  - Minerals from water deposited on surface(s) of the water pool - including the piezo. This disrupts/changes the resonance/output of the piezo - and you see the effect.
  - Clogged air filter - there should be a little 'trap door' somewhere on the case with a little grill. Pop it out and wash the filter found therein. Replace.
  - Driver of the piezo going down that hill. Time to get another one or look for the warranty card if it applies.

  CAUTION: Unless you know what you are doing (and have gotten shocked a few times in your life) DO NOT play with the piezo driver module. Most run at line voltage with sometimes 100+V on heatsinks - which are live.

- No output:
  - Dead piezo driver - get a new unit unless under warranty.
  - Dead wire or float-switch or humidity switch or 'volume'... that should be easy - use an ohmmeter and look for shorts/opens/resistance.
  - Dead fan - should still have mist - just none of it getting out.
  - No power in the outlet you're using ;-)

Note: piezo's in general are driven with voltage, as opposed to current. This explains why you can expect high voltages - even in otherwise low-voltage circuits. Case in point: the Polaroid ultrasonic sonar modules.

(From: Dave VanHorn" (dvanhorn@cedar.net).)

The Devilbiss units I used to repair, used about 1 W at 1 MHz (if I recall correctly into a thick barium titanate transducer. Their most common problem was cracked transducers.

There was a shaped cavity above the transducer, I would guess some sort of Helmholtz resonator. You had to tune the operating frequency around to maximize the plume, and then trim for a certain plume height with the output drive.

Don't stick your finger in the plume. Although the water is not hot, you will discover that your finger is mostly water. It's kind of like slamming your finger in a car door.

(From: Daniel Cilevitz (rpf.20.foobar0@antichef.com).)

Thinking about the above info on ultrasonic humidifiers and their power output, I decided to experiment with an ultra-cheap ultrasonic humidifier (useless for its intended application) and the clear polystyrene front cover of a CD jewel case. With the water level correctly set, placing the plastic sheet at the tip of the plume (cone shaped tip of the water) just above the transducer resulted in a cone-shaped section of material deforming outwards from the center of the wave. In normal operation, a mist of water is ejected from this location. The bottom of the sheet intersects the cone, and the truncated part of the wave doesn't like this and melts its way through. With the sheet in motion, a cut/trough about 3 mm wide appears. Moving slowly results in a slightly larger amount of material being displaced, up to about 5 mm. It doesn't go all the way through the plastic for some reason. The effect is the same as pressing a hot piece of metal against the plastic. The process is continuous and you can draw patterns by moving the material around on top of the standing wave. The deformed plastic was only warm, not hot, though it may have been cooled by contact with the water.

After seeing this firsthand, you will never feel the urge to stick your finger in the plume again! I would not want to discover the effects of a larger humidifier or ultrasonic cleaner on parts of your body. This was with a $25 unit from a store closing special, so imagine what a larger, more powerful one could do!

As an aside: Jewel cases are made from two kinds of polystyrene: General Purpose Polystyrene (GPPS) and High-Impact Polystyrene (HIPS). GPPS is crystal- clear but very brittle, and is used to mold the front and back covers. HIPS is translucent to opaque but more flexible, and is used to mold the tray. The tray needs to be flexible so that the tray hub can grab the disc hub without breaking off. It's unfortunate that the hinged part of the jewel case is made of such a brittle material, as it's always the first thing to break ;)

Ultrasonic waterfalls?

I don't suppose you are likely to encounter these but if you do, servicing procedures will be similar to those described in the section: Ultrasonic humidifiers.

(From: Roger Vaught (vaurw@onramp.net).)

At a local shop they sell small water fall displays made from limestone in a marble catch basin. These are made in China. They use a small water pump for the flow.

When I first saw one I thought the store had placed dry ice in the cavity where the water emerged as there was a constant stream of cloud flowing from it. Very impressive. It turns out they use the ultrasonic piezo gizmo to make the cloud. The driver is a small 3 X 5 X 3 inch box with a control knob on top. If you look into the cavity you can see the piezo plate and a small red LED. The water periodically erupts into vapor. I haven't been able to get a close look at the driver so I can't tell where it is made or if there is a product name or manufacturer. They will sell that part of it for $150!

Ultrasonic cleaners

Ultrasonic cleaning is a means of removing dirt and surface contamination from intricate and/or delicate parts using powerful high frequency sound waves in a liquid (water/detergent/solvent) bath.

An ultrasonic cleaner contains a power oscillator driving a large piezoelectric transducer under the cleaning tank. Depending on capacity, these can be quite massive.

A typical circuit is shown below. This is from a Branson Model 41-4000 which is typical of a small consumer grade unit.

```
               R1        D1

        C \|    | 10K, 1 W     |    F ):: +---+    |               |
      Q1   |--+-+--------------+  6 o )::     |    |               |
        E /|  |  D3     R4       +---+        +----+------->>------+
         |    +--|<|---/\/\--+  _|_
         |           47, 1 W |  ---       Input: 115 VAC, 50/60 Hz
         |                   |   |        Output: 460 VAC, pulsed 80 kHz
N o------+-------------------+---+
```

The power transistor (Q1) and its associated components form an self excited driver for the piezo-transducer (PT1). I do not have specs on Q1 but based on the circuit, it probably has a Vceo rating of at least 500 V and power rating of at least 50 W.

Two windings on the transformer (T1, which is wound on a toroidal ferrite core) provide drive (D) and feedback (F) respectively. L1 along with the inherent capacitance of PT1 tunes the output circuit for maximum amplitude.

The output of this (and similar units) are bursts of high frequency (10s to 100s of kHz) acoustic waves at a 60 Hz repetition rate. The characteristic sound these ultrasonic cleaners make during operation is due to the effects of the bursts occuring at 60 Hz since you cannot actually hear the ultrasonic frequencies they use.

The frequency of the ultrasound is approximately 80 kHz for this unit with a maximum amplitude of about 460 VAC RMS (1,300 V p-p) for a 115 VAC input.

WARNING: Do not run the device with an empty tank since it expects to have a proper load. Do not touch the bottom of the tank and avoid putting your paws into the cleaning solution while the power is on. I don't know what, if any, long term effects there may be but it isn't worth taking chances. The effects definitely feel strange.

Where the device doesn't oscillate (it appears as dead as a door-nail), first check for obvious failures such as bad connections and cracked, scorched, or obliterated parts.

To get inside probably requires removing the bottom cover (after pulling the plug and disposing of the cleaning solution!).

CAUTION: Confirm that all large capacitors are discharged before touching anything inside!

The semiconductors (Q1, D1, D2, D3) can be tested for shorts with a multimeter (see the document: Basic Testing of Semiconductor Devices.

The transformer (T1) or inductor (L1) could have internal short circuits preventing proper operation and/or blowing other parts due to excessive load but this isn't kind of failure likely as you might think. However, where all the other parts test good but the cleaning action appears weak without any overheating, a L1 could be defective (open or other bad connections) detuning the output circuit.

Where the transistor and/or fuse has blown, look for a visible burn mark on the transducer and/or test it (after disconnecting) with a multimeter. If there is a mark or your test shows anything less than infinite resistance, there may have been punch-through of the dielectric between the two plates. I don't know whether this could be caused by running the unit with nothing in the tank but it might be possible. If the damage is localized, you may be able to isolate the area of the hole by removing the metal electrode layer surrounding it to provide an insulating region 1/4 inch in diameter. This will change the resonant frequency of the output circuit a small amount but hopefully not enough to matter. You have nothing to lose since replacing the transducer is likely not worth it (and perhaps not even possible since it is probably solidly bonded to the bottom of the tank).

When testing, use a series light bulb to prevent the power transistor from blowing should there be a short circuit somewhere (see the document: Troubleshooting and Repair of Consumer Electronic Equipment) AND do not run the unit with and empty tank.

Here are some comments on ultrasonic cleaner repair. These would appear to be more for larger units but some of the info should apply to the small ones as well:

(From: B. Clark (bclarkson@primary.net).)

I spend a great deal of time repairing ultrasonic generators from sinks in medical use. I can tell you this. While different manufacturers use different circuits, the basic design is the same everywhere. The most common failure mode is that the switching transistor(s) are shorted. When this happens, does the fuse blow in your case? If this is true, replace the rectifier bridge. If the circuit contains extra diodes, check those for shorts as well. Always replace both transistors at the same time. You can use ECG/NTE equivalents, so long as both are the same - don't count on a new 2N6308 and an ECG283 working together in this case.

Assuming the fuse never blows and the output frequency is around 40 to 50 khz, that rules out most of the small caps and resistors. Most generators that I have worked on produce a wave around 45 khz. A bad cap or resistor would cause it to be off frequency. The transducers should test as open. If they test as anything other than open on an multimeter (after allowing for settling as they are sensitive to vibration), then they could be bad. Transducer failure in my experience is not that common. It may suggest that your customer has been running the unit with the tank empty or only partially full.

The circuit is tuned. 100% of all generators sent to me have one or more shorted transistors. The customer complaint is usually "No ultrasonic action" or "Weak ultrasonic action". 99.999% of the time, using an ohmmeter and replacing shorted semiconductors corrects the problem. I have had one unit where a precision cap was out of tolerance and detuned the circuit. One nearby hospital has sent in three 500 watt units that were ran without the transducers connected. In all cases, the fuse didn't blow, however each of the three caught on fire. One of these has a 1/8 in hole through a coil in the transformer.

If any part drifts out of tolerance, the transistor will short. I have seen perfectly fine circuits short switching transistors when the unit is ran with no water in the tank. Do not attempt to run with one transducer. You will meet with failure. You should attempt to replace with the exact oem part when available. If you cannot find the original and have determined a adequate substitute, replace both of them.

I keep mentioning transistors realizing that small units have only one. The units I work on have 4 to help generate 500 watts of power.

Fog machines

If you don't know what a fog machine does, you probably don't need to read this section!

(From: Lance Edmonds (lanceedmonds@xtra.co.nz).)

Essentially, a fog machine consists of a heater unit and a pump, plus electronics to control the heater temperature, and control how much fog juice is pumped through the heater.

Most common failures are severed remote control leads, burned out pumps, or heating unit blockages.

I've never seen one with a fan, but many folks use a fan to disperse the fog to the desired locations across a stage, etc.

Unlike dry-ice, fog from a "fogger" rises and disperses quite quickly unless there is no ventilation... you can add some perfume (a few drops to the large tank) to reduce the "flavor" of the fog... when it's thick it tastes and smells horrid!

(From: krbjmpr@hotmail.com)

I have examined a couple machines just out of personal curiosity. what I found was, and keep in kind that these were the lower end series, was basically a high power heater and a small fluid pump.

From what I have seen , and can deduce, is that a high wattage heater block constantly is heating a 'transition' tube. Temperature is unknown, but it is damn hot. Temperature was controlled by a simple bimetal strip that looks like it activated a triac or similar device. Heater power was supplied by the triac. The fog fluid was pumped from the reservoir by a small fluid pump that ran on 6 to 12 VDC. The amount of fog produced was controlled by a large rheostat that had 12 volts applied to it, thereby creating a variable voltage divider. Activation of the 12 volts to the pump for fog was through a small relay that was able to be activated either through a switch added to the fog machine that completed a circuit, or the machine was set on a timer (internal) for fixed interval. Switch voltage was also 12 volts. Fog fluid was injected into the transition tube, and the output nozzle was significantly larger than the input. Estimated age of the machines was about 14 years or so.

After I saw the insides of these things, I am amazed that they are able to demand $300 to $400 price tags. I am thinking about making one of these out of a water-cooled resistor and gravity feeding a gallon jug of the juice through an older 24 VAC sprinkler valve. One of those rainy day projects.

From: don@Misty.com (Don Klipstein)

I once fixed a "Ness" brand "Mini-Fogger". Turned out there was a broken solder joint where the jack for the plug-in "remote" button went into a circuit board.

Also sometimes, the pump sticks. Tapping the pump with a screwdriver while attempting to run it may unstick it.

This thing is simple enough and made of parts that are reliable enough, with the possible exception of the pump. I would mostly look for broken connections or bad solder joints or clogs.

Dehumidifiers

Electric dehumidifiers use a refrigeration system to cool a set of coils which condenses water vapor. The heat is then returned to the air and it is returned back to the room. On the surface, this seems like an incredible waste of energy - cooling the air and heating it back up - but it is very effective at removing moisture. A typical large dehumidifier will condense something like 30 pints in 24 hours - which, unless you have it located over a drain - then needs to be dumped by hand.

There is supposed to be a cutoff (float) switch to stop the dehumidifier when the container is full. Hopefully, it works (and you didn't neglect to install it when the unit was new!)

Common problems with these units are often related to the fan, humidistat, or just plain dirt - which tends to collect on the cooling coils. The sealed refrigeration system is generally quite reliable and will never need attention.

An annual cleaning of the coils with a soft brush and a damp cloth is a good idea. If the fan has lubrication holes, a couple of drops (but no more) of electric motor oil should be added at the same time.

The fan uses an induction motor - shaded pole probably - and may require cleaning and lubrication. See the section: Problems with induction motors.

The humidistat may develop dirty or worn contacts or the humidity sensing material - sort of like a hot dog wrapper - may break. If you don't hear a click while rotating the control through its entire range, this may have happened. If you hear the click - and the dehumidifier is plugged into a live outlet - but nothing happens, then there is probably a problem in the wiring. If just the fan turns on but not the compressor, (and you have waited at least 5 minutes for the internal pressures to equalize after stopping the unit) then there may be a problem with the compressor or its starting relay (especially if the lights dim indicating a high current).

A very low line voltage condition could also prevent a refrigeration system from starting or result in overheating and cycling. A sluggish slow rotating or seized fan, or excessive dirt buildup may also lead to overheating and short cycling.

A unit that ices up may simply be running when it is too cold (and you don't really need it anyway). Dehumidifiers may include sensors to detect ice buildup and/or shut off if the temperature drops below about 60 degrees F.

Garbage disposals

A garbage disposal is just an AC induction motor driving a set of centrifugal hammers (they use to use sharp cutters but these were even more dangerous). The cutters throw the food against an outer ring with relatively sharp slots which break up the food into particles that can be handled (hopefully) by the waste system. However, always use generous amounts of cold water (which helps to cool the motor as well) and let it run for a while after there is nothing left in the disposal and it has quieted down. This will assure a trouble free drain. Otherwise, you may be inviting your friendly plumber over for a visit!

Common problems with garbage disposals relate to three areas:

- Something stuck in grinding chamber - disposal hums or trips internal protector (red button) or main fuse or circuit breaker. Unplug disposal! Then use the wrench (or appropriate size hex wrench) that came with the disposal to work rotor back and forth from bottom. If there is no hole for a wrench (or you misplaced yours), try a broom handle from above but NEVER put your hand in to try to unjam it (there are still relatively sharp parts involved). With the disposer unplugged, you can carefully reach in and feel for any objects that may be stuck or which cannot be broken up by the grinding action (like forks, toys, rocks, beef bones, etc.) and fish these out. Once free, restore power (if needed) and/or reset red button ((usually underneath the motor housing - you may have to wait a couple minutes until it will reset (click and stay in). Then run the unit with full flow of cold water for a couple of minutes to clear anything remaining from the grinding chamber and plumbing.

- Motor - although these only run for a few seconds a day, motor problems including shorted windings or defective rotors are possible. Assuming rotor turns freely, these may include a hum but no movement, repeated blown fuses or tripped circuit breakers, or any burning smells.

- Leaking shaft seal - probably what causes most disposals to ultimately fail. The upper seal develops a slight leak which permits water to enter the motor housing damaging the bearing and causing electrical problems. Symptoms include seized rotor, excessive noise or vibration, actual water leaking from inside the motor housing, burning smells, etc.

- Power switch (built into batch feed models) - wall switches can go bad like any other application. The built in magnetic or microswitch in a batch feed disposal can also fail. Intermittent or no operation may result.

- Drain blockage - disposal runs but water doesn't get pumped out of sink or backs up. Use plumber's helper (plunger) or better yet, remove U-trap under sink and use a plumber's (steel) snake to clear blockage in the waste pipe. NEVER NEVER use anything caustic!!! First of all, it will not likely work (don't believe those ads!). More importantly, it will leave a dangerous corrosive mess behind for you or the plumber to clean up. The plunger or snake will work unless the blockage is so impacted or in a bad location (like a sharp bend) in which case a professional will need to be called in any case.

Unless you are the truly die-hard doit-yourselfer, repair of disposals is probably not a good use of your time. The ultimate reliability of all but the most obvious and simple repairs is usually unknown and could be very short. However, other than time, there is nothing to be lost by at least investigating the source of the problem.

Garbage disposal pops reset button but nothing blocked

Even if nothing is stuck in it, is the rotor free - not too tight? If you have that little wrench that comes with many disposers, you should be able to turn the rotor relatively easily (I would say about 1 foot-pound of torque or less if your arm is calibrated). A tight bearing may be the result of a shaft seal leak - see the next section: Garbage disposal seizes repeatedly.

The red reset button is a circuit breaker. Either the motor is drawing too much current due to a shorted winding or a tight bearing or the breaker is faulty. Without an ammeter, it will be tough to determine which it is unless the rotor is obviously too tight.

If you have a clamp-on ammeter, the current while the motor is running should be less than the nameplate value (startup will be higher). If it is too high, than there is likely a problem with the motor. As an alternate you could try bypassing the circuit breaker with a slow blow fuse of the same rating as the breaker (it hopefully will be marked) or a replacement breaker (from another dead garbage disposal!. If this allows the disposer to run continuously your original little circuit breaker is bad. These should be replaceable.

If the bearings are tight, it is probably not worth fixing unless it is due to something stuck between the grinding disk and the base. Attempting to disassemble the entire unit is likely to result in a leak at the top bearing though with care, it is possible to do this successfully.

Garbage disposal is stuck - hums but does not turn

Here are typical problems:

> "I need help. Our garbage disposal is stuck. It hums but doesn't turn. If I leave it on for more than a few seconds it trips the circuit breaker on the unit. Any tips on how to solve this shy of buying a new unit? The unit is 7 years old."

> "I have an ISE In-Sink-Erator (tm), Badger I model. I tried turning mine on a few minutes ago, the motor started then stopped and now nothing happens when I flip the wall switch, not even a click."

Of course, first make sure there is nothing jamming it - use a flashlight to inspect for bits of bone, peach pits, china, glass, metal, etc. Even a tiny piece - pea size - can get stuck between the rotating disk and the shredder ring. WITH THE DISPOSAL UNPLUGGED OR THE BREAKER OFF, work the the rotor back and forth using the hex wrench that came with the unit or a replacement (if your unit is of the type that accepts a wrench from below. If it is not of this type, use the infamous broom handle from above.)

The internal circuit breaker will trip to protect the motor if the rotor doesn't turn. Turn off the wall switch, wait a few minutes for the circuit breaker and motor to cool, and then press the red reset button underneath the disposal. If it does not stay in, then you didn't wait long enough or the circuit breaker itself is defective. Then, turn on the water and try the wall switch again (in-sink switch if it is a batch feed model).

Assuming it is still tight with nothing stuck inside and/or jams repeatedly:

(From: Rob-L (rob-l@superlink.net).)

That's about how long it takes for the nut to rust away on the shredder disc of Insinkerator/Sears units. My comments will address ISE/Sears deluxe models with the stainless disc, for those who might have one.

When the nut/washer rusts away, the disc will wobble and get jammed. With the power off, try to rock the disc inside the unit. You might need to wiggle the motor shaft with a 1/4" hex wrench under the unit.

If you can free things up, and the disc can be rocked, it's the nut/washer. When that goes, so does the gasket, and unfortunately it requires total disassembly of the grinding chamber to replace the little gasket, because the disc will not come out otherwise. And if you don't replace the gasket, water/gunk will run down the motor shaft and into the motor. When those units go, you're better off to get a new disposer.

I think they intentionally use a non-stainless steel nut, because otherwise the units would last a long time. Even the replacement nuts will corrode. The motor shaft will also corrode, but not as fast as the nut. With a stainless shaft and nut/washer, the disposer would give many more years of service. And that's why they don't make 'em that way. :)

One part that is worth replacing is the mounting gasket. It's the part with the flaps that you feed things through. It gets cut-up and damaged by chlorine from sink cleaning or dishwasher discharge. (brittle, rough) It's a $4 part, usually available at Home Depot next to the new disposers, and it slips on in a matter of minutes -- you just disconnect the trap, then drop the disposer down by undoing the retaining ring. Swap the gasket, re-attach things, and your sink drain looks brand new.

Garbage disposal seizes repeatedly

A garbage disposal that doesn't have anything stuck in the cutting chamber but seems to be hard to turn or will work with effort until left alone for a day or two probably has a bad bearing caused by a leak at the shaft seal. Of course, water gushing out of the lower part of the disposal (or *any* amount of water dripping from inside the motor housing) is one indication that there is a leak! This also represents a safety hazard so the disposal should be left unplugged and not be used even if it still runs.

By the time the leak is detected, it is probably too late to save the disposal as corrosion of the steel shaft, excessive wear of the bronze bushing, as well as possible electrical damage has already occurred.

Realistically, there is nothing that could have likely been done in any case. It is virtually impossible to repack such a bearing in such a way to assure that a leak will not develop in the near future.

Garbage disposal replacement (or upgrade)

My general recommendation is to get the approximately $100 1/2-3/4 Hp Sears (ISE In-Sinkerator(tm) manufactured) unit when it is on sale (which is about every week). These now have at least a 4 year warranty.

If your previous garbage disposal was an ISE In-Sinkerator or Sears, then replacement is usually a 10 minute job if the under-sink plumbing is in reasonably good condition (doesn't crumble to dust when you touch it). If the part that mounts to the sink is not corroded and not leaking, I just leave it alone. The only tools required are a screwdriver and wire strippers (possibly) to move the power cord or cable to the new unit and a screwdriver or socket driver and a large adjustable wrench or pliers to unscrew the drain pipe and dishwasher connection (if used). Complete instructions should be provided with the replacement unit.

Sump pumps and utility pumps

Sump pumps come in two major varieties:

1. **Pedestal:** A motor on top of a 3 foot or so pole drives an impeller at the bottom of its long shaft. Only the base may be submerged.

   These motors are quite reliable but the bearing can rot/rust/sieze at the base where it may be under water or at least in a humid environment.

2. **Submersible:** A motor, usually totally enclosed in a sealed pump housing within an oil bath drives an impeller. The entire unit is designed to be fully or partially submerged in the sump hole.

   The casing may leak at the bearing (if not magnetically coupled) or at the wire connections. Repair of these motors is probably not worth the effort.

Utility pumps are often of the submersible variety.

Three types of automatic switches are commonly used:

1. **Float/weight on a wire, rod, or string** pulls on a spring action toggle type switch. The length of the linkage is adjusted for the appropriate low and high water settings. These will be used mostly with pedestal pumps. If properly sized, this type of switch can be quite reliable - I have a sump pump using this type of switch which is easily 30 years old at this point without ever having any problems with the switch.

2. **Mercury tilt switch** sealed inside a rubber float. By fastening its connecting wire to a suitable location, the level of the water will cause the float to pivot from horizontal the more vertical. An enclosed mercury switch then controls power to the pump motor. These are not serviceable but replacements are readily available.

3. **Diaphragm pressure switch** designed to sense the depth of the water from the trapped pressure. As above, these are not really serviceable but can be easily replaced by the same or a mercury type (2).

Most common problems are with switches that are no longer reliable or totally broken. Universal replacements are generally available since the switch is not usually an integral part of the motor/pump unit.

Toys

Since there are a semiinfinite number of variations on electrically powered toys, the only comment I have is that these are almost always combinations of small PM motors, switches, batteries, light bulbs - and totally impossible to identify electronic components. With small kids, physical destruction is probably a much more common occurrence than a part failure!

Incorrect response for remote control toys

The following may apply when there is no response or an uncontrolled response for certain commands like turn left or move backwards:

(From: Pete Peterson (peterson@usaor.net).)

I've repaired a couple with the same problem and its been the motor driver transistors each time. There are two or three direct coupled transistors from each side of the motor (probably equates to an H bridge) and one or all of these go open. Probably under designed for the current they carry. Just trace the wires from the motor out through the circuit and check the first several transistors you come to.

Garage door operators

Typical garage door operators use a 1/3 to 3/4 horsepower induction motor with a belt drive chain or screw mechanism to move the 'trolley' that actually grabs the door. A switch or pair of switches activated at each end of travel stops the motor and toggles the state (up or down) of the controller. Door blockage sensors detect obstructions and stop or reverse travel. A light turns on with motor start and stays on for 3-5 minutes thereafter, controlled by a simple timer.

Parts of a typical garage door operator (chain drive). Details may differ on operators with worm screw or other drive schemes.

1. **Motor:** Single-phase induction motor of about 1/2 horsepower at 862 or 1,725 (or so) RPM. It is electrically reversible with a large ratio V-belt drive (probably about 25:1 for a 1725 RPM motor between motor shaft and chain sprocket).

2. **Chain or screw drive:** This often needs lubrication. Make sure grease will not harden at low temperatures if relevant (e.g., Lubriplate).

3. **Limit switches** set top and bottom positions of door.

4. **Safety stop:** A means of sensing when excessive force is required to move the door. Some types use a compliant motor mount such that excessive torque will result in a twist which closes a set of contacts to reverse or stop the door.

5. **Logic controller:** The 'brains' which consists of some relays or a microcontroller.

6. **Remote receiver:** A radio receiver tuned to the frequency of the hand unit. Logic here or in the controller checks the transmission to determine if the codes match. More sophisticated units employ a pseudo-random code changing scheme to reduce the chance of code theft. This is usually in a box on the wall connected to the motor unit by a pair of wires.

   On units with DIP switches, both transmitter and receiver settings must match exactly. In addition, for older units in particular, the contacts on the switches may be dirty and/or oxidized so flipping each switch back and forth a few times may be needed to make a reliable connection. I have also seen a situation where one bit wouldn't work in one position - the other position was fine.

7. **Light bulbs and timer:** In many Sears as others, the timer is a bimetal strip heated to operate a set of contacts. The on-time is determined by how long it takes for the bimetal strip to cool. These fail after about 10 years but replacements are readily available. More modern units may switch and time the light from the microcontroller.

General garage door operator problems

1. No response from remote or local buttons. Test power to both the motor unit and control box (they may be separate) outlets. The operator or some other device might have blown a fuse or tripped a circuit breaker. Verify that the connection between the wall box and the motor unit is in tact - check the screw terminals on the motor unit - a wire may have fallen off. Check the circuit breaker (red button) on the motor unit - an overload or an undetected cycling condition (an obstruction causing the door to keep going up and down continuously) may have tripped it. Warning: pressing this button may result in the door starting to move immediately.

2. Local (inside) buttons work but remote unit is dead. Check and/or replace batteries in the remote unit, confirm that the the code settings have not accidentally changed (unit dropped, for example), go through the set up procedure outlined in your users manual. Find a cooperative neighbor with the same model and try their remote unit (after writing down their settings and reprogramming it for your door). If this works, your remote unit is bad. If this does not work, you have a receiver problem.

3. Remote unit has reduced range. Of course, first replace the batteries. If possible check with an identical model remote set to the same code to see if it is a problem with the hand unit or the receiver. Make sure any antenna wire (remote and/or receiver) hasn't fallen off or become disconnected. It is also possible that radio frequency emissions from something in the area is interfering with reception. Have you added any electronic equipment or even just rearranged its location recently - even a VCR or TV? What about your neighbors?

4. Motor operates (you can hear it) but door does not move. This can be caused by a broken or loose belt, snapped door counterbalance spring, locked door, disconnected or broken trolley, logic problems causing the motor be turning in the wrong direction, and other mechanical problems. If the motor runs for about the normal time, then the trolley is probably moving but not attached to the door. If it runs until forever or the overload pops, then a broken belt is likely.

5. Door opens or closes part way and reverses, stops, or twitches back and forth:

   - The tracks may need lubrication, there may be an obstruction like a broom that fell over into the vertical rails.

   - The gear timing may be messed up. The upper and lower limits may be determined by switches operated from a cam separate from the trolley that moves the door. If you just reassembled the mechanism, this is a likely possibility.

   - The safety stop sensors may be set to be too sensitive.

   - In extremely cold weather, the grease may simply be too viscous or just gummed up.

6. Door opens and closes at random. There can be several possible causes:

   - A neighbor has a similar model and has selected the same code (probably the factory default - did you actually ever pick your own code?).

   - Interference from nearby high power amateur, CB, or military or commercial radio transmitters may be confusing the receiver. Suggest to them that they relocate. :-)

     Are there such things as IR remote controls for garage door openers instead of the usual radio frequency variety?

   - The push button switch on your one of your remotes or receiver module is defective - a weak or broken spring - and it is activating the door due to vibration or just because it feels like it. Test the switches. On the hand units, you can just remove the batteries for a day and see if the door stops misbehaving.

Garage door operator light does not work correctly

Assuming the unit otherwise operates normally and you have tried replacing the light bulb(s):

For many types (Sears, Genie, etc.), there is a thermally operated time delay consisting of a coil of resistance wire, a bimetal strip, and a set of contacts. When the operator is activated, power is applied to the heater which causes the bimetal strip to bend and close the contacts turning on the light. Due to the mass of the bimetal strip, it takes a couple of minutes to cool down and this keeps the light on.

The most common failure is for the fine wire in the heater to break at some point. If you can locate the break, it may be repairable at least as a temporary solution. You cannot solder it, however, so a tiny nut and bolt or crimp will be needed. However, sticking contacts resulting in a light that does not always go off are also possible. Cleaning the contacts may help.

This part is very easily accessed once the sheetmetal cover is removed. It is probably somewhere in the middle of the unit fastened with three screws. Just remember to unplug the operator first!

Depending on the manufacturer, the original part may be available. I know that it is for Sears models.

You could also use a time delay relay or a solid state circuit (RC delay controlling a triac, for example) but an exact replacement should be just a whole lot less hassle.

Garage door operator loses track of where it is

You press the button to close the door and it works fine. However, next time you press the button to make the door go up and it tries to go down into the ground.

When it gets to the end of the track - be it at the top or bottom, there must be something that it trips to shut down the motor. At the same time, this is supposed to set things up so that the next activation will reverse the door.

Does the door stop and shut off when it reaches the end or does it eventually just give up and trip on the safety?

When it trips the switch to stop at the end of its travel, some mechanism is toggled to change the 'state' of the door logic so that it knows to go up the next time it is activated. It is probably this device - be it a latching relay, mechanical two position switch, or a logic flip flop - that is not being properly toggled.

I would recommend attempting to determine what device that switch is actually supposed to toggle - it probably is in the operator unit itself (not the control box).

Garage door remotes behave differently

> "I've got 2 Genie garage door remotes. One of them works from about 100 yards away; the other I almost have to be right next to receiver. I suspect that the antenna is the problem; either too short, or blocked by something."

First compare the antennas on the two remotes. If they are the same and there are no broken connections, your problem lies elsewhere. The chance of the wire itself being bad is pretty slim.

It could also be that the receiver and transmitter frequencies are not quite identical. If the remote units have been abused, this is more likely. I don't know about Genie but my (old) Sears has trimmers and I was able to adjust it *very* slightly to match that of the receiver and boost sensitivity.

CAUTION: If you try this (1) mark the exact position where it was originally and (2) do it only on the transmitter that has the problem. This will minimize the possibility of shifting the frequency to where it might interfere with other devices. See the section: Adjusting garage door operator remote unit for more information.

Adjusting garage door operator remote unit

This situation may arise if one hand unit operates normally but the other has a very short range. If you have only one hand unit, it might also be the problem though not likely to have just happened on its own - either it was improperly set up at the factory (if new) or hand unit was dropped once too often.

It should not work at all if the switches are set improperly. In such a case, first test and/or replace the battery. If this does not help, check the switch settings.

The tuning is done via a variable capacitor trimmer (probably).

There will probably be a trimmer inside the hand unit (don't touch the one in the receiver). Position yourself at a reasonable distance and use a plastic tool to adjust it until the door operates while holding the button down. The door will respond at increasing distances as you approach the optimal setting.

Note: mark the original position first in case this has no effect!

This assumes there is an adjustment - if there is none, you may have an actual electronic failure, bad connections, etc.

Improving sensitivity of garage door openers receivers

Where a garage is constructed with aluminum siding, the remote signal may be significantly attenuated and of insufficient strength to activate the receiver module (inside the garage) of the opener at any useful distance or at all. Assuming the system operates normally otherwise (i.e., activation is normal with the door open), two approaches (either or both together) can be taken to solve this problem:

1. Locate the receiver module (well, actually, its antenna) in an area of unsided wood, glass window, or other non-metallic area of the building. Note that construction insulation may use aluminum foil as part of its vapor barrier so there could be problems even in an area with no siding.

2. Extend the antenna on the receiver module. This may not always work but is worth a try. A 1 or 2 foot length of copper wire may help dramatically.

3. There are external antenna kits available for some door openers. The antenna goes outside, and connects to the receiver through a hole in the wall using coaxial cable. You will probably have to go directly to the manufacturer of your garage door opener or a garage door opener service company.

Universal remote/receiver units for garage door operators

So you lost your garage door remote or it got run over by your 4x4 :-). Or, it just expired due to age. There are alternatives other than an entire new operator if the remote is no longer available:

(From: Kirk Kerekes (redgate@tulsa.oklahoma.net).)

Go to a home center, and wander over to the garage door openers. Nearby, you will find GDO accessories, and among the accessories will be a universal replacement remote kit that includes a receiver, a transmitter and possibly a power supply. For about $40, you can by and install the receiver in place of the existing receiver. If your home center carries Genie openers, you can even get an Intellicode add-on unit that uses Genie's scanner-proof code-hopping technology.

Garage door operator doesn't work reliably in cold weather

First, check the lubrication. The most common problem is likely to be gummed up grease in the chain drive (if used) or the bearings of the rollers. Note: the track itself generally doesn't require lubrication.

Increasing the safety override force settings may help but are not a wise solution as the door will then be more of a hazard to any legitimate obstructions like people and pets.

Another possibility is that the motor start/run capacitor has weakened and is not permitting the motor to provide the proper torque. You can test the capacitor if you have a DMM with a capacitance scale or LCR meter. Better yet, just replace it.

Chamberland garage door opener repair?

> "My remote broke for my very old (defunct) chamberlain automatic garage door opener.
>
> Chamberlain tech support told me they suggest I buy a whole new unit. Is there any other way to make my door usable with a different remote, or some other arrangement?"

(From: Panayiotis Panayi (panikos@mishka.win-uk.net).)

Which Chamberlain operator is it, i.e., which model number. You can buy the handsets for Chamberlain operators up to 5 years old. If it is older you will have to buy a new Rx & Tx for it. Most operators have three screw terminals on the back for the attachment of Rxs. The old Chamberlain operators conformed to this. The new ones have the Rx built onto the main PCB inside the operator and have 4 screws externally for pushbuttons and infra red safety beams. If yours has 4 screws you will have to provide a separate PSU for the new Rx or solder two pieces of wire after the step down transformer on the PCB. You must do it before the rectifiers. Otherwise the current drain from the Rx will be too big for them. Besides almost all modern separate Rxs take 24 VAC.

Garage door operator security

While manufacturers of garage door operators make excellent claims of security, this is of no value if you don't take advantage of whatever features are included in your unit.

If there is access to your house from the garage, this security is even more critical. Once inside the garage, a burglar can work in privacy at their leisure - and a nice set of tools is probably there for their convenience in getting through your inside door! Filling up a good sized car or truck with loot - again in complete privacy - drive out and close the door behind. No one will be the wiser until you get back.

