there is any possibility of getting them mixed up. If the circuit board(s) are soldered to the rest of the equipment, then you will have to improvise.

2. Wash with water and dry thoroughly. This does work. I use it routinely for degunking remote controls and rubber membrane keypads, for example. The most important objective should be to get corrosive liquids off the components and circuit traces as quickly and completely as possible. A final rinse with isopropyl alcohol will decrease drying time. However, there is a slight risk of damage to sensitive electronic components should some be trapped inside. Moisture will be trapped in controls, coils, selector switches, relays, transformer cores, connectors, and under large components like ICs. Pat dry, then use warm air from a hair dryer (or heat gun on low) to completely dry every nook and cranny. DO NOT operate until everything inside and out is thoroughly dry.

3. Inspect for damage due to short circuits including blown fuses, fried components, and melted traces. These will need to be repaired or replaced.

4. Use spray contact cleaner on the switches and control cleaner on the user controls and adjustment pots. DO NOT turn the internal adjustments without precisely marking the original positions - else realignment will be needed. Exercise the user controls to help the cleaning process.

Once everything is reassembled, power the unit up and see what happens. Be prepared to pull the plug or pop the batteries if there are serious problems. Attempt to play a garbage tape to determine if there are any problems that might damage the tape. Look and listen for any abnormalities which may require additional attention. There could still be electronic faults not repairable without schematics and test equipment.

Obviously, this description is very simplistic. The important thing is to get every last grain of sand, salt, and other contaminants off of the mechanisms quickly.

Similar comments apply to equipment that went for an actual swim - you dropped your portable CD player in the toilet. The most important objective is to clean and dry it as quickly as possible and then relube any motor and other bearings. Use your judgement as to the severity of the dunking in terms of how deeply the liquid penetrated. Surface moisture will not hurt anything as long as it is dried up quickly. If you left it soaking on the other hand....

As noted above, moisture may collect inside certain electronic parts and it is essential that these be dried completely before attempting to apply power to the unit. If you do not, at best it will not work properly and you may do additional serious damage due to short circuits.

For the mechanics, the same applies though this is trickier since certain parts need to be lubricated and these may not be readily accessible or obvious. Don't be tempted to overdo the lubrication either - too much is worse that too little.

For high tech devices like CD players, some parts of the internal optics or shielded DC-DC convertors may be impossible to access and clean of scum.

Salt water salvage

(From: John Baker (jbaker@flash.net).)

I have repaired equipment that has been soaked in salt water and it depends on what type of components it has on the boards. If they have any batteries on them, get them off as soon as possible. transformers are usually good for rusty paperweights. Get the boards out of the salt water and into fresh water ASAP. I have not found any chemicals that will remove the salt deposits and leave the traces. The best bet is to use a small nylon brush along with a chemical called Flux Off-nr, there are several types of Flux-Off, get the one that does not harm plastic parts, it is not as strong but it workes just as well in this case. From there it takes a lot of time. Use the brush and remove all salt deposits, try and get under all components, especially IC's. Most components can take being under salt water with no damage, it is the batteries and metal that cause problems.

Fil's notes on rescuing soggy equipment

(From: Filip "I'll buy a vowel" Gieszczykiewicz (filipg@repairfaq.org).)

Greetings. I've recently had the opportunity to rescue several rather expensive electronic units after the owner flipped the canoe and spilled the beans, so to speak.

The dead units were: a Casio solar-powered calculator, a car-alarm key ring transmitter, a 10-satellite GPS unit (yowser!), and some smaller items.

Note: GPS unit was waterproofed and did not suffer much.

Solution (sorry, pun) was: purchase 1 gallon of distilled water, disassemble the units and submerge the PCBs (and keypads and displays) in containers. The devices were left soaking for more than 20 minutes. Then, they were removed and dried with a hair dryer (and fan for less expensive items).

Results: excellent. All items have been brought back to life. Some *did* require purchase of new (rather expensive) Lithium batteries but that was a small price to pay.