1. DIP switches. Many garage door operators use a set of 8, 12, 16, or more little switches to set the codes of the remote and base unit. If you have never set these, then your are probably still using the manufacturer's default - and all instances of the same model probably have the same code! Change it to something random - pick a number out of a random page in a telephone directory or something like that. Do not select something cute - others, perhaps with not totally honest intentions - will think the same way. You don't have to remember it so an arbitrary totally random setting is fine. However, even the types with 24 switches - that is over 16 million possible codes - can be sniffed: a relatively simple device can monitor your transmission as you open the door and program a special remote unit to duplicate it.

2. More sophisticated units incorporate a scheme whereby the codes change each time the operator is used in a pseudo-random manner which is almost impossible to duplicate. Even sniffing such a code is of no use as the next instance is not predictable.

3. Don't leave your remote unit prominently displayed in your car - it is an inviting target. Theft is not necessary - just a moment to copy down the switch settings may be enough. Lock your car! Also, leave a bogus remote unit in plain view (from your previous operator).

4. Just because the codes are secure doesn't mean that you are safe. The keylocks that are present on many operators to open the door from the outside are pretty pathetic. They can be picked in about the same time it takes to use a key - with ordinary tools - or often with any key that will fit the keyhole. My advice: replace with a high quality pick resistant keyswitch. A well designed electronic lock may be best. When going away for an extended period, use the physical lock on the garage door itself as added protection and unplug the garage door operator.

Identifying unknown transformer ratings in garage door operator

In a garage door operator, the transformer likely powers the controller and receiver. If you can look at where its outputs go, you may be able to infer something about the voltage even if the transformer is a charred mass.

- If there are AC relays in the box, they almost certainly run off the transformer and their coil voltage will be the same if it is the only one).

- Check the capacitors in the power supplies of the controller and/or receiver. They will give an indication of the approximate secondary voltage of the transformer. Their voltage rating will typically be 1.5 to 2 times the RMS of the transformer.

- Many of these transformers include a thermal fuse under the outer wrappings of insulating material. These may fail from old age or due to a fault. If the transformer works fine without overheating when replaced (or bypassed temporarily on a fused circuit), then it may be fine. However, shorted windings can cause a thermal fuse to blow and there is then no electrical test that will reveal the proper output voltage. See the docuemnt: Notes on the Troubleshooting and Repair of AC Adapters, Power Supplies, and Battery Packs.

- Disassemble the transformer and count the number of turns of the primary and secondary windings. The ratio multiplied by 115 is the output voltage.

- Get a 24 V transformer (it is probably not more than this) and connect its primary to a Variac and its secondary to the opener. Slowly increase the variac until everything works. (check every volt or so from 5 to 24). Measure the output voltage of the transformer, add 10-20%, you've probably got the secondary rating. If it is near a standard value like 12 or 24, this is most likely correct.

- Buy a new opener.

Electromechanical doorbells and chimes

Most of these consist of a low voltage transformer powered directly from the house wiring providing 10 to 20 VAC at its output, one or more switches for the front door(s), one or more switches for the back door(s), and an electromagnetic chimes unit.

All of the switches for a given location (i.e., inside and outside the storm door) are wired in parallel. There will be three terminals on the chimes unit - Common (C), Front (F), and Back or Rear (B or R). This notation may differ slightly for your unit. Typical wiring is shown below. An optional second chimes unit is shown (e.g., in the basement or master bedroom - more can be added in parallel as long as the bell transformer had an adequate VA rating.)

```
             Bell Transformer                               Chimes
          H o----+                                           Unit
                 )||       X      _|_ Front door               F
                 )|| +-----+------- -------------------o
                 )||(      |
```

```
    115 VAC    )||(      |      _|_ Back door        B
(Junction box) )||(      +------- -------------------o
               )||(
               )||(      Y                           C
               )|| +---------------------------------o
               )||
       N o----+
```

- The primary side of the transformer is generally wired permanently inside a junction box. This could be almost anywhere but the most common location is near the main electrical service panel.

- The common goes to terminal 1 of the transformer (the designation 1 and 2 is arbitrary - it may not be marked).

- All the front door buttons are wired in parallel and this combination connects between terminal 2 of the transformer and the F terminal of the chimes unit.

- All the back door buttons are wired in parallel and this combination connects between terminal 2 of the transformer and the B or R terminal of the chimes unit.

Where the pushbuttons are lighted, a small incandescent bulb is wired across the switch contacts and mounted inside the button unit. It is unlikely that this bulb will ever burn out since it is run at greatly reduced voltage. However, if the button does not light but the bell works, this has happened. Replace the pushbutton/light combination - locating a replacement bulb may not worth the effort though Radio Shack is supposed to have something that will work.

Most 'not-chiming' problems are due to the one or more of the following:

- **Defective switches:** These do go bad due to weather and use. Test with a multimeter on the AC voltage range. You should see the transformer voltage across the switch when it is not pressed and near 0 voltage across it when it is pressed. If only one location does not work, a defective switch is likely. Sometimes the wires just come loose or corrode at the terminals. These can be cleaned - with fine sandpaper if necessary - and reconnected.

  Note: where multiple switches operate the chimes from similar locations, multiple wires may be connected to each switch terminal. Don' mix these up or lose them inside the wall!

- **Bad connections:** These could be anywhere but unless you just did some renovation which may have damaged the wiring, the most likely locations are at the switches, transformer terminals, or chimes. However, this sort of installation might have been done by just twisting wires together when extra length was needed and these can go bad. They could be anywhere. Good luck finding the corroded twists! Then, use Wire Nuts(tm) or solder them together to assure reliability in the future.

  If just a single location doesn't work, that should narrows down the problem. If only one switch does not work, first test the switch. If disconnecting the wires from the switch does not result in full transformer voltage across the wires, then there is a bad connection between you and the transformer, the transformer has no power, is defective, or there is a short circuit somewhere.

- **Incorrect wiring at chimes unit:** This commonly happens when someone replaces the chimes unit and forgets to label the wires. :-(It is often difficult to follow the wires since they pass through door jams, finished basement ceilings, and may not be color coded. But checking it is easy to with a multimeter or the chimes themselves. An assistant would be helpful - else you can just short across the front or back buttons as required below.

  1. Disconnect the wires from the chimes unit terminal block.

2. Have your assistant press the front door button.

3. Determine which pair of wires has full voltage - use the multimeter or touch them between C and F on the chimes unit. Make a note of which ones they are. One of these wires is will be C and the other is F.

   Note: due to coupling between the wires, there may be some voltage across all combinations. The most will be across the relevant one (and this will be the only combination that will sound the chimes if you are using them as a voltage indicator).

4. Have you assistant press the back door button.

5. Determine which pair of wires now has voltage.

6. Connect the wire that is the same as one of those in (3) to the C terminal, the other wire of the pair to B, and the remaining wire to F.

- **Bad transformer or loss of power to transformer:** The transformer will often be located near the main service panel but not always. Sometimes it is a challenge to locate! To test, proceed as follows (this can be done with power on - the low voltage is safe but test first to make sure you have the correct transformer!):

  1. Disconnect one of the wires from its output terminals and then test across it with a multimeter on the AC voltage range. There should be the full rated transformer voltage across these terminals (actually, it will probably be 10 to 20 percent greater). The rated voltage of the transformer should be marked on it somewhere.

     - If there is voltage and it is approximately equal to the transformer's rated voltage, the transformer is probably good.

     - If there is none, check for a blown fuse, tripped breaker, or tripped GFCI; some other equipment may have overloaded the circuit. Actual failure of the transformer blowing a fuse or tripping a breaker is rare.

       A quick test to determine if the transformer is being powered is to feel it! The transformer should be warm but not hot to the touch. If it is stone cold, either there is no power or a bad connection in the input line) circuit.

     - If there is voltage and it is approximately equal to the transformer's rating, the transformer is probably good.

     - If the voltage is much lower than the rated voltage, the transformer may be bad. In this case, it will likely be quite hot due to a short circuit inside.

  2. Assuming the voltage checks out, reconnect the wire your previously removed.

     - If it is now low or 0, there is a short circuit somewhere. Note: a short on the secondary of this type of transformer will cause it to run quite hot but may not result in a blown fuse or tripped breaker or even any permanent damage to the transformer.

     - If the chimes sound as you reconnect the wire, there is a short in or at one of the pushbutton switches or associated wiring.

- If the voltage remains the same, then the transformer is probably good and the problem lies elsewhere - bad switch, bad connection, defective chimes.

3. **Dirty or defective chimes:** Most common problems are not electrical but mechanical - the plungers that strike the actual chime or gong do not move freely due to dirt and grime (especially in a kitchen location) or corrosion. Usually, wiping them clean or some light sanding will restore perfect operation. Do not lubricate as the oil will just collect crud and you will be doing this again in the near future. If they move freely, then you have an electrical problem. Also note that these chimes are designed to be mounted with the plungers moving vertically. There is likely a 'this side up' indication on the unit - if you are experiencing problems with a new installation in particular, verify your mounting!

   Test for voltage between the Common and Front or Back terminals when the appropriate button is pressed.

   - If correct voltage is present, disconnect the non-common wire and check the resistance between the Common and the terminal for the chime that is not working - it should be reasonably low, under 100 ohms. If the resistance is infinite, the coil is open. Unless you can locate the broken wire, the chimes unit will need to be replaced.

   - If the voltage is missing, the problem is probably elsewhere.

   - If the voltage is low, there may be a partial short in the coil, the transformer may be underrated for your chimes (not all chimes take the same amount of power), or there may be a high resistance somewhere else in the wiring.

Weak or erratic mechanical chimes

This can be due to several things:

- A transformer that doesn't put out enough voltage - 10 V instead of 16 V, for example. Modern chimes usually want 16 V - some transformers can be jumpered for multiple output voltages - check and change the jumper or replace if needed.

- A transformer with inadequate VA rating - quite likely if you have been adding additional chimes units to a house the size of Bill Gates' mansion. Install a larger transformer. The package will list the number of typical chimes that can be used.

- Bad buttons (especially if only one location is a problem). Use a screwdriver or paper clip to short between connections at each button. If this produces reliable chiming, the button probably needs to be replaced.

- Bad connections at transformer, chimes unit, buttons, or wire splices. Inspect and tighten if needed.

- Gummed up or defective chimes unit. Inspect, clean, or repair or replace as needed.

- Chimes unit mounted incorrectly (upside-down or on its side). Yes, they have a proper orientation! The weight of each plunger and its spring must balance - especially for the one that goes 'ding-dong'. :-) So, if you just installed this thing - quick, check it! :)

Adding an additional set of chimes

There are at least two ways of doing this (though the first one is more straightforward and intuitive and therefore generally preferred).

1. Locate the wires going to the first chimes unit. There will be either 2 or 3 (both front and back door). Connect the new chimes unit to these same wires in parallel:

```
          Bell Transformer                         Chimes    Chimes
       H o----+                                    Unit 1    Unit 2
               )||       X      _|_ Front door        F         F
               )|| +-----+------- --------------------o---------o
               )||(      |
    115 VAC    )||(      |      _|_ Back door         B         B
(Junction box) )||(      +------- --------------------o---------o
               )||(
               )||(      Y                            C         C
               )|| +----------------------------------o---------o
               )||
       N o----+
```

The only concern is whether the existing transformer that operates the chimes has enough capacity - you may need to replace it with one with a higher 'VA' rating (the voltage rating should be the same). These are readily available at hardware and electrical supply stores and home centers.

Some people might suggest just paralleling an additional transformer across the original one (which may be possible if the output phases match). I would really recommend simply replacing it. (This is probably easier mechanically in any case.) Unless the transformers output voltages as designed are identical, there will be some current flowing around the secondaries at all the times. At the very least, this will waste power ($$) though overheating is a possibility as well.

2. Each additional chimes unit or group of chimes units can use its own transformer but share the doorbell pushbuttons. Just wire point 'X' of the transformers together and each point 'Y' separately to the C (common) terminal on its respective chimes unit(s):

```
          Bell Transformer                         Chimes    Chimes
       H o----+                                    Unit 1    Unit 2
               )||       X      _|_ Front door        F         F
               )|| +-----+------- --------------------o---------o
               )||(      |
    115 VAC    )||(      |      _|_ Back door         B         B
(Junction box) )||(      +------- --------------------o---------o
               )||(
               )||(      Y                            C         C
               )|| +----------------------------------o    +----o
               )||                                         |
       N o----+        From output Y of identical o--------+
                        second bell transformer
                        (H, N, X, wired in parallel)
```

However, since the 'Y' outputs of the transformers are connected at all times to the 'C' terminals of the of the chimes units AND the 'X' outputs are tied together, any voltage difference between the 'Y' outputs will result in current flow through the chimes coils even if no button is pressed. Thus, the transformers must be phased such that there is no (or very little) voltage between 'Y' outputs. Test between 'Y' outputs with a multimeter set on AC Volts after you have the transformers powered: if you measure about double the transformer voltage rating (e.g., 32 VAC), swap ONE set of transformer leads (input or output but not both) and test again. If it is still more than a couple volts, your transformers are not matched well enough and you should purchase identical transformers or use the approach in (1), above.

Note: For either of these schemes, beyond some number of chimes units, the current rating of the pushbutton switches will be exceeded resulting in early failure. However, this should not happen unless your house is similar in size to Bill Gates' mansion.

3. Another alternative: If you have an unused baby monitor type intercom (your kid is now in college and you remembered to remove the old batteries which might otherwise now be a congealed mass of leaked goo), stick the transmitter next to the main chimes and put the receiver in your workshop or wherever you want it :-).

How to add an addition button to a door bell

Refer to the diagram in the section: Electromechanical doorbells and chimes.

Another button can be added in parallel with any of the existing ones (i.e., between points X and F or X and B in the diagram). The only restriction is that you may not be able to have more than one lighted button in each group as the current passing through the lighted bulbs may be enough to sound the chimes - at least weakly.

If you cannot trace the wiring (it is buried inside the wall or ceiling) the only unknown is which side of the transformer to use. If you pick the wrong one, nothing will happen when you press the button.

Wireless doorbells or chimes

The transmitter and receiver portion of these units are virtually identical to those of garage door operators. See the relevant sections on those units for problems with activation.

The bell or chimes portion may be either an electromechanical type - a coil forming an electromagnet which pulls in a plunger to strike a gong or bell. See the section: Electromechanical doorbells and chimes.

Others are fully electronic synthesizing an appropriate tone, series of tones, or even a complete tune on demand. Repair of the electronics is beyond the scope of this document. However, there are several simple things that can be done:

- Check for dead batteries and dirty battery contacts in both the pushbutton and chimes unit.
- Confirm that the channel selection settings have not accidentally been changed on the pushbutton or chimes unit. Flick each switch back and forth (where switches are used) just to make sure they are firmly seated.
- Check for improper programming or program loss due to a power failure (if AC operated) on units that are more sophisticated than a personal computer.

Doorbell rings on its own

- For mechanical chimes, this is almost certainly an intermittent short circuit in the button wiring or a defective button. First check or replace the outside pushbutton switches as this is the most likely location due to environment and small multilegged creatures.
- For electronics chimes, the problem could either be in the transmitter(s) or chimes unit or due to external

interference. Someone in your vicinity could have the model also set to the default code (which is probably what you have, correct?).

First, remove the batteries or kill power to all transmitters and wait see if the problem still occurs.

- If it does, either the chimes unit is defective or there is an external source of interference.

- If it now behaves, try each one individually to identify the culprit. In some cases, a low battery could produce these symptoms as well.

Old garage door operator guts for wireless chime

Don't toss the electronic remains of that old garage door operator. It would probably be possible to use it as the basis for a wireless doorbell. Instead of starting the motor, use its output to enable an electronic chime or buzzer. The RF transmitter and receiver for a wireless chime is virtually identical to that of a typical garage door operator.

TV antenna rotators

These consist of a base unit with some sort of direction display and knob and a motor unit to which the TV antenna is mounted. Of course, the troubleshooting of these installations is complicated by the remote and somewhat inaccessible location of the motor unit. :-(Before climbing up on the third story roof, confirm that you haven't lost power to the motor unit and/or base station and that the connections between them are secure.

A common type of motor that may be used in these is a small AC split phase or capacitor run induction motor. The relative phase of the main and phase coils determines the direction. These probably run on 115 VAC. A capacitor may also be required in series with one of the windings. If the antenna does not turn, a bad capacitor or open winding on the motor is possible. See the chapter: Motors 101 for more info on repair of these types of motors.

The base unit is linked to the motor unit in such a way that the motor windings are powered with the appropriate phase relationship to turn the antenna based on the position of the direction control knob. This may be mechanical - just a set of switch contacts - or electronic - IR detectors, simple optical encoder, etc.

Here is some info on connections for some types:

(From: Will Shears (wshearsN@wyzz.sbgnet.com).)

The rotor is operated on 24 volts AC. The wires are used like this:

- Pin 1 is a common
- Pin 2 is a forward direction lead
- Pin 3 is the reverse direction lead
- Pin 4 is a contact closure that will close regularly as the rotor operates.

This was connected to a knob switch, which also turned. Scenario is: the unit is pointed halfway through the circle. turn the knob left, the rotor turns and the indicator turns with it. when the rotor turns the same number of "clicks" as you turned the knob, it stops. same for reverse.

OR, the third lead was a meter lead, and the rotor turned a pot that changed the meter reading according to the position of the pots' turning. The rest is the same.

Inside the box was a 70 uF, 50 V or so NON POLARISED capacitor, or an AC capacitor. Usually the capacitor was connected across the #2 and #3 lead. It provided a phase shift for the motor, and you put 24 volts from #1 to #2 for forward, and to #1 and #3 for reverse. The other lead will either pulse as the rotor turns, or the voltage will change between the #1 & #4 lead, assuming there is a load resistor across the terminals. I would try a 470 ohm 1 watt resistor to start, and probably a 100 to 200 will be right. If you have a VOM, check for resistance across 1 and 4, if you get some, not a short, it is the second type, if you get a short or open, it is a pulse type.

(From: Al Cunniff (acunniff@erols.com).)

Here is one place that is devoted to antenna rotors if you give up:

- Norm's Rotor Service

5263 Agro Drive
Frederick, MD 21703
Phone 301-874-5885
Web: http://www.rotorservice.com/

Note: They don't have email built into their site, but the site tells you just about everything else you need to know about their business and service. It has a good rotor FAQ section too.

I'm not connected in any way with Norm's,

- Back to Small Appliances and Power Tools Repair FAQ Table of Contents.

Power Tools

Types of motors found in power tools

A variety of motor types are used depending on the type of tool. AC powered portable tools usually use a universal motor due to it high power/weight ratio and ease of electronic speed control. Cordless tools usually use a high performance permanent magnet DC motor. Stationary power tools almost always use some form of AC induction motor except where variable speed is required.

See the sections on these types of motors for more details than the following summaries provide.

Motors in AC line operated portable tools

Line operated portable (corded) power tools usually use a universal type AC motor providing 3,000 to 30,000 RPM at the motor shaft. For the same power rating, these will be significantly lighter than an induction motor.

A single or multiple stage gear reducer drops the relatively high speed at which these motors are most efficient to whatever the tool actually requires, increasing the torque as well.

Universal motors can also be speed controlled relatively easily using a variant of a simple light dimmer type circuit. Excellent torque is maintained over a very wide range extending to nearly 0 RPM.

Motors in cordless power tools

These are usually high performance permanent magnet DC motors using advanced high strength and exotic magnetic materials. They are very compact and light weight for their power output. As with all DC (brush type) motors, brush wear is a common problem.

Speed control is easily accomplished by low cost electronic circuits which chop the power (pulse width modulation) rather than simply using a rheostat. This is much more efficient - extremely important with any battery operated device.

Motors in stationary power tools

Stationary power tools which do not require continuous speed control will generally use some type of AC induction motor - split phase or capacitor start/run. The motors generally operate at a fixed speed of around either 1725 or 3450 RPM (U.S., 60 Hz power). Stepped pulleys or continuous mechanical speed/torque changers are used to obtain (usually) lower work piece speeds.

For example, a typical drill press may have one or two sets of stepped pulleys providing 3 to 15 or more speeds by changing belt positions. A continuously variable cone drive is also available as an option on some models. This is extremely convenient but does add cost and is usually not found on less expensive models.

An internal thermal overload protector may be incorporated into larger motors. WARNING: this may be self resetting. If the tool stops on its own, switch off and unplug it before attempting to determine the cause.

Generally, these induction motors are virtually maintenance-free though cleaning, tensioning, and lubrication may be required of the drive system.

However, electronic speed control of induction motors, while possible, is relatively complex and expensive requiring a variable frequency variable voltage power supply. Therefore, universal motors may be used on stationary tools like scroll saws with continuously variable electronic speed control.

As technology marches on, there will be increasing use of electronically controlled motors in all sorts of appliances and power tools. Greatly increased efficiency and finer control are possible by using 3 phase permanent magnet motors - similar to larger versions of brushless DC fan motors - with integrated power control electronics. But, for these applications, that is largely in the future (currently: Spring 2000).

About horsepower ratings

One horsepower is equal to 746 watts of electrical power (100% efficiency). Therefore, the most you can get continuously from a normal 115 V 15 A outlet is about 2 HP. Any claims (for air compressors, for example) of higher ratings on a normal outlet are totally bogus. Companies such as Sears (Craftsman) like to specify 'Reserve Power' for their power tools which as best as I can determine refers to the power available for a short time and may relate to the mass - and inertia - of the rotating parts but not the continuous power available. This may be useful to help saw through a tough knot in a piece of hardwood but may not be terribly meaningful for a wet/dry vacuum! Therefore, pay most attention to the continuous power ratings if they can be found anywhere. A good indication is probably the maximum amps required for the electrical service.

As with over-the-counter drugs, extra strength does not necessarily translate into faster relief, higher current does not always mean better performance, and horsepower ratings much above what you would compute from V x A may be more of a marketing gimmick than anything really beneficial.

Cords for AC line operated portable power tools

Really old power tools had two wire cord plugs and no safety ground yet were of all metal (solid and heavy!) construction. I would recommend that as a matter of policy, these be retrofitted with a 3 wire grounded cordset.

Newer ones have the grounded cordset while the newest 'double insulated tools' are of mostly plastic construction and are back to a 2 wire ungrounded cord.

As with any electrical appliances, inspect cords regularly and repair or replace any that are seriously damaged - if the inner wiring is showing, nicked, or cut; if the plug is broken or gets hot during use, or where the cord is pulled from or broken at the strain relief.

Portable drills

The portable electric drill (now the rage is cordless) is probably one of the two first tools that any handyman should own (the other being a saber saw). It is used for many things in addition to drilling little holes - drilling large holes, sanding, polishing, driving screws, etc. Therefore, these tools get a lot of use - and abuse.

AC line powered drills

An AC line powered electric drill is just a universal motor with a two stage (typical) gear reduced powering a chuck to hold the drill bit or attachment. A continuous range speed control with a reversing switch is now standard on most AC line powered drills.

Typical problems include:

- **Worn bearings:** These may be replaceable. Also see the section: Upgrading the bearings on a Craftsman drill.

- **Worn motor brushes:** Replacements should be available. from the manufacturer or a motor/appliance repair shop.

- **Broken or chipped gears:** This is rare under normal conditions but if the drill was abused, then failure is possible.

- **Bad cord or plug:** Repair or replace for safety reasons.

- **Bad speed controller/reversing switch:** Replacement trigger assemblies are available but may cost half as much as an entire new drill. One common wear item is the linear potentiometer operated by the trigger and this is not likely to be a standard component. The drill may work fine as a single speed model if this control fails (either as-is or by bypassing the triac). You could always use an inexpensive external motor speed controller in this case.

- **Bad motor:** Failures are possible but unless abused, not nearly as common as other simple problems like bad brushes or bearings. It may not be cost effective to replace a bad armature or stator unless this is an expensive high quality drill or you have a similar model available for parts.

- **Rusted or gummed up chuck (or, lost chuck key!):** The chuck is replaceable. Depending on type, it may mount with a right or left hand screw thread and possibly a right or left hand retaining screw through the center. See the owner's manual to determine what your drill uses as you could be attempting to tighten rather than loosen the chuck if you turn the wrong way. If by some slight chance you do not have the owner's manual, a reversible drill will usually have a left hand (reversed) thread on the chuck and a retaining screw with a right hand (normal) thread. A non-reversible drill will only have a right hand thread on the chuck and probably no retaining screw. There may be a hole to insert a locking rod to prevent the shaft from turning as you attempt to loosen the chuck. Inserting the chuck key or a suitable substitute and gently tapping it with a hammer in the proper direction may be useful as well to free the chuck.

  A gummed up but not too badly rusted chuck can be rescued with penetrating oil like WD40 or Liquid Wrench: spray it into the chuck, let it sit for few minutes, then use the chuck key to start working it back and forth. Pretty soon it should be free - rotate through its entire range back and forth. Spray and spin a couple more times and it should be fine for another 20.000 holes.

Upgrading the bearings on a Craftsman drill

Very inexpensive models (like the $30 Father's day specials) may use sleeve bearings in various locations instead of better quality longer lived ball or roller bearings. One particular bearing tends to deteriorate rapidly, especially if the drill is used for sanding or in dusty work environments (as opposed to clean rooms :-)). This is the motor bearing at the handle end. The lubrication dries out or is absorbed by dust particles, the bearing runs dry, wears, and fails with an ear shattering squeal. Even if you use ear plugs, the speed and power are not adequate as the motor is laboring and overloaded and motor failure would result from prolonged operation.

I have upgraded a couple of these drills to ball bearings. The substitution is straightforward requiring disassembly of the drill - removing of the front gear reducer and then one side of the case. At this point, the old sleeve bearing is easily freed from its mounting (just the plastic of the case) and pulled from the shaft. The shaft is likely undamaged unless you attempted to continue running the drill even after going deaf.

The drills I upgraded had bearings that were 7/8" OD, 5/16" thick, and with a 5/16" ID center hole. The old ones were worn by almost 1/32" oversize for the center hole but the motor shaft was undamaged. I found suitable replacement double sealed ball bearings in my junk box but I would assume that they are fairly standard - possibly even available from Sears Parts as I bet they are used in the next model up.

If the gear reducer needs to come apart to access the motor, take note of any spacer washers or other small parts so you can get them back in exactly the correct locations. Work in a clean area to avoid contaminating the grease packing.

The bearing should be a press fit onto the shaft. Very light sanding of the shaft with 600 grit sandpaper may be needed - just enough so that the new bearing can be pressed on. Or, gently tap the center race with hammer (protected with a block of wood). Make sure that the bearing is snug when mounted so that the outer race cannot rotate - use layers of thin heat resistant plastic if needed to assure a tight fit (the old sleeve bearing was keyed but your new ball bearing probably won't have this feature).

These drills now run as smoothly as Sears' much more expensive models.

Cordless drills

Cordless drills use a permanent magnet DC motor operating off of a NiCd (usually) battery pack. Manufacturers make a big deal out of the voltage of the pack - 6, 7.2, 9.6, 12, 14, 18, etc. - but this really isn't a sure measure of power and time between charges as a motor can be designed for any reasonable voltage. A gear reducer follows the motor driving a chuck for holding the drill or screwdriver bit, or attachment. These are most often have a single or two speeds with reverse.

In addition to the problems listed in the section: AC line powered drills, these are also subject to all the maladies of battery operated appliances. Cordless tools are particularly vulnerable to battery failure since they are often use rapid charge (high current) techniques.

- **Bad NiCd batteries:** Reduced capacity or shorted cells. In most cases, a new pack will be required.
- **Bad power/speed selection/reversing switch:** Replace.
- **Bad motor:** These are usually permanent magnet brushed type motors. Worn brushes and bearings are common problems. In addition, a partially shorted motor due to commutator contamination is also possible - see the sections on PM DC motors. Disassembly, cleaning, and lubrication may be possible.

Other direct drive tools

- **Rotary (Moto) tools:** high speed compact universal or PM motors with a variety of chucks and adapters for holding tiny bits, grinding stones, cutters, etc.
- **Routers, biscuit cutters:** high speed (30,000 RPM typical) universal motor with a 1/4" (fixed size, router) chuck for common router bits.

  Ball bearings are used which have long life but are probably replaceable if they fail (noisy, excessive runout, etc.).

  The plug, cord, trigger, and interlock switches are prone to problems and should be checked if the tool doesn't run at all.
- **String trimmers:** Universal motor on long handle with trigger control. Check for a bad cord, switch, and dirt in the motor if the unit appears dead. The motor brushes could also be worn or not seating properly.

Saber saws, reciprocating saws

These use a universal motor which drives a gear reducer and reciprocating mechanism. Better models have a variable speed control so that the sawing rate can be optimized to the work. All but the most inexpensive allow the head to be rotated or rotate automatically based on feed direction adding a bit of complexity.

A reciprocating saw is very similar but uses a much larger motor and beefier gearing.

In addition to motor problems, there can be problems with damage, dirt, or need for lubrication of the reciprocating mechanism.

Electric chain saws

WARNING: Read and follow all safety instructions using any type of chain saw.

These have a high power universal motor and gear reducer. Most have the motor mounted transversely with normal pinion type gears driving the chain sprocket. A few models have the motor mounted along the axis of the saw - I consider this less desirable as the gyroscopic character of the rotating motor armature may tend to twist the saw as it is tilted into the work.

Inexpensive designs suffer from worn (plain) bearings, particularly at the end of the motor opposite the chain since this is exposed to the elements. Normal maintenance should probably include cleaning and oiling of this bearing. A loud chattering or squealing with loss of speed and power is an indication of a worn and/or dry bearing Replacement with a suitable ball bearing is also a possibility (see the section: Upgrading the bearings on a Craftsman drill since the approach is identical.

Keep the chain sharp. This is both for cutting efficiency and safety. A dull chain will force you to exert more pressure than necessary increasing the chance of accidents. Chains can be sharpened by hand using a special round file and guide or an electric drill attachment. Alternatively, shops dealing in chain saws will usually have an inexpensive chain sharpening service which is well worth the cost if you are not equipped or not inclined to do it yourself.

One key to long blade and bar life is the liberal use of the recommended chain oil. Inexpensive models may have a manual oiler requiring constant attention but automatic oilers are common. These are probably better - if they work. Make sure the oil passages are clear.

The chain tension should be checked regularly - the chain should be free to move but not so loose that it can be pulled out of its track on the bar. This will need to snugged up from time-to-time by loosening the bar fastening nuts, turning the adjustment screw, then retightening the nuts securely.

There may be a slip clutch on the drive sprocket to protect the motor if the chain gets stuck in a log. After a while, this may loosen resulting in excessive slippage or the chain stopping even under normal conditions. The slip clutch can generally be tightened with a screwdriver or wrench.

Circular saws, miter, and cutoff saws

These have a high power universal motor either directly driving the blade or driving a gear reducer (high torque/large blade variety).

Miter and cutoff saws are similar but are mounted on a tilting mechanism with accurate alignment guides (laser lights in the most expensive!).

Grinding wheels

A dual shaft induction motor drives rotating grinding stones (or other tools like wire brushes). Most common are fixed speed - usually around 3450 RPM but variable speed operation is highly desirable to avoid overheating of tempered metal during sharpening. All but the most inexpensive use sealed ball bearings requiring no routine maintenance.

Small light duty grinders may be 1/4 HP or less. However, this is adequate for many home uses.

Wet wheels may run at much slower speeds to keep heat to a minimum. Being in close proximity to water may in itself create problems.

Polishers, rotary sanders

A gear reduced universal motor drives a rubber (usually) mounting plate to which a sanding disk or polishing pad is attached.

Due to the nature of their use, sanders in particular may accumulate a lot of dust and require frequent cleaning and lubrication.

Orbital sanders and polishers

In addition to the usual universal motor and its bearings, the orbital mechanism may require cleaning and greasing periodically.

Belt sanders, power planers

A typical portable belt sander uses a gear or belt reduced universal motor driving one of the rollers that the sanding belt rotates on under tension. In decent quality tools, these should use ball or roller bearings which require little attention.

A power planer is similar in many ways but the motor drives a set of cutters rather than a sanding belt.

Air compressors

A direct or belt drive induction motor (probably capacitor start) powers a single or multiple cylinder piston type compressor. Typical continuous motor ratings are between 1/4 and 2 HP (for a 115 VAC line). Over and under pressure switches are used to maintain the pressure in an attached storage tank within useful - and safe - limits. Most will include an unloading valve to remove pressure on the pistons when the compressor stops so that it can be easily restarted without damage to the motor and without blowing fuses or tripping circuit breakers.

I much prefer a belt driven compressor to a direct drive unit. One reason is that a motor failure does not render the entire compressor useless as any standard motor can be substituted. The direct drive motor may be a custom unit and locating a replacement cheaply may be difficult.

Drain the water that collects in the tank after each use.

Inspect the tank regularly for serious rust or corrosion which could result in an explosion hazard.as well.

Paint sprayers

Traditional air powered paint sprayers may simply be an attachment to an air compressor or may be a self contained unit with the compressor built in. Since the active material is paint which dries into a hard mass (what a concept!), cleaning immediately after use is essential. Otherwise, strong solvents will be needed to resurrect a congealed mess - check your user's manual for acceptable deadly chemicals.

Portable airless paint sprayers use a solenoid-piston mechanism inside the spray head itself. There is little to go wrong electrically other than the trigger switch as long as it is cleaned after use.

Professional airless paint sprayers use a hydraulic pump to force the paint through a narrow orifice at extremely high pressure like 1000 psi.

With all types, follow the manufacturer's recommendations as to type and thickness of paint as well as the care and maintenance before and after use and for storage.

Warning: high performance paint sprayers in particular may be a safety hazard should you put your finger close to the output orifice accidentally. The pressures involved could be sufficient to inject paint - and anything else in the stream - through the skin resulting in serious infection or worse.

Heat guns

These are similar to high performance hair dryers and subject to the same problems - bad cord or switch, open heating element, defective thermostats, universal motor problems, and just plain dirt and dust buildup.

Paint strippers

These are just a high power heating element attached to a cord. If there is no heat, check for a bad plug, cord, or open element with your multimeter.

Soldering irons

Simple pencil irons use an enclosed heating element is attached to the 'business' end in some manner - screw thread, set screw, clamping ring, etc. Failure to heat may be due to a bad plug, cord, bad connections, or defective element.

Some types package the heating element and replaceable tip in a separate screw-in assembly. These are easily interchangeable to select the appropriate wattage for the job. Damage is possible to their ceramic insulator should one be dropped or just from constant use.

High quality temperature controlled soldering stations incorporate some type of thermostatic control - possibly even with a digital readout.

Soldering guns

The common Weller Dual Heat soldering gun is a simple transformer with the tapped primary winding in the bulk of the case and a single turn secondary capable of 100 or more amps at around 1.5 V. The soldering element is simply a piece of copper (possible with a shaped tip) which is heated due to the high current passing through it even though it is made mostly of copper. The 'headlight(s)' (flashlight bulbs) operate off of a winding on the transformer as well.

Possible problems include:

- **No response to trigger:** Bad cord, bad switch, open transformer primary.
- **Low or high (dual heat models) does not work:** Bad switch, bad transformer primary.
- **Lack of sufficient heat:** Bad connections where soldering element mounts. Clean and/or tighten. Tin the tip if needed (not permanently tinned). Use the high setting (dual heat models).
- **Tip too hot:** Use the lower setting (if dual heat). Do not keep the trigger depressed for more than 30 seconds or so at a time. Manually pulse width modulate the power level.
- **Entire unit overheats:** This could be a shorted winding in the transformer but more likely is that you are simply not giving it a chance to cool. These are not designed for continuous operation - something like 2 minutes on, 5 minutes off, is usually recommended.
- **No light:** Bad bulbs, bad connections, bad winding (unlikely).

Note: a soldering gun is not a precision instrument and should not be used for fine electronics work - you will ruin ICs and printed circuit boards.

Wet-dry vacs, yard blowers/vacs

A powerful universal motor driving a centrifugal blower is all there is in this equipment. Unfortunately, many common models use cheaply made motors which may fail simply due to use or from the dust and proximity to liquids. The blower sucks air and whatever else into the holding tank. A filter is supposed to prevent anything from getting through. The motor itself should be sealed against direct contact with the dust/liquid section of the machine.

Problems occur with bad cords, switch, motor brushes, bearings, or a burnt out motor from excessive use under adverse conditions.

As with inexpensive electric drills, sleeve bearings (usually, the top bearing which is exposed somewhat) in the motor can become worn or dry. Replacing with a ball bearing is a worthwhile - but rather involved - undertaking if this happens. See the section: Upgrading the bearings on a Craftsman drill as the technique is similar (once you gain access - not usually a 10 minute job).

Hedge trimmers

A gear reduced universal motor drives a reciprocating mechanism not too dissimilar to a saber saw. In addition to the usual motor/electrical problems, lubrication may be needed periodically. Should you accidentally try to trim a steel fence instead of a bush, damage to one or more teeth may occur. In this case, light filing may be needed to remove nicks and burrs.

Of course, you probably will not get away without cutting the power cord a couple of times as well! See the sections on power cords. One way to avoid the humiliation (other than being half awake) is to wrap a cord protector around the first 2 or 3 feet of cord at the tool. This will make the cord larger in diameter than the inter-tooth spacing preventing accidental 'chewups'.

Electric lawn mowers

A large universal or permanent magnet DC motor drives one or two sets of rotating blades. A load or dead short may be thrown across the motor to act as a dynamic brake when stopping. As usual, when the mower does not operate, check for bad plug, cord, switch, brushes, dirt, etc. See the sections on motors.

Incandescent Light Bulbs, Lamps, and Lighting Fixtures

Editor's note: More information on incandescent light bulbs can be found at: http://www.misty.com/~don/.

Incandescent light bulbs - single and three way

The basic incandescent lamp operates on the same basic principles as the original carbon filament lamp developed by Thomas Edison. However, several fundamental changes have made it somewhat more efficient and robust. However, modern bulbs are hardly efficient at producing lighte. Typically, only about 3 to 7 percent of the electrical energy used by a typical incandescent light bulb is turned into useful (visible) light. The rest goes to waste (usually) as heat.

Tungsten replaced carbon as the filament material once techniques for working this very brittle metal were perfected (Edison knew about tungsten but had no way of forming it into fine wire). Most light bulbs are now filled with an inert gas rather than containing a vacuum like Edison's originals. This serves two purposes: it reduces filament evaporation and thus prolongs bulb life and reduces bulb blackening and it allows the filament to operate at a higher temperature and thus improves color and brightness. However, the gas conducts heat away so some additional power is wasted to heating the surroundings.

Incandescent lamps come in all sizes from a fraction of a watt type smaller than a grain of wheat to 75 kW monster bulbs. In the home, the most common bulbs for lighting purposes are between 4 W night light bulbs and 250-300 W torch bulbs (floor standing pole lamps directing light upwards). For general use, the 60, 75, and 100 W varieties are most common. Recently, 55, 70 and 95 W 'energy saving' bulbs have been introduced. However, these are just a compromise between slightly reduced energy use and slightly less light. My recommendation: use compact fluorescents to save energy if these fit your needs. Otherwise, use standard light bulbs.

Most common bases are the Edison medium (the one we all know and love) and the candelabra (the smaller style for night lights, chandeliers, and wall sconces.

Three-way bulbs include two filaments. The three combinations of which filaments are powered result in low, medium, and high output. A typical 3-way bulb might be 50 (1), 100 (2), and 150 (1+2) W. If either of the filaments blows out, the other may still be used as a regular bulb. Unfortunately, 3-way bulbs do tend to be much more expensive than ordinary light bulbs. There may be adapters to permit a pair of normal bulbs to be used in a 3-way socket - assuming the space exists to do this safely (without scorching the shade).

The base of a 3-way bulb has an additional ring to allow contact to the second filament. Inexpensive 3-way sockets (not to be confused with 3-way wall switches for operation of a built-in fixture from two different locations) allow any table lamp to use a 3-way bulb.

Flashlight bulbs are a special category which are generally very small and run on low voltage (1.5-12 V). They usually have a filament which is fairly compact, rugged, and accurately positioned to permit the use of a reflector or lens to focus the light into a fixed or variable width beam. These usually use a miniature screw or flange type base although many others are possible. When replacing a flashlight bulb, you must match the new bulb to the number and type of battery cells in your flashlight.

Automotive bulbs are another common category which come in a variety of shapes and styles with one or two filaments. Most now run on 12 V.

Other common types of incandescent bulbs: colored, tubular, decorative, indoor and outdoor reflector, appliance, ruggedized, high voltage (130 V).

Why do my light bulbs seem to burn out at warp speed?

The lifespan of an average incandescent bulb is 750-1000 hours which is about 1.5 months if left on continuously or roughly 4 months if used 8 hours a day. So, if you are seeing a 3-4 month lifespan, this may not be that out of line depending on usage. With a lot of bulbs in a house, you may just think you are replacing bulbs quite often.

Having said that, several things can shorted lamp life:

1. Higher than normal voltage - the lifespan decreases drastically for slight increases in voltage (though momentary excursions to 125 V, say, should not be significant).

2. Vibration - what is the fixture mounted in, under, or on?

3. High temperatures - make sure you are not exceeding the maximum recommended wattage for your fixture(s).

4. Bad switches bad connections due to voltage fluctuations. If jiggling or tapping the switch causes the light to flicker, this is a definite possibility. Repeated thermal shock may weaken and blow the filament.

A bad neutral connection at your electrical service entrance could result in certain circuits in your house having a higher voltage than normal - multimeter would quickly identify any.

It may be possible to get your power company to put a recording voltmeter on your line to see if there are regular extended periods of higher than normal voltage - above 120 to 125 V.

To confirm that the problem is real, label the light bulbs with their date (and possibly place of purchase or batch number - bad light bulbs are also a possibility). An indelible marker should be satisfactory.

Of course, consider using compact or ordinary fluorescent lamps where appropriate. Use higher voltage (130 V) bulbs in hard to reach places. Bulbs with reinforced filament supports ('tuff bulbs') are also available where vibration is a problem.

Halogen bulbs

(From: Don Klipstein (don@misty.com).)

A halogen bulb is an ordinary incandescent bulb, with a few modifications. The fill gas includes traces of a halogen, often but not necessarily iodine. The purpose of this halogen is to return evaporated tungsten to the filament.

As tungsten evaporates from the filament, it usually condenses on the inner surface of the bulb. The halogen is chemically reactive, and combines with this tungsten deposit on the glass to produce tungsten halides, which evaporate fairly easily. When the tungsten halide reaches the filament, the intense heat of the filament causes the halide to break down, releasing tungsten back to the filament.

This process, known as the halogen cycle, extends the life of the filament somewhat. Problems with uneven filament evaporation and uneven deposition of tungsten onto the filament by the halogen cycle do occur, which limits the ability of the halogen cycle to prolong the life of the bulb. However, the halogen cycle keeps the inner surface of the bulb clean. This lets halogen bulbs stay close to full brightness as they age. (recall how blackened an ordinary incandescent bulb can become near the end of its life --- sam).

In order for the halogen cycle to work, the bulb surface must be very hot, generally over 250 degrees Celsius (482 degrees Fahrenheit). The halogen may not adequately vaporize or fail to adequately react with condensed tungsten if the bulb is too cool. This means that the bulb must be small and made of either quartz or a high-strength, heat-resistant grade of glass known as "hard glass".

Since the bulb is small and usually fairly strong, the bulb can be filled with gas to a higher pressure than usual. This slows down the evaporation of the filament. In addition, the small size of the bulb sometimes makes it economical to use premium fill gases such as krypton and xenon instead of the cheaper argon. The higher pressure and better fill gases can extend the life of the bulb and/or permit a higher filament temperature that results in higher efficiency. Any use of premium fill gases also results in less heat being conducted from the filament by the fill gas, meaning more energy leaves the filament by radiation, meaning a slight improvement in efficiency.

Efficiency, lifetime, and failure modes of halogen bulbs

A halogen bulb is often 10 to 20 percent more efficient than an ordinary incandescent bulb of similar voltage, wattage, and life expectancy. Halogen bulbs may also have two to three times as long a lifetime as ordinary bulbs, sometimes also with an improvement in efficiency of up to 10 percent. How much the lifetime and efficiency are improved depends largely on whether a premium fill gas (usually krypton, sometimes xenon) or argon is used.

Halogen bulbs usually fail the same way that ordinary incandescent bulbs do, usually from melting or breakage of a thin spot in an aging filament.

Thin spots can develop in the filaments of halogen bulbs, since the filaments can evaporate unevenly and the halogen cycle does redeposit evaporated tungsten in a perfect, even manner nor always in the parts of the filament that have evaporated the most. However, there are additional failure modes which result in similar kinds of filament degradation.

It is generally not a good idea to touch halogen bulbs, especially the more compact, hotter-running quartz ones. Organic matter and salts are not good for hot quartz. Organic matter such as grease can carbonize, leaving a dark spot that absorbs radiation from the filament and becomes excessively hot. Salts and alkaline materials (such as ash) can sometimes "leach" into hot quartz, which typically weakens the quartz, since alkali and alkaline earth metal ions are slightly mobile in hot glasses and hot quartz. Contaminants may also cause hot quartz to crystallize, weakening it. Any of these mechanisms can cause the bulb to crack or even violently shatter. For this reason, halogen bulbs should only be operated within a suitable fully enclosed fixture. If a quartz halogen bulb is touched, it should be cleaned with alcohol to remove any traces of grease. Traces of salt will also be removed if the alcohol has some water in it.

Use of dimmers with halogen bulbs

Dimming a halogen bulb, like dimming any other incandescent lamp, greatly slows down the formation of thin spots in the filament due to uneven filament evaporation. However, "necking" of the ends of the filament remains a problem. If you dim halogen lamps, you may need "soft-start" devices in order to achieve a major increase in bulb life.

Another problem with dimming of halogen lamps is the fact that the halogen cycle works best with the bulb and filament at or near specific optimum temperatures. If the bulb is dimmed, the halogen may fail to "clean" the inner surface of the bulb. Or, tungsten halide that results may fail to return tungsten to the filament.

Halogen bulbs should work normally at voltages as low as 90 percent of what they were designed for. If the bulb is in an enclosure that conserves heat and a "soft-start" device is used, it will probably work well at even lower voltages, such as 80 percent or possibly 70 percent of its rated voltage.

Dimmers can be used as soft-start devices to extend the life of any particular halogen bulbs that usually fail from "necking" of the ends of the filament. The bulb can be warmed up over a period of a couple of seconds to avoid overheating of the "necked" parts of the filament due to the current surge that occurs if full voltage is applied to a cold filament. Once the bulb survives starting, it is operated at full power or whatever power level optimizes the halogen cycle (usually near full power).

The dimmer may be both "soft-starting" the bulb and operating it at slightly reduced power, a combination that often improves the life of halogen bulbs. Many dimmers cause some reduction in power to the bulb even when they are set to maximum.

(A suggestion from someone who starts expensive medical lamps by turning up a dimmer and reports major success in extending the life of expensive special bulbs from doing this.)

The humorous side of light bulbs

Also see the document: Engineering, Science, and Other (Pretty Clean) Jokes Collection for all the light bulb jokes you could never want.

(From: Susanne Shavelson (shavelson@binah.cc.brandeis.edu).)

People have often mentioned experiencing epidemics of light-bulb-death after moving into a new (to them) house. The same thing happened to us for a few months after moving last year into a 55-year-old house. After most of the bulbs had been replaced, things settled down. I am persuaded by the theory advanced by David (?) Owen in his wonderfully informative and witty book "The Walls Around Us" that houses undergo a sort of nervous breakdown when a new occupant moves in, leading to all sorts of symptoms like blown bulbs, plumbing problems, cracks in the walls, and so forth. Now that the house has become more accustomed to us, the rate at which strange phenomena are occurring has slowed.

Notes on bulb savers

These are usually either Negative Temperature Coefficient (NTC) thermisters or simple diodes.

When cold, NTC thermisters have a high resistance. As they warm up, the resistance decreases so that the current to the light bulb is ramped up gradually rather than being applied suddenly.

With a properly selected (designed) thermistor, I would not expect the light output to be affected substantially. However, while reducing the power on surge may postpone the death of the bulb, the filament wear mechanism is due to evaporation and redeposition of the tungsten during normal operation. This is mostly a function of the temperature of the filament.

A thermistor which was not of low enough hot resistance would be dissipating a lot of power - roughly .8 W/volt of drop for a 100W bulb. Any really substantial increase in bulb life would have to be due to this drop in voltage and not the power-on surge reduction. The bulb saver (and socket) would also be heating significantly.

The bulb savers that are simply diodes do not have as much of a heat dissipation problem but reduce the brightness substantially since the bulbs are running at slightly over half wattage. Not surprisingly, the life does increase by quite a bit. However, they are less efficient at producing light at the lower wattage and it is more orange. If you are tempted to then use a higher wattage bulb to compensate, you will ultimately pay more than enough in additional electricity costs to make up for the longer lived bulbs.

My recommendation: use high efficiency fluorescents where practical. Use 130 V incandescents if needed in hard to reach places where bulb replacement is a pain. Stay away from bulb savers, green plugs, and other similar products claiming huge energy reduction. Your realized savings for these products will rarely approach the advertised claims and you risk damage to your appliances with some of these.

Can you prove that bulb savers do not work?

No, sorry, I don't have conclusive proof. I would love to be proved wrong - I could save a lot on light bulbs. However, new bulbs do not fail upon power on. Old bulbs do. If you examine the filament of a well worn light bulb, you will see a very distinct difference in surface appearance compared to a brand new one. The surface has gone from smooth to rough. This change is caused by sustained operation at normal light bulb temperatures resulting in unequal evaporation of the filament.

Reducing the power on surge with a thermistor will reduce the mechanical shock which will postpone the eventual failure. 5X or even 20 % increase in life is pushing it IMHO.

I do believe that Consumer Reports has tested these bulb savers with similar conclusions (however, I could be mistaken about the kind of bulb savers they tested - it was quite awhile ago).

Motors 101

Small motors in consumer electronic equipment

A large part of the functionality of modern appliances is based on the use of motors of one form or another. They are used to rotate, blow, suck, sweep, spin, cut, grind, shred, saw, sand, drill, plane, time, and control.

Motors come in all shapes and sizes but most found in small appliances can be classified into 5 groups:

1. **Universal motors:** Run on AC or DC, speed may be varied easily. Relatively efficient but use carbon brushes and may require maintenance.

2. **Single-phase induction motors:** AC, fairly fixed speed except by switching, windings, very quiet. Quite efficient and low maintenance.

3. **Shaded pole induction motors:** AC, somewhat fixed speed, very quiet, not very efficient and low maintenance.

4. **Small permanent magnet DC motors:** DC, variable or constant speed, often cheaply made, fairly quiet, prone to problems with metal brushes.

5. **DC brushless motors:** DC usually (but some may have built in rectifiers to run on AC), somewhat variable or fixed speed, very quiet, low maintenance.

6. Synchronous timing motors: Constant speed absolutely tied to power line. The long term accuracy of clocks based on the AC line exceed that of most quartz oscillator based time pieces since the ultimate reference is an atomic frequency standard.

Each type of motor has its advantages and disadvantages. More than one type may be suitable for any particular application.

Identifying type of unknown motor

Determining the actual type of motor is the first step toward being able to test to see if it is being powered properly or if there is a fault in the motor itself.

Open frame motors in line operated appliances with a single coil off to one side are almost always shaded pole induction motors. To confirm, look for the copper 'shading rings' embedded in the core. There will usually be either 1 or 2 pairs of these. Their direction is determine by the orientation of the stator frame (position of the shading rings).

For enclosed motors, first check to see if there are carbon brushes on either side of a commutator made of multiple copper bars. If so, this is almost certainly a series wound 'universal' motor that will run on AC or DC though some may be designed for DC operation only.

If there are no brushes, then it is likely a split phase induction or synchronous motor. If there is a capacitor connected to the motor, this is probably used for starting and to increase torque when running.

Where there is a capacitor, it is likely that how this is wired to the motor determines the direction of rotation - make sure you label the connections!

Very small motors with enclosed gear reducers are usually of the synchronous type running off the AC line. Their direction of rotation is often set by a mechanical one-way clutch mechanism inside the casing.

Motors used in battery operated tools and appliances will usually be of the permanent magnet DC type similar to those found in toys and electronic equipment like VCRs and CD players. Most of these are quite small but there are exceptions - some electric lawnmowers use large versions of this type of motor, for example. These will be almost totally sealed with a pair of connections at one end. Direction is determined by the polarity of the DC applied to the motor.

For universal and DC permanent magnet motors, speed control may be accomplished with an internal mechanical governor or electronic circuitry internal or external to the motor. On devices like blenders where a range of (useless) speeds is required, there will be external switches selecting connections to a tapped winding as well as possibly additional electronic circuitry. The 'solid state' design so touted by the marketing blurb may be just a single diode! A similar approach may also be used to control the speed of certain types of induction motors (e.g., ceiling fans) but most are essentially fixed speed devices.

Once identified, refer to the appropriate section for your motor.

COLIN Electric Motor Service has a page with some Motor Connection Diagrams for large motors that may be of some value (though more so if you have a few' 100 horsepower three-phase motors in your concrete processing plant!).

Universal motors

The Universal motor is the most common type of high speed motor found in appliances and portable line operated power tools. Typical uses include vacuum cleaners, floor polishers, electric drills, routers, and sewing machines. They are likely to be found anywhere medium power, high speed, and/or variable speed control are required capabilities. Note that quiet operation is NOT a feature of these motors. Therefore, they will not often be found in electronic equipment.

Construction consists of a stationary set of coils and magnetic core called the 'stator' and a rotating set of coils and magnetic core called the 'armature'. Incorporated on the armature is a rotating switch called a 'commutator'. Connection to the armature is via carbon (or metal) contacts called 'brushes' which are mounted on the frame of the motor and press against the commutator. Technically, these are actually series wound DC motors but through the use of steel laminated magnetic core material, will run on AC or DC - thus the name universal.

Speed control of universal motors is easily achieved with thyristor based controllers similar to light dimmers. However, simply using a light dimmer as a motor speed controller may not work due to the inductive characteristics of universal motors.

Changing direction requires interchanging the two connections between the stator and the armature.

This type of motor is found in blenders, food mixers, vacuum cleaners, sewing machines, and many portable power tools.

Problems with universal motors

These motors can fail in a number of ways:

- Open windings - this may result in a bad spot, a totally dead motor, lack of power, or excessive sparking. Windings can open from a major overload/overheating episode either melting the wire or solder connections (the latter on the armature usually), defective manufacturing and thermal cycling, or damage during servicing.

  However, the source of the open may not be the windings but a blown thermal fuse - see below.

- Shorted windings - this may result in excessive current, severe sparking, reduced speed and power, and overheating. The thermal protector, fuse, or circuit breaker may trip. Continuing to run such a motor may result in a meltdown or burned coils and insulation - i.e., a burned out motor.

- Worn carbon brushes - while these usually last for the life of the appliance, this is not always the case. The result could be erratic or sluggish operation, excessive sparking, damage to the commutator, or a motor that does a pretty good imitation of a paper weight :-).

  For appliances subject to dust or dirt like vacuum cleaners and woodworking toole (and others as well), the brushes may just get stuck from accumulated debris and not be able to make consistent contact. Carefully remove the brushes and clean them and their mounting channels so they slide in and out freely.

  Note: Whenever removing carbon brushes, make a note as to their exact orientation as replacing them in the same way will minimize wear and break-in time.

- Dry/worn bearings - this may result in a tight or frozen motor or a motor shaft with excessive runout. The result may be a spine tingling squeal during operation and/or reduced speed and power, and overheating. Running such a motor may eventually lead to burnout due to overheating from the increased load.

- Faulty speed control or speed regulator. There are several types in common use:

  - Switch which selects between various taps on the field winding. This type common in blenders and portable food mixers.

- A mechanical speed control inside the motor - a set of weights with adjustable spring tension so that the current to the motor is reduced when the set speed is reached. If the motor only runs at full speed, except for obvious mechanical problems, check for a shorted component like a resistor or capacitor across the contacts - or welded contacts. Where it doesn't run at all, check for an open resistor or bad connection. Bypass the governor if possible and see if the motor will run.

- Electronic control - This is similar to a light dimmer and uses a triac to regulate current to the motor. See the section: Dimmer switches and light dimmers.

Sometimes, there is a thermal fuse buried in the windings that will blow due to overheating before any serious damage has occurred. If so, cleaning and relubing the bearings or remedy of whatever other problem caused the overload and replacement of the thermal fuse may be all that is needed. See the section: Thermal protection devices - thermal fuses and thermal switches for precautions when replacing these and the document: Notes on the Troubleshooting and Repair of AC Adapters, Power Supplies, and Battery Packs.

WARNING: Don't just bypass the protection device or the next time you may be dealing with your fire insurance company!

Testing of universal motors

Test the field coils for continuity with an ohmmeter. An open winding is bad and will require replacement of the entire stator assembly unless the break can be located. Compare the resistance of the two windings - they should be nearly equal. If they are not, a short in one of the windings is likely. Again, replacement will be necessary.

Also test for a short to the frame - this should read infinity. If lower than 1 M or so, the motor will need to be replaced unless you can locate the fault.

An open or shorted armature winding may result in a 'bad spot' - a position at which the motor may get stuck. Rotate the motor by hand a quarter turn and try it again. If it runs now either for a fraction of a turn or behaves normally, then replacement will probably be needed since it will get stuck at the same point at some point in the future. Check it with an ohmmeter. There should be a periodic variation in resistance as the rotor is turned having several cycles per revolution determined by the number of commutator segments used. Any extremely low reading may indicate a shorted winding. Any erratic readings may indicate the need for brush replacement or cleaning. An unusually high reading may indicate an open winding or dirty commutator. Cleaning may help a motor with an open or short or dead spot.

A motor can be tested for basic functionality by disconnecting it from the appliance circuit and running it directly from the AC line (assuming it is intended for 115 VAC operation - check to be sure).

CAUTION: series wound motors can overspeed if run without a load of any kind and spectacular failure may result due to centrifugal disassembly of the armature due to excess G forces. In other words, the rotor explodes. This is unlikely with these small motors but running only with the normal load attached is a generally prudent idea.

About commutators and brushes in universal motors

A commutator is essentially a rotating switch which routes power to the appropriate windings on the armature so that the interaction of the fixed (stator) and rotating (armature) magnetic fields always results in a rotational torque. Power is transferred to the commutator using carbon brushes in most motors of this type. The carbon is actually in the form of graphite which is very slippery as well. Despite that fact that graphite is a relatively soft material, a thin layer of graphite is worn off almost immediately as the motor is started for the first time and coats the commutator. After this, there is virtually no wear and a typical set of carbon brushes can last thousands of hours - usually for the life of the appliance or power tool.

A spring presses the brush against the rotating commutator to assure good electrical contact at all times. A flexible copper braid is often embedded in the graphite block to provide a low resistance path for the electric current. However, small motors may just depend on the mounting or pressure spring to provide a low enough resistance.

The typical universal motor will have between 3 and 12 armature windings which usually means a similar number of commutator segments. The segments are copper strips secured in a non-conductive mounting. There are supposed to be insulating gaps between the strips which should undercut the copper. With long use, the copper may wear or crud may build up to the point that the gaps between the copper segments are no longer undercut. If this happens, their insulating properties will largely be lost resulting in an unhappy motor. There may be excessive sparking, overheating, a burning smell, loss of power, or other symptoms.

Whenever checking a motor with a commutator, inspect to determine if the commutator is in good condition - smooth, clean, and adequately undercut. Use a narrow strip of wood or cardboard to clean out the gaps assuming they are still present. For larger motors, a hacksaw blade can be used to provide additional undercutting if needed though this will be tough with very small ones. Don't go too far as the strength of the commutator's mounting will be reduced. About 1/32 to 1/16 inch should do it. If the copper is pitted or worn unevenly, use some extra fine sandpaper (600 grit, not emery cloth or steel wool which may leave conductive particles behind) against the commutator to smooth it while rotating the armature by hand.

Since the carbon brushes transmit power to the rotating armature, they must be long enough and have enough spring force behind them to provide adequate and consistent contact. If they are too short, they may be unstable in their holders as well - even to the point of being ripped from the holder by the commutator causing additional damage.

Inspect the carbon brushes for wear and free movement within their holders. Take care not to interchange the two brushes or even rotate them from their original orientation as the motor may then require a break-in period and additional brush wear and significant sparking may occur during this time. Clean the brushes and holders and/or replace the brushes if they are broken or excessively worn.

An appliance, vacuum cleaner, or motor repair shop may have replacement carbon brushes. However, even if you cannot locate an exact replacement, buy a set of slightly larger ones. They can usually be filed down to fit rather easily (the graphite is soft but messy).

I don't know whether the following approach is viable but it may be worth a try if you can't locate a proper replacement carbon brush. I wonder if the brand of battery matters? :-)

(From: rtotman@oanet.com).

Why on earth would you not make new brushes yourself from the carbon rod from the center of a cheap battery. You can file or grind the graphite to just the size you need. Free too.

I have done this many times with motors as small as an electric shaver to ones as large as vacuum cleaners. There is very little difference I can see in both the life of the new brushes and of the commutator segments they bear on. Electric drills are hard on brushes if you use them a lot and they get hot. I have re-brushed several drills and they are all still in service.

Repairing small universal motors

Too bad that the Sears lifetime warranty only applies to hand (non-power) tools, huh?

Which part of the motor is bad? The armature or stator? How do you know? (A smelly charred mess would probably be a reasonable answer).

Rewinding a motor is probably going to way too expensive for a small appliance or power tool. Finding a replacement may be possible since those sizes and mounting configurations were and are very common.

However, I have, for example, replaced cheap sleeve bearings with ball bearings on a couple of Craftsman power drills. They run a whole lot smoother and quieter. The next model up used ball bearings and shared the same mounting as the cheaper sleeve bearings so substitution was straightforward.

Single-phase induction motors

Where a fixed speed is acceptable or required, the single-phase induction motor is often an ideal choice. It is of simple construction and very robust and reliable. In fact, there is usually only one moving part which is a solid mass of metal.

Most of the following description applies to all the common types of induction motors found in the house including the larger fractional horsepower variety used in washing machines, dryers, and bench power tools.

Construction consists of a stationary pair of coils and magnetic core called the 'stator' and a rotating structure called the 'rotor'. The rotor is actually a solid hunk of steel laminations with copper or aluminum bars running lengthwise embedded in it and shorted together at the ends by thick plates. If the steel were to be removed, the appearance would be that of a 'squirrel cage' - the type of wheel used to exercise pet hamsters. A common name for these (and others with similar construction) are squirrel case induction motors.

These are normally called single-phase because they run off of a single-phase AC line. However, at least for starting and often for running as well, a capacitor or simply the design of the winding resistance and inductance, creates the second (split) phase needed to provide the rotating magnetic field.

For starting, the two sets of coils in the stator (starting and running windings) are provided with AC current that is out of phase so that the magnetic field in one peaks at a later time than the other. The net effect is to produce a rotating magnetic field which drags the rotor along with it. Once up to speed, only a single winding is needed though higher peak torque will result if both windings are active at all times.

Small induction motors will generally keep both winding active but larger motors will use a centrifugally operated switch to cut off the starting winding at about 75% of rated speed (for fixed speed motors). This is because the starting winding is often not rated for continuous duty operation.

For example, a capacitor run type induction motor would be wired as shown below. Interchanging the connections to either winding will reverse the direction of rotation. The capacitor value is typical of that used with a modest size fan motor.

```
                            1
      Hot o------+------------+
                 |             )||
                 |             )|| Main winding
                 |            2 )||
  Neutral o---+---------------+
              |  |
              |  |    C1     3          C1: 10 uF, 150 VAC
              |  +----||------+
              |               )||
              |               )|| Phase winding
              |             4 )||
              +---------------+
```

Speed control of single-phase induction motors is more complex than for universal motors. Dual speed motors are possible by selecting the wiring of the stator windings but continuous speed control is usually not provided. This situation is changing, however, as the sophisticated variable speed electronic drives suitable for induction motors come down in price.

Direction is determined by the relative phase of the voltage applied to the starting and running windings (at startup only if the starting winding is switched out at full speed). If the startup winding is disconnected (or bad), the motor will start in whichever direction the shaft is turned by hand.

This type of motor is found in larger fans and blowers and other fixed speed appliances like some pumps, floor polishers, stationary power tools, and washing machines and dryers.

Shaded pole induction motors

These are a special case of single-phase induction motors where only a single stator winding is present and the required rotating magnetic field is accomplished by the use of 'shading' rings which are installed on the stator. These are made of copper and effectively delay the magnetic field buildup in their vicinity just enough to provide some starting torque.

Direction is fixed by the position of the shading rings and electronic reversal is not possible. It may be possible to disassemble the motor and flip the stator to reverse direction should the need ever arise.

Speed with no load is essentially fixed but there is considerable reduction as load is increased. In many cases, a variable AC source can be used to effect speed control without damaging heating at any speed.

This type of motor is found in small fans and all kinds of other low power applications like electric pencil sharpeners where constant speed is not important. Compared to other types of induction motors, efficiency is quite poor.

Problems with induction motors

Since their construction is so simple and quite robust, there is little to go bad. Many of these - particularly the shaded pole variety - are even protected from burnout if the motor should stall - something gets caught in a fan or the bearings seize up, for example.

Check for free rotation, measure voltage across the motor to make sure it is powered, remove any load to assure that an excessive load is not the problem.

If an induction motor (non-shaded pole) won't start, give it a little help by hand. If it now starts and continues to run, there is a problem with one of the windings or the capacitor (if used).

For all types we have:

- Dirty, dry, gummed up, or worn bearings - if operation is sluggish even with the load removed, disassemble, clean, and lubricate with electric motor oil. The plain bearings commonly used often have a wad of felt for holding oil. A add just enough so that this is saturated but not dripping. If there is none, put a couple of drops of oil in the bearing hole.

- Open coil winding - test across the motor terminals with your ohmmeter. A reading of infinity means that there is a break somewhere - sometimes it is at one end of the coil and accessible for repair. For those with starting and running windings, check both of these.

- Shorted coil winding - this will result in loss of power, speed, and overheating. In extreme cases, the motor may burn out (with associated smelly byproducts) or blow a fuse. The only way to easily test for a winding that is shorted to itself is to compare it with one from an indentical good motor and even in this case, a short which is only a few turns will not show up (but will still result in an overheating motor).

- Coil shorted to the frame - this will result in excessive current, loss of power, overheating, smoke, fire, tripped breaker or overload protector, etc.

If any of these faults are present, the motor will need to be replaced (or rewound if economical - usually not for typical appliance motors). The only exception would be if the location of the open or short is visible and can be repaired. They usually are not.

For capacitor run type:

- A bad capacitor may be the cause of a motor which will not start, has limited power, excessive hum, or overheats. A simple test with your ohmmeter on the high resistance scale can give some indication of whether the capacitor is good. remove at least one lead of the capacitor and measure across it. A good capacitor will show an initially low reading which will quickly climb to infinity. If there is no low reading at all or it remains low, then the capacitor is bad (open or shorted respectively). This does not really prove the capacitor is good but if the test shows open shorted, it is definitely bad. Substitution is best.

For larger induction motors with centrifugal starting switches:

- A centrifugal switch which does not activate the starting winding will result in a motor that will not start on its own but will run if it is rotated initially by hand. A centrifugal switch that does not cut off when the motor is up to speed will result in excessive power use, overheating, and may blow a line fuse or trip a circuit breaker. These are usually pretty simple and a visual inspection (may require disassembly) should reveal broken, worn, or otherwise defective parts. Check for proper switch contact closing and opening with a continuity tester or ohmmeter. Inspect the rotating weights, springs, and the sliding lever for damage.

- Bad rotor - this is somewhat rare but repeated heating and cooling cycles or abuse during starting can eventually loosen up the (supposedly) welded connections of the copper bars to the end rings. The result is a motor that may not start or loses power since the required shorted squirrel cage has been compromised. One indication of this would be a rotor that is asymmetric - it vibrates or has torque at only certain large angular positions indicating that some of the bars are not connected properly. Normally, an induction motor rotor is perfectly symmetric.

Disassembling and reassembling a universal or induction motor

The description below assumes that the construction is of an enclosure with an integral stator and brush holder. For those with an internal structural frame, remove the outer casing first.

For the case of induction motors, ignore any comments about brushes as there are none. With shaded pole motors, the entire assembly is often not totally enclosed with just stamped sheet metal brackets holding the bearings.

Follow these steps to minimize your use of 4 letter expletives:

1. Remove the load - fan blades, gears, pulleys, etc. If possible, label and disconnect the power wiring as well as the motor can them be totally removed to the convenience of your workbench.

2. Remove the brushes if possible. Note the location of each brush and its orientation as well to minimize break-in wear when reinstalled. Where the brushes are not easily removable from the outside, they will pop free as the armature is withdrawn. Try to anticipate this in step (6). (Universal motors only).

3. Confirm that there are no burrs on the shaft(s) due to the set screw(s) that may have been there. For motors with plain bearings in particular, these will need to be removed to allow the shaft(s) to be pulled out without damage to the bushing. For ball bearing motors, the bearings will normally stay attached to the shaft as it is removed.

4. Use a scribe or indelible pen to put alignment marks on the covers so that they can be reassembled in exactly the same orientation.

5. Unscrew the nuts or bolts that hold the end plates or end bells together and set these aside.

6. Use a soft mallet if necessary to gently tap apart the two halves or end bells of the motor until they can be separated by hand.

7. Remove the end plate or end bell on the non-power shaft end (or the end of your choice if they both have extended shafts).

8. Remove the end plate or end bell on the power (long shaft) end. For plain bearings, gently ease it off. If there is any resistance, double check for burrs on the shaft and remove as needed so as not to damage the soft bushing.

9. Identify any flat washers or spacers that may be present on the shaft(s) or stuck to the bushings or bearings. Mark down their **exact** location and orientation so that they may be replaced during reassembly. Clean these and set aside.

Inspect all components for physical damage or evidence of overheating or burning. Bad bearings may result in very obvious wear of the shaft or bushings or show evidence of the rotor scraping on the stator core. Extended overloads, a worn commutator, or shorted windings may result in visible or olfactory detected deterioration of wire insulation.

While it is apart, brush or blow out any built up dust and dirt and thoroughly clean the shaft, bushings, commutator, and starting switch (present in large induction motors, only).

Relubrication using electric motor oil for plain bearings and light grease for non-sealed ball/roller bearings.

CAUTION: cleanliness is absolutely critical when repacking bearings or else you will be doing this again very soon.

Badly worn ball bearings will need replacement. However, this may be better left to a motor rebuilding shop as they are generally press fit and difficult to remove and install.

Reassemble in reverse order. If installation of the brushes needs to be done before inserting the armature, you will need to feed them in spring end first and hold them in place to prevent damage to the fragile carbon. Tighten the nuts or bolts evenly and securely but do not overtighten.

Wiring up a capacitor run induction motor

The following assume that the wires are unmarked and the motor is for use on 110 VAC, 60Hz (make appropriate changes if 220 VAC):

Measure the resistance between each pair of windings to determine the common. That goes to the AC Neutral.

The one with the higher resistance is probably the phase winding. The other winding goes directly to the AC Hot. If the resistances are similar, it doesn't matter which you use. If the resistances are very different, it may be a split phase induction motor that doesn't even need a capacitor. (It won't hurt to try it without for a short time. If the motor has enough torque and doesn't overheat, no cap is needed.)