Hint: It is highly useful to have a brush to clean the area between ICs' pins after 10+ minutes of soaking. This helps to remove any minerals that are not as soluble in water as others. This is more of an issue if the items came in contact with flood-stage stream than a sinkful of tap water. :-)

Observation: devices that were "on" at the time of the dunking were the most damaged and required the most time to soak. Batteries had to be replaced since they *all& started to leak.

REALLY cleaning electronic equipment

The following is probably excessive for most needs and should be used with caution since there are some types of components which will not take kindly to forced hot water cleaning. In addition what is mentioned below, mechanical assemblies like motors and solenoids should be removed and dealt with separately. And, of course, any moving parts that are left in place should be thoroughly dried as soon as possible and then lubricated with the proper oil or grease.

(From: Gray Frierson Haertig (gfh@haertig.com).)

I have had excellent results cleaning electronics in the dishwasher. I try to do a bit of disassembly so that as much of the instrument is exposed as possible. If you can separate chassis from electronics, so much the better. I have generally avoided putting unpotted transformers and inductors and the such through the wash. I either hand clean those boards or dismount the sensitive item. Mechanical parts can be run through the whole cycle, if your water is reasonably soft. A second rinse cycle doesn't hurt. The electronics should not go through the heat dry cycle. They should be thoroughly flushed in deionized or distilled water after they come out of the washer to prevent mineral and salt deposits. Then go after it with a blow dryer set to low heat, or if you're blessed with sunshine, smear on the cocoa butter and let them work on their melanoma.

Reviving old (antique) equipment

If you have a true antique - really old, and valuable, you should refer to the extensive literature available on this subject. The following applies more to that 30 year old record player/amp found in the storage loft of your garage during spring cleaning.

Common problems relate to two types of components: vacuum tubes (valves for all of you on the other side of the lake) and capacitors (paper and electrolytic type). Push all the tubes down in their sockets as well - they will work their way loose with non-use and vibration. However, thorough cleaning of all socket and switch contacts, and controls will almost certainly be needed.

WARNING: the voltages inside tube type equipment can exceed 400 V - and contact with that can be real painful not to say dangerous. AC-DC type sets are not isolated from the power line. (In some really old equipment, even the chassis may be tied to one side of the line). This could also happen as a result of a shorted component. The electrolytic capacitors can hold a charge for quite a while. Read, understand, and follow the recommendations in the document: Safety Guidelines for High Voltage and/or Line Powered Equipment. Use extreme care when probing or even touching anything. This isn't 5 V logic!

Vacuum tubes:

It is not possible to fully test vacuum tubes without proper equipment but the inspection and tests below will find most bad tubes but will not pick up weak tubes. As a side note, when a repair shop replaced tubes, perhaps 20% of the tubes they replaced were actually bad (I know because the local TV repair shop's trash can was a favorite hangout on pickup day and nearly all the tubes I scrounged tested perfectly good on a real tube tester once they were washed of coffee grounds and cigarette ash!) Whether this represented legitimate preventive maintenance or just IPM - Increased Profit Margin, I really do not know.)

1. Look for a silvery metallic spot somewhere inside the tube. This is the getter and is there to remove the last traces of gasses. If you see this, the vacuum is intact. If it is milky white or red, the tube has lost its vacuum and is dead-dead.

2. Use an ohmmeter to test for filament continuity. The nice thing about tubes (aside from their cheery glow) is that you can see inside (at least for the ones with a glass envelope) and locate the filament connections by tracing from the pins - it will be the whitish fine wire in the center of each of the tube sections. (The filament is almost always pins 3 & 4 on a 7 pin tube, 4 & 5 on a 9 pin tube, and 2 & 7 on an 8 pin tube.)

3. You can check for inter-element shorts (but not at normal operating conditions) with a VOM or DMM. For glass tubes, even without a tube manual, you should be able to deduce which elements are supposed to be isolated by visual examination.

Now, just jump into your time machine, back about 20-30 years should do it (remember?) when every corner drugstore and TV repair shop had a tube tester. There is, of course a good chance that your local TV repair shop still has one (if they can find it under an inch layer of dust) and it may even work.

Capacitors and resistors:

If you just dug this thing out of the attic, it is very likely that electrolytic capacitors have dried up and paper capacitors have turned leaky. Professional restorers will often install modern replacements for all of these capacitors without even testing the old ones. To maintain the authenticity of the vintage equipment, they may actually remove the guts of the old capacitors and mount the new ones (which are much smaller anyhow) inside the original cans.

Old carbon resistors can absorb moisture and change value. If your measurements do not agree with their marked rating based on their tolerance, consider replacements. However, if within, say, 20 %, for now, leave them alone.

Sockets, switches, and controls:

Vacuum and/or use a small paintbrush to remove dust, spider webs, dead insects (and anything larger).

Remove each tube (or transistor) one at a time and use contact cleaner on the sockets. Tubes are usually keyed against incorrect installation. However, for transistors, make sure which way they go! You don't want to make a mistake. Use contact cleaner on all the switches and exercise them to help the contact cleaner do its job. Use control cleaner on all the potentiometers and rheostats and rotate them back and forth to help clean the track. Put a drop of oil into the bearings of any non-enclosed (multiplate) variable capacitors. Lubricate mechanical dial pointers, pulleys, and and other similar mechanical parts.

Testing (use an isolation transformer with AC-DC line connected sets):

Much of this old equipment had schematic diagrams pasted to the cover - really handy if the paper hasn't totally disintegrated.

Turn on the power but be prepared to pull the plug in a hurry if, for example, a capacitor should decide to blow up (this shouldn't be a problem if you replaced them all unless some electrolytics are in backwards).

It is probably best to use a Variac to increase the voltage gradually. In fact, this will help to 'reform' old electrolytic capacitors that have developed excessive leakage. However, by 'gradually', we may be talking hours or days to reform capacitors! I would still recommend replacement even if this appears to work.

Do the filaments light up? If your equipment has a power transformer, the filaments are probably wired in parallel, so if one tube is out, that tube is bad (or its socket). If they are all out, then the power transformer or AC line input is bad.

If it is an AC-DC set like a table radio, then the tube filaments are wired in series. If one is bad, they will all be out. Get out your ohmmeter, pull each tube, and check it for filament continuity.

Assuming the filaments check out - all sections glowing (for metal tubes, feel the case for warmth after a few minutes though this won't guarantee that all sections are alive) when power is applied:

WARNING: It is possible for metal cased tubes to develop a short between one of the high voltage electrodes like the plate and the metal case. Test with a voltmeter before grabbing one of these and keep that other hand in your back pocket!

Check for DC voltages out of the power supply. There will be big filter capacitors - check across those. Watch out: we are talking several hundred volts and BIG capacitors - ouch.

With no signal, check plate voltages on the various stages - there should something. If you measure 0, then a plate resistor or coil could be open or the tube may be shorted.

The rest is just basic troubleshooting. Think of the vacuum tubes as oversize high voltage depletion mode FETs (field effect tubes, why not?). This is not much different than modern equipment except for the bites the relatively high voltages can take out of your hide.

There are some links in Sam's Neat, Nifty, and Handy Bookmarks to vacuum tube information and troubleshooting.

Additional comments on old equipment restoration

(From: Carl Ratner (artdeco@bway.net).)

A good place to post problems is rec.antiques.radio+phono. There are often discussions there about fixing vintage electronic gear.

Many long books have been written about fixing old radios! If you don't want to do a lot of reading and learn a lot of theory, here are some practical tips: First, give the radio a thorough physical inspection with the power disconnected. Use your eyes and your nose. Look carefully for broken or disconnected wires, charred components, damaged insulation, etc. If you see wax dripping from a transformer or if it smells burnt, there has been an overload of some sort that will need to be identified. If the set has an internal antenna, make sure that it is connected. If an external antenna is required, connect a long piece of insulated wire, say 15 feet, and lay it on the floor. Old sets will play very weakly or not at all if the antenna is missing. Always replace the power cord if it is deteriorated.