Select a capacitor value so that its impedance at 60 Hz (1/2pifC) is between 1 and 2 times the resistance of the winding. It has to be a cap rated for 250 VAC, continuous duty. The value I gave is sort of a guess but will get it running. The idea is to maximize the phase shift while still getting useful power to the phase winding. For a small motor, a few uF should work. The cap goes between AC Hot and the phase winding.

This should get it going. If torque is too low, the uF value of the cap may need to be increased. Check that the motor isn't overheating once you have it running.

Also see the section: Single-phase induction motors.

Determining wiring for multispeed induction motor

Many motors have a wiring diagram on their nameplate. However, where this is not the case, some educated guessing and experimentation will be necessary.

Here is an example for a common multispeed furnace blower motor. In this case there is no capacitor and thus there are few unknowns.

> "Here's the problem - I have a squirrel cage fan that I would like to wire up. Unfortunately, there's only these four wires hanging there and I would hate to burn it up trying combinations. Here's what I know:
>
> - The motor came out of a furnace.
> - It's marked with three amp ratings (4.5, 6.1, 7.5) - three speeds, right?
> - The wires look like they were white, black, red and blue.
>
> - With a ohm meter set on 200, I tried the following combinations:
>
> ```
>          White   Black   Blue   Red
> -----------------------------------
>  White    0       1.5     2.2    2.9
>  Black    1.5     0        .7    1.3
>  Blue     2.2      .7     0       .7
>  Red      2.9     1.3      .7    0
> ```
>
> So, how do I connect the motor?"

From the resistance readings, it would appear that the Black, Blue, and Red are all taps on a single winding. My guess (and there are no warranties :-) would be: White is common, black is HIGH, blue is MEDIUM, red is LOW.

I would test as follows:

- Put a load in series with the line. Try a 250 W light bulb. This should prevent damage to the motor if your connections are not quite correct.

- Connect each combination of White and one other color. Start with black. It should start turning - not nearly at full speed, however. If it does turn, then you are probably safe in removing the light bulb.

  Alternatively, if you have a Variac (variable autotransformer) of sufficient ratings, just bring up the voltage slowly.

If it does not make any effort to start turning - just hums, go to plan B. It may require a starting/running capacitor and/or not be a 3 speed motor.

Small permanent magnet DC motors

These are constructed like small versions of universal motors except that the stator field is provided by powerful ceramic permanent magnets instead of a set of coils. Because of this, they will only operate on DC as direction is determined by the polarity of the input voltage.

Small PM DC motors are used in battery or AC adapter operated shavers, electric knives, and cordless power tools.

Similar motors are also used in cassette decks and boomboxes, answering machines, motorized toys, CD players and CDROM drives, and VCRs. Where speed is critical, these may include an internal mechanical governor or electronic regulator. In some cases there will be an auxiliary tachometer winding for speed control feedback. This precision is rarely needed for appliances.

As noted, direction is determined by the polarity of the input power and they will generally work equally well in either direction.

Speed is determined by input voltage and load. Therefore, variable speed and torque is easily provided by either just controlling the voltage or more efficiently by controlling the duty cycle through pulse width modulation (PWM).

These motors are usually quite reliable but can develop shorted or open windings, a dirty commutator, gummed up lubrication, or dry or worn bearings. Replacement is best but mechanical repair (lubrication, cleaning) is sometimes possible.

Problems with small PM motors

These motors can fail in a number of ways:

- Open or shorted windings - this may result in a bad spot, excess current drain and overheating, or a totally dead motor.
- Partial short caused by dirt/muck, metal particle, or carbon buildup on commutator - this is a common problem in CD player spindle and cassette deck motors but not as common a problem with typical appliances.
- Dry/worn bearings - this may result in a tight or frozen motor or a motor shaft with excessive runout. The result may be a spine tingling squeal during operation and/or reduced speed and power.

Testing of small PM motors

An open or shorted winding may result in a 'bad spot' - a position at which the motor may get stuck. Rotate the motor by hand a quarter turn and try it again. If it runs now either for a fraction of a turn or behaves normally, then replacement will probably be needed since it will get stuck at the same point at some point in the future.

Check across the motor terminals with an ohmmeter. There should be a periodic variation in resistance as the rotor is turned having several cycles per revolution determined by the number of commutator segments used. Any extremely low reading may indicate a shorted winding. An unusually high reading may indicate an open winding or dirty commutator. Cleaning may help a motor with an open or short or dead spot as noted below. Erratic readings may indicate the need for cleaning as well.

Also check between each terminal and the case - the reading should be high, greater than 1M ohm. A low reading indicates a short. The motor may still work when removed from the equipment but depending on what the case is connected to, may result in overheating, loss of power, or damage to the driving circuits when mounted (and connected) to the chassis.

A motor can be tested for basic functionality by disconnecting it from the appliance circuit and powering it from a DC voltage source like a couple of 1.5 V D Alkaline cells in series or a DC wall adapter or model train power pack. You should be able to determine the the required voltage based on the battery or AC adapter rating of the appliance. If you know that the appliance power supply is working, you can use this as well.

Identifying voltage and current ratings small PM motors

If the carcass of the device or appliance is still available, the expected voltage may be determined by examining the original power supply - batteries, voltage regulator, wall adapter, etc.

The following applies to the common DC permanent magnet (PM) motors found in tape players and cassette decks used for the capstan.

- This motor may have an internal speed regulator. In that case, you can determine the appropriate voltage by using a variable supply and increasing it slowly until the speed does not increase anymore. This will typically be between 2 and 12 V depending on model. The motor should then run happily up to perhaps 50% more input voltage than this value.

  Note that many motors are actually marked with voltage and current ratings. Internal regulators may be electronic or mechanical (governor). One way to tell if there is an internal electronic regulator is to measure the resistance of the motor. If it is more than 50 ohms and/or is different depending on which direction the meter leads are connected, then there is an electronic regulator.

Motors without internal speed regulators are used for many functions in consumer electronics as well as toys and small appliances.

- If it does not have an internal regulator, typical supply voltages are between 1.5 and 12 V with typical (stopped) winding resistances of 10 to 50 ohms. Current will depend on input voltage, speed, and load. It *cannot* be determined simply using Ohms law from the measured resistance as the back EMF while running will reduce the current below what such a calculation would indicate.

The wire color code will probably be red (or warm color) for the positive (+) lead and black (or dark cool) color for the minus (-) lead.

Reviving a partially shorted or erratic PM motor

Dirt or grime on the commutator can result in intermittent contact and erratic operation. Carbon or metal particle buildup can partially short the motor making it impossible for the controller to provide enough voltage to maintain desired speed. Sometimes, a quick squirt of degreaser through the ventilation holes at the connection end will blow out the shorting material. Too much will ruin the motor, but it would need replacement otherwise anyway. This has worked on Pioneer PDM series spindle motors.

Another technique is to disconnect the motor completely from the circuit and power it for a few seconds in each direction from a 9 V or so DC source. This may blow out the crud. The long term reliability of both of these approaches is unknown.

WARNING: Never attempt to power a motor with an external battery or power supply when the motor is attached to the appliance, particularly if it contains any electronic circuitry as this can blow electronic components and complicate your problems.

It is sometimes possible to disassemble the motor and clean it more thoroughly but this is a painstaking task best avoided if possible. See the section: Disassembling and reassembling a miniature PM motor.

Disassembling and reassembling a miniature PM motor

Note: for motors with carbon brushes, refer to the section: Disassembling and reassembling a universal or induction motor. This procedure below is for those tiny PM motors with metal brushes.

Unless you really like to work on really tiny things, you might want to just punt and buy a replacement. This may be the strategy with the best long term reliability in any case. However, if you like a challenge, read on.

CAUTION: disassembly without of this type should never be attempted with high quality servo motors as removing the armature from the motor may partially demagnetize the permanent magnets resulting in decreased torque and the need to replace the motor. However, it is safe for the typical small PM motor found in appliances and power tools.

Select a clean work area - the permanent magnets in the motor will attract all kinds of ferrous particles which are then very difficult to remove.

Follow these steps to minimize your use of 4 letter expletives:

1. Remove the load - fan blades, gears, pulleys, etc. Label and disconnect the power wiring as well as the motor will be a whole lot easier to work on if not attached to the appliance or power tool. Note: polarity is critical - take note of the wire colors or orientation of the motor if it is directly soldered to a circuit board!

2. Confirm that there are no burrs on the shaft(s) due to the set screw(s) that may have been there. For motors with plain bearings in particular, these will need to be removed to allow the shaft(s) to be pulled out without damage to the bushing.

3. Use a scribe or indelible pen to put alignment marks on the cover so that it can be replaced in the same orientation.

4. Make yourself a brush spreader. Most of these motors have a pair of elongated holes in the cover where the power wires are connected to the commutator. These allow the very delicate and fragile metal brushes to be spread apart as the armature is removed or installed. Otherwise, the brushes will get hung up and bent. I have found that a paper clip can be bent so that its two ends fit into these holes and when rotated will safely lift the brushes out of harm's way.

5. Use a sharp tool like an awl or dental pick to bend out the 2 or 3 tabs holding the cover in place.

6. Insert the brush spreader, spread the brushes, and pull the cover off of the motor. If done carefully, no damage will be done to the metal brushes.

7. The armature can now be pulled free of the case and magnets.

8. Identify any flat washers or spacers that may be present on the shaft(s). Mark down their **exact** location and orientation so that they may be replaced during reassembly. Clean these and set aside.

Inspect all components for physical damage or evidence of overheating or burning. Bad bearings may result in very obvious wear of the shaft or bushings or show evidence of the rotor scraping on the stator core. Extended overloads, a worn commutator, or shorted windings may result in visible or olfactory detected deterioration of wire insulation.

Check that the gaps in the commutator segments are free of metal particles or carbonized crud. Use a sharp instrument like an Xacto knife blade to carefully clear between the segments. Clean the brushes (gentle!), shafts, and bushings.

When reassembling, make sure to use your brush spreader when installing the cover.

DC brushless motors

These are a variation on the small DC motors described above and uses a rotating permanent magnet and stationary coils which are controlled by some electronic circuitry to switch the current to the field magnets at exactly the right time. Since there are no sliding brushes, these are very reliable.

DC brushless motors may be of ordinary shape or low profile - so called pancake' style. While not that common in appliances yet, they may be found in small fans and are used in many types of A/V and computer equipment (HD, FD, and CD drives, for example). Fortunately, they are extremely reliable. However, any non-mechanical failures are difficult to diagnose. In some cases, electronic component malfunction can be identified and remedied. Not that common in appliances but this is changing as the technology matures.

Direction may be reversible electronically (capstan motors in VCR require this, for example). However, the common DC operated fan is not reversible.

Speed may be varied over a fairly wide range by adjusting the input voltage on some or by direct digital control of the internal motor drive waveforms.

The most common use for these in appliances are as small cooling fans though more sophisticated versions are used as servo motors in VCRs and cassette decks, turntables, and other precision equipment.

Disassembling and reassembling a DC brushless fan

This is the type you are likely to encounter - modify this procedure for other types.

1. Remove the fan from the equipment, label and disconnect the power wires if possible.

2. Remove the manufacturer's label and/or pop the protective plastic button in the center of the blade assembly. Set these aside.

3. You will see an E-clip or C-clip holding the shaft in place. This must be removed - the proper tool is best but with care, a pair of fine needlenose pliers, narrow screwdriver, dental pick, or some other similar pointy object should work. Take great care to prevent it from going zing across the room.

4. Remove the washers and spacers you find on the shaft. Mark down their positions so that they can be restored exactly the way you found them.

5. Withdraw the rotor and blades from the stator.

6. Remove the washers and spacers you find on the shaft or stuck to the bushings. Mark down their positions so that they can be restored exactly the way you found them.

For fans with plain bearings, inspect and clean the shaft and the hole in the bushing using a Q-tip and alcohol or WD40 (see there is a use for WD40!). Check for any damage. Lubricate with a couple drops of electric motor oil in the bushing and any felt pads or washers.

For fans with ball bearings, check the bearings for free rotation and runout (that they do not wobble or wiggle excessively). If bad, replacement will be needed, though this may not be worth the trouble. These are generally sealed bearings so lubrication is difficult in any case. On the other hand, they don't go bad very often.

Reassemble in reverse order.

Synchronous timing motors

Miniature synchronous motors are used in mechanical clock drives as found in older clock radios or electric clocks powered from the AC line, appliance controllers, and refrigerator defrost timers. These assemblies include a gear train either sealed inside the motor or external to it. If the motor does not start up, it is probably due to dried gummed up lubrication. Getting inside can be a joy but it is usually possible to pop the cover and get at the rotor shaft (which is usually where the lubrication is needed). However, the tiny pinion gear may need to be removed to get at both ends of the rotor shaft and bearings.

These consist of a stator coil and a magnetic core with many poles and a permanent magnet for the rotor. (In many ways, these are very similar to stepper motors). The number of poles determines the speed precisely and it is not easily changed.

Direction is sometimes determined mechanically by only permitting the motor to start in the desired direction - they will usually be happy to start either way but a mechanical clutch prevents this (make note of exactly how is was positioned when disassembling). Direction can be reversed in this manner but I know of no actual applications where it would be desirable. Others use shading rings like those in a shaded pole induction motor to determine the direction of starting.

Speed, as noted, is fixed by construction and for 60 Hz power it is precisely equal to: 7200/(# poles) RPM. Thus, a motor with 8 poles will run at 900 RPM.

Disassembling and reassembling a small timing motor

The best approach is usually replacement. In some designs, just the rotor and gear unit can be replaced while retaining the stator and coils.

However, if your motor does not start on its own, is sluggish, or squeals, cleaning and lubrication may be all that is needed. However, to get to the rotor bearing requires removal of the cover and in most cases the rotor as well. This may mean popping off a press-fit pinion gear.

1. Remove the motor from the appliance and disconnect its power wires if possible. This will make it a lot easier to work on.

2. Remove the cover. This may require bending some tabs and breaking an Epoxy seal in some cases.

3. Inspect the gears and shafts for gummed up lubrication. Since these motors have such low torque, the critical bearing is probably one for the main rotor. If there is any detectable stiffness, cleaning and lubrication is called for.

4. You can try lubricating in-place but this will usually not work as there is no access to the far bearing (at the other end of the shaft from the pinion gear). I have used a small nail or awl to pop the pinion gear from the shaft by gently tapping in the middle with a small hammer.

5. Withdraw the rotor from the motor.

6. Identify any flat washers or spacers that may be present on the shaft. Mark down their **exact** location and orientation so that they may be replaced during reassembly. Clean these and set aside.

7. Inspect and clean the shaft and bushings. Lubricate with electric motor oil.

8. Reinstall the rotor and washers or spacers. Then press the pinion gear back onto the shaft just far enough to allow a still detectable end-play of about .25 to .5 mm. Check for free rotation of the rotor and all gears. Replace the cover and seal with household cement once proper operation has been confirmed.

Motor bearing problems

A dry or worn bearing can make the motor too difficult to turn properly or introduce unacceptable wobble (runout) into the shaft as it rotates.

Feel and listen for a dry bearing:

The shaft may be difficult to turn or it may turn with uneven torque. A motor with a worn or dry bearing may make a spine tingling high pitched sound when it is turning under power. A drop of light machine oil (e.g. electric motor oil) may cure a dry noisy bearing - at least temporarily.

Runout - wobble from side to side - of a motor shaft is rarely critical in a small appliance but excessive side-to-side play may result in noise, rapid bearing wear, and ultimate failure.

Motor noise

If the noise is related to the rotating motor shaft, try lubricating the motor (or other suspect) bearings - a single drop of electric motor oil, sewing machine oil, or other light oil (NOT WD40 - it is not a suitable lubricant), to the bearings (at each end for the motor). This may help at least as a temporary fix. In some cases, using a slightly heavier oil will help with a worn bearing. See the section: Lubrication of appliances and electronic equipment.

For AC motors in particular, steel laminations or the motor's mounting may be loose resulting in a buzz or hum. Tightening a screw or two may quiet it down. Painting the laminations with varnish suitable for electrical equipment may be needed in extreme cases. Sometimes, the noise may actually be a result of a nearby metal shield or other chassis hardware that is being vibrated by the motor's magnetic field. A strategically placed shim or piece of masking tape may work wonders.

Finding a replacement motor

In many cases, motors are fairly standardized and you may be able to find a generic replacement much more cheaply than the original manufacturer's part. However, the replacement must match the following:

1. Mechanical - you must be able to mount it. In most cases, this really does mean an exact drop-in. Sometimes, a slightly longer shaft or mounting hole out of place can be tolerated. The pulley or other drive bushing, if any, must be able to be mounted on the new motor's shaft. If this is a press fit on the old motor, take extreme care so as not to damage this part when removing it (even if this means destroying the old motor in the process - it is garbage anyway).

2. Electrical - the voltage and current ratings must be similar.

3. Rotation direction - with conventional DC motors, this may be reversible by changing polarity of the voltage source. With AC motors, turning the stator around with respect to the rotor will reverse rotation direction. However, some motors have a fixed direction of rotation which cannot be altered.

4. Speed - depending on the type appliance, this may or may not be that critical. Most induction motors run at slightly

under 900, 1800, or 3600 RPM (U.S., 60 Hz power). DC motor speed can vary quite a bit and these are rarely marked.

MCM Electronics, Dalbani, and Premium Parts stock a variety of small DC replacement motors. Appliance repair shops and distributors may have generic replacements for larger motors. Junk and salvage yard or your local dump may actually have what you want for pennies on the pound or less!

Is motor rebuilding economical?

So you left your electric cement mixer mixing away and forgot about it - for 3 days. Now the motor is a black charred ruin. You can rent a jack hammer to break up the cement but the motor is a lost cause. The manufacturer has been out of business for 20 years. What should you do besides give the tool a decent burial?

Here is a possible option for, in this case, a planer:

(From: Ed Schmitt (easchmitt@penn.com).)

I located a person who rewinds motors and had the job done for $60.00. That was over 7 years ago, and the planer is still working. Look around and find some of our elderly craftsman who know how to rewind motors. You'll save a bundle, and have a working tool.

(From: Michael Sloane (msloane@worldnet.att.net).)

That is an interesting thought - I have a 1942 Cat road grader with burned out wiring in the 6 V wiper motor. Cat wants $200(!) for a new one, so I would like to find someone who would rewind the old one (and make it 12 V at the same time). I wouldn't even bother with the so-called auto-electric guys, all they do is replace the brushes and diodes on starters and alternators.

Motor armature testing - or - what is a growler?

A common fault that cannot always be reliably identified with a simple ohmmeter test is a couple of shorted turns in the winding that do not affect the total resistance significantly.

A growler is basically an AC electromagnet exciting the windings in the armature. A shorted armature winding will act as a the secondary of a transformer resulting in a high current flow and high induced magnetic field.

Hold a piece of spring steel like a hacksaw blade as a probe over the armature as you rotate it slowly on the electromagnet. A shorted winding will show up as a strong audible vibration of the 'probe' - thus the name growler.

Small motor repair and replacement

(From: mjsrnec (mjsrnec@prairie.lakes.com).)

Most motor shops won't bother with the universal motors because they are much cheaper to replace than repair. However, if yours is a special be prepared to pay standard rates for the service. Email the Electrical Apparatus Service Association found at: http://www.easa.com/ to find the EASA shop nearest you.

If you think the motor may be fairly common pick up a Grainger catalog or go to: Grainger or: Grainger Universal Motor Index.

If this is for a power tool, contact the tool manufacturer for the authorized service center nearest your location.

Large Appliances

Editor's note: Yes, I know this is supposed to be the "Small Appliance FAQ" but so be it. Until and if I write a "Large Appliance FAQ", this chapter will have to do. :-)

Web resources for large appliance troubleshooting

There are a number of Web sites dedicated to large appliance repair. Most are companies selling parts or manuals but they may also have on-line forums, replies to requests for assistance via email, or other free DIY information. However, very few, if any, have the sort of in-depth treatment of appliance repair provided by a good book on the subject. These are listed in more-or-less alphabetical order:

- A-1 Appliance Parts. Mostly a parts supplier but includes an on-line appliance repair forum. They used to have a tech-tips/diagnostics area but that seems to have disappeared.

- All Appliance Parts, Inc.. This is basically an appliance parts supplier but includes "Appliance Troubleshooting Live Chat Sessions" and free help via email. Alternate site: http://applianceparts.net/.

- Appliance411 Includes information on purchasing, service, and repair parts, as well as links and a Q and A forum.

- Appliance Aid. Lots of info including how appliances work, links, model specific help, help by email, parts and manual suppliers, etc.

- Appliance Clinic. Tips (often by manufacturer/model) for clothes washers, dryers, and refrigerators/icemakers. Also, some parts, other info, free email replies.

- Appliance Repair Net. This site is selling repair manuals for large appliances. I do not have any idea if they are any good. This appears to be the same as: EB Repair Manuals.

- Appliance Service Center. Another parts supplier but includes an appliance repair BBS, repair tips for various large appliances, and more. There is also another forum which is associated with this site: Appliance Service Center Forum.

- Braun service manuals (Courtesy of The Mending Shed).

- Fixit.com. Large appliances includes some tips, discussion group, direct email replies.

- Garrell's Appliance Center. Washers, dryers, stoves, ovens, refrigerators, air conditioners. Parts, manufacturers, manuals, free email replies.

- Gracie Appliance. Heating and air conditioning. They used to have an extensive DIY area with troubleshooting information but apparently that wasn't profitable enough so a new smaller page may be forthcoming. :(

- RepairClinic.com. Large appliances including a wee bit on microwave ovens. Parts supplier but does have some tips and direct email help.

- The Fridge Doctor. Basic information on principles of operation, maintenance, and repair of refrigerators and freezers. He's also trying to sell his book.

- The Virtual Repairman. Some basic info and free email repair advice.

- Point and Click Appliance Repair. Parts and free repair help.

The USENET newsgroups alt.home.repair, misc.consumers.house, and sci.electronics.repair may be appropriate for appliance repair questions as well.

There may be additional links in the "Appliance Sites/Information" section of Sam's Neat, Nifty, and Handy Bookmarks.

Electric oven calibration

If your cakes come out all drippy or your chicken breasts end up hard as a rock and charred, this discussion is for you! It is possible that the thermostat on your oven needs calibration. However, major errors in temperature may be the result of a bad heating element, blown fuse or tripped breaker, a door that doesn't close or seal properly, etc. Confirm that the oven is in otherwise good operating condition before attempting calibration.

The procedure given below assumes that your oven has a mechanical thermostat which is still the most common type. For an electronic thermostat - one in which the set-point is entered via a touchpad - the adjustment (if any) will likely be on the controller circuit board rather than under the temperature knob. If you do attempt calibration of an electronic thermostat, make double sure that you have located the correct adjustment screw!

(Portions from: ken859@sprynet.com).

Most thermostats have a calibration screw located under the knob. Try pulling the knob off and look at the shaft. Some shafts have a small screw located in the center. Rotating this screw will change the trip point at which the thermostat will turn on and off. This is determined by the sensor located inside the oven itself.

You can also have your oven calibrated by an appliance service technician by locating them in your yellow pages and have him/her make a house call but you wouldn't be reading this if you wanted someone else to do it!

The following procedure can be performed by almost anyone who knows which end of a screwdriver to poke into the screw head :-).

1. Locate 2 thermometers that are oven safe and place them inside the oven on a shelf approximately in the center of the oven. Make sure the actual sensing elements of the thermometers do not touch anything.

2. Remove the knob from the thermostat and locate an appropriate screwdriver for the adjusting screw. Re-install the knob.

3. Turn on the oven and set it for 300 degrees F. Allow it to come up to temperature (set light goes out). Then wait an additional 10 minutes.

4. Look at the temperature of the thermometers (averaging the two) and determine the error amount and direction. Note: if the error is large (greater than, perhaps, 50 degrees F) then there may be a problem with the oven (such as a

bad temperature sensor) which will not be remedied by calibration.

5. Remove the knob and adjust the screw in the shaft one way or the other depending on which way the oven set-point is off. If the direction is not marked to increase or decrease the temperature, just pick one - there is no standard. You may be wrong on the first attempt :-(.

   Note: Rotate the adjustment in small increments!

6. Place the knob back on the shaft.
7. Again wait 10 minutes after the oven set light goes off.
8. Look at the temperature of the thermometers and see how far off the error is now.
9. Repeat the steps above until this set-point is accurate.
10. Now set the thermostat to 400 degrees F and repeat the steps above for this setting.
11. The oven set-point should now be a lot closer to the actual temperature.

If you really want to be the oven to be accurate, Turn the oven off and allow it to completely cool. The, repeat the above complete procedure 2 more times or until the accuracy you desire is achieved.

Repeating this procedure may seem redundant but some thermostats because of their mechanical nature have a margin of error. Also due to the mechanical nature, some settling of the parts inside does occur.

As long as the heating elements in the oven do not fail. The oven should maintain its accuracy for quite some time. A simple check of the oven once every 6 months or once every year will assure you that your baking temperatures will be accurate.

Heat control in electric range surface units

The typical electric range surface unit has two spiral elements. In older ranges, they are used in various combinations across the 120 and 240. We have a GE range like this which has 5 heat settings (and off) for each 'burner'.

Given 2 element and 2 voltages there are 8 possible connection possibilities. I don't know which 5 my GE range uses.

Newer ranges use a single element or just parallel the two elements and use variable power control (pulse width modulation or thyristor phase control) to obtain arbitrary heat levels and/or a thermostat to sense the actual temperature.

BTW, this GE range is about 46 years old and still going strong (except for the 1 hour timer which died about 5 years ago.)

(The following experiments from: Mark Zenier (mzenier@netcom.com).)

From my multiple renovations of my mother's stove of a similar vintage:

Warm is 120 volts applied to both elements of a burner in series.

Low is 120 volts applied to one of the two elements. The burners are wired so that they are not the same. Half of the burners used the center element, the others used the rim element. Usually split between front burners and rear. (This is a GE, other companies used two interleaved spiral elements.)

Third is 120 volts applied to both elements.

Second is 240 volts applied to one element, like Low, it varies from burner to burner.

High is 240 volts applied to both elements.

Electric range top element does not work properly

If all the elements are dead, check for blown fuses/tripped circuit breakers. There may be some in the range unit itself in addition to your electrical service panel.

If one element is completely dead on all heat settings, the control is probably bad or there is a broken wire. If it is stuck on high for all control settings or is erratic, the control is bad - replacements are readily available and easily installed.

On ranges with push button heat selection, a pair of heating elements are switched in various combinations across 120 and/or 240. If some heat settings do not work, the most likely cause is that one of the heatings elements is burnt out although a bad switch is also possible. Kill power to the range and test the heating elements for continuity. Replacements are available from appliance parts stores or the places listed in the section: Parts suppliers.

Improvised welding repair of heating elements

Due to the high temperatures at which they operate, welding may provide better long term reliability of heating elements than mechanical fasteners. However, in most cases, the following extreme measures are not really needed.

Warning: only consider the following if you are absolutely sure you understand the safety implications of working directly with line voltage - it is not very forgiving. There is both an electrocution and fire hazard involved.

(From: Donald Borowski (borowski@spk.hp.com).)

I have had success with welding heating element wires back together using a "carbon arc torch". I did this on a ceramics kiln recently.

I extracted the carbon rods from two carbon/zinc D cell ('Classic' or 'Heavy Duty' variety, alkalines do hot have carbon rods). I filed one end to a point.

I wired a circuit as follows:

- Hot side of line to one connection of 1500 electric heater.
- Other connection of heater to one carbon rod.
- Second carbon rod connected to neutral.
- I twisted together the heater wires to be welded, making a pigtail about 3/4" long.

Then I touched the carbon rods together and drew them apart, producing a carbon arc. I moved the carbon rods and arc to position the tip of the heater wire pigtail in the arc. I slowly moved the arc in along the pigtail until a molten ball of nichrome formed between the two wires of the pigtail. When this happened, I immediately withdrew the arc.

Of course, all safety warnings apply: Dangerous power line voltages, welder's mask needed for protect eyes, possible dangerous chemicals in D cell, etc.

This should work for other types of Nichrome coiled or ribbon heating elements as well.

I vaguely recall seeing many years ago a suggestion of making a paste of borax and putting it over the twisted-together ends. I guess it was supposed to act as a self-welding flux. Anyone else recall this?

Due to the high temperatures at which they operate, welding may provide better long term reliability of heating elements than mechanical fasteners. However, in most cases, the following extreme measures are not really needed.

Warning: only consider the following if you are absolutely sure you understand the safety implications of working directly with line voltage - it is not very forgiving. There is both an electrocution and fire hazard involved.

Induction cooktops

These operate by generating a high frequency current in a coil under the cooking container using it's bottom as the (shorted) secondary of a transformer. The very high currents result in heating of the contain and its contents, but little power is wasted elsewhere (though the power drive circuits aren't 100 percent efficient).

(Portions from: K. T. Chan (ktchan@hk.gin.net).)

The circuit inside is a chipset handling the generation the of driving signal to the MOSFET power invertor. Control by the Q of the resonance power coil. If the load ia low the Q is high and the circuit cuts the drive. And then sends out probing pulses to test the load (your pan). If the load is big enough, the drive will be turned on to the power circuit. There has to be a large enough load - a wedding ring won't do it!

I damaged the 110 V one and opened up an old 200 V one.

I wanted to repair one before but the spare parts and circuit diagram are rare. And the product is cheap (at least in some parts of the world. Check at Sunpentown. (Too bad it is mostly in Chinese!). The one I had been using for 10 years. The price is less then $200 US. I had the first one from Japan, a 110 V model.

Range, oven, and furnace electronic ignition

Many modern gas stoves, ovens, furnaces, and other similar appliances use an electronic ignition rather than a continuously burning pilot flame to ignite the fuel. These are actually simple high voltage pulse generators.

- Where starting is manual (there is a 'start' position on the control(s), a set of switch contacts on the control(s) provides power to the ignition module.
    - A problem of no spark with only one control indicates that the fault is with it or its wiring.
    - A problem with continuous sparking even with all the controls off or in their normal positions indicates a short - either due to a defective switch in one of the controls or contamination (e.g., spilled liquid) bypassing the switch contacts.
- Where starting is automatic, an electronic sensor, thermocouple, or bimetal switch provides power to the ignition module as needed.

The Harper-Wyman Model 6520 Kool Lite(tm) module is typical of those found in Jenne-Aire and similar cook-tops. Input is 115 VAC, 4 mA, 50/60 Hz AC. C1 and D1 form a half wave doubler resulting in 60 Hz pulses with a peak of about 300 V and at point A and charges C2 to about 300 V through D2. R2, C3, and DL1 form a relaxation oscillator triggering SCR1 to dump the charge built up on C2 into T1 with a repetition rate of about 2 Hz.

```
           C1                A       D1                     T1 o

```

Before you blame the ignition module for either lack of spark or continuous spark, make sure the wiring is in good condition and completely dry and clean (well reasonably clean!). Confirm that proper voltage is reaching the module with a multimeter or neon test lamp. The modules are actually quite robust:

- Any liquid that may have dripped into the module may result in temporary or permanent failure. Fortunately, as with the model cited above, it may be possible to pop off the bottom cover (with power OFF or the module removed!) and clean it. The most likely failure would be the SCR if you are into component level repair. Else, just replace it.

  WARNING: There are several capacitors inside that may be charged to as much as 300 volts. The charge they can hold is probably not dangerous but may be painful or startling. Discharge these before touching anything inside or attempting to check components. Use a screwdriver blade or test clips and then confirm that they are discharged with your multimeter.

- Contamination of the controls from spilled liquid (did your tea kettle boil over?) may result in continuous activation of the ignition module since any electrical leakage across the switch contacts will likely be enough to activate it - only a few mA are required. Remove the control panel cover and dry it out or unplug the range or oven for a couple of days. If the contamination is not just plain water, it is a good idea to clean it thoroughly to prevent future problems.

- Spills into the area of the electrodes at the gas burner assembly may short out the ignition for ALL the burners since they probably use the same module. Again, clean and dry it out or let it dry out on its own (if just water).

These are probably standard modules and replacements should be available from your local appliance repair shop or parts supplier. An exact mechanical match is not needed as long as the specifications are compatible.

Oven door seal repair

(From: Brian Symons (brians@mackay.net.au).)

If you need a high temp silastic (e.g., for refitting glass windows in ovens) then the Black silastic sold for car windscreen sealing from the local service station or garage is the stuff. Works well. Someone here waited several months and paid $80 for what he could buy down the road for $10 - it was even the same brand.

Freezer is normal but fresh food compartment isn't even cool ---

Some possibilities:

- The door is not properly closing for some reason.
- Someone messed with the controls accidentally.
- Something is blocking the passageway between the evaporator and the fresh food compartment.
- The defrost cycle is not working and ice has built up in the evaporator coils. This could be due to a bad defrost timer (most likely), bad defrost heater, or bad defrost thermostat.
- The interior light is not going out when the door is closed - that small amount of heat can really mess up the temperature (remove the bulb(s) as a test if you are not sure.
- Low Freon can result in problems of this type but that is a lot less likely. (These refrigeration systems are hermetically sealed (welded). Slow leaks are unlikely.)

If you are handy, you can narrow down the problem and possible fix it - a defrost timer can be easily replaced. See the section: Defrost system operation and wiring.

Refrigerator not cooling after a week

First, clean the condenser coils. It is amazing how much dust collects there and interferes with proper cooling.

If you just turned it on a week ago and it is not acting up, a failure of the defrost timer is quite likely. On an old fridge, the grease inside dries out/gunks up and restarting from cold results in it not running. It takes about a week for enough ice to build up to be a problem.

This is a $12 repair if you do it yourself or $100 or so if you call someone.

Could be other things but that is what I would check first. On a GE, it is usually located at the bottom front and there is a hole in the front in which you can poke your finger to turn it clockwise by hand. Turn it until you hear a click and the fridge shuts off. You should not get melting in the evaporator compartment and water draining into the pan at the bottom. The fridge compressor should start up again in 10-20 minutes but I bet in your case it won't as the timer needs replacement.

Defrost system operation and wiring

The most common type of defrost system on a no-frost refrigerator or freezer usually consists of:

- Defrost timer - motor driven (typically) switch which selects between the compressor and its associated devices (like the evaporator fan) and the defrost heater (located adjacent to the evaporator coils). The timer motor likely only runs when the main thermostat calls for cooling.

- Defrost heater - resistance element located in the evaporator compartment to melt ice built up on the coils

- Defrost thermostat - closed when the temperature is below about 32 degrees F to allow current to flow to the defrost heater. Shuts off once the ice melts as indicated by the temperature rising above 32 degrees F.

Testing: It should be possible to easily identify the bad components. For the following, it is assumed that the main thermostat is set such that the compressor is on.

- Usually, it is possible to manually turn the defrost timer shaft (through a hole in the timer case) with a finger or small screwdriver - try both directions - one should rotate easily with a slight ratcheting sound until a distinct 'click' is heard.

- The click indicates that the switch has changed position. The compressor should shut off (or start up if it was stuck in defrost). Over 90% of the rotation range enables the compressor with a short time (e.g., 20 minutes) for defrost. The total time is several hours (6 typical).

- At this point, the defrost heater should come on if there is enough ice to keep the defrost thermostat below 32 F. You will know it comes on because there will be crackling sounds as ice melts and parts expand and the element may even glow red/orange when hot. Water should start flowing to the drip pan. If there is no sign of heating:

    - Test (with power off) the resistance of the element - it should measure under 100 ohms (31 ohms typical).

      If open - at the terminals of the element - it is bad.

    - Test (with power applied) for AC voltage across the element. If there is none, test across the defrost thermostat - there should be none. Or, test across the series combination of the defrost heater and thermostat. There should be full line voltage across the series combination.

      If there is still none, the contacts on the defrost timer may be bad, you may be in the normal cycle by mistake, the main thermostat may be defective or not calling for cooling, the wiring may be incorrect or have bad connections, or there may be no power to the outlet.