In radios of 1930s vintage, it's very likely that all wax paper capacitors, as well as the electrolytic capacitors, are bad. First thing to do is replace all the wax paper ones with modern mylar types. If you have the tall metal can electrolytics, you can put modern ones under the chassis (the new ones are tiny). However, you must disconnect the old ones from the circuit... don't bridge the new ones across the old. Be sure to observe polarity of electrolytics. You may leave the old cans in place to retain original appearance. BTW, the old square mica capacitors seldom need to be replaced unless the cases are cracked open of they have other obvious damage.

Even if some of the old wax paper capacitors are still good, they are likely to fail within a few days if you start using the set. I've restored hundreds of old radios and have learned this from experience. Get them all out of there and save yourself a lot of trouble.

You should also check the value of all the carbon resistors in the set. They tend to go high or open with age. Replace the bad ones with modern equivalents (same resistance and wattage). You may have to disconnect one side of a resistor when testing it, as the associated circuitry can cause a low reading. However, if a resistor reads way too high, you don't have to bother disconnecting it for testing as it is definitely bad.

Your set should start playing quite well after you change all the capacitors and possibly some resistors. You noted that you had changed the tubes, and I'll assume that all the replacements are good. Tubes don't fail nearly as often as people would expect, however, and it's possible that the set's original tubes were OK. Once you get the set working, you can substitute the old tubes one at a time to see if the set continues to play. Then just keep the good ones as spares.

Set still dead? If you have a multimeter, check the B+ voltage. The audio output tube's plate connection is a good place to do this. This can be 250-350 hundred volts in a transformer set, so work with care. If B+ is absent or some very low value, you have a problem in the power supply. (If you tell me the tube numbers in your set, I can give you some of the pinouts for testing) If the rectifier tube is known to be good, and you have already changed the electrolytics, then you may have a bad power transformer (large black box, usually near a back corner of the chassis. These are hard to find nowadays and very costly. I'm assuming here that you don't have a B+ short somewhere else in the radio. You will know about that because something will be smoking if such a short exists!

There are other components that can fail. Inspect the speaker for physical damage. You can test the voice coil and field coil for continuity. Replace if open. A modern permanent magnet speaker can be substituted for an old field coil speaker, but a power resistor of abut 1500 ohms, 20 watts must be added to replace the field coil. Dirty volume controls and band switches can cause noisy, weak or intermittent sound too. Clean them with a good spray cleaner such as Deoxit D5. Avoid the "tuner cleaner" that is sold at Radio Shack. It is worthless for fixing old radios.

As a final step, your set may need an alignment. This consists of adjusting all the tuned circuits to factory specifications to obtain the best possible performance from your set. You need a signal generator and an output meter to do this properly. It is strongly recommended that you do not twiddle any screwdriver adjustments on the IF transformer cans or elsewhere in the set unless you know exactly what you are doing. Misadjustment will cause the set to play very poorly or not at all.

End of short course in fixing old radios.

(From: R. G. Keen.)

1. Use a battery or ohmmeter to verify that the speaker clicks when electricity hits it.

2. Disconnect the output transformer primary and use the battery on the primary to verify that it makes the speaker click, albeit faintly.

3. Power the amp. verify that the plate(s) on the output tube(s) are sitting slightly below B+, and that cathode is near ground, grid more negative than cathode.

4. Touch a probe to the grid of the output tube, listen for a click in the speaker. No click means that the output tube or it's surrounding circuitry is bad.

5. Assuming that (4) worked, go one tube back up the signal chain at a time, touching grids and listening for clicks. When the clicks stop, that tube or the circuitry around it is bad.

6. When you find the bad one(s), measure all the resistors and check the capacitors for leakage. Measure the tube pin voltages for plate high, cathode low and grid less than cathode. sub in a new tube.

7. It could be an open volume or tone pot between stages. Also a bad solder joint. remelt and touch with a bit of rosin core solder every joint in the bad stage.

(From: John Mitchell (j.b.mitchell@qmw.ac.uk).)

Get a hold of the "The Amp Book" (or something like that) by Aspen Pittman. It's stuffed full of dozens and dozens of tube amp schematics plus other info on mods servicing etc.

Capacitors in old equipment

(From: George R. Gonzalez (grg@umn.edu).)

I used to repair mostly oooold radios from the 1930s and 40s. Now I'm doing more of the newer stuff, including test equipment and stereos from the 60s and 70s. Here's my rundown of what needs replacing capacitor-wise:

- 1920-1935: Radios have non-polarized paper-oil filter caps. These are usually in very good shape. You maybe have to replace 5% of them.

- 1935-1950: At least half the electrolytics have dried out. Some of the others will reform, the rest are too leaky to use. About 80% of the wax- covered caps are leaky, although this depends on how dry the radio was kept.

- 1950-1970: 80% of the black and blue-green bakelite caps are very leaky. About 30% of the electrolytics have dried out. One exception, the Sprague 350Ds look nice on the outside, but about 80% are dried out, leaky, or shorted, especially those with date codes before 1970. Those bakelite-cased electrolytics sealed with black, yellow, or red goop are almost all leaky or dried out.

I think I'm going to stock up on small electrolytics, as those seem to only have a 30-year life, even in the cooler-running more modern equipment.

TV/VCR combos

These hybrids which include both a TV and VCR (and sometimes other stuff as well) seem to combine the worst of all possibilities. Although, in principle, the idea of a combination TV/VCR sounds good - no cabling to worry about, ease of use, compatibility assured, the result may be less than meets the eye. While TV/VCR combo units do include both a TV screen and a VCR transport, very often there is only a single shared tuner so that viewing and recording of different programs is not possible unless one is from an external baseband video source (assuming there is a suitable input jack) like - you guessed it - a VCR or laserdisc player.

If either the TV or VCR poops out and needs repair, the entire unit may be unusable either because of shared circuitry or because the whole thing is in the shop. Construction quality tends to be shoddy and some designs are poor to begin with. Finally, as if this is not enough, servicing is difficult and painful because everything is crammed into a single compact (at least that is a good feature!) unit.

Refer to the appropriate documents for your particular problems.

Boomboxes and compact stereo systems

These combine a stereo receiver and a single or dual cassette deck, and/or a CD player or changer, and a pair of detachable speakers, into a single unit. Most are fairly portable but larger boomboxes and compact stereos may require a forklift to move any great distance.

While the individual subsystems - CD player for example - are usually relatively self contained electrically except for a common power supply, mechanically, everything tends to be jumbled together - even on units that have an outward appearance of separate components. Both cassette transports are usually driven from a single motor. Getting at the CD player may require removal of both cassette decks, audio amplifier, and power supply. Working on these is not fun. As usual, take careful notes as you disassemble the unit and expect it to require some time just to get to what you are after. Be especially careful when removing and replacing the individual modules if printed flex cables are used for interconnections.

Refer to the relevant sections on cassette transports, loudspeakers, and power supplies for problems with these units. Refer to the document: Notes on the Troubleshooting and Repair of Compact Disc Players and CDROM Drives for CD specific problems.

Since these do get abused - bumped, dropped, dunked, etc., bad connections, and other damage is very common. See the sections: "General intermittent or erratic behavior" as well as "Noisy or intermittent switches and controls".

Design to discourage repair

Here is a description of the pain involved in attempting to get at the CD player part of a Garrard boombox. Sadly, this is all too typical of 'Getto Blaster' construction.

(From: BELJAN E (lvpy67c@ix.netcom.com).)

I managed to get the whole Garrard mess disassembled (this thing is a major pain to service). The CD mechanism is removable, but just try it. This boombox has all sorts of modules: main board, display, cassette, radio, power supply, and CD are all separate. The problem is the way it is designed you simply cannot reach all the connectors to get the CD player out. If I could get the CD player out, I could disassemble it and find the solution. By the way, voltage to CD section appears OK. I would not have been able to find loose connections had there been any. I put it back together, CD still dead, everything else still works. It is convenient to service only if you intend on replacing the entire mechanisms (possibly Garrard's motive?). If I really needed to, I could simply detach the CD mechanism and replace it. I wouldn't bother. I see they now have Garrard Boombox with Dual CD players, and one with all sorts of features, one with detachable speakers and so on. This is a mystery, with the voltages OK, it would seem that there would be a loose connection, but none are visible (remember I cannot get the whole thing out).