      If there is voltage across the defrost thermostat, it is defective or the temperature is above 32 F. Confirm by jumpering across the defrost thermostat and see if the defrost heater comes on.

- If ice buildup is modest, the defrost thermostat should shut off the heater in a few minutes. In any case, the timer should advance and switch to the normal position with the compressor running and defrost heater shut off in about 10 to 20 minutes.

  If the timer never advances, the motor is likely not running due to gummed up lubrication, a broken or loose gear, or a broken wire. On some of these timers, the connections to the motor are to the moving contacts and break after a few years. These can be repaired by soldering them to a more stable location.

  One indication that the motor is not being powered is for it to be ice cold even after several hours with the compressor (and thus the timer) being on. Normally, the coil runs warm to hot. If the timer never advances even with a toasty winding, the lubrication is gummed up or a gear has broken.

Defrost timers are readily available at appliance parts distributors. A generic timer will cost about $12. An exact replacement, perhaps up to $35. If you call in a service person, expect to pay over $100 for the part and labor.

Generally, the defrost timer is an SPDT switch operated by a cam on a small motor with a 4 to 8 hour cycle (depending on model). For an exact replacement, just move the wires from the old timer to the same terminals on the new unit. For a generic replacement, the terminal location may differ. Knowing what is inside should enable you to determine the corresponding terminal locations with a multimeter.

The terminal numbering and wire color code for the defrost timer in a typical GE refrigerator is shown below:

```
                     Black (4)
    Gray (3)      /o---------o Normal position - Compressor, evaporator fan.
H* o-----+------/
         |         o---o Blue (2)
       Timer           |         Defrost heater  Defrost Thermostat
       Motor (3180     o------------/\/\/\------------o/o----------+
         |    ohms)                 31 ohms          32 F          |
         |                                                         |
         | Orange (1)                                              |
         o---------------------------------------------------------+--o Common

   * H is the Hot wire after passing through the main thermostat (cold control)
     in the fresh food compartment.
```

Since the defrost timer only runs when the compressor is powered, it will defrost more frequently when the fridge is doing more work and is likely to collect more frost. This isn't perfect but seems to work.

Compressor starting relays

Most refrigeration compressors use a current mode relay to engage the starting winding of their split phase induction motor. However, a PTC (Positive Temperature Coefficient) thermistor might also be used.

A starting relay senses the current flowing to the run winding of the compressor motor (the coil is a few turns of heavy wire in series with the run winding) and engages the starting winding when that current is above a threshold - indicating that the rotor is not up to speed.

A PTC thermistor starts with a very low resistance which increases to a high value when hot. Proper operation depends on the compressor getting up to speed within a specific amount of time.

For testing only, you can substitute an external switch for the starting device and try to start it manually.

CAUTION: Do not bypass a faulty starting device permanently as the starting winding is not intended to run continuously and will overheat and possibly burn out if left in the circuit.

Assuming you have waited long enough for any pressures to equalize (five minutes should do it if the system was operating unless there is some blockage - dirt or ice - inside the sealed system), you can test for proper operation by monitoring the voltage on the start and run windings of the compressor motor. If there is line voltage on both windings and it still does not start up - the overload protector switches off or a fuse or circuit breaker pops - the compressor is likely bad.

Refrigeration compressor wiring

The following applies to a typical GE refrigerator compressor. YOURS MAY BE DIFFERENT! There may be a wiring diagram tucked in with your customer information, attached to the back of the unit, or hidden underneath somewhere.

The sealed unit has 3 pins usually marked: S (Start), R or M (Run or Main), and C (Common). The starting relay is usually mounted over these pins in a clip-on box. The original circuit is likely similar to the following:

```
                      |<- Starting Relay ->|<---- Compressor Motor ---->|

               ___            L
     AC H o----o o--------------+--o/   S    S
            "Guardette"         |    o---->>-------------+
             (Thermal           +-+                      |
             Protector)            )||                   +-+
                        Relay Coil )||                      )||
                                   )||                      )|| Start
                                +-+                         )|| Winding
                                |                           )||
                                |      M    R/M          +-+
                                +-------->>------+       |
                                                  )||    |
                                         Run/Main )||    |
                                          Winding )||    |
                                                  )||    |
                                               +-+       |
                                            C   |        |
     AC N o------------------------------>>-----+--------+
```

The Starting Relay engages when power is applied due to the high current through the Run winding (and thus the relay coil) since the compressor rotor is stationary. This applies power to the Start winding. Once the compressor comes up to speed, the current goes down and the Starting Relay drops out.

Note the Thermal Protector (often called a "Guardette" which I presume is a brand name). This shuts off power to the compressor if the temperature rises too high due to lack of proper cooling (defective compressor/condenser cooling fan, missing cardboard baffle, or clogged up (dusty) comdensor; an overload such as a blockage in the sealed system (bad news), or low line voltage.

Changing the temperature range of a small refrigerator

It is simple in principle. The cold control - the thing with the knob - needs to be modified or replaced. It is a simple on/off thermostat. You may be able to figure out how to adjust its limits (mechanical) or simply locate a suitable thermostat and install it in place of the existing unit. Note: if it uses a capillary tube to a sensing bulb, don't attempt to modify that part - it is sealed and should remain that way. The mechanism it operates may still be adjustable. However, you will likely loose the low end of your temperature range.

Washer sometimes spins

When it should be spinning, is the motor running? Does it complete the cycle in the normal time?

I would guess that the solenoid to shift it into spin is binding or erratic. Thus opening the door gives switches it on and off like the timer but since it sometimes works, it sometimes works by cycling the door switch.

Clothes washer does not fill (cold or hot)

This assumes the unit has power and otherwise operates normally. However, determining this may be difficult if the completion of the cycle is dependent on a water weight or volume sensor.

There are several possibilities:

1. The appropriate water inlet filter is clogged. This will be accessible by unscrewing the hose connection. Clean it.

2. The solenoid is bad. If you are electrically inclined, put a multimeter on the cold water valve to see if it is getting power.

3. The temperature selector switch is bad or has bad connections.

4. The controller is not providing the power to the solenoid (even for only hot or cold, these will have separate contacts).

Maytag washer timer motor repair

The following applies to many Maytag models manufactured over the last 25 or 30 years. A typical example is "A106" of 1970s vintage but much more recent models use the same mechanism. After 20 or 30 years, even a Maytag washer may need a service call. :) It also likely applies to other makes of washers.

One common failure is of the motor that drives the electromechanical controller. And, the problem may be a 2 cent plastic gear! The symptoms are that the timer never advances. The cause is that due to age, use, or gummed up grease, the pinion gear on the rotor of the timing motor cracks and the timer fails to move. As of 2001, the entire motor was available from Maytag for about $55, and generic versions from other appliance parts suppliers for around $30. (An Internet search of "Maytag parts" will turn up several possible suppliers.) However, a repair may be possible. There is no way to order just the gear but what's left of it is usually salvageable. Whether the repair lasts a week or 10 years, no guarantees but it is fairly easy. Here is the sequence of steps to perform the repair:

- Unplug the washer!!!! Provide a container to hold small parts so they won't get lost. :)

- Remove the sheet metal cover over the controls by unscrewing two screws on top.

- Use a thin tool like a butter knife to pop off the decorative center piece on the knob.

- Pop off the metal clip on the shaft and remove the knob, spring, and dial plate.

- Note which way the controller assembly is oriented and then use a socket driver to remove the two hex screws holding it to the control panel. Hold onto it while removing the screws and rest it on something soft to prevent damage. The motor will be visible on the side which used to face the front panel.

- Pull off the two wires of the motor from their terminals and note where they went.

- Remove the two screws holding the motor in place and remove the motor.

- Test the motor by carefully connecting it to a source of 115 VAC. There should be a hum but the drive gear won't move, or will be easily stopped. This confirms that the motor is the problem. If it's difficult or impossible to stop the drive gear from moving, the motor is probably not the problem. The controller may be really gummed up or damaged.

- Using a power drill or drill press, drill out the two rivets holding the motor shell together. Take care to only drill deep enough to remove the rivet shoulder - the shafts are needed to align the shells upon reassembly. Take care that the half with the gears doesn't fall apart.

- Examine the pinion gear on the metal shaft. This is a piece of plastic/rubber material (orange in the samples I've seen) that is supposed have a slot on one end into which fits two projections from the rotor. Typically, the gear fractures at this point.

- Use a small file, knife, or other suitable tool to trim the remaining end flat and then fashion some new slots in what's left. Remove only the minimum material necessary. It doesn't have to be a perfect fit.

- Clean both the gear and rotor where they mate and use some quick setting adhesive to join them together. I've had success with an initial use of SuperGlue(tm) followed by an overcoat of windshield sealer. In another case I used some hot melt glue. Make sure the gear and rotor don't get stuck to the shaft (which doesn't rotate!).

- Since the gear is now shorter than before, it will be necessary to add some sort of spacer to keep it (and the rotor) in position. If a suitable washer isn't handy, make something from a tiny bit of plastic. Make sure there is still a small amount of end clearance when the two halves are put back together.

- Check lubrication of the gear train. A few drops of light machine or electric motor oil won't hurt.

- Reassemble the motor shell temporarily and power it up to check that it now rotates. It should start reliably and be very difficult or impossible to stop by grabbing the gear.

- Reinstall the motor in the controller using the same two screws that were there originally. Put the wires back onto their respective terminals (which one doesn't matter as long as they are the same terminals!).

- Flip the controller over and remove the sheet metal cover concealing the gears that drive the switch mechanism by bending the tab holding it in place.

- Clean up the old, possibly dried or caked grease on these gears, and then lubricate with new light grease. Replace the cover. PROBLEMS WITH LUBRICATION HERE MAY IN FACT BE THE ACTUAL CAUSE OF THE MOTOR GEAR FAILURE so don't neglect this step!

- Reassemble the controller, knob, and cover. Plug the washer in.

Now you (or your spouse) will have no excuses to deal wtih those piles of dirty laundry!

Window air conditioner preventive maintenance

Very little needs to be done to get many years of service from a typical window air conditioner.

Of course, clean the inside filter regularly. This is usually very easy requiring little or no disassembly (see your users manual). Some slide out without even removing the front cover (e.g., Emerson Quiet Kool).

I generally do not bother to open them up each year (and we have 4). Generally, not that much dirt and dust collects inside. A cover during the winter also helps.

Use a vacuum cleaner on the condenser coils in the back and any other easily accessible dirt traps.

If you do take the cover off, check the fan motor for free rotation. If it is tight indicating bad bearings or lack of lubrication, it will have to be disassembled, cleaned, and lubricated - or replaced. If there are lubrication holes at the ends of the motor, put a couple drops of electric motor oil in there while you have it open.

These units have a sealed freon system - so if anyone's been into it before - you can tell from obvious saddle valves clamped on. Generally, if it cools and the air flow is strong, it is OK.

These units tend to be very reliable and low maintenance.

Window air conditioner doesn't cool

This means the fan runs but you do not hear the compressor kick in.

It could be several things:

- If you hear the 'click' of the thermostat but nothing happens (Your room lights do not dim even for a second) and there is no other sound, it could be bad connections, bad thermostat, dirty switch contacts, bad compressor, etc. Or, you have it set on fan instead of cool. Try cycling the mode selector switch a couple times.

- If you do not hear a click at all, then the thermostat is probably bad or it is cooler in your room than you think! Try tapping on the thermostat. Sometimes they just stick a bit after long non-use.

- If you get the click and the lights dim and then a few seconds later there is another click and the lights go back to normal, the compressor, or its starting circuitry is bad. It is trying to start but not able to get up to speed or rotate at all.

Except for a bad compressor, all these are repairable relatively inexpensively but if it is real old, a new high efficiency model may be a better solution.

Air conditioner freezes up

When this happens, airflow is reduced greatly since ice is blocking the evaporator. Turning the unit off for a while or running it on fan-only will clear the ice but this may indicate the need for maintenance or an actual problem. Similar comments apply to window and central air conditioners as well as heat pumps.

The three major causes of an air conditioner freezing up are:

1. Reduced airflow due to a dirty filter or clogged evaporator. If you are not aware that there is a filter to clean, this is probably the cause :-).

2. Low Freon. While your intuition may say that low Freon should result in less cooling, what happens is that what is there evaporates too quickly and at the input end of the evaporator coils resulting in lower temperatures than normal at that end (which results in condensed water vapor freezing instead of dripping off) but part of the evaporator will likely be too warm.

   You cannot fix this yourself without specialized equipment. For a room air conditioner that isn't too old, it may be worth taking it in to a reputable shop for an evaluation. For a central air conditioner, you will have to call an HVAC service company for repairs.

   The fact that the Freon is low means that there is a leak which would also need to be repaired. Freon does not get used up.

3. Outside and/or inside temperature may be very low. The unit may not be designed to operate below about 65 degrees F without freezing up.

If it is 90 degrees F and you have full air flow with the fan set on high and still get the freezup on a part of the evaporator, then low Freon is likely.

Comments on electric clothes dryer problems and repair

For quite a lot of useful information, do a web search for 'appliance repair'. There are a couple of decent sites with DYI information.

(From: Bernie Morey (bmorey@aardvark.apana.org.au).)

I've repaired our electric dryer several times over the years and kept it going well beyond its use-by date.

My main problems have been:

1. Mechanical timer failure. Easy fix.

2. Leaking steam damaging the element. Have replaced element twice -- fairly easy job. Had to replace some stainless stand-offs at the same time. Elements readily available and equivalent of USD24 each.

3. Bearing replacement -- have to be done carefully or they don't last.

4. Belt replacement. (Make sure you center the belt with respect to the idler and rotate the drum by hand to double check it before buttoning things up. Else, it may pop off the first time the motor starts. --- sam).

5. Exhaust fan bearing replacement. This was the trickiest, although far from impossible. It is a sealed unit subject to high heat and dust contamination -- not a good environment.

The only problem for the past two years has been the dryer throwing the exhaust fan belt. Cleaning up the fluff fixes it for another year.

Did all these without any guide -- just carefully inspecting the work before starting and making diagrams of wiring and ESPECIALLY the main drum belt. I generally have to get my wife to help me with the main belt -- hard to get the tensioner in position while stopping the belt slipping down the far side of the drum.

These things are mechanically and electrically pretty simple -- if it's not working the fault is usually obvious.

(From: Larry Brackett (appliparts@aol.com).)

Here are some things to check for a Kenmore or Whirlpool dryer not running. These things will apply to any dryer. The difference being the identification and location of these parts in different dryers. Always look at the wiring picture for your product to see what these are. The identifying numbers and letters here will not apply to all Whirlpool dryers. Please remember this.

- Power supply: Check at terminal block where the cord connects. There should be 220V on the two outer terminals. Should read 110V from center terminal to either of the two outer terminals. Unplug the dryer.

- Timer contact: Remove wires from Y & BG on timer. Set timer to timed dry. Read across Y & BG with ohm meter. Should read continuity if timer contact good.

- Door switch: Remove wires from door switch. Read with ohm meter. Should read continuity with switch depressed.

- Thermal fuse: If the dryer has a thermal fuse, read with an ohm meter. Should show continuity. The thermal fuse is located in the blower housing air duct. It is normally white in color.

- Push to start switch: Read across CO to NO with switch depressed. Should read continuity.

- Broken wires between these components.

- If all the above are OK, then check the motor.

- This is how I check a dryer motor. I unplug the dryer. Remove all 5 wires coming from controls to the motor. Do not remove the 3 wires going from the external switch into the motor. Put a test cord [any cord that you can devise to put 110V to the motor] on terminals 4 & 5 on the motor switch. Plug the test cord in. If the motor will not run, it is normally defective. Again, 4 & 5 are the wires in use for many years on lots of motors to put 110V on to make them run. But you should check your wiring picture to be certain of terminals to use for checking and running components on your dryer.

Dryer shuts down after a few minutes

There are multiple thermostats in a dryer - one that sets the air temperature during normal operation (and controls power to the heating element) and one or more that sense fault conditions (and may shut everything down) such as those described below.

(From: Bernie Morey (bmorey@aardvark.apana.org.au).)

The dryer is likely cutting out because a thermostat is tripping. The fundamental reason is probably that the exhaust air is too hot. And the air flow is probably too hot because it is restricted -- lower volume of air at higher temperature. Check these things out:

1. Lint filter. Although these can look clean (and I assume you do clean it after every load!) the foam variety can gradually clog up with very fine dust and restrict air flow. If it's a foam disk, a new one is fairly cheap.

2. Can you feel the exhaust air? If not, the exhaust fan belt may be worn broken or slipping. The exhaust fan bearing could be partly seized -- try turning the fan by hand and check for stiffness.

3. Air outlet blockage. Lint and dust may have built up in the exhaust side of the machine. Check for restrictions. Our machine just vents up against the laundry wall as it is too difficult to vent it to the outside.

   Outside vents are often plastic tubing with a spiral spring steel coil for stiffness -- check for kinks or obstructions.

4. 'Clutching at straws' Dept #1: Element may have developed a hot-spot near a thermostat. Involves dismantling the machine and checking the element. NB -- if you dismantle the machine, make a diagram of how the drive belt fits over the drum, motor, and idler!

5. 'Clutching at straws' Dept #2: The drum may be restricted from turning freely. This would slow the motor and hence the exhaust fan. Check for socks, women's knee-highs (these thing seem to breed everywhere!) & caught near the bearings (probably the front).

You cannot completely check the thermostat with a meter -- they are either open or closed. To test it properly you would have to know the temperature at which it opens (from the manufacturer's specs), and then measure the temperature of the exhaust air with a probe while watching the thermostat.

Why has my dryer (or other high current) plug/socket burned up?

This sort of failure is not unusual. The brass (or whatever) corrodes a bit over time and/or the prongs loosen up. It doesn't take much resistance at 20 or 30 Amps to produce a substantial amount of heat. The hotter it gets, the more the resistance goes up, heating increases, it loosens more, and so on until something melts. The power is I*I*R (where I is current and R is the resistance) so at 20 A, a .1 ohm resistance at the contact results in 40 W - think of the heat of a 40 W light bulb.

An exact cause would be hard to identify. However, only the plug and receptacle are involved - this is not a case of an outside cause. Such a failure will not normally blow a fuse or trip a breaker since the current does not increase - it is not a short circuit.

It is definitely wise to replace both the plug and receptacle in such cases since at the very least, the socket has lost its springiness due to the heating and will not grip well.. Make sure that the prongs on the new plug make a secure fit with the socket.

On plugs having prongs with a pair of metal strips, spreading them out a bit will make much better contact in an old receptacle.

In general, if a plug is noticeably warm, corrective action should be taken as it will likely get worse. Cleaning the prongs (with 600 grit sandpaper) and spreading the metal strips apart (if possible) should be done first but if this does not help much, the plug and/or socket should be replaced. Sometimes, the original heating problem starts at the wire connections to the plug or socket (even inside molded units) - loose screws, corroded wires, or deteriorated solder joints.

Four year old gas dryer just started popping GFCI

Why is it on a GFCI in the first place? A grounded outlet is all the protection that is needed and any type of appliance with a motor or transformer could be a potential nuisance tripper with a GFCI (though not always).

As to why it is now different, I assume that this is a dedicated outlet so nothing else you added could affect it. Thus you are left with something changing in the dryer or the GFCI somehow becoming overly sensitive.

It is possible that there is now some electrical leakage in the dryer wiring just from accumulated dirt and grime or dampness. This could be measured with an AC milliamp meter or by measuring the resistance between the AC wires and the cabinet. If this test shows up nothing, I would recommend just putting on a grounded outlet without a GFCI. It could also be that due to wear, the motor is working harder at starting resulting in just a tad more of an inductive current spike at startup.

Checking dishwasher solenoids

(From: Filip "I'll buy a vowel" Gieszczykiewicz (filipg@repairfaq.org).)

Greetings. Well, since it's a moist/damp environment... I'd suspect a bad connection first. You will need to pop off the front bottom panel and get at the wires that actually connect the solenoid to the timer motor (and/or wire harness). You will need an ohmmeter to check the resistance of the coil - if it's OK (20-200 ohms I would guess), that's not the problem. Well, that leaves you with pretty much the wires that connect the timer motor (a MULTI-contact switch driven by a timer motor like those found in old clocks that plugged into outlets) and the switch itself. I hope the dishwasher is unplugged... Since the dishwasher operates as a closed system (because of the "darned" water :-) it will be difficult to test it in circuit. I suggest that you try to trace the wires that come off the solenoid to their other ends... and then test the wires themselves. If you feel this is too much for you, call the repair folks - ask around... see if anyone else knows a particular service that has a good record...

Electrical Wiring Information and Problems

Safe electrical wiring

This chapter is in no way intended to be a comprehensive coverage of wiring issues but includes a discussion of a few of the common residential wiring related questions. For more information, see the official Usenet Electrical Wiring FAQ or a DIY book on electrical wiring. The NEC (National Electrical Code) handbook which is updated periodically is the 'bible' for safe wiring practices which will keep honest building inspectors happy. However, the NEC manual is not what you would call easy to read. A much more user friendly presentation can be found at the CodeCheck Web Site. This site includes everything you always wanted to know about construction codes (building, plumbing, mechanical, electrical) but were afraid to ask.

In particular, the following series of sections on Ground Fault Circuit interrupters is present at the CodeCheck web site and includes some nice graphics as well. Specifically: GFCI by Sam Goldwasser.

What is a GFCI?

A Ground Fault Circuit Interrupter (GFCI) is a device to protect against electric shock should someone come in contact with a live (Hot) wire and a path to ground which would result in a current through his/her body. The GFCI operates by sensing the difference between the currents in the Hot and Neutral conductors. Under normal conditions, these should be equal. However, if someone touches the Hot and a Ground such as a plumbing fixture or they are standing in water, these currents will not be equal as the path is to Ground - a ground fault - and not to the Neutral. This might occur if a short circuit developed inside an ungrounded appliance or if someone was working on a live circuit and accidentally touched a live wire.

Continuing with the water analogy used elsewhere in this document, the Hot is equivalent to the water supply and the Neutral is equivalent to the drain. The flow rate (current) can be high and do work like running a pump as long as all the water goes down the drain. But if there is a leak and the water splashes out on to the ground, then the the water equivalent of a GFCI will trip and shut off the water.

The (electrical) GFCI will trip in a fraction of a second at currents (a few mA) well below those that are considered dangerous. Note that a GFCI is NOT a substitute for a fuse or circuit breaker as these devices are still required to protect equipment and property from overloads or short circuits that can result in fire or other damage.

GFCIs can be installed in place of ordinary outlets in which case they protect that outlet as well as any downstream from it. There are also GFCIs that install in the main service panel. Either will provide the same level of safety but the breaker will automatically protect everything on its circuit no matter how it is wired while the outlet version will only protect the outlet and other outlets downstream from it.

Note that it may be safe and legal to install a GFCI rated at 15 A on a 20 A circuit since it will have a 20 A feed-through. Of course, the GFCI outlet itself can then only be used for appliances rated 15 A or less.

Many (if not most) GFCIs also test for a grounded neutral condition where a low resistance path exists downstream between the N and G conductors. If such a situation exists, the GFCI will trip immediately when power is applied even with nothing connected to the protected outlets.

GFCIs, overloads, and fire safety

A GFCI is NOT a substitute for a fuse or circuit breaker (unless it is a combined unit - available to replace circuit breakers at the service panel).

Therefore, advice like "use a GFCI in place of the normal outlet to prevent appliance fires" is not really valid.

There may be some benefit if a fault developed between Hot and Ground but that should blow a fuse or trip a circuit breaker if the outlet is properly wired. If the outlet is ungrounded, nothing would happen until someone touched the metal cabinet and an earth ground simultaneously in which case the GFCI would trip and provide its safety function. See the section: Why a GFCI should not be used with major appliances for reasons why this is not generally desirable as long as the appliance or outlet is properly grounded.

However, if a fault occurs between Hot and Neutral - a short in the motor, for example - a GFCI will be perfectly happy passing almost any sort of overload current until the GFCI, wiring, and appliance melts down or burns up - a GFCI is not designed to be a fuse or circuit breaker! That function must be provided separately.

How does a GFCI work?

GFCIs typically test for the following condition:

1. A Hot to Ground (safety/earth) fault. Current flows from the Hot wire to Ground bypassing the Neutral. This is the test that is most critical for safety.

2. A grounded Neutral fault. Due to miswiring or a short circuit, the N and G wires are connected by a low resistance path downstream of the GFCI. In this case, the GFCI will trip as soon as power is applied even if nothing is connected to its protected (load) circuit.

To detect a Hot to Ground fault, both current carrying wires pass through the core of a sense coil (transformer). When the currents are equal and opposite, there is no output from its multiturn sense voltage winding. When an imbalance occurs, an output signal is produced. When this exceeds a threshold, a circuit breaker inside the GFCI is tripped.

GFCIs for 220 VAC applications need to monitor both Hots as well as the Neutral. The principles are basically the same: the sum of the currents in Hot1 + Hot2 + Neutral should be zero unless a fault exists.

To detect a grounded neutral fault, a separate drive coil is continuously energized and injects a small 120 Hz signal into the current carrying conductors. If a low resistance path exists between N and G downstream of the GFCI, this completes a loop (in conjunction with the normal connection between N and G at the service panel) and enough current flows to again trip the GFCI's internal circuit breaker.

GFCIs use toroidal coils (actually transformers to be more accurate) where the core is shaped like a ring (i.e., toroid or doughnut). These are convenient and efficient for certain applications. For all practical purposes, they are just another kind of transformer. If you look inside a GFCI, you will find a pair of toroidal transformers (one for H-N faults and the other for N-G faults as described above). They look like 1/2" diameter rings with the main current carrying conductors passing once through the center and many fine turns of wire (the sense or drive winding) wound around the toroid.

All in all, quite clever technology. The active component in the Leviton GFCI is a single chip - probably a National Semiconductor LM1851 Ground Fault Interrupter. For more info, check out National's LM1851 Specs.

More on how the GFCI detects a N-G short

To detect a Neutral to Ground fault there is a second transformer placed upstream of the H-G sense transformer (see the illustration of the internal circuitry of the GFCI at: http://www.national.com/pf/LM/LM1851.html). A small drive signal is continuously injected via the 200 T winding which induces equal voltages on the H and N wires passing through its core.

- If N and G are separate downstream (as they should be), no current will be flow in either wire and the GFCI will not trip. (No current will flow in the H wire as a result of this stimulus because the voltage induced on both H and N is equal and cancels.)

- If there is a N-G short downstream, a current will flow through the N wire, to the G wire via the short, and back to the N wire via the normal N-G connection at the service panel. Since there will be NO similar current in the H wire, this represents a current unbalance and will trip the GFCI in the same manner as the usual H-G short.

- Interestingly, this scheme automatically detects a H-H fault as well. This unlikely situation could occur if the Hots from two separate branch circuits were accidentally tied together in a junction box downstream of the GFCI. It works the same way except that the unbalance in current that trips the GFCI flows through the H wire, through the H-H fault, and back around via the Hot busbar at the service panel. Of course if the two Hots are not on the same phase, there may be fireworks as well :-).

GFCIs and safety ground

Despite the fact that a Ground Fault Circuit Interrupter (GFCI) may be installed in a 2 wire circuit, the GFCI does not create a safety ground. In fact, shorting between the Hot and Ground holes in the GFCI outlet will do absolutely nothing if the GFCI is not connected to a grounded circuit (at least for the typical GFCI made by Leviton sold at hardware stores and home centers). The Ground holes are only connected to the green screw on the outside of the GFCI, not to any circuitry inside the GFCI and it will trip only if a fault occurs such that current flows to a true ground. If the original circuit did not have a safety ground, the Ground Holes aren't going anywhere. What this means is that an appliance with a 3 prong plug can develop a short between Hot and the (supposedly) grounded case but the GFCI will not trip until someone touches the case and an earth ground (e.g., water pipe, ground from some other circuit, etc.) at the same time.

Note that even though this is acceptable by the NEC, I do not consider it desirable. Your safety now depends on the proper functioning of the GFCI which is considerable more complex and failure prone than a simple fuse or circuit breaker. If it's not tested periodically, reliability is even lower. Therefore, if at all possible, provide a proper Code compliant ground connection to all outlets feeding appliances with 3 wire plugs.

Where are 3 wire grounded outlets required?

If you move into a house or apartment where some or all of the outlets are the old 2 prong ungrounded type, don't panic. There is no reason to call an electrician at 2:00 AM in the morning to upgrade them all at great expense. (This also applies to 3 prong outlets that don't have their third prong hooked up.)

You don't need grounded outlets for two wire appliances, lamps, etc. They do essentially nothing if the third hole isn't occupied :-). A GFCI will provide much more protection and it is permissible retrofit these into ungrounded wiring.

You should have grounded outlets for the following:

- Computers in order for the line filters and surge suppressors to be most effective. Note that since all the third prongs of your computer system (e.g., PC, monitor, printer) will likely be connected together by the outlet strip, a fault in one unit resulting in its third prong becoming live could result in damage somewhere else without a proper ground. And, no, you shouldn't just cut off all the third prongs to avoid this possibility!

- High-end entertainment gear if it uses 3 prong plugs for similar reasons.

- Microwave ovens. For safety, these really should be on a grounded circuit. (A GFCI will not protect against a fault on the high voltage side of a microwave oven, though this sort of fault is extremely unlikely. And, some microwave oven-GFCI combinations may result in nuisance tripping).

- Large appliances including refrigerators, freezers, clothes washers and dryers, dehumidifiers, window air conditioners, etc.

In most cases, there will only be a few circuits where this is needed and only these need to be upgraded. To what extent the wiring plan of your residence separates lighting type circuits from those with outlets that will be used for 3 wire equipment will determine how easy it is to upgrade only those outlets that are affected. It may be cheaper to just add new branch circuits for specific equipment needs.

However, if you are replacing old worn outlets anyhow, it does make sense to upgrade to 3 prong outlets if they can be properly grounded without pulling a new wire - for example, if the box is already grounded but simply not connected to the old outlet.

In all cases, make sure that the new outlet is properly wired with respect to the ground and H-N polarity. An improperly wired 3 prong outlet may be worse than any 2 prong variety!

Why you should NOT connect G to N

The question often arises: "Why can't I just connect the G to the N if my outlets are only two prong?"

For one reason, consider the 'appliance' below:

```
            +-----------------+
            |                 |        Open Fault
  Hot o---------o-o----/\/\---------+------ X -----o Neutral
            | Switch  Load    |    |
            |  (On)           |----+ Case should be G but is connected to N
            +-----------------+
```

With the appliance 'on', current passes through the internal wiring/motor/etc. of the appliance to the N but this is now connected to the case as well. If the house wiring opens (or even if the plug is loose, it is possible to have line voltage on the case.

The 'appliance' can actually be *all* loads on the circuit upstream of the the Open Fault - all those with a grounded cabinet have it then become live!

Testing installed GFCIs

These tests should be performed periodically to assure that the GFCIs are providing the protection for which they were designed. It is possible for the GFCI's circuitry to go bad or for the contacts to get stuck. The usual recommendation is once a month but more frequently won't hurt.

The built-in tester is designed to actually introduce a small leakage current so its results should be valid. Therefore, testing a single GFCI outlet with an external widget is not really necessary except for peace-of-mind. However, such a device does come in handy for identifying and testing outlets on the same circuit that may be downstream of the GFCI.

An external tester is easy to construct - a 15 K ohm resistor between H and G will provide a 7 mA current. Wire it into a 3 prong plug and label it "GFCI Tester - 7 mA". The GFCI should trip as soon as you plug the tester into a protected outlet. On a GFCI equipped for grounded neutral detection (as most are), shorting the N and G conductors together downstream of the GFCI should also cause it to trip (push buttons for both functions would be a useful enhancement).

Note that such a tester will only work for GFCI protected outlets that are on grounded (3 wire) circuits (unless you add an external ground connection). Thus, just using a commercial tester may falsely indicate that the GFCI is bad when in fact it is simply on an ungrounded outlet (which is allowed by Code in a retrofit situation).

The test button will work whether or not the circuit includes a safety ground because it passes an additional current through the sense coil between Hot and Neutral tapped off the wiring at the line side of the GFCI and therefore doesn't depend on having a safety Ground.

I suppose you can purchase suitable low cost testers as well (but they are subject to the same must-be-grounded restrictions). Try your local home center or electrical supply distributor.

The general procedure for the test is as follows. (This assumes a live GFCI circuit. If there is no power and the RESET button doesn't restore it, testing will need to be done to determine if the problem is in the GFCI, wiring, or a blown fuse/tripped circuit breaker at the service panel.):

- Plug a night light, radio (with a hard on/off switch, not a pushbutton!), or similar low power device into the GFCI outlet and turn it on.

- Press the TEST button or plug in (or activate) your tester -> The outlet should trip within a fraction of a second and the device should go off.

- Press the RESET button -> Power should be restored and the device should come back on.

- Carefully short together N and G with an insulated jumper or the button on your tester -> The outlet should trip.

- Press the RESET button -> Power should be restored and the device should come back on.

- Repeat the above steps for each outlet downstream of the GFCI.

If any of these don't work as expected, the GFCI is defective or the outlet is miswired and there may be no protection.

Reminder: A separate Ground connection must be provided to use a GFCI tester in an ungrounded outlet. Without one, the GFCI's TEST button must be used.

John's comments on the use of GFI breakers

(From: John Grau (affordspam@execpc.com).)

I personally would not feed a subpanel with a GFI breaker. Here are just a few of the reasons:

1. GFI breakers for personnel protection are set to trip at 5 mA (1/1000ths of an Amp). The longer the circuit conductors, the greater the potential for leakage. If you subfeed a panel, you would have the cumulative distances of all circuits connected to that panel to contend with and hope that the breaker would hold.

2. You would not be able to connect any thing to that subpanel that would be a critical load. e.g. freezer, sump pump, well pump, furnace, etc. An unnoticed nuisance trip, could mean that you would come home to a thawed freezer, frozen pipes, flooded basement, etc.

3. Using breakers to achieve GFI protection has 2 downsides: expense, and usually, an inconvenient location to reset the tripped device. A GFI outlet at the point of usage, is usually more convenient to reset, should it trip. Here in Wisconsin, I can buy about 6 GFI outlets for the cost of 1 breaker.

There is no compulsory language in the National Electrical Code the forces an update to current code standards, unless you repair, replace or update the affected component. Not all changes in the 1996 code made sense, and I would not update the wiring in my own home (built in 1995) to current standards.

Phantom voltage measurements of electrical wiring

When making measurements on household wiring, one expects to see one of three voltages: 0, 115 VAC, or 230 VAC (or very similar). However, using a typical multimeter (VOM or DMM) may result in readings that don't make sense. For example, 2 VAC between Neutral and safety Ground or 40 VAC between a Hot wire (with its breaker off) and Neutral or safety Ground.

The most likely reason for these strange readings is that there is E/M (electromagnetic) coupling - capacitive and/or inductive - between wires which run near one another - as inside a Romex(tm) cable. Where one end of a wire is not connected to anything - floating, the wire acts as an antenna and picks up a signal from any adjacent wires which are energized with their 60 (or 50) Hz AC field. There is very little power in these phantom signals but due to the very high input resistance/impedance of your VOM or DMM, it is picked up as a voltage which may approach the line voltage in some cases.

Another possibility is that the you didn't actually walk all the way down to the basement to shut off power completely and the circuit is connected to a high tech switch (such as one with a timer or an automatic dimming or off feature) or a switch with a neon light built in. There will be some leakage through such a switch even if it is supposed to be off - kill power completely and test again.

Putting any sort of load between the wires in question will eliminate the voltage if the cause is E/M coupling. A small light bulb with test probes can be used to confirm this both by serving as a visual indication of significant voltage (enough to light the bulb, if weakly) and to short out the phantom voltage for testing with the multimeter.