I say this thing is a pain to service, here is why:

1. You must have an 8 inch long thin phillips screwdriver to disassemble it.

2. You must remove the cassette player to reach the Display.

3. You must remove the display to reach the switches.

4. You must remove the switches to reach the CD mechanism.

   An interesting note: the display modules are connected to the CD mech, along with the headphone module, they work fine.

5. you must unscrew the CD player from behind, then attempt to slide it forward, while it is connected to the main board from behind with white push on connectors. You get it halfway out, careful now, you don't want to damage the Cassette deck, which is connected somewhere out of visibility.

6. Once you slide it forward, you must try to loosen the slide on connectors without dropping the whole mechanism on the main board. (you need 6 hands and screwdrivers to try to do this.

7. On top of all that, the Whole Front of the unit is hanging there, connected also out of site

This unit is incredible. Truly incredible. It is easy to replace whole components, but servicing?

Panel lamps out

In the old days, this was due to the failure of easily replaceable and widely available miniature incandescent lamps. Even today, may displays are not LEDs as you might think but LCDs with backlighting provided by - you guessed it - incandescent lamps. Unfortunately, they are rarely easily replaceable and or as widely available.

This will be particularly likely if the display color is anything but the most common for LEDs - red. You might find green LEDs but will not likely find orange and certainly not blue or purple. LEDs would not be orange because the additional cost of orange LEDs would not translate into increased sales of boomboxes (or whatever). Blue LEDs are very expensive and purple ones do not exist.

The bulbs are replaceable. Getting at them may be easy or require entirely disassembling the unit. Soldering may be required as the manufacturer saved a nickel by not providing a socket. They may be tiny and special - try places like MCM Electronics for replacements.

If they are really red LEDs or vacuum fluorescent displays, then the most likely problem is a bad connection or other physical damage.

Adjusting station/channel settings on tuning dials

So 95.7 MHz comes in a 100.1 MHz on the dial.

Don't touch any of the trimmers on the tuning capacitor! They didn't magically change their settings. Just move the pointer on the dial cord to match a known centrally located station. If it is glued, you may have to carefully break the bond between the pointer and the dial cord. Then put a drop of household cement to fix its position when you are satisfied with the adjustment. Only if the ends of the dial are way off frequency should you consider anything beyond this mechanical fix.

Caution: Be careful! Should you accidentally cut the dial cord or have it pop off of the pulleys, you will have a much bigger job ahead of you. In this unfortunate circumstance, see the section: Repairing a broken dial cord or tuning gang wire.

Repairing a broken dial cord or tuning gang wire

With age, use, or through some mishap, it is inevitable: your analog dial no longer works because the string that runs between the tuning knob, variable capacitor, and dial indicator has broken. How does one repair it?

The simple answer is: very carefully! :-)

Demonstrating your skill in stringing dial cords is one of those rites of passage that has (thankfully) pretty much disappeared :-). Usually, it succumbs to a bit of logical thinking and carefully placed bits of tape to keep the entire mess in place until the last knot is tied!

These are a royal pain - especially if you do not know the original routing. In this case, some of it is going to be by trial and error. Some of my learned-the-hard-way tips:

1. Major electronics distributors will actually be able to supply dial cord material without making too much of a face though they may have to go into a dusty old bin to locate it!

2. Start at the variable capacitor pulley. Tie your favorite knot and secure it with some semi-flexible adhesive like Duco Cement(tm) or windshield sealer.

3. Route the cord around the appropriate idlers and the tuning knob shaft.

4. As a default, 3 turns on the tuning knob shaft seems to be common. If there isn't enough space for 3 turns, use 2 turns. If it slips with 3 turns, use 4 turns.

5. If in doubt about the direction, determine which way it will end up turning the variable capacitor.

Clockwise rotation of the tuning knob should increase the channel frequency by decreasing the capacitance - plates separating.

6. Use bits of electrical tape or putty to keep the cord from popping off of the idlers, etc., until you have it firmly attached to the spring on the other side of the variable capacitor pulley.

7. Once you are happy with the routing, pull it tight enough to stretch the tensioning spring about half-way. With the cord held in place with your finger, confirm free and smooth movement throughout the entire tuning range.

8. Tie the cord off and seal it as in (1) above.

9. Install the dial pointer - it usually just clips on. Tune a known station and slide the pointer along until it lines up with the correct frequency. Use a dab of sealer to keep it from wandering off.

Congratulations! You are done. Hopefully, only 3 or 4 iterations were needed. Now, if you need to do this again, it will be easier! And, your supply of tuning cord will probably last centuries.

One more gotcha: Don't attempt to solder circuitry near a dial cord - get your iron near it and the stuff often used melts instantly - much fun! Push it out of the way or shield it with something.

Revival of dead or tired remote control units

There are two types of problems with hand held remote controls: they have legs of their own and they get abused or forgotten. I cannot help you with walking remotes.

Where response is intermittent or the reliable operating distance is reduced, first check the batteries and battery contacts. If some buttons are intermittent or dead, than the most likely cause is dirty or worn contacts under the rubber buttons or on the circuit board.

If there is no response to any functions by the TV or VCR, verify that any mode switches are set correctly (on both the remote and the TV or VCR). Unplug the TV or VCR for 30 seconds (not just power off, unplug). This sometimes resets a microcontroller that may have been confused by a power surge. Confirm that the remote has not accidentally been set to an incorrect mode (VCR instead of TV, for example). If it a universal type, it may have lost its programming - reset it. Make sure you are using the proper remote if have multiple similar models.

Test the remote with an IR detector. An IR detector card can be purchased for about $6. Alternatively, construct the IR detector circuit described in the companion document: Notes on the Troubleshooting and Repair of Hand Held Remote Controls.

If the remote is putting out an IR signal, then the remote or the TV or VCR may have forgotten its settings or the problem may be in the TV or VCR and not the hand unit. The following is just a summary - more detailed information is available in the companion document: Notes on the Troubleshooting and Repair of Hand Held Remote Controls.

Problems with remote hand units:

All except (1) and (2) require disassembly - there may be a screw or two and then the case will simply 'crack' in half by gently prying with a knife or screwdriver. Look for hidden snap interlocks.

1. Dead batteries - solution obvious.

2. Corroded battery contacts, Thoroughly remove chemical deposits. Clean contacts with pencil eraser and/or sandpaper or nailfile.

3. Broken connections often between battery contacts and circuit board, possibly on the circuit board - resolder.

4. Bad resonator or crystal - replace, but diagnosing this without an oscilloscope may be tough. Broken connections on resonator legs are common.

5. Dirt/spills/gunk preventing keys from operating reliably. Disassemble and wash rubber membrane and circuit board with water and mild detergent and/or then alcohol - dry completely.

6. Worn or corroded contact pads on circuit board. Clean and then use conductive Epoxy or paint or metal foil to restore.

7. Worn or dirty pads on rubber keypad. Clean. If worn, use conductive paint or metal foil to restore.

8. Cracked circuit board - can usually be repaired as these are usually single sided with big traces. Scrape off insulating coating and jumper breaks with fine wire and solder.

9. Bad LED. If IR tester shows no output, remove LED and power it from a 9V battery in series with a 500 ohm resistor. If still no output, replace with readily available high power IR LED. Otherwise, check driver circuits.

10. Bad IC - if it is a custom chip, forget it! Failure of the IC is usually quite unlikely.

    (The following is from Duane P Mantick:)

    An awful lot of IR remotes use IC's from the same or similar series. A common series comes from NEC and is the uPD1986C which, incidentally is called out in the NTE replacements book as an NTE1758. A lot of these chips are cheap and not too difficult to find, and are made in easy-to-work-with 14 or 16 pin DIP packages. Unless you have no soldering or desoldering skills, replacement isn't difficult.

There are a large variety of universal remotes available from $10-$100. For general TV/VCR/cable use, the $10 variety are fine. However, the preprogrammed variety will not provide special functions like programming of a TV or VCR. Don't even think about going to the original manufacturer - they will charge an arm and a leg (or more). However, places like MCM Electronics do stock a variety of original remotes - prices range from $9 - $143 (Wow $143, for just a stupid remote! It doesn't even have high definition sound or anything exotic). The average price is around $40.