There can be other causes of such unexpected voltage readings including incorrect or defective wiring, short circuits in the wiring or an appliance, and voltage drops due to high current in a circuit. However, the E/M coupling explanation is often overlooked when using a multimeter.

I did an experiment using a Radio Shack DMM with a 10 M ohm input impedance. It was set to AC volts and the red lead was plugged into the Hot side of a live outlet:

- Black lead not touching anything: 14 VAC.
- Black lead in contact with unconnected 4 inch metal utility box: 16 VAC.
- Holding INSULATION ONLY of black lead tightly: 30 to 50 VAC.

There may also be resistive leakage in an actual wiring installation but capacitance alone can easily mess up your multimeter readings if you have unconnected conductors! Adding any sort of load like a 25 W bulb in parallel with the multimeter will make the voltage drop nearly to zero if either of these are the cause of the phantom readings.

Checking wiring of a 3-wire outlet

The following assumes a simple duplex outlet, not split or switched. For each of the tests below, check both halves of the outlet.

The easiest thing to do is use an outlet tester. This simple gadget gives a fairly reliable indication using three neon lamps. See the section: Test equipment for details.

Or, using a multimeter set to "AC Volts":

- 115 VAC (nominal, may vary from 110 to 125 VAC and still be considered normal) between Narrow slot (Hot) and wide slot (Neutral).
- 115 VAC between Narrow slot (Hot) and U-hole (Ground).
- Near 0 VAC between Neutral and Ground.

  This is best done with a lamp or other load plugged into the outlet. The load will elminate the phenomenon of "phantom voltage" should one of the wires not be connected. See the section: Phantom voltage measurements of electrical wiring.

Or turn off the breaker for that outlet and remove the cover plate:

- Black wire should be on brass screw or pushed into hole next to brass screw.
- White wire should be on silver screw or pushed into hole next to silver screw.
- Green or bare copper wire should be attached to green screw or box, if metal.

Of course, the wiring could be screwed up at the service panel or an outlet upstream of this one.

Determining wiring of a 2-wire outlet

Connect a wire between one prong of a neon outlet tester and a known ground - cold water pipe if copper throughout, heating system radiator, ground rod, etc.

(Experienced electricians would just hold onto the other prong of the tester rather than actually grounding it. Their body capacitance would provide enough of a return path for the Hot to cause the neon to glow dimly but you didn't hear this from me :-). Yes, they survive without damage and don't even feel anything because the current is a small fraction of a mA. DON'T try this unless you are absolutely sure you know what you are doing!)

With one prong grounded, try the other prong in the suspect outlet:

- The Hot should glow brightly and the Neutral should not light at all. This is the normal situation.

- If neither side glows, the fuse is blown, the circuit breaker is tripped, this is a switched outlet and the switch is off, or there is a wiring problem elsewhere - or your ground isn't really ground.

- If both sides glow and using the tester between the slots results in no glow, then you have an open Neutral and something else on the circuit that is on is allowing enough current to flow to light the neon tester.

- If both sides glow and using the tester between the slots results in an even brighter glow, the outlet is wired for 220 V, a dangerous violation of the NEC Code unless it is actually a 220 V approved outlet. It is unlikely you will ever see this but who knows what bozos worked on your wiring in the past!

Outlet wiring screwed up?

So your $6 outlet tester displays a combination of lights that doesn't make sense or one or more lights is dim. For example, all three lights are on but K and X (see below) are dim.

The three neon bulbs are just between what should be (The first letter is how the light is marked on mine):

- K Hot to Ground (GROUND OK).
- O Hot to Neutral (HOT OK?).
- Neutral to Ground (HOT/NEUTRAL REVERSE - should not light).

I suspect at the very least that your ground is not connected at the service panel. I may run from some/all the outlets but ends somewhere. You are seeing capacitive/inductive pickup between the floating ground and the other wires in the circuit. Your N and H may be reversed as well but this cannot be determined without checking with a load between H/N and a proper ground.

I would recommend:

1. Determining if the ground wire for those 3 prong outlets does indeed go anywhere.

2. Determining if the Hot and Neutral polarity is correct by testing between each of the prongs and a confirmed ground (properly connected 3 prong outlet, service panel, or a cold water pipe in an all metal water system) with a load like a 25 W light bulb. The neon lamps in the tester or a high impedance multimeter can be fooled by capacitance and other leakage paths.

For a computer or other 3 wire appliance, you should really install a proper 3 prong outlet wired correctly. Otherwise, any power line filters and surge suppressors will not have the safety ground (which a GFCI does NOT create). Some UPSs may get away without one but then their surge suppressor and/or line filters will not work correctly.

Some appliances like microwave ovens MUST have a proper safety ground connection for safety. This not only protects you from power line shorts to the case but also a fault which could make the case live from the high voltage of the microwave generator.

220 V outlet reads 0 VAC between slots

> "I have a 220 outlet that I need to plug an AC unit into. The AC unit works fine in another outlet, but not in this specific outlet. I pulled out my handy dandy meter and checked the voltage across the two line slots - the meter read 0.
>
> But when I tried one line and the ground I got 125 V. Similarly, when I tried the other line and the ground I also got 125 V. What's the scoop? Why does the meter, and obviously the AC, think that there isn't 220 V coming in? Any help is greatly appreciated - as this room is stinking hot right now!"

Did it ever work? It sounds like both slots are being fed from the same phase of the power from the service panel. Check with a load like a 100 W light bulb between each slot and ground. This could have happened during the original installation or during renovation.

Another possibility is that there is some other 220 V appliance on the same line with its power switch in the ON position (and not working either) AND one side of the line has a tripped breaker or blown fuse.

Yet another possibility:

(From: David L. Kosenko (davek@informix.com).)

My load center is GE unit. They make both full height and half height breakers. If you use a half height breaker set for a 220 line, you must be careful to install it across the two phases. It is very easy (especially if you don't know about 220) to place the ganged breakers into a single full height slot in the load center, giving you both lines off the same phase line.

Testing for fault in branch circuit

This may trip the breaker or blow a fuse - or trip a GFCI if so protected. The procedure below is specifically for GFCI tripping. You will need a multimeter.

- First, unplug everything from the circuit and see if it still trips. If it now does not trip, one of the appliances was the problem. Try them one at a time to see which is the problem and then check the section for that or a similar appliance elsewhere in this document.

Assuming the circuit is at fault:

- You need to determine whether this is a H-G leakage fault (which is what most people think is the only thing GFCIs test for) or a shorted G-N fault.

- A H-G fault that doesn't trip the normal breaker might be due to damp wiring (an outside outlet box that gets wet or similar) or rodent damage.

- A shorted G-N fault means that G and N are connected somewhere downstream of the GFCI - probably due to incorrect wiring practices or an actual short circuit due to frayed wiring or wires touching - damage during installation or renovation.

Assuming the line is separate from any other wiring:

- With the line disconnected from the service panel (all three wires), first test between each pair of wires with the multimeter on AC to make sure it is truly dead - there should be virtually no voltage. H-G, N-G, and H-N should all be close to 0 (say, less than a volt).

- If this passes, test across the dead line's H and G for leakage on the resistance range. It should be greater than 15 K ohms (it should really be infinity but to trip the GFCI requires around 15 K ohms or less).

- Then, test for resistance between H and G - this too should be infinity.

One of these will show a fault - possibly the N-G test indicating a short or improperly wired outlet since this would not result in any operational problems until a GFCI is installed (though it does represent a safety hazard).

Locating wires inside a wall

There are gadgets you can buy that look like test lights but sense the electric field emitted by the Hot wire. One is called 'Volt Tick' and may be available at your local home center or large hardware or electrical supply store.

It is also possible to inject a signal into the wire and trace it with a sensitive receiver.

However, if you are desperate, here is a quick and easy way that is worth trying (assuming your wiring is unshielded Romex - not BX - and you can power the wire). Everything you need is likely already at your disposal.

Get a cheap light dimmer or a fixture with a light dimmer (like that halogen torchier that is now in the attic due to fire safety concerns) and plug it into an outlet on the circuit you want to trace. Set it about half brightness.

Now, tune a portable AM radio in between stations. If you position the radio near the wire, you should hear a 120 Hz hum - RFI (Radio Frequency Interference) which is the result of the harmonics of the phase controlled waveform (see the section: Dimmer switches and light dimmers. Ironically, the cheaper the dimmer, the more likely this will work well since no RFI filtering is built in.

I have tried this a bit and it does work though it is somewhat quirky. I do not know how sensitive it is or over how large a circuit it is effective. It is somewhat quirky and even normal power may have enough junk on the waveform to hear it in the radio. However, with a partner to flip the dimmer off and on to correlate its position with what you hear, this may be good enough.

(From: author unknown.)

The probe is really simple. All it consists of is a LM386 and a MPF102 JFET from Radio Shack. The MPF102 is connected as a source follower with a 4.7k load resistor from source to ground. The gate has a 10M resistor to ground and a 1M from gate to the probe tip. The drain of course connects to the plus 9 VDC. There is a .1 uF coupling cap between source and the input to the LM386. The LM386 is the standard circuit found in the data sheet. You can put a 5K volume control between the two pins to increase the gain. And of course you have to find a small 1.3 inch or 3 cm speaker to fit the probe. Use a 9 V battery.

The tone generator can be anything that oscillates. You could use a hex inverter in the typical circuit. Or you could use a two transistor astable multivibrator with 2.2k collector load resistors. Whatever you use, make sure the coupling capacitor to the phone line is a 200 V or higher NON POLARIZED capacitor, so it won't make any diff how you connect it up. Remember that this little box takes a lot of beating from stray voltages and stuff, like ringing currents. So it's best to buy this and get one that's safe. I've burnt them out on occasion so I suggest you don't build it but buy it for under $30.

Lights dim when high current load is switched on

Heating appliances space heaters toasters draw a large current when their operating. Appliances with large motors like air conditioners and washing machines draw a very large current momentarily when starting. And, tools like bench grinders and power saws draw a large current until they get up to speed. All of these conditions increase the voltage drop of the wiring in the branch circuit they are on and thus reduces voltage to lights on the same circuit. Normally, this isn't anything to worry about but do make sure your wiring is properly rated for the equipment in use AND that the fuses or circuit breakers are of the correct rating. If the amount of dimming is erratic, it could mean that there are some corroded or loose high resistance connections due to age/use and/or aluminum wiring. These are serious conditions that can result in an electrical fire and would need to be found and repaired. Where lights *brighten* under these conditions, a bad Neutral connection may be the problem. See the next section.

Bad Neutral connections and flickering lights or worse

Residential service comes from a centertapped 110-0-110 V transformer on the utility pole. There are 3 wires into your house - 2 Hot or live wires and the Neutral which is the centertap of the transformer. If the connection between the Neutral bus in your service panel and the pole transformer centertap becomes loose and opens or develops a high resistance, then the actual voltage on either of the Hots with respect to the Neutral bus (which is divided among your branch circuits) will depend on the relative loads on either side much in the way of a voltage divider using resistors. Needless to say, this is an undesirable situation.

Symptoms include excessive flickering of lights (particularly if they get brighter) when large appliances kick in, light bulbs that seem too bright or too dim or burn out frequently, problems with refrigerators or freezer starting due to low voltage, etc. In the worst case, one set of branch circuits can end up with a voltage close to 220 VAC - on your poor 110 V outlets resulting in the destruction of all sorts of appliances and electronics. The opposite side will see a much reduced voltage which may be just as bad for some devices.

It is a simple matter for an electrician to tighten up the connections but this is not for the DIY'er unless you are familiar with electrical wiring and understand the implications of doing anything inside the service panel while it is live! Furthermore, the problem may actually be in the Neutral cable outside your residence and that can only be dealt with by the power company. Since it's exposed to the elements as well as squirrels and such, damage is possible. An electrician will be able to eliminate internal problems, and recommend contacting the power company if necessary.

Here is what can happen if you don't remedy the situation:

(From: Sinbad (sschwartz@moou.edu).)

Speaking from experience, I can tell you that if your ground goes you will have no doubt about.

When I lost mine I was watching TV. The picture tore and then smoke came out of the back of it. I also lost two VCR's, a dryer, a scanner, a microwave, an AM/FM receiver, an amplifier (everything with a remote control since these always have power going to them), a CD player and a scanner, which also smoked.

The incandescent bulbs that were turned on turned blue and then white before they burned out and a couple fluorescent fixtures burned out as the bulbs arced and melted and cracked.

Fortunately, my insurance policy specifies replacement with no deductible, but I still had to run around buying new stuff (except for the dryer, which was repairable.)

Lightning storm trips GFCIs protecting remote outdoor outlets

> "I have several outdoor 110V outlets, protected by GFCI breakers. These circuits nearly always trip when there are nearby lightening strikes. I am satisfied that there is no short circuit caused by water as:
>
> - A lightning storm without rain will still trip the GFCI.
> - Water from the sprinklers does not cause a problem.
> - I can immediately reset the GFCI when it is still raining and it comes back on.
>
> The electrical cables buried underground run for about 600 feet.
>
> Is GFCI tripping caused by electrical storms normal ? Are my GFCI breakers too sensitive ? Is there any way to modify the circuits to avoid this?"

This doesn't surprise me. Long runs of cable will be sensitive to the EM fields created by nearby lightning strikes. Those cables probably have 3 parallel wires: H, N, G. The lightning will induce currents in all three which would normally not be a problem as long as H and N are equal. However, I can see this not being the case since there will be switches in the Hot but not the Neutral so currents could easily unbalance.

These are not power surges as such and surge suppressors will probably not help.

Since it happens with all of your GFCIs, it is not a case of a defective unit. Perhaps there are less sensitive types but then this would reduce the protection they are designed to provide.

GFCI trips when it rains (hard)

Most likely, moisture/water is getting into some portion of the GFCI's protected wiring (at the GFCI or anywhere downstream) and the GFCI is simply doing its job. You will have to trace the wiring through all junction boxes and outlets to determine where the problem is located. Yes, I know this may not be your idea of fun!

Why a GFCI should not be used with major appliances

A Ground Fault Circuit Interrupter is supposed to be a valuable safety device. Why not use them everywhere, even on large appliances with 3 wire plugs?

1. A properly grounded 3 prong outlet provides protection for both people and the appliance should a short circuit develop between a live wire and the cabinet.

2. Highly inductive loads like large motors or even fluorescent lamps or fixtures on the same circuit can cause nuisance tripping of GFCIs which needless to say is not desirable for something like a refrigerator.

Nuisance tripping of GFCIs

When used with highly inductive loads like motors or even fluorescent lamps, GFCIs may occasionally (or more frequently) trip due to the voltage/current spikes at power on/off. While the NEC/UL specifications apparently allow for some time delay in their response to combat this problem, it is not known if all manufacturers of GFCIs incorporate this into their product. However, the very common Leviton GFCI outlet probably does use the National chip (LM1851 Ground Fault Interrupter) referred to below. Also see the section: How does a GFCI work?.

(From: James Phillips (jamarno@juno.com).)

I quit having GFCI trouble after I fixed all the bad wiring connections, and I haven't had trouble at all with GFCIs and my workshop, which I wired myself. GFCI controller chips include a time delay to reduce false tripping. I used to think GFCIs always tripped at 5 to 6 mA, but the UL allows up to a whopping 200 mA if the GFCI stops the current within 30 ms, and 6 mA leakage is allowed to last 6 seconds.

According to National Semiconductor, their GFCI chips will stop a 200 mA fault in 20 ms, a 6mA fault in .5 sec.

Toasters and GFCIs

The following is a reason to use GFCIs on kitchen outlets that may not be obvious:

(From: David Buxton (David.Buxton@tek.com).)

In addition to the usual explanations dealing with safety around water, another reason why kitchen outlets need a GFCI is the toaster. All too often people stick a butter knife in there to dislodge some bread. If the case was grounded there would be short from the element to the case. So toasters are two wire instead of 3-pronged. So, you must have a GFCI for any outlet that might take on a toaster.

Problems with outlets getting hot

With normal loads, electrical outlets should get at most just warm to the touch. A number of factors can result in hot or dangerously hot outlets. Check the following:

- Make sure you have tight fit - spread leaves of prongs out and clean them with fine sandpaper. An old, rarely used outlet will also develop corrosion increasing resistance.

- Make sure the cord itself is in good condition - sometimes the connections at the plug corrode and result in a hot plug independent of the outlet. Replace with suitable high current heater rated cord if this is the case.

- If you have aluminum wiring that hasn't been upgraded (either replaced or terminated with the proper Al/Cu rated wiring devices or pigtails), check it out. Aluminum wiring can definitely be a fire hazard all over - where high current appliances are plugged in as well as any connections (including feed-throughs) upstream.

Reverse polarity outlets - safety and other issues

> "Our new home has reverse polarity in all of the electrical outlets. The house inspector didn't seem to think this was a major problem, and neither did he think it was worth fixing. Can anyone explain how this might matter for us? The best I understand this is that when something is plugged in, even when it's not turned on, there is still a current going through it--is that true at all, or is that normal? Our biggest concern is our computers, and the possibility that our surge protectors won't be effective. If anyone could clear this up, that would be great."

New as in brand new or new for you? If it is a totally new home, the builder should have them fixed and you should not sign off on the house until this is done. While there is no imminent danger, the house inspector was being a bit too casual for my tastes. It is not a big deal as in should stop you from going through with the purchase but it really should be fixed.

As far as current present when the appliance is off, this is not quite true. When properly wired, the power switch is the first thing in the circuit so it cuts off power to all other parts of the internal wiring. With the reversal, it is in the return - the rest of the wiring will be live at all times. Except for servicing, this is really not that big a concern and does not represent any additional electricity usage.

Normally (I assume these are 3 prong grounded outlets) you have the following:

- Hot - the live conductor - the narrow slot.
- Neutral - the return for the current used by the device - the wide slot.
- Ground (or safety ground) - the U shaped slot.

Reverse polarity means that Hot and Neutral are interchanged. (any other variation like an interchange with the ground represents a serious safety hazard and it should be corrected as soon as possible. The outlet should not used until it is).

For most appliances and electronics, this does not really matter. By design, it must not represent a safety hazard. However, there can be issues - as you are concerned - with surge suppressors and susceptibility to interference. In some cases, the metal case of a stereo could be coupled to the Neutral by a small capacitor to bypass radio frequency interference. This will be coupled now to Hot instead. While not a safety hazard, you might feel an almost imperceptible tingle touching such a case.

Surge suppressors may or may not be affected (to the extent that they are ever effective in any case - unplugging the equipment including modem lines and the like during an electrical storm is really the only sure protection but that is another section). It depends on their design. Some handle the 3 wires in an identical manner and interchanging them makes no difference. Others deal differently with the Hot and Neutral in which case you may lose any protection you would otherwise have.

My advice: If you are handy electrically, correct them yourself. If not, get them corrected the next time you have an electrician in for any reason. It is a 5 minute job per outlet unless the wiring is extremely screwed up.

Use a properly wired outlet for your computer to be doubly sure.

It is not an emergency but I consider proper wiring to be very desirable.

Here is another example:

> "I was checking some outlets in my apartment. As I recall, the narrow prong should be hot, i.e., there should be 120 V between it and the wide prong or the ground prong. The wide prong should be neutral, i.e., it should show no voltage relative to the ground prong. Well, it appears that the Neutral and Hot wires are reversed in some outlets. In others, they are correct."

Well, there should be very little voltage although it may not be 0.

Reversed polarity outlets are not unusual even in new construction.

Reversed H and N is not usually dangerous as appliances must be designed so that no user accessible parts are connected to either H or N - even those with polarized plugs. Think of all the times people use such appliances in old unpolarized outlets or with unpolarized extensions cords. (There are exceptions like electric ranges where there may be no separate safety ground conductor but I assume you are talking about branch circuits, not permanently wired-in appliances.)

> "In still others, I get some voltage between ground and either the wide or narrow prong. Ack. Should I worry? Should I do more than worry?"

You should, of course, measure full line voltage between the H and G. The safety ground, G, does not normally carry any current but is at the same or nearly the same potential as N.

The voltage between G and (actual) N if quite low - a couple volts or less - is probably just due to the the voltage drop in the current carrying N wire. Turn off everything on this branch circuit and it should go away. However, there could also be a bad (high resistance connection) somewhere in the N circuit.

If the voltage reads high to either H or N - say, 50 volts - and you are measuring with a high impedance multimeter, this is probably just due to an open ground: a three prong outlet was installed without connecting the ground (in violation of Code unless on a GFCI) and this leakage is just due to inductive/capacitive pickup from other wires. See the section: Phantom voltage measurements of electrical wiring.

Full line voltage on the G conductor relative to an earth ground (like a copper cold water pipe) would represent a serious shock hazard to be corrected as soon as possible - the appliance or outlet should *not* be used until the repair is made. While unlikely, for anyone to screw up this badly, it could happen if someone connected the green or copper wire, or green screw to H instead of G.

In any case, it would be a good idea to correct the H-N reversals and determine if the voltage on the G is an actual problem.

Comments on whole house surge suppressors

These are typically offered your power company:

> "I have a surge suppressor that was put between my meter and the service panel. It's rented from my power company. The advertised product is part of a 'package' that includes plug in surge suppressors. The package price is $4.95/month. I didn't want the plug in suppressors so they said that it would be $2.75/month. Is this a good deal?"

(From: Kirk Kerekes (redgate@oklahoma.net).)

The power company just passes on the warranty of the manufacturer, which is, in turn, merely an insurance policy whose premium in included in the normal retail price of the unit. Basically, the power company is taking a product with a wholesale cost of about $30, and "renting" it to consumers for $40 to $100 a year.

Forever!

Nice work if you can get it.

Note that most homeowner and similar insurance policies *already* cover lightning damage, and that the policy from the surge protector is generally written to only apply to losses not already covered by other insurance. As a result, you are paying for insurance that you will likely *never* be able to make a claim against, even if the device is totally ineffective.

The simplest whole-house protection is to purchase an Intermatic whole house surge protector ($40 from Home Depot or Lowe's) and install it yourself (or pay an electrician to do so -- maybe 15 minutes of work). Then purchase inexpensive ($10 and under) plug-in surge protectors and surge-protected power strips and use them all over the house at sensitive equipment. Note that surge protectors and surge protected power strips protect the _other_ outlets in the house as well as the ones they contain (because the MOV's in inexpensive surge protectors are simply connected in parallel with the power line), so the more of that that you have plugged in, the more effectively protected your home is. Some power strips need to be turned "on" for the MOV's to be connected to the power lines.

You can also buy MOV's and add your own custom protection -- but if you don't already know that, you probably shouldn't be tinkering with such things.

Note that you should only purchase surge protectors that contain a monitor LED to tell you if the protector is still functioning -- MOV's deteriorate when zapped by large surges. This is one reason why I recommend the multiple-power-strip distributed-protection approach -- it is doubtful that all of your surge protectors/power strips will get zorched at once.

Electric tingles or shocks from plumbing

This it not what is meant by a stimulating shower. :-)

Needless to say, any sensation of electricity while using the water indicates a potentially very dangerous situation. (More so, apparently, for cows but that is another story!).

The most likely cause assuming you haven't actually wired the plumbing into the electrical system's Hot bus bar is some variation of bad or lack of connections of the electrical system's ground. What happens is that the unavoidable electrical leakage to the grounds of appliances and computer equipment with 3 prong plugs (from line filter capacitors and such) feeds into the grounding system of your house. If that is bonded to the actual earth ground via the plumbing supply system and that has a bad connection, you can get a voltage between the metal plumbing fixtures and the drain - which is pretty well grounded going into the earth. The reverse is also possible depending if there is plastic pipe at some point in your drain line.

While a tingle is unpleasant, an actual short in an appliance would be quite deadly where such a situation exists.

- Check the main means of grounding for your electrical system. There should be a grounding wire between the main service panel and the ground rod or metal supply pipe. Check the integrity of this and any jumpers that may be present including one bypassing the water meter (if applicable).

- Check for appliances and computer equipment that is grounded via the supply, waste, or radiator pipes (usually against NEC Code but still very commonly done by DIYers and even some electricians). This is especially risky if there is any plastic pipe in the feed or drain lines which isolates the metal pipes making them all one big shocking electrode and attempting to ground these devices is than worse than useless!

- Check for bad connections in the service panel(s) - particularly for the Neutral and Ground busbars. Make sure they are bonded together properly in the main service panel.

Of course, it is also possible to create a situation of electrically live pipes during renovation - by nailing a metal pipe bracket into an electrical wire without realizing it. However, this type of screwup usually takes some effort. :-)

All About Wire and the AWG (American Wire Gauge) Numbers

Some types of wire

Note: For an understanding of the AWG numbers, you may want to first see the section: American Wire Gauge (AWG) table for annealed copper wire.

A semi-infinite variety of wire and cable is used in modern appliances, electronics, and construction. Here is a quick summary of the buzz words so you will have some idea of what your 12 year old is talking about!

- Solid wire: The current carrying conductor is a single solid piece of metal (usually copper. It may be bare, tinned (solder coated), silver plated, or something else.

  Solid wire may be used for general hookup inside appliances and electronics, and building (and higher power wiring) but not for cords that need to be flexible and flexed repeatedly.

- Stranded wire: The current carrying conductor consists of multiple strands of copper or tinned copper (though other metals may be found in some cases). The individual strands are NOT insulated from one-another. The wire gauge is determined by the total cross sectional area (which may be a bit greater than the specified AWG number due to discrete number of strands). See the section: What about stranded wire?.

  Stranded wire is used for general hookup, building wiring, etc. It is easier to position than solid wire (but tends not to stay put) and more robust when flexed repeatedly. Cordsets always use finely stranded wire but despite this, may develop problems due to flexing after long use.

- Magnet wire: This is a solid copper (or sometimes aluminum or silver) conductor insulated with a very thin layer of varnish or high-tech plastic. This coating must be removed either chemically, by heating in a flame, or fine sandpaper, before the wire can be connected to anything.

  Magnet wire is used where a large number of turns of wire must be packed as tightly as possible in a limited space - transformers, motors, relays, solenoids, etc.

  The very thin insulation is susceptible to nicks and other damage.

- Litz wire: This is similar to stranded wire EXCEPT that the strands are individually insulated from each other (like multiple pieces of magnet wire).

  Litz wire is used in high frequency transformers to reduce losses (including the skin effect which results in current only traveling near the surface of the wire - using multiple insulated strands increases its effective surface area).

Like magnet wire, the insulation needs to be removed from all strands before making connections.

- Tinsel wire: A very thin, metallic conductor is wound around a flexible cloth or plastic core.

  Tinsel wire is found in telephone and headphone cords since it can be made extremely flexible.

  Repair is difficult (but not impossible) since it very fine and the conductor must be unraveled from the core for soldering. The area of the repair must be carefully insulated and will be less robust than the rest of the cord.

- Shielded wire: An insulated central conductor is surrounded by a metal braid and/or foil shield.

  Shielded wire is used for low level audio and video, and other analog or digital signals where external interference needs to be minimized.

- Coaxial cable: This is similar to shielded wire but may be more robust and have a specified impedance for transmitting signals over long distances.

- Zip cord: This is 2 or 3 (or sometimes more) conductor cable where the plastic insulation is scored so that the individual wires can be easily separated for attachment to the plug or socket.

- 14/2, 12/3, etc.: These are the abbreviations used for building (electrical) wire like Romex (which is one name brand) and for round or zip-type cordsetwire. The conductor material is usually copper.

  Note: Some houses during the '50s and '60s were constructed with aluminum wiring which has since been found to result in significantly increased risk of fire and other problems. For more information, see the references listed in the section: Safe electrical wiring. However, aluminum wiring is safe if installed according to very specific guidelines (and is used extensively in power transmission and distribution - probably for your main connection to the utility - due to its light weight and low cost).

  The first number is the AWG wire gauge.

  The second number is the number of insulated conductors (excluding any bare safety ground if present). For example:

  - A 14/2 Romex cable has white and black insulated solid #14 AWG current carrying conductors and a bare safety ground (some older similar types of cable had no safety ground, however).

  - A 16/3 cordset has white, black and green insulated stranded #16 AWG wires (or, overseas, blue, brown, and green or green with yellow stripe).

So, where did AWG come from?

Nearly everyone who has done any sort of wiring probably knows that the AWG or American Wire Gauge number refers to the size of the wire somehow. But how?

(From: Frank (fwpe@hotcoco.infi.net).)

According to the 'Standard Handbook for Electrical Engineers' (Fink and Beaty) the 'gauge' you referenced to is 'American Wire Gauge' or AWG and also known as Brown & Sharp gauge.

According to above handbook, the AWG designation corresponds to the number of steps by which the wire is drawn. Say the 18 AWG is smaller than 10 AWG and is therefore drawn more times than the 10 AWG to obtain the smaller cross sectional area. The AWG numbers were not chosen arbitrary but follows a mathematical formulation devised by J. R. Brown in 1857!

For the marginally mathematically inclined

Each increase of 3 in the gauge halves the cross sectional area. Each reduction by 3 doubles it. So, 2 AWG 14 wires is like one AWG 11.

It seems that everyone has their own pet formula for this (though I prefer to just check the chart, below!).

(From: Tom Bruhns (tomb@lsid.hp.com).)

As I understand it, AWG is defined to be a geometric progression with AWG 0000 defined to be 460 mils diameter and 36 gauge defined to be 5.000 mils diameter. This leads directly to the formula:

```
Diameter(mils) = 5 * 92^((36-AWG)/39)
```

That is, 460 mils is 92 times 5 mils, and the exponent accounts for 39 steps of AWG number starting at 36 gauge.

(From: David Knaack (dknaack@rdtech.com).)

You can get a fairly accurate wire diameter by using the equation:

```
Diameter(inches) = 0.3252 * e^(-0.116 * AWG)
```

where 'e' is the base of the natural logarithms, 2.728182....

I don't know where it came from, but it is handy (more so if you can do natural base exponentials in your head).

In its simplest form, the cross sectional area is:

```
A(circular mils) = 2^((50 - AWG) / 3)
```

Here's a Web site that has a program to calculate most of the useful specifications based on the AWG number, diameter, or cross-sectional area:

- Mogami Wire Gauge Calculator.

They also have a bunch of other useful CAD programs at:

- Mogami Wire and Cable Related CAD Programs.

American Wire Gauge (AWG) table for annealed copper wire

(Similar tables exist for other types of wire, e.g., aluminum.)

(Table provided by: Peter Boniewicz (peterbon@mail.atr.bydgoszcz.pl).)

Wire Table for AWG 0000 to 40, with diam in mils, circular mils, square microinches, ohms per foot, ft per lb, etc.

AWG gauge	Dia in mils	Circ. Mils	Square MicroIn	Ohms per 1000 ft	lbs per 1000 ft	Feet/ Pound	Feet/ Ohm	Ohms/ Pound

Note: Values for AWG #41 to #46 extrapolated from AWG #35 to #40 based on wire gauge formula.

Ohms per 1000 ft, ft per Ohm, Ohms per lb, all taken at 20 degC (68 degF). Sizes assume bare wire - insulation is extra. For hookup and similar wire, this is easy to determine. For magnet wire, the additional diameter will be a fraction of mil (0.001 inch) up to several mils depending on the wire gauge and type. When in doubt, use a micrometer to compare the original wire and the wire with insulation removed using a non-mechanical (e.g., chemical) stripper.

Apparently, you can buy wire down (up?) to size #60 - less than .000350 inches in diameter! Check out MWS Wire Industries if you are really curious about fine wire.)

What about stranded wire?

(From: Calvin Henry-Cotnam (cal@cate.ryerson.ca).)

In addition to the cross-section area, there are a few other factors. First off, a stranded wire effectively has more surface area than a solid wire of the same gauge, but much of this surface is "inside" the wire.

I checked out the label of a spool of #18 stranded wire and found it was comprised of 16 strands of #30 wire. Given the info above that each reduction of 3 in the gauge, then #18 has a cross-section area that is 16 times greater than #30 -- so it *appears* to translate exactly.

Looking through a catalog for wire, I found that this more-or-less holds true, though the occasional wire might have an extra strand or two. Here is what I quickly found -- there are many more, but this is a sample:

```
 Overall gauge      Typical stranded wires made up of:
--------------------------------------------------------------
    #32                  7 x #40
    #30                  7 x #38
    #28                  7 x #36
    #26                  7 x #34
    #24                  7 x #32    19 x #36
    #22                  7 x #30    19 x #34
    #20                  7 x #28    10 x #30    19 x #32
    #18                 16 x #30
    #16                 19 x #29    26 x #30
    #14                 41 x #30
    #12                 65 x #30
    #10                 65 x #28
     #8                 84 x #27
```

Items of Interest

Editor's note: Not all of these actually apply to small appliances but may be of use nonetheless.

Determining electricity usage

So, where does all the electricity (or money, same thing) go?

You could put a watt-hour meter on every appliance in your house but that is probably not needed to estimate the expected electricity usage.

Check the nameplate on heating appliances or those with large motors. They will give the wattage. Multiple these by hours used and the result is W-hours (or kW-hours) worst case. Appliances that cycle like refrigerators and space heaters with thermostats will actually use less than this, however.

Multiple light bulb wattages by hours used to get the W-hours for them.

Things like radios, clocks, small stereos, etc., are insignificant.

Add up all the numbers :-).

It would be unusual for an appliance to suddenly increase significantly in its use of electricity though this could happen if, for example, the door on a freezer or refrigerator is left ajar or has a deteriorated seal.

How your electric (kW-hour) meter works

While there have been a variety of technologies used to measure the amount of electric power used by residential and industrial customers, the most common is probably the one that uses a rotating aluminum disk to operate a clockwork mechanism with a visible readout in kW-hours.

The implementation is quite clever - and often misunderstood. This type of meter is designed to read true power (for residential customers, at least) and operates as follows:

There is both a current electromagnet (which passes the user load current) and a voltage electromagnet (connected across the AC line). The pole pieces of these electromagnets are mounted in close proximity to the aluminum disk and close to one-another. When the voltage and current are in phase, their magnetic fields are roughly 90 degrees out of phase. Why? Because the load current is in-phase with the AC voltage but the current in the voltage electromagnet lags by 90 degrees since its winding acts like an inductor.

This results in a net torque on the disc which is proportional to voltage times current. The disk acts like the rotor of an induction motor and rotates, operating the dials. A permanent magnet also acts on the disk and acts to limit the rotation due to induced eddy-currents - its restraining force is proportional to speed. Rotation rate is therefore proportional to the instantaneous power being consumed with a direct readout in kW-hours.

Where reactive power is involved and the voltage and current are out of phase, the peak current will be higher (for the same real power) but the phase angle will change resulting in reduced torque. These effects will tend to cancel so the rotation rate will be essentially unchanged. Therefore, adding capacitors or inductors to change the power factor in a house or apartment (either to legitimately improve power factor or to cheat the power company) will have little effect on the measured power usage. Note: Power factor is equal to: cos(phase angle between voltage and current).

That's why it is called a kW-hour meter and not a VA-hour meter :-).

(Note that large industrial customers ARE charged for reactive power since that extra current DOES stress generating and transmission facilities thus requiring excess capacity so this does not apply in that case.)

It is quite possible that under extremely low power factor conditions, accuracy may be compromised due to friction and materials non-linearities but over the range of power factors generally encountered, these should be quite accurate.

Taking equipment overseas (or vice-versa)

When does it make sense to take an appliance or piece of electronic equipment to a country where the electric power and possibly other standards differ?

For anything other than a simple heating appliance (see below) that uses a lot of power, my advise would be to sell them and buy new when you get there. For example, to power a microwave oven would require a 2kVA step down (U.S. to Europe) transformer. This would weigh about 50 pounds and likely cost almost as much as a new oven.

There are several considerations:

1. AC voltage - in the U.S. this is nominally 115 VAC but in actuality may vary from around 110 to 125 VAC depending on where you are located. Many European countries use 220 VAC while voltages as low as 90 or 100 VAC or as high as 240 VAC (or higher?) are found elsewhere.

2. Power line frequency - in the U.S. this is 60 Hz. The accuracy, particularly over the long term, is excellent (actually, for all intents and purposes, perfect) - better than most quartz clocks. In many foreign countries, 50 Hz power is used. However, the stability of foreign power is a lot less assured.

3. TV standards - The NTSC 525L/60F system is used in the U.S. but other countries use various versions of PAL, SECAM, and even NTSC. PAL with 625L/50F is common in many European countries.

4. FM (and other) radio station channel frequencies and other broadcast parameters differ.

5. Phone line connectors and other aspects of telephone equipment may differ (not to mention reliability in general but that is another issue).

6. Of course, all the plugs are different and every country seems to think that their design is best.

For example, going to a country with 220 VAC 50 Hz power from the U.S.:

For electronic equipment like CD players and such, you will need a small step down transformer and then the only consideration power-wise is the frequency. In most cases the equipment should be fine - the power transformers will be running a little closer to saturation but it is likely they are designed with enough margin to handle this. Not too much electronic equipment uses the line frequency as a reference for anything anymore (i.e., cassette deck motors are DC).

Of course, your line operated clock will run slow, the radio stations are tuned to different frequencies, TV is incompatible, phone equipment may have problems, etc.

Some equipment like PCs and monitors may have jumpers or have universal autoselecting power supplies - you would have to check your equipment or with the manufacturer(s). Laptop computer, portable printer, and camcorder AC adapter/chargers are often of this type. They are switching power supplies that will automatically run on anywhere from 90-240 VAC, 50-400 Hz (and probably DC as well).

Warning: those inexpensive power converters sold for international travel that weigh almost nothing and claim to handle over a kilowatt are not intended and will not work with (meaning they will damage or destroy) many electronic devices. They use diodes and/or thyristors and do not cut the voltage in half, only the heating effect. The peak voltage may still approach that for 220 VAC resulting in way too much voltage on the input and nasty problems with transformer core saturation. For a waffle iron they may be ok but not a microwave oven or stereo system. I also have serious doubts about their overall long term reliability and fire safety aspects of these inexpensive devices..

For small low power appliances, a compact 50 W transformer will work fine but would be rather inconvenient to move from appliance to appliance or outlet to outlet. Where an AC adapter is used, 220 V versions are probably available to power the appliance directly.

As noted, the transformer required for a high power heating appliance is likely to cost more than the appliance so unless one of the inexpensive converters (see above) is used, this may not pay.

Note that if you plan to be moving between countries with different standards, it may pay to invest in appliances specifically designed for multisystem operation. However, there are all sorts of definitions of 'multisystem' - not all will handle what you need so the specifications must be checked carefully and even then, marketing departments sometimes get in the way of truth in advertising!

For additional information, see the document: International Power and Standards Conversion.

Controlling an inductive load with a triac

Thyristor based controllers need to be designed with inductive loads in mind or else they may not work correctly or may be damaged when used to control a motor or even a transformer or large relay.

There are a couple of issues:

1. Will it switch correctly? Assuming it uses a Triac to do the switching, the inductive nature of the load may prevent the current from ever turning off. Once it goes on the first time, it stays on.

2. Inductive kickback. Inductive loads do not like to be switched off suddenly and generate a voltage spike as a result of the rapid change in current. This may damage the Triac resulting the load staying on through the next millennium.

3. Heating. Due to the inductive load, this will be slightly greater for the switch but I wouldn't expect it to be a major issue. However, some derating would be advised. Don't try to switch a load anywhere near the rated maximum for a resistive load.

Where feasible, adding a light bulb in parallel with the load will decrease the effect of the inductance. There is no way of knowing whether it will be effective without analyzing the design or trying it.

Using a relay controlled by the Triac to then switch the inductive load may work but keep in mind that a relay coil is also an inductive load - a much smaller one to be sure - but nonetheless, not totally immune to these effects.

Dan's notes on low voltage outdoor lighting

(From: Dan Hicks (danhicks@millcomm.com).)

Most major brands of 12V lights are "sort of" interchangeable. (Occasionally you have trouble getting the wire from one brand to connect with the fixtures of another brand, but with a little fudging it can usually be done.) So look for the brand/model that gives you most of the lights you want in the styles you want, then augment with add-ons from other brands. Be aware of the current limit of transformers, though -- some kits have small transformers not sized for add-ons, while others have quite a bit of excess capacity. I've got a (mostly) Toro system I'm semi-satisfied with, though the built-in photocell system has failed twice. (I'm going to install a separate photocell & timer and just set the transformer to "On".)

Effects of brownouts and blackouts on electronic equipment and appliances

Brownouts down to 100 V, maybe even 90 volts should not affect electronic equipment. It is possible that there is a no-man's land in between 0 and 90 volts (just an estimate) where strange things may happen. Whether this will cause permanent damage I cannot say. The surge, spikes, and overvoltage possibly associated with repeated brownouts or blackouts can damage electronics, however.

Induction motors - the type in most large appliances - will run hotter and may be more prone to failure at reduced line voltage. This is because they are essentially constant speed motors and for a fixed load, constant power input. Decrease the voltage and the current will increase to compensate resulting in increased heating. Similar problems occur with electronic equipment using switching power supplies including TVs, some VCRs, PCs and many peripherals. At reduced line voltage, failure is quite possible. If possible, this type of equipment should not be used during brownout periods.

Grounding of computer equipment

While electronic equipment with 3 prong plugs will generally operate properly without an earth ground (you know, using those 3-2 prong adapters without attaching the ground wire/lug), there are 3 reasons why this is a bad idea:

1. Safety. The metal cases of computer equipment should be grounded so that it will trip a breaker or GFCI should an internal power supply short occur.

   The result can be a serious risk of shock that will go undetected until the wrong set of circumstances occur.

2. Line noise suppression. There are RLC filters in the power supplies of computer and peripheral equipment which bypass power supply noise to ground. Without a proper ground, these are largely ineffective.

   The result may be an increased number of crashes and lockups or just plain erratic weird behavior.

3. Effectiveness of surge suppressors. There are surge suppression components inside PC power supplies and surge suppression outlet strips. Without a proper ground, H-G and N-G surge protection devices are not effective.

   The result may be increased hard failures due to line spikes and overvoltage events.

Removing gummed labels (or other dried or sticky gunk)

My order of attack: water, alcohol, WD40, Windex, then stronger stuff like ammonia, acetone, degreaser, flux-off, carburetor cleaner, lacquer thinner, gasoline. WARNING: most of these are flammable and harmful to your health - use only in a well ventilated areas away from open flames. Test that they are safe for plastics and painted surfaces by trying some in an inconspicuous location first.

(From: Paul Grohe (grohe@galaxy.nsc.com).)

I use "Desolv-it", one of those citrus oil (orange) based grease and "get's-the-kids-gum-out-of-your-carpet" cleaners (These are usually touted as "environmentally friendly" or "natural" cleaners).

Spray it right on the label and let it soak into the paper for a minute or two, then the sticker slips right off (it also seems to do well on tobacco and kitchen grease residue).

The only problem is you have to remove the oily residue left by it. I just use Windex (a window cleaner) to remove the residue, as I usually have to clean the rest of the unit anyways.

(From: Bob Parnass, AJ9S (parnass@radioman.ih.att.com).)

I spray the label with WD40 and let it soak in for several minutes. This usually dissolves the glue without damaging the paint and I can remove the label using my fingernail.

Preventing radio frequency interference from whacking out appliances

This probably applies to many of the new high tech appliances including touch lamps, smart irons and coffeemakers, etc.

(From: James Leahy (jleahy@norwich.net).)

My lamps were flashing each time I transmitted on 2 meters. HF transmissions don't seem to cause any trouble. (that just knocks the neighbor's TV out, har de har). Believe it or not, a simple snap-on toroidal choke with the lamp cord wrapped as many turns possible near the plug end cured it. Didn't want to bother with the several type of filter circuits one could build to fix the problem. It may be a simple fix for others with similar 2-way interference problems. One can get these chokes at Radio Shack among other sources.

Yard lights cycling and maintenance humor

(From: John Rowe (johnrowe@lightresource.com).)

The new maintenance man at one of our customers, a rather large apartment complex in Minneapolis, had purchased from us a case of 200 watt incandescents. He returned to our office about a week later with the lamps, complaining that they 'flashed' and that the residents were really upset that these lights (used outside) were not letting them sleep.

Under the 'customer is right' rule, I replaced them immediately, no questions asked. Of course I tested the 'bad' ones and found no defects.

When he returned with the new batch and the same complaint, he was really upset, because the residents were now complaining to the management company (his employer) about the situation.

I sat him down and asked him about the application. He explained that they were being used in 16" white poly pole lights, along all the footpaths around the complex.

I asked how they were switched, and he replied that they used to be on timers but that after complaints that the lights were on during the daylight hours, he had purchased, from his local hardware store, screw-in photocells. The type into which the bulb screws. These were then, inside the globes with the bulbs.

Of course the reflection within the poly globe was enough to prompt the photocell to switch the circuit off and cycle the lights all night.

It took him a minute or two to comprehend his error. I was able to recommend an electrician to install more appropriate photocells. He remained a good customer for several more years after this incident.

My amusement comes from the picture I have in my mind of the residents of this rather up-scale apartment complex looking out of their windows to see all the walkway security lights going on and off all night, and wondering what the heck was going on! I imagine it was quite a sight.

Will a hard-wired appliance save energy over a plugged in variety?

The resistance of the connection may be slightly lower - .05 versus .1 ohm, for example. Other than the reduced amount of power lost in this wiring, there is otherwise no functional difference.

With fancy expensive test equipment you might be able to detect it but not in normal use. The savings of a hard wired appliance would be quite small even for a high wattage device like a space heater.

However, the hard wired connection will be more reliable and should not deteriorate over time whereas a plug and outlet can corrode and the spring force decreases with multiple plugins and outs. The added resistance will increase the losses. So, in this regard, directly connecting the device into the house wiring is better.

Note that if the cord and/or plug gets hot in use, this is a loss (though for a space heater, the heat is just coming from the cord/plug instead of the elements inside) - and a possible fire hazard as well and should be checked out. Sometimes, all it takes to remedy such a problem is to expand the metal strips of the prongs of the plug so it makes better contact.

A short history of heat

(From: Bill (bill394@juno.com).)

In the beginning we had but rocks and wood, not an efficient safe or practical way to heat your home. This system was refined and did do a fair job, as long as you didn't mind cold spots or care about your safety.

Then we got more creative and used coal and then oil. Oil was a far safer and a better controlled system. Then came gas now that's the fuel, the fuel of choice for most. It's also the one we are here to explain.

The older systems were really very simple. You had a small pilot light which was always on. No safety, it just was lit, and we hoped it stayed lit. When the thermostat called for heat we opened a solenoid (electric valve) and allowed gas to flow in and hopefully get lit by the pilot light. If the pilot had gone out the theory was that the majority of the gas would go up the chimney and vent to the outside. This simple system, used for years did a fair job. It lacked many features we take for granted today.

With the coming of more technology people started thinking more of safety and expected more from there equipment. A device commonly known as a thermocouple was a great start in the direction of safety. It is a union of dissimilar metals that when heated generates electricity. Now we had a way to stop gas flow if our pilot went out. By putting a solenoid in the pilot gas line we could use a thermocouple to keep it powered open by the heat of the pilot. Thus if our pilot went out the thermocouple would cool and stop producing power to hold the solenoid open, gas flow would be interrupted. Power from this control was also required prior to the main valve opening, this making uncontrolled gas flows a thing of the past.

With the coming of the R.E.A. (Rural Electric Authority) power to every home became a reality. We now could introduce a new concept, blowers. The fan motor made forced air heat a reality. Now even the most distant room could be heated and even temperatures became a real happening.

The addition of electricity allowed for the addition of safety controls which resulted in greatly reducing the fiscal size of a furnace. We now had the means to control running temperatures using the fan - turning it on and off by the temperature and the on and off valve of the fire. Should by chance the fan not start, the furnace would over heat and a high temperature switch would turn the fire off. No melt down! very safe.

We all know that something simple that works well can't be left alone. Man just has to make it more labor complex. Soon came the addition of some actually neat ideas. First being the addition of humidity, in cold climates a must, that also lowers your heat bill. The ability to run the fan just to stir air, not add heat or cool. Then the electronic air cleaner. This one if you have allergy is a must. I don't have one so can't tell if it is on or off. BUT my son can tell in a matter of hours if its off.

And let's not forget the best of all air conditioning! In my world a must. All of these additions were working steps towards our modern furnace.

The older burners were called ribbon (they sat in the combustion chamber) and did a good job until we started going for higher efficiency. Then a major problem arrived, with colder heat exchangers came condensation. This caused the mild steel burners to rust and the size of the openings to get smaller, making for a poor air to fuel ratio and just a terrible dirty burn, lots of soot. The good news is stainless steel burners did solve this, how ever it's an expensive fix.

Now remember what we said about something that worked? You got it! new style burners, not all bad though. With the high efficiency furnaces comes a colder stack temperature (fumes to chimney). They are cold enough that they possibly would not raise without a little help. So a venter (blower) motor is used to draw the fumes out of the heat exchanger and up the chimney. This made possible a new style burner. It is in reality a far better burner then the previous style. We call it, in shot. This burner is self adjusting for it's air mixture and is positioned out side of the heat exchanger. It is more like the fire from a torch. The fire is now sucked in to the heat exchanger by the draft of the venter. keep in mind the burner sits out in mid air. In most modern furnaces the heat exchanger is basically a piece of pipe with a burner on one end and a venter on the other.

Knowing that good things get better, next we worked over the controls. Rather then using temperature to turn on the fan we use a solid state timer. This controls all fan functions. Remember the pilot light? It's gone. We now use either a hot surface igniter or if your lucky a spark. The hot surface is much like the filament of a light bulb. It upon demand gets very hot and is used as the source for ignition, unfortunately like a light bulb it burns out. Again remember the thermal couple? Yes it to is gone. We now use a micro processor and electronically sense if the fire is lit.

On most modern furnaces the sequence of operation is as follows:

1. The thermostat call for heat. It starts only the venter.

2. The venter comes to speed and if the chimney is not blocked and intake air is present it will draw a vacuum on the heat exchanger. This is sensed by a vacuum switch, it now will turn on our timer.

3. The timer lets the ignition come on and after a delay the gas valve opens and if all is well we finally get FIRE!

4. A rod in the fire passes an extremely small current through the fire to ground. If the microprocessor accepts the signal the fire will remain on.

5. Our timer will soon turn on the blower.

When the thermostat no longer calls for heat:

Venter stops. Vacuum is lost. Fire is turned off. Blower will run till timer tells it to stop. You still have the old style over temperature switches. All of this has made new furnaces extremely small, efficient and safe. Do they require more maintenance? YES. If someone tells you different, they tell less then the truth! But I will gladly pay the cost to have my family safe and comfortable.

About those automatic toilets

I bet you will probably never have to repair one of these but I also bet that you were curious as to how they work. :) In addition to what is said below, I should add that only the initial push to open or close the valve comes from the solenoid. Most of thw work is done by a clever hydraulic amplifier which uses water pressure as the power source.

(From: Hauser Christoph (chhauser@bluewin.ch).)

The automatic toilets are active infrared devices. This means, you have a IR transmitter and an IR receiver basically. More sophisticated systems use more emitters and receivers or a PSD to get a triangulation. Some systems are battery-operated with lithium 2CR5, CR-P2 or simply with four AA-cells.

Usually, the infrared system is activated every second up to every 4 seconds. If the receiver sees a response, the sampling is higher. There also several time delays included. The systems detects persons or objects in the range of 10 to 100 cm (4 to 40").

The valve for the flush is a bistable solenoid device. With a short pulse you open the valve and with another and opposite polarity you close it. It's possible to reach about 200,000 flushes with batteries and a life-cycle of 4 years. Often PIC's (Programmable Interface Controllers - one chip micros) are used, because they have a low stand-by consumption.

You wonder, why I know this? It's my job to develop these devices!

Service Information

Wiring diagrams

Many larger appliances like washing machines and microwave ovens have a wiring diagram or connection diagram pasted inside the cover. However, this is rare for small appliances.

In most cases, wiring is trivial and five minutes with your Mark I Eyeball(s) and a pencil and paper (remember those? If not, use your PC and a schematic capture software package) will result a complete schematic. There may still be some uncertainties with respect to motor, transformer, or switch wiring but testing with an ohmmeter or continuity checker should eventually prevail.

Removing screw with stripped head

Even if a Phillips head screw head is severely damaged, it is sometimes possible to free it just by applying enough pressure while turning with a properly shaped screwdriver. This can only be attempted if it is possible to press hard without risk of breaking or damaging anything.

Other more drastic measures:

1. Drill it out - the same way you would remove a rivet - with a sharp twist drill bit on slow speed. If necessary, use a metal or plastic sleeve to guide the drill bit.

2. Use a Dremel tool with a disk cutter or fine hacksaw blade to cut a slot in the head and then use a straight blade screwdriver to remove it.

3. Take a pair of sharp diagonal cutters and grip between the center and one edge or the entire head. Or, grab the head with a pair of miniature locking pliers (Vice-Grips(tm).)

4. Drill a hole in the head and use a screw extractor (E-Zout(tm).)

Take care to avoid excessive mechanical shock to delicate equipment and avoid allowing metal particles to fall into the interior of the appliance.

Fil's tips on improvised parts repair

(From: Filip "I'll buy a vowel" Gieszczykiewicz (filipg@repairfaq.org).)

Whenever I'm stuck with some "Unprofitable" with a broken part, I see if I can duplicate the functionality of the part. My raw materials include:

- 5 minute 2-part epoxy (under $8 from a RC hobby store).
- 30 minute 2-part epoxy (under $8 from a RC hobby store).
- Wire: copper, steel, SS, "piano", spring, etc.
- Springs (a box of 1000s from hamfests, stripped monsters).
- Plastic stock: all types (you will learn which glue well).
- Plastic build up kit: two parts - foul smelling polymer and "dust".
- Aluminum stock: from thin foil to .080" to .5".
- Brain: regular edition. :-)

As long as you know what the part does (you need not HAVE it... as long as you can see where it goes in, what it moves, what activates it, etc).

If it's something intricate, my parts bin door is NEVER closed.. and it gives it's "body" to science :-)

If you have part of the old plastic lever, it's usually easy to build up the broken off part. I like to heat up a segment of piano wire and insert it into the remaining part in such a way as to hit the most "meat" of the part. Then, using either epoxy or plastic build up material, I form something that does the job.

Overall, I have about a 75% "plastic broken part" repair ratio. After a while, you will be able to judge if it's doable. "lever"s are usually easy... sliding assemblies are a pain in the @ss...

Fixing stripped plastic threaded holes

(From: Gordon S. Hlavenka (cgordon@worldnet.att.net).)

Simply set the screw on top of the hole, and press LIGHTLY on it with the tip of your soldering iron. The iron will heat the screw, which then slides into the post. After everything cools, you can take the screw out normally and the threads are as good as new! If the post is badly stripped, you may want to stuff the hole with extra plastic shaved from some non-critical area to provide additional material.

You have to be careful not to overheat, or push too hard. But it works very well.

Interchangeability of components

The question often arises: If I cannot obtain an exact replacement or if I have another appliance carcass gathering dust, or I just have some extra parts left over from a previous project, can I substitute a part that is not a precise match? Sometimes, this is simply desired to confirm a diagnosis and avoid the risk of ordering an expensive replacement and/or having to wait until it arrives.

For safety related items, the answer is generally NO - an exact replacement part is needed to maintain the specifications within acceptable limits with respect to line isolation (shock prevention) and to minimize fire hazards. However, these components are not very common in small appliances.

For other components, whether a not quite identical substitute will work reliably or at all depends on many factors. Some designs are so carefully optimized for a particular part's specifications that an identical replacement is the way to return performance to factory new levels. With appliances in particular, may parts which perform common functions - like thermostats - utilize custom mounting arrangements which precluded easy substitution even if the electrical and thermal characteristics are an exact match.

Here are some guidelines:

1. Fuses - exact same current rating and at least equal voltage rating. I have often soldered a normal 3AG size fuse onto a smaller blown 20 mm long fuse as a substitute. Also, they should be the same type - slow blow only if originally specified. A fuse with a faster response time may be used but it may blow when no faults actually exist.

2. Thermal fuses and thermal cutouts - exact same temperature and current rating (if stated). Physical size may also be important when these are buried in motor or transformer windings. Also see the document: Notes on the Troubleshooting and Repair of AC Adapters, Power Supplies, and Battery Packs.

3. Thermostats - temperature range must be compatible (or slightly wider may be acceptable). Electrical current and voltage ratings must meet or exceed original. With some devices, hysteresis - the tendency of a thermostat that has switched to stay that way until the temperature changes by a few degrees - may be an issue. For example, electric heaters use a thermostat which has a typical hysteresis of 3-5 degrees F. However, heating appliances like waffle irons and slow cookers may depend on the thermal mass of the castings and use a thermostat with very little hysteresis.

4. Resistors, capacitors, inductors, diodes, switches, trimpots, lamps and LEDs, and other common parts - except for those specifically marked as safety-critical - substitution as long as the replacement part fits and specifications are met should be fine.

5. Rectifiers - use types of equal or greater current and PRV ratings. A bad bridge rectifier can be replaced with 4 individual diodes. However, high efficiency and/or fast recovery types are used in parts of electronic ballasts and other switching power supplies.

6. Transistors and thyristors (except power supply choppers) - substitutes will generally work as long as their specifications meet or exceed those of the original. For testing, it is usually ok to use types that do not quite meet all of these as long as the breakdown voltage and maximum current specifications are not exceeded. However, performance may not be quite as good. For power types, make sure to use a heatsink.

7. Motors - small PM motors may often be substituted if they fit physically. Make sure you install for the correct direction of rotation (determined by polarity). For universal and induction motors, substitution may be possible but power input, speed, horsepower, direction of rotation, and mounting need to be compatible.

8. Sensor switches - some of these are common types but many seem to be uniquely designed for each appliance.

9. Power transformers - in some cases, these may be sufficiently similar that a substitute will work. However, make sure you test for compatible output voltages to avoid damage to the regulator(s) and rest of the circuitry. Transformer current ratings as well as the current requirements of the equipment are often unknown, however.

10. Belts or other rubber parts - a close match may be good enough at least to confirm a problem or to use until the replacements arrives.

11. Mechanical parts like screws, flat and split washers, C- and E-clips, and springs - these can often be salvaged from another unit.

The following are usually custom parts and substitution of something from your junk box is unlikely to be successful even for testing: SMPS (power supply) transformers, microcontrollers, other custom programmed chips, display modules, and entire power supplies unless identical.

Appliance repair books

Your local large public or university library should have a variety of books on appliance repair and general troubleshooting techniques.

Here are a few titles for both small and large appliance repair:

1. Chilton's Guide to Small Appliance Repair and Maintenance
   Gene B. Williams
   Chilton Book Company, 1986
   Radnor, PA 19089
   ISBN 0-8019-7718-5

2. Chilton's Guide to Large Appliance Repair and Maintenance
   Gene B. Williams
   Chilton Book Company, 1986
   Radnor, PA 19089

ISBN 0-8019-7687-1

3. Major Appliances, Operation, Maintenance, Troubleshooting and Repair
Billy C. Langley
Regents/Prentice Hall, A Division of Simon and Schuster, 1993
Englewood Cliffs, NJ 07632
ISBN 0-13-544834-4

4. Major Home Appliances, A Common Sense Repair Manual
Darell L. Rains
TAB Books, Inc., 1987
Blue Ridge Summit, PA 17214
ISBN 0-8306-0747-1 (Paperback: ISBN 0-8306-0747-2)

5. Home Appliance Servicing
Edwin P. Anderson
Theodore Audel & Co., A Division of Howard W. SAMS & Company, Inc., 1969
2647 Waterfront Parkway, East Drive
Indianapolis, IN 46214
Telephone: 1-800-428-7267

6. Handbook of Small Appliance Troubleshooting and Repair
David L. Heisserman
Prentice-Hall, Inc. 1974
Englewood Cliffs, NJ 07632
ISBN 0-13-381749-0

7. Fix It Yourself - Power Tools and Equipment
Time-Life Books, Alexandria, VA
ISBN 0-8094-6268-0, ISBN 0-8094-6269-9 (lib. bdg.)

8. Readers Digest Fix-It-Yourself Manual
The Readers Digest Association, 1996
Pleasantville, New York/Montreal
ISBN 0-89577-871-8

Overall, this is an excellent book which I would not hesitate to recommend as long as one understands its shortcomings. The coverage of both small and large appliances, tools, and common yard equipment, as well as a variety of other categories of household repair (furniture, plumbing, etc.) is quite comprehensive.

It is very well illustrated with hundreds upon hundreds of easy to understand exploded diagrams. In fact, that is probably its most significant feature. Where the equipment is similar to yours, it is possible to use the pictures almost exclusively for understanding its construction, operation, and disassembly/reassembly procedures.

The discussion of each type of more complex equipment provides one or more troubleshooting charts. Each entry includes the level of difficulty and identifies any needed test equipment (e.g., multimeter) for dealing with that problem or repair.

However, this book is at best an introduction and once-over. Much of the material is presented based on one or two models of a particular type of devices while sort of implying that all the rest are similar. In all fairness, very often this is sufficient as most models of simpler differ only in details. However, for all but the most general repairs on the more complex appliances, a book with more specific information would be highly desirable before actually tackling the repair.

One significant shortcoming is that there are NO wiring diagrams of any kind for any of the appliances. Their approach seens to be to just check parts for failure. While this will be successful in many cases. a wiring diagram would be useful when explaining appliance operation and would help in logical troubleshooting to localize the problem.

Although there is a chapter on home electronics - audio, video, computer, security systems, etc. - don't expect anything useful beyond very general information and simple repairs like replacing belts and looking for bad connections. While it isn't surprising that the treatment of this complex equipment is superficial at best in a book of this type, in some cases it is as though the editing was based on a page limit rather than including a more complete summary but with fewer details. For example, the only repair on a CD player beyond belts and lens cleaning is to test and replace the tray loading motor (one particular model). Unfortunately, some of the specific information is not entirely accurate either and may be misleading and expensive. The safety instructions for the electronics (as well as microwave ovens) is also a bit lacking considering some of the suggestions for troubleshooting and parts replacement.

Some errata: Testing of microwave oven HV diodes (good ones will test bad), HV discharging of TVs and monitors always (not needed) and possibly to wrong place (should be to picture tube ground, not chassis ground) but no mention of power supply capacitor discharging, not specific enough on 'good' and 'bad' resistance readings for various parts like motors.

9. All About Lamps - Construction, Repair, Restoration
   Frank W. Coggins
   Tab Books, 1992
   Blue Ridge Summit, PA 17214
   ISBN 0-8306-0258-5 (hardback), 0-8306-0358-1 (paperback)

10. How to Repair and Care for Home Appliances
    Arthor Darack and the Staff of Consumer Group, Inc.
    Prentice-Hall, Inc. 1983
    Englewood Cliffs, NJ 07632
    ISBN 0-13-430835-2 (hardcover), ISBN 0-13-430827-1 (paperback)

11. Popular Mechanics Home Appliance Repair Manual
    Hearst Books, NY, 1981
    ISBN 0-910990-75-1

12. Microsoft Home (CDROM)
    Based on the Readers Digest Complete Do-It-Yourself Guide
    The Readers Digest Association, 1991
    Microsoft, 1996
    ISBN 0-57231-259-9

    This isn't the Fix-It-Yourself Manual but I expect that is coming on CDROM if it is not out already. However, there is some information including nice diagrams relating to door chimes, telephone wiring, incandescent and fluorescent lighting fixtures, electrical switches, and heating and air conditioning systems (in addition to everything else you ever wanted to know about how your house works, tools and tool skills, materials and techniques, and home repair and maintenance).

Manufacturer support

Major manufacturers may provide a variety of types of support for their products including technical assistance, parts sourcing, unadvertised repair or replacement beyond the expiration of the warranty, upgrade or replacement to fix known defects whether covered by official recalls or not, etc.

I have on several occasions been pleasantly surprised to find that some companies really do stand behind their products and all it took was a phone call or short letter. One only hears of the horror stories!

(From: lizard3 (lizard3@ix.netcom.com).)

Sears sells schematics and plans of all their appliances. This includes a breakout of the entire machine with each part number. They have a toll-free number to call. All you need is the model number and a credit card. We have used their washing machine schematic a couple of times to replace some very minor parts.

Parts suppliers

Common parts like cordsets, plugs, wire, and some light bulbs can be found a larger hardware stores, home centers, or electrical supply houses. Small electronic components like resistors and capacitors, can be found at any electronics distributor - including even Radio Shack in a pinch.

The original manufacturer of the appliance is often the best source for unusual or custom parts. Many are quite willing to sell to the consumer directly. Check for an 800 number and have complete information on model and a part number if possible. However, their prices may be high - possibly rendering a repair uneconomical.

There are numerous appliance repair centers that may be able to obtain parts at lower cost - check your Yellow Pages. Their prices may be less than half of those of the original manufacturer.

The following is a good source for consumer electronics replacement parts, especially for VCRs, TVs, and other audio and video equipment but they also carry a variety of common electronic components and appliance parts like switches, range elements, defrost timers, light bulbs, and belts

- MCM Electronics, 1-800-543-4330, http://www.mcmelectronics.com/.

  VCR parts, Japanese semiconductors, tools, test equipment, audio, consumer electronics including microwave oven parts and electric range elements, etc.

- Global Micro Parts, 1-800-325-8488, http://www.allapplianceparts.com/.

  They specialize in microwave oven parts, but also carry some other major appliance parts.

Also see the documents: "Troubleshooting of Consumer Electronic Equipment" and "Electronics Mail Order List" for additional parts sources.

DISCLAIMER

AC adapters, transformers, and even batteries, are critical safety components. Replacement with an improperly rated or incompatible device can result in damage or destruction of the powered equipment as well as the risk of shock or electrocution in certain cases.

We will not be responsible for damage to equipment, your ego, blown parts, county wide power outages, spontaneously generated mini (or larger) black holes, planetary disruptions, or personal injury that may result from the use of this material.

- Back to AC Adapters and Power Supplies Table of Contents.

Introduction

Scope of this Document

This collection of information deals with the troubleshooting, repair, and use (normal or unconventional) of AC (wall) adapters, transformers, equipment power supplies (non-switching type), and batteries used in portable electronic devices and power tools.

- AC adapters (may also be called: wall adapters, power packs, or wall warts) are those boxes hanging on the end of the power cords of many modern consumer electronic devices. Their output may be a single AC or DC voltage, or several, with or without regulation. Most of those outputting AC are simple transformers and with the addition of a diode or bridge and filter capacitor for DC. (Often, people refer to all types of AC adapters including those outputting DC as 'transformers' but this is not really correct.) Others (those that are compact and weigh almost nothing) may be sophisticated switchmode power supplies. In most cases, the output will be totally isolated from the power line for safety. However, some that are designed for applications like battery chargers may **not** be line isolated and should not therefore be used for any other purposes.

- Transformers in this context refer to the actual magnetic components which may be found in AC adapters or equipment power supplies.

- Equipment power supplies are those portions of the equipment that provide various (usually DC) voltages for its operation. Note that in this document, non-switchmode types are discussed. For switchmode power supply information, see the document: Notes on the Troubleshooting and Repair of Small Switchmode Power Supplies.

- Batteries are found in all sorts of portable equipment nowadays. The discussions in this document related directly to problems and repair. This is not intended as a comprehensive battery "FAQ".

Note: This document replaces the chapters relating to these topics in the documents "Notes on the Troubleshooting and Repair of Small Household Appliances and Power Tools" and "....Audio Equipment and Other Miscellaneous Stuff".

Where another document is referenced, it is assumed to be at this site. If the link doesn't work, find the document of the same name at the Sci.Electronics.Repair FAQ or one of its mirror sites.

SAFETY

For the common transformer based AC adapter, there is no danger anywhere inside the device once unplugged. For the switchmode variety, see the document: Notes on the Troubleshooting and Repair of Small Switchmode Power Supplies for information beyond what is covered in this document.

Any internal overcurrent fuses or thermal fuses represent essential safety features of an AC adapter. These must **not** be removed except during testing. Where a fuse is found to be blown, use only an exact replacement. I really don't recommend running a repaired cobbled together AC adapter unattended in any case since even the sealed case provides some additional amount of fire protection. Inexpensive replacements are generally available.

For power supplies inside equipment, the same basic precautions apply but access and repair are generally much more easily accomplished.

The only real danger from an unplugged heavy iron transformer would be accidentally dropping it on your foot. :(

- Back to AC Adapters and Power Supplies Table of Contents.

General AC Adapter Information

AC Adapter Basics

It seems that the world now revolves around AC Adapters or 'Wall Warts' as they tend to be called. There are several basic types. Despite the fact that the plugs to the equipment may be identical THESE CAN GENERALLY NOT BE INTERCHANGED. The type (AC or DC), voltage, current capacity, and polarity are all critical to proper operation of the equipment. Use of an improper adapter or even just reverse polarity can permanently damage or destroy the device. Most equipment is protected against stupidity to a greater or lessor degree but don't count on it.

The most common problems are due to failure of the output cable due to flexing at either the adapter or output plug end. See section: AC Adapter Testing.

1. AC Transformer. All wall warts are often called transformers. However, only if the output is stated to be 'AC' does the device consist of only a (stepdown) transformer. These adapters typically put out anywhere from 3 to 20 VAC or more at 50 mA to 3 A or more. The most common range from 6 to 15 VAC at less than 1 A. The regulation is typically very poor so that an adapter rated at 12 VAC may put out 15 VAC with no load and drop to less than 12 VAC at rated load. However, some may actually output up to *two times* the rated voltage *or more* with a light load. To gain agency approval, the transformer needs to be protected internally so that there is no fire hazard even if the output is shorted. There may be a fuse or thermal fuse internally located (and inaccessible).

   If the output tested inside the adapter (assuming that you can get it open without total destruction - it is secured with screws and is not glued or you are skilled with a hacksaw - measures 0 or very low with no load but plugged into a live outlet, either the transformer has failed or the internal fuse had blown. In either case, it is probably easier to just buy a new adapter but sometimes these can be repaired. Occasionally, it will be as simple as a bad connection inside the adapter. Check the fine wires connected to the AC plug as well as the output connections. There may be a thermal fuse buried under the outer layers of the transformer which may have blown. These can be replaced but locating one may prove quite a challenge. Also see the section: Comments on Importance of Thermal Fuses and Protectors.

2. DC Power Pack. In addition to a step down transformer, these include at the very least a rectifier and filter capacitor. There may be additional regulation but most often there is none. Thus, while the output is DC, the powered equipment will almost always include an electronic regulation.

   As above, you may find bad connections or a blown fuse or thermal fuse inside the adapter but the most common problems are with the cable.

3. Switching Power Supply. These are complete low power AC-DC converters using a high frequency inverter. Most common applications are laptop computers and camcorders. The output(s) will be fairly well regulated and these will often accept universal power - 90-250 V AC or DC.

   Again, cable problems predominate but failures of the switching power supply components are also possible. If the output is dead and you have eliminated the cable as a possible problem or the output is cycling on and off at approximately a 1 second rate, then some part of the switching power supply may be bad. In the first case, it could be a blown fuse, bad startup resistor, shorted/open semiconductors, bad controller, or other components. If the output is cycling, it could be a shorted diode or capacitor, or a bad controller. See the document: Notes on the Troubleshooting and Repair of Small Switchmode Power Supplies for more info, especially on safety while servicing these units.