Problems with keypads or touchpanels

Most common are moisture problems followed by physical damage:

Very often, a little overzealous cleaning results in moisture trapped inside a not quite perfectly sealed membrane keypad or touchpanel.

First, of course, dry off the exterior as best you can. Any moisture that seeped inside may be difficult to remove without surgery - which is definitely not something you want to undertake as the long term reliability will be compromised.

I would recommend waiting a while - a week may be required - for it to totally dry out. You could also try confirming across the touchpad contacts with an ohmmeter that there is still low resistance (even 10s of K ohms may look like a button press). It is nearly impossible to speed up this process without subjecting the device to conditions that may harm the device - heat and/or vacuum. You possibly try something like isopropyl alcohol in the hope that it will displace the water and dry quickly. I do not know if this will be safe in every situation, however.

Of course, it is also possible that are other problems but I have seen these things take a very long time to dry out.

However, significant damage - a membrane type touchpad is punctured - may require replacement unless you can repair the internal wiring. The connections are usually made with flex-cables which are difficult or impossible to repair. See the section: Repairing flexible printed cables. Damage to any membrane buttons may result in stuck buttons or improper operation of other buttons.

Repairing flexible printed cables

It seems that more and more consumer devices from pocket cameras to laptop computers are being built with miniature multiconductor flexible printed cables. Very often one or more traces to develop hairline cracks due to repeated flexing. In addition, damage from moving circuit boards and modules during servicing is all to common.

Needless to say, repairing any kind of flex cable is a real pain!

Caution: many devices like calculators have printed cables that use a material that will not take solder and are glued rather than soldered at their ends - the logic board and LCD panel, for example. Repair of problems with the cables is virtually impossible. Take great care when working inside of devices with this sort of cabling to prevent damage to the cables or their termination.

With types like these in particular where soldering is not possible at all, the use of conductive paint, conductive Epoxy, or the stuff in a windshield defrost heater repair kit are worth trying.

For the metallic conductor types, I have succeeded by carefully scraping the plastic off with an Xacto knife and then soldering fine wire (#30 gauge wire wrap for example) to the traces. This presumes that the conductors on your cable will even take solder. I then cover up the joints with a flexible sealer for electrical and mechanical protection.

However, you need to make sure that the wire you use can be flexed or that the joint is set up in such a way that the wire does not flex much - else you will just end up with broken wires pretty quickly.

Soldering from end point to end point if possible may be preferable. Even going to only one endpoint would reduce the risk of immediate damage and reliability problems in the future.

With multiple traces broken or damaged, you are probably better off replacing the cable entirely.

Where the break is near one end and the equipment will be happy with a cable that is slightly shorter, it may be possible to cut off the bad part, carefully scrape the insulation from the appropriate side exposing a new set of contact strips to go in the socket.

(From: Steinar Botten (sbo@nera.no).)

I just fixed an electronic kitchen scale where the glued-on flex cable had begun to come loose from the LCD display, causing some of the segments to grow faint and disappear, while others showed when they shouldn't. In my first attempts I used conductive paint, but I couldn't get the viscosity right so that the paint didn't spread and short-circuit some of the connections. So I removed and discarded the flex cable and cleaned the tracks on the PCB where the cable had been attached. I searched through my collection of IC sockets and found one type with "fork-type" contact springs that could be removed from the socket and that fit snugly over the glass edge of the display. The spacing of the contact points of the display left just enough room for insulation (I used linen thread because the subsequent soldering would have melted plastic tape) between the contact springs. After having fixed the display back on the PCB with double-sided tape I soldered fine copper wire between the springs and the PCB. And voila, the display was OK again.

Some ASCII art might make things clearer, here is a side view of the LCD display:

```
          ___
         ! ! !
         ! ! !
         ! ! !
 contact !_! !
  side --> ! !
          !! !!
          !!_!!
          !___! <-- contact spring from IC socket
          !
          !
```

Obviously, this probably wouldn't work on a pocket calculator because of the size of the contact springs.

(From: Bob/Brad (santek@mb.aibn.com).)