Also see the chapter on "Equipment Power Supplies" in the document: Notes on the Troubleshooting and Repair of Audio Equipment and Other Miscellaneous Stuff.

About AC Adapter Ratings

The following mainly applies to AC adapters using transformers. Those based on switchmode power supplies adapters have tended to be well designed with decent regulation and realistic ratings. Of course, they are generally also much more expensive!

There is no standard for rating AC adapters. When a particular adapter is listed as, say, 12 V, 1 A max, there's a good chance the output will average 12 V when outputting 1 A but what it does at lower currents is not known. In fact, lightly loaded, the output voltage may be more than double its nameplate rating! This could be disastrous where a piece of equipment is plugged into it that doesn't expect such a high voltage. The rating also doesn't say anything about the ripple (for DC models) - it could be almost anything.

The lifetime of an AC adapter (particularly those outputting DC) when run at or near its nameplate rating may be very short. Why? Because they often use low temperature (cheap!) components that can't take the heat. For AC output models, the transformer itself may fail (or at least the thermal fuse). For DC models, the electrolytic capacitor(s) may go bad very quickly. The likely result will be that the output voltage will disappear entirely (AC models) or drop in value with greatly increased ripple (DC models).

Where the adapter is used with its intended equipment, one can presume the manufacturer did the proper testing to assure compatibility and adequate life (though this isn't always the case!). However, where it is used in some other application, the life of the adapter and the equipment may be much shorter than expected, possibly failing almost immediately.

Protect Yourself from "Unknown AC Adapter Syndrome"

Apparently, manufacturers of equipment powered by AC adapters have discovered that they can improve their bottom line by *not* printing the AC adapter ratings on the device itself, and possibly not even in the user manual. I don't know whether this is actually done for liability reasons (so you aren't tempted to actually use an AC adapter other than their own exorbitantly priced replacement) or just to same 3 microcents on printing ink but the net result is that the owner has no idea what adapter in that drawer that collects adapters is the correct one. They could at least specify a particular model adapter if they don't think the average consumer has an intelligence greater than a carrot.

For example, I own 2 U.S. Robotics modems. One uses a 9 VAC adapter; the other uses a 20 VAC adapter. The power jacks are identical and totally unmarked. Guess what happens if I guess wrong? With too little voltage, the modem may appear to work but be unreliable. With too much voltage, the smoke will very likely be released instantly. :(

To save yourself a lot of hassle and possible damaged equipment, put a label on each AC adapter powered device you own with the voltage, current, AC or DC (with polarity), and model number of the adapter (make one up if nothing is obvious and put it on the device and adapter). Then, if you misplace the adapter, you'll know what to look for and if it is nowhere to be found, will have enough information to purchase a replacement.

Why do AC Adapters Usually Use Heavy Transformers?

The main reasons are safety and cost.

Line isolation is essential for safety with respect to electrical shock - no part accessible to the user must be connected to either side of the power line. A regular transformer provides this automatically. While combinations of passive components can reduce the risk of shock, nothing quite matches the virtually fail-safe nature of a simple transformer between the power line and the low voltage circuitry. To achieve similar isolation without a line transformer generally requires a switchmode power supply which actually contains a small high frequency transformer to provide the isolation. Until recently, such systems were much more expensive than a simple iron transformer but that is changing and many modern devices do now use a wall adapter based on this approach. These can be recognized by their light weight, DC (probably regulated) output, and the required warnings NOT to cut them off and replace them with an ordinary plug! I wonder how many people have ignored the warnings when their equipment stopped working and replaced that fat "plug"? What a scenario for disaster!

Compact AC Adapters

These use switchmode power supply technology and can therefore be quite small and light weight. In addition to the applications noted below, they are turning up on a variety of other high tech gadgets from shavers to Personal Digital Assistants.

WARNING: DON'T attempt to disassemble or repair one of these unless you are familiar with the safety and troubleshooting information for larger switchmode power supplies - they can be quite deadly. See the document: Notes on the Troubleshooting and Repair of Small Switchmode Power Supplies.

(From: Mike Schuster (schuster@panix.com).)

For some reason I've been fascinated by tiny wall wart AC adaptors that use switch mode power supplies, since they're light and can supply more current than similar linear power cubes.

One type that keeps catching my eye is used a lot for "AC travel charger" accessories for cellular phones. These things connect via a cable to the bottom of a cell phone, much like the cigarette-lighter "charger/saver" accessories, only these are driven by house current.

The typical wart is a small rectangular box, about the size of two 9V transistor batteries side by side, manufactured in China or Taiwan. The wall side is distinguished by the fact that the AC prongs line up with the long axis of the box, rather than the other way around as with most wall cubes. This makes it possible to put them side by side on an AC power strip. The opposite face contains a tri-mode LED which may display red, green, or orange under conditions I've yet to figure out.

Recently I noticed one of these thingies in K-Mart as part of a modular power system for cell phones. There are several models of cigarette lighter cords, however the actual 12VDC car plug in _interchangeable_ and connected to the cable using a 4-pin modular telephone handset jack. Each model comes with a cable constructed to mate with the phone it's sold for.

Next to these on the pegboard is a variant of the wall wart being discussed, also having a 4-pin handset socket, and sold as an accessory to the DC cords. Instead of using the cigarette lighter plug, you connect the cable to the wall wart and create a new device which uses house current. So I picked up the wall wart and started to play.

It's marked as being capable of 5-15 VDC at 750 mA. Playing with the 4 output pins; one is ground, two are tied together and supply 14.35 VDC open circuit, and can deliver about 1.5 amps. The other reads about 13 volts between it and the ground. Unpowered there is a small leakage between the ground and the "13 volt" pin.

Looking inside, there are two 8-pin DIPs on the PC board; both having identifiers sanded off. One is near the transformer end and the other is near the DC output end. All of the DC side output traces lead, directly or indirectly, to the second IC.

My guess is that the "13 volt" pin is really used to program the output voltage between ground and the other two pins that are tied together. The cable sold for any specific phone has some passive components inside that will cause the second IC to produce the required output voltage. Am I warm?

I'd like to try programming this myself ... any ideas? Resistors?

AC Adapter Troubleshooting and Repair

AC Adapter Testing

AC adapters that are not the switching type (1) and (2), above, can easily be tested with a VOM or DMM. The voltage you measure (AC or DC) will probably be 10-25% higher than the label specification. If you get no reading, wiggle, squeeze, squish, and otherwise abuse the cord both at the wall wart end and at the device end. You may be able to get it to make momentary contact and confirm that the adapter itself is functioning.

The most common problem is one or both conductors breaking internally at one of the ends due to continuous bending and stretching.

Make sure the outlet is live - check with a lamp.

Make sure any voltage selector switch is set to the correct position. Move it back and forth a couple of times to make sure the contacts are clean.

If the voltage readings check out for now, then wiggle the cord as above in any case to make sure the internal wiring is intact - it may be intermittent.

Although it is possible for the adapter to fail in peculiar ways, a satisfactory voltage test should indicate that the adapter is functioning correctly.

It's also possible that the power jack on the device itself is damaged from use or abuse. If possible, confirm proper operation with a **COMPATIBLE** adapter. With battery operated devices, there is usually a set of contacts that should close when the adapter is removed to connect the internal battery to the circuitry. If these don't operate properly, the device may not work off batteries (they may appear to not be charged), the AC adapter, or both. Check the jack for obvious signs of damage (cracked, loose, etc.). A squirt of contact cleaner into the jack may clear up intermittent contact problems not due to actual damage.

Pocket Wall Adapter Tester/Polarity Checker

This handy low cost device can be built into an old ball point pen case or something similar to provide a convenient indication of wall adapter type, operation, and polarity:

```
            Probe(+) o-----/\/\-----+----|>|----+---o Probe(-)
                         1K, 1/2 W  | Green LED |
                                    +----|<|----+
                                       Red LED
```

- The green LED will light up if the polarity of an adapter with a DC output agrees with the probe markings.
- The red LED will light up if the polarity of an adapter with a DC output is opposite of the probe markings.
- Both LEDs will light up if your adapter puts out AC rather than DC.
- The LED brightness can provide a rough indication of the output voltage.

Getting Inside an AC Adapter

Manufacturers come up with all sorts of creative ways of making access a challenge:

- Some are secured with screws - possibly with strange heads. If this is the case, disassembly is possible without damage, at least in principle. However, you may need to find or improvise for the special tool.
- Some are fully potted and impossible to open without dynamite. Forget it, move on with your life. :) These will feel solid and there will be no 'give' when pressing the sides.

For those that are glued:

- A hacksaw or thin file can be used to carefully cut along the glue line just deep enough so that the two halves can be popped apart. Make sure you don't rip into internal components! Gently whacking a large knife with a soft mallet may be a bit more persuasive. :)
- A vise can be used to squeeze on diagonally opposing corners which will hopefully pop the case open along the glue line (or somewhere!).

After the repair, the two halves (or pieces!) can be glued back together using something like Duco Cement or windshield sealer.

AC Adapter Repair

Although the cost of a new adapter is usually modest, repair is often so easy that it makes sense in any case.

The most common problem (and the only one we will deal with here) is the case of a broken wire internal to the cable at either the wall wart or device end due to excessive flexing of the cable.

Usually, the point of the break is just at the end of the rubber cable guard. If you flex the cable, you will probably see that it bends more easily here than elsewhere due to the broken inner conductor. If you are reasonably dextrous, you can cut the cable at this point, strip the wires back far enough to get to the good copper, and solder the ends together. Insulate completely with several layers of electrical tape. Make sure you do not interchange the two wires for DC output adapters! (They are usually marked somehow either with a stripe on the insulator, a thread inside with one of the conductors, or copper and silver colored conductors. Before you cut, make a note of the proper hookup just to be sure. Verify polarity after the repair with a voltmeter.

The same procedure can be followed if the break is at the device plug end but you may be able to buy a replacement plug which has solder or screw terminals rather than attempting to salvage the old one.

Once the repair is complete, test for correct voltage and polarity before connecting the powered equipment.

This repair may not be pretty, but it will work fine, is safe, and will last a long time if done carefully.

If the adapter can be opened - it is assembled with screws rather than being glued together - then you can run the good part of the cable inside and solder directly to the internal terminals. Again, verify the polarity before you plug in your expensive equipment.

WARNING: If this is a switching power supply type of adapter, there are dangerous voltages present inside in addition to the actual line connections. Do not touch any parts of the internal circuitry when plugged in and make sure the large filter capacitor is discharged (test with a voltmeter) before touching or doing any work on the circuit board. For more info on switching power supply repair, refer to the document: Notes on the Troubleshooting and Repair of Small Switchmode Power Supplies.

If it is a normal adapter, then the only danger when open are direct connections to the AC plug. Stay clear when it is plugged in.

AC Adapter Substitution and Equipment Damage

Those voltage and current ratings are there for a reason. You may get away with a lower voltage or current adapter without permanent damage but using a higher voltage adapter is playing Russian Roulette. Even using an adapter from a different device - even with similar ratings, may be risky because there is no real standard. A 12 V adapter from one manufacturer may put out 12 V at all times whereas one from another manufacturer may put out 20 V or more when unloaded.

A variety of types of protection are often incorporated into adapter powered equipment. Sometimes these actually will save the day. Unfortunately, designers cannot anticipate all the creative techniques people use to prove they really do not have a clue of what they are doing.

The worst seems to be where an attempt is made to operate portable devices off of an automotive electrical system. Fireworks are often the result, see below and the section on: "Automotive power".

If you tried an incorrect adapter and the device now does not work there are several possibilities (assuming the adapter survived and this is not the problem):

1. An internal fuse or IC protector blew. This would be the easiest to repair.

2. A protection diode sacrificed itself. This is usually reverse biased across the input and is supposed to short out the adapter if the polarity is reversed. However, it may have failed shorted particularly if you used a high current adapter (or automotive power).

3. Some really expensive hard to obtain parts blew up. Unfortunately, this outcome is all too common.

Some devices are designed in such a way that they will survive almost anything. A series diode would protect against reverse polarity. Alternatively, a large parallel diode with upstream current limiting resistor or PTC thermistor, and fuses, fusable resistors, or IC protectors would cut off current before the parallel diode or circuit board traces have time to vaporize. A crowbar circuit (zener to trigger an SCR) could be used to protect against reasonable overvoltage.

I inherited a Sony Discman from a guy who thought he would save a few bucks and make an adapter cord to use it in his car. Not only was the 12-15 volts from the car battery too high but he got it backwards! Blew the DC-DC converter transistor in two despite the built in reverse voltage protection and fried the microcontroller. Needless to say, the player was a loss but the cigarette lighter fuse was happy as a clam!

Moral: those voltage, current, and polarity ratings marked on portable equipment are there for a reason. Voltage rating should not be exceeded, though using a slightly lower voltage adapter will probably cause no harm though performance may suffer. The current rating of the adapter should be at least equal to the printed rating. The polarity, of course, must be correct. If connected backwards with a current limited adapter, there may be no immediate damage depending on the design of the protective circuits. But don't take chances - double check that the polarities match - with a voltmeter if necessary - before you plug it in! Note that even some identically marked adapters put out widely different open circuit voltages. If the unloaded voltage reading is more than 25-30% higher than the marked value, I would be cautious about using the adapter without confirmation that it is acceptable for your equipment. Needless to say, if you experience any strange or unexpected behavior with a new adapter, if any part gets unusually warm, or if there is any unusual odor, unplug it immediately and attempt to identify the cause of the problem.

Or, a more dramatic result of the same principles:

(From: Don Parker (tazman@yournet.com).)

A guy brought a Johnson Messenger CB to my shop a few decades back. He had been told it would run on 12 VDC *and* 115 VAC - so he tried it! I never saw so many little leads sticking up from any PCB since - that once were capacitors and top hat transistors. There was enough fluff from the caps to have the chassis rated at least R-10 :->).

Power Reversal - Better Pray

> "That's right, I reversed power and ground on a Sony XR-6000 AM/FM cassette car stereo. (12V negative ground).

> The little fellow made a stinky smell, so I assume that at least one component is cooked."

If it had not been turned on before you discovered your error, the damage may have been limited to the display and some filter caps. Then again...

The problem is that an auto battery has a very high current capacity and any fuses respond too slowly to be of much value in a situation such as this. Any capacitors and solid state components on the 12 V bus at the time power was applied are likely fried - well done.

> "Is there any hope of my repairing it? (This assumes I show more ability than I did when installing it.) Which part(s) are likely damaged?"

(From: Onat Ahmet (onat@turbine.kuee.kyoto-u.ac.jp).)

Well, based on that last statement ;-)

- **Bad:** car batteries can provide amps and amps of current (much worse than reverse connecting a wall adapter for example.)

- **Good:** The stinking might be due to a component getting too hot and vaporizing the solder paste/preserver/dust on it, but not actually giving up the ghost.

  I would find and check any fuses, or components directly in-line with or parallel to the power lines (the latter might include the IC's unfortunately...)

- **Good:** There might have been a protecting diode somewhere (but why did it stink then (^_^)

- **Neutral:** Did you disassemble it to see if there were any blackened areas/components? Smell from a close distance; I can often locate a burnt component that way even after a long time.

If not, join the happy crowd, and gut the good old stereo for parts!

Determining Voltage and Polarity of AC Adapter Powered Devices

This is often required when the original adapter is lost or misplaced or isn't labeled so you are not sure if it is the correct one for your device. It's amazing how many things like modems and phone answering machines don't list the voltage and polarity on the case - it's not like the extra printing would cost anything! While I would stop short of calling this a conspiracy, there does appear to be an industry-wide practice of leaving out key information to encourage replacement of the equipment rather than the much less costly and much less profitable repair or replacement of only the wall adapter. Information on voltage, current, and AC or DC polarity, is often missing on the equipment itself. And, absolutely totally incompatible wall adapters having similar plugs can be attached with the possible result being instant destruction of the device. This even applies to equipment from the same manufacturer! At least wall sockets are standardized - wall adapters are not.

If you are simply replacing a broken adapter with a universal type, check the label on the old one - they almost always provide this information. There are three issues: AC versus DC, the voltage, and polarity. Unfortunately, fully determining these requirements experimentally can be non-trivial. While many devices have built in protection for reverse polarity (which would probably also include putting AC into a device requiring DC), others do not and may be damaged or may at least blow an internal fuse. Few devices protect against extreme overvoltage.

If you have a multimeter, there are also some tests you can perform without opening the device but they are not foolproof. Here are some general guidelines. The more of these you can confirm, the greater the confidence of avoiding disaster.

1. The best way would be to find the information without serious testing. It may be readily available:

    - Examine the device for labels, either embossed near the power jack or on the rear or underneath such as:

      ```
      DC 5V ----     AC 12 V ~
            ____             _
      ```

    - If there is a voltage listed but no indication of AC/DC, 6 V or less is likely to be DC (and may require decent regulation; higher voltages could be either AC or DC (probably filtered but unregulated though not always).

    - A symmetric (non-polarized) jack means it is supposed to operate on AC.

    - If the device has a metal case or you can get to the metal shields on connectors, check for continuity to the power jack. This probably is the negative input (though no guarantee - some manufacturers do really strange things!).

    - Check your user manual!

    - Contact the manufacturer or their Web site.

2. The next best way would be to open it up and trace enough of the power circuitry to identify components which have obvious voltage ratings and polarities like electrolytic capacitors. There may even be labeling on the circuit board.

    - There will almost always be at least one electrolytic cap very near the power input.

    - If there is nothing between it and the power jack, then polarity will be that of the cap and you will have an upper bound on voltage (but the actual safe operating voltage will probably be considerably less).

    - If there is a diode in series with the cap, then the voltage and polarity will be as above (except for the 0.7 or so V diode drop) and the device is probably designed to operate on DC (and possibly AC but there may not be enough filtering).

    - If there is a bridge rectifier or multiple rectifier diodes between the input and any DC loads, it is probably designed to operate on AC.

- If the device also has a battery compartment and the battery powers the device the same way as the adapter (possibly with one connection going through a diode or an interlock on the power jack), then the AC adapter polarity and voltage will be the same (+/- 0.7 V or so) as the battery. However, some devices use totally different means of powering themselves with battery and AC operation!

3. If you have a multimeter for which you know the polarity of its output on the ohms ranges (VOMs may be reversed from the probes; DMMs are often the same - this can be determined by testing a diode or with another meter), then test on the low ohms range first in one direction, than the other. This is like applying a very low safe voltage to the device:

    - Open in one direction and a charging cap (resistance starts low and increases relatively slowly) indicates a series diode (protection or a rectifier). The probe polarity where the cap is charging is the correct one. (Note: once the internal caps charge up, reversing the leads again may result in an apparent open reading.)

    - A diode drop in one direction and charging cap in the other indicates a parallel protection diode. Again, the slowly charging direction is correct.

    - Symmetric behavior may indicate it is supposed to use AC. However, this could just mean that a filter cap is directly across the input and DC is required.

Anything else will probably require you do (1) or (2). And, except for manufacturer supplied information, even these are no guarantee of anything!

Once AC versus DC and polarity (if relevant) are determined, start low on voltage to see at what point the device behaves normally. Depending on design, this may be quite low compared to the recommended input voltage or very near it - no way to really know. Devices with motors and solenoids may appear to operate at relatively low voltage but fail to do the proper mechanical things reliably if at all. RF devices capable of transmitting may behave similarly when asked to transmit. Devices with more constant power requirements may operate happily at these reduced voltages. However, depending on the type of power supplies they use, running at a low voltage may also be stressful (e.g., where DC-DC converters are involved).

NOTE: Some devices with microcontrollers and/or logic will require a fast power turn-on so it may be necessary to switch off and then on for each input voltage you try for proper reset.

Again, determining the requirements from the manufacturer is best!

- Back to AC Adapters and Power Supplies Table of Contents.

AC Adapter Modifications or Enhancements

Using AC Adapters in Series for Multiple Voltages

Where a bipolar DC power supply is needed, it is possible to create this with a pair of DC output adapters in series. Each adapter must have voltage and current ratings adequate for your application. They can be used with or without external regulators (see the section: Adding an IC Regulator to a Wall Adapter or Battery. Since they are fully isolated from the AC line and each other, they can be tied together with any desired polarity and common point.

The only cautions are that if one of them is unpowered for any reason (it falls out of the AC outlet!) or the current rating of one of the adapters is exceeded, then current may be forced through the other one in the wrong direction possibly damaging its electrolytic capacitors or other components. To prevent this possibility, place a rectifier like a 1N4002 (this is 1 A, use a larger one if your adapters are really huge) in REVERSE across each output. This will bypass current safely around the internal circuitry.

The idea of using multiple adapters can be extended to even more outputs but this is left as an exercise for the student.

Using AC Adapters in Series for Higher or Lower Voltage

Wall adapters are totally isolated from everything (except possibly for a very high value resistor to one side of the AC line which for this purpose can be ignored) so using one set of wires as a common for the series connection won't blow anything.

However, obtaining an AC adapter with the proper ratings for long term use would be a good idea.

There are two cases:

1. DC output. It's probably not recommended and only the sum case (higher voltage output) is generally possible but will work (at least for testing purposes) as long as neither current rating is exceeded and both units are powered. (Else, you could end up with the wrong polarity on one of the unit's electrolytic capacitors.)

2. AC output. There should be no problem as long as the current rating of neither adapter is exceeded. Unless they are identical units, you will probably have to experiment with the phasing to get the sum or difference of the voltages WITHOUT the equipment attached!

   WARNING: If one of the adapters is not plugged in, high voltage (possibly even more than the normal line voltage) may appear on its exposed prongs due to the AC from the other adapters present on its output (being stepped up going the wrong way through the transformer). The voltage and available current may be enough to be dangerous in some cases.

   CAUTION: For the difference case, if one of the units isn't powered, you may get a HIGHER voltage than expected at the output of the series combination which may let the smoke out of your equipment. :(

Replacing Batteries With an AC Adapter

While most appliances that run off of internal batteries also include a socket for an wall adapter, this is not always the case. Just because there is no hole to plug one in doesn't necessarily mean that you cannot use one.

The type we are considering in this discussion are plug-in wall adapter that output a DC voltage (not AC transformers). This would be stated on the nameplate.

The first major consideration is voltage. This needs to be matched to the needs of the equipment. However, what you provide may also need to be well regulated for several reasons as the manufacturer may have saved on the cost of the circuitry by assuming the use of batteries:

- The maximum voltage supplied by a battery is well defined. For example, 4 AA cells provide just over 6 V when new. The design of the device may assume that this voltage is never exceeded and include no internal regulator. Overheating or failure may result immediately or down the road with a wall adapter which supplies more voltage than its nameplate rating (as most do especially when lightly loaded).

- Most wall adapters do not include much filtering. With audio equipment, this may mean that there will be unacceptable levels of hum if used direct. There are exceptions. However, there is no way of telling without actually testing the adapter under load.

- The load on the power source (batteries or adapter) may vary quite a bit depending on what the device is doing. Fresh batteries can provide quite a bit of current without their voltage drooping that much. This is not always the case with wall adapters and the performance of the equipment may suffer.

Thus, the typical universal adapter found at Radio Shack and others may not work satisfactorily. No-load voltage can be much higher than the voltage at full load - which in itself may be greater than the marked voltage. Adding an external regulator to a somewhat higher voltage wall adapter is best. See the section: Adding an IC Regulator to a Wall Adapter or Battery.

The other major consideration is current. The rating of the was adapter must be at least equal to the *maximum* current - mA or A - drawn by the device in any mode which lasts more than a fraction of a second. The best way to determine this is to measure it using fresh batteries and checking all modes. Add a safety factor of 10 to 25 percent to your maximum reading and use this when selecting an adapter.

For shock and fire safety, any wall adapter you use should be isolated and have UL approval.

- Isolation means that there is a transformer in the adapter to protect you and your equipment from direct connection to the power line. Most of the inexpensive types consist of nothing more than a transformer (and for DC types), rectifier and filter capacitor. However, if what you have weighs almost nothing and is in a tiny case, it may be meant for a specific purpose like a battery chargers or rechargeable device where human contact is not possible and may not include line isolation. But, if there is a low voltage plug with exposed contacts and/or the powered equipment has exposed shields or other parts, the compact light-weight types are actually miniaturized switchmode power supplies which are functionally equivalent to the heavier, bulkier adapters and do provide line isolation.

- UL (Underwriters Lab) approval means that the adapter has been tested to destruction and it is unlikely that a fire would result from any reasonable internal fault like a short circuit or external fault like a prolonged overload condition.

To wire it in, you can obtain a socket like those used on appliances with external adapter inputs - from something that is lying in your junk-box or a distributor like MCM Electronics. Use one with an automatic disconnect (3 terminals) if possible. Then, you can retain the optional use of the battery. Cut the wire to the battery for the side that will be the outer ring of the adapter plug and wire it in series with the disconnect (make sure the disconnected terminal goes to the battery and the other terminal goes to the equipment). The common (center) terminal goes to other side of the battery, adapter, and equipment as shown in the example below. In this wiring diagram, it is assumed that the ring is + and the center is -. Your adapter could be wired either way. Don't get it backwards!

```
                   +--+
                 X V  | (Inserting plug breaks connection at X)
Battery (+) o-------  |
Adapter (+) o---------+------------------o Equipment (Ring, +)
                       \_______
                                o===+
Battery/                            |
Adapter (-) o-----------------------+----o Equipment (Center, -)
```

WARNING: if you do not use an automatic disconnect socket, remove the battery holder or otherwise disable it - accidentally using the wall adapter with the batteries installed could result in leakage or even an explosion!

A possibly simpler alternative is to fashion a 'module' the size and shape of the battery or battery pack with screw contacts at the same locations and connect your external power supply to it. For example, a couple of pieces of wooden dowel rod about 2-1/4" long taped together with wood screws in the appropriate ends would substitute for a pair of side-by-side AA batteries. Then, you don't need to modify the Walkman or whatever at all (or at most just file a slot for the wire to exit the battery door).

Converting an AC Output Wall Adapter to DC

Where a modest source of DC is required for an appliance or other device, it may be possible to add a rectifier and filter capacitor (and possibly a regulator as well) to a wall adapter with an AC output. While many wall adapter output DC, some - modems and some phone answering machines, for example - are just transformers and output low voltage AC.

To convert such an adapter to DC requires the use of:

- Bridge rectifier - turns AC into pulsating DC.
- Filter capacitor - smooths the output reducing its ripple.
- Regulator - produces a nearly constant output voltage.

Depending on your needs, you may find a suitable wall adapter in your junk box (maybe from that 2400 baud modem that was all the rage a couple of years ago!).

The basic circuit is shown below:

```
         Bridge Rectifier   Filter Capacitor

 AC o-----+----|>|-------+---------+-----o DC (+)
         ~|              |+        |
In from   +----|<|----+  |       +_|_   Out to powered device
AC wall               |  |      C ___   or voltage regulator
Adapter   +----|>|----|--+       - |
          |           |            |
```

```
     AC o-----+----|<|----+-----------+-----o DC (-)
              ~                 -
```

Considerations:

- An AC input of Vin VRMS will result in a peak output of approximately 1.4 Vin - 1.4 V. The first factor of 1.4 results from the fact that the peak value of a sinusoid (the power line waveform) is 1.414 (sqrt(2)) times the RMS value. The second factor of 1.4 is due to the two diodes that are in series as part of the bridge rectifier. The fact that they are both about 1.4 is a total coincidence.

  Therefore, you will need to find an AC wall adapter that produces an output voltage which will result in something close to what you need. However, this may be a bit more difficult than it sounds since the nameplate rating of many wall adapters is not an accurate indication of what they actually produce especially when lightly loaded. Measuring the output is best.

- Select the filter capacitor to be at least 10,000 uF per 1000 mA of output current with a voltage rating of at least 2 x Vin. This rule of thumb will result in a ripple of less than 1 V p-p which will be acceptable for many devices or where a voltage regulator is used (but may be inadequate for some audio devices resulting in some 120 Hz hum. Use a larger or additional capacitor or a regulator in such a case.

- Suitable components can be purchased at any electronics distributor as well as Radio Shack. The bridge rectifier comes as a single unit or you can put one together from 1N400x diodes (the x can be anything from 1 to 7 for these low voltage applications). Observe the polarity for the filter capacitor!

The following examples illustrate some of the possibilities.

- Example 1: A typical modem power pack is rated at 12 VAC but actually produces around 14 VAC at modest load (say half the nameplate current rating). This will result in about 17 to 18 VDC at the output of the rectifier and filter capacitor.

- Example 2: A cordless VAC battery charger adapter might produce 6 VAC. This would result in 6 to 7 VDC at the output of the rectifier and filter capacitor.

Limiting your load to the VA ratings of the transformer should keep it from overheating. Whether you will get a decently smooth output will depend on how much filtering you have AND on the peak current available from the transformer to recharge the filter capacitors on each half-cycle. A high quality transformer (e.g. something from a manufacturer like Stancor or Thorderson that is designed with much more copper) will be much much better in this respect. A wall adapter is likely to have limited peak current and significant droop.

Adding an IC regulator to either of these would permit an output of up to about 2.5 V less than the filtered DC voltage.

Adding an IC Regulator to a Wall Adapter or Battery

For many applications, it is desirable to have a well regulated source of DC power. This may be the case when running equipment from batteries as well as from a wall adapter that outputs a DC voltage or the enhanced adapter described in the section: Converting an AC Output Wall Adapter to DC.

The following is a very basic introduction to the construction of a circuit with appropriate modifications will work for outputs in the range of about 1.25 to 35 V and currents up 1 A. This can also be used as the basis for a small general purpose power supply for use with electronics experiments.

For an arbitrary voltage between about 1.2 and 35 V what you want is an IC called an 'adjustable voltage regulator'. LM317 is one example - Radio Shack should have it along with a schematic. The LM317 looks like a power transistor but is a complete regulator on a chip.

Where the output needs to be a common value like +5 V or -12 V, ICs called 'fixed voltage regulators' are available which are preprogrammed for these. Typical ICs have designations of 78xx (positive output) and 79xx (negative output).

For example:

```
         Positive                    Negative
     Voltage Regulator           Voltage Regulator
   -----------------------     -----------------------
       7805      +5 V              7905      -5 V
       7809      +9 V              7909      -9 V
       7812     +12 V              7912     -12 V
       7815     +15 V              7915     -15 V
```

and so forth. Where these will suffice, the circuit below can be simplified by eliminating the resistors and tying the third terminal to ground. Note: pinouts differ between positive and negative types - check the datasheet!

Here is a sample circuit using the LM317:

```
                  I +-------+ O
    Vin (+) o-----+---| LM317 |---+--------------+-----o Vout (+)
                  |   +-------+   |              |
                  |       | A     /              |
                  |       |       \ R1 = 240     |
                  |       |       /              |                ___
                 _|_ C1   |       |            +_|_ C2      |_O_|  LM317
                 ___ .01  +-------+             ___ 1 uF    |   |  1 - Adjust
                  |  uF   |                    - |          |___|  2 - Output
                  |       \                      |           |||   3 - Input
                  |       / R2                   |           123
                  |       \                      |
                  |       |                      |
    Vin(-) o------+-------+----------------------+-----o Vout (-)
```

Note: Not all voltage regulator ICs use this pinout. If you are not using an LM317, double check its pinout - as well as all the other specifications.

For the LM317:

1. R2 = (192 x Vout) - 240, where R2 in ohms, Vout is in volts and must be at between 1.2 V and 35 V.

2. Vin should be at least 2.5V greater than Vout. Select a wall adapter with a voltage at least 2.5 V greater than your regulated output at full load.

   However, note that a typical adapter's voltage may vary quite a bit depending on manufacturer and load. You will have to select one that isn't too much greater than what you really want since this will add unnecessary wasted power in the device and additional heat dissipation.

3. Maximum output current is 1 A. Your adapter must be capable of supplying the maximum current safely and without its voltage drooping below the requirement in (2) above.

4. Additional filter capacitance (across C1) on the adapter's output may help (or be required) to reduce its ripple and thus the swing of its input. This may allow you to use an adapter with a lower output voltage and reduce the power dissipation in the regulator as well.

   Using 10,000 uF per *amp* of output current will result in less than 1 V p-p ripple on the input to the regulator. As long as the input is always greater than your desired output voltage plus 2.5 V, the regulator will totally remove this ripple resulting in a constant DC output independent of line voltage and load current fluctuations. (For you purists, the regulator isn't quite perfect but is good enough for most applications.)

   Make sure you select a capacitor with a voltage rating at least 25% greater than the adapter's *unloaded* peak output voltage and observe the polarity!

   Note: wall adapters designed as battery chargers may not have any filter capacitors so this will definitely be needed with this type. Quick check: If the voltage on the adapter's output drops to zero as soon as it is pulled from the wall - even with no load - it does not have a filter capacitor.

5. The tab of the LM317 is connected to the center pin - keep this in mind because the chip will have to be on a heat sink if it will be dissipating more than a watt or so. P = (Vout - Vin) * Iout.

6. There are other considerations - check the datasheet for the LM317 particularly if you are running near the limits of 35 V and/or 1 A.

More information on this topic can be found in the document: Various Schematics and Diagrams.

Equipment Power Supplies

Types of Power Supplies

See the document: Safety Guidelines for High Voltage and/or Line Powered Equipment before tackling any power supply problems!

If your equipment uses an AC adapter (wall wart), see the sections on those devices.

The power supplies built in to consumer electronic equipment are usually one of three types or a hybrid combination of these (There are no doubt others):

1. Power transformer with linear regulator using 78/79XX ICs or discrete components. The power transformer will be large and very near the AC line cord.

2. Power transformer with hybrid regulator like STK5481 or any of its cousins - multioutput with some outputs switched by power on. If it has one of these, check ECG, SK, or NTE, or post to sci.electronics.repair and someone can probably provide the pinout. Again, the power transformer will be large and very near the AC line cord.

3. Small switching power supply. Most common problems: shorted semiconductors, bad capacitors, open fusable resistors. In this case there is usually no large power transformer near the line input but a smaller transformer amidships. This is rare in audio equipment as the switching noise is difficult to keep out of the audio circuits. These are more often found found in some VCRs, TVs, monitors, fax machines, and printers.

Some comments for each type:

1. Troubleshooting is quite straightforward as the components are readily identified and it is easy to trace through from the power transformer, bridge or centertapped full wave rectifiers, regulators, caps, etc.

2. Failures of one or more of the outputs of these hybrid regulators are very common. Use ECG/STK/NTE cross reference to identify the correct output voltages. Test with power switch in both positions. Any discrepancy indicates likely problem. While an excessive load dragging down a voltage is possible, the regulator is the first suspect. Replacement cost is usually under $10.

3. Switching supplies. These are tougher to diagnose, but it is possible without service literature by tracing the circuit and checking for bad semiconductors with an ohmmeter. Common problems - dried up capacitors, shorted semiconductors, and bad solder joints. See the document: Notes on the Troubleshooting and Repair of Small Switchmode Power Supplies for more detailed information.

- Back to AC Adapters and Power Supplies Table of Contents.

Power Supply Troubleshooting

Totally Dead Power Supply (Non-Switching Type)

Don't overlook the possibility of bad solder connections or even a bad line cord or plug. Maybe Fido was hungry.

First, make sure the outlet is live - try a lamp. Even a neon circuit tester is not a 100% guarantee - the outlet may have a high resistance marginal connection.

Check for blown fuses near the line cord input. With the unit unplugged, test for continuity from the AC plug to the fuse, on/off switch and power transformer. With the power switch in the 'on' position, testing across the AC plug should result in a resistance of 1 to 100 ohms depending on the size of the equipment:

- Small AC adapter - 100 to 500 ohms.
- Large AC adapter - 10 to 100 ohms.
- VCR - 15 to 30 ohms.
- Cassette deck or CD player - 25 to 100 ohms.
- Stereo receiver or amplifier - .5 to 10 ohms.

If the fuse blew and the readings are too low, the transformer primary may be partially or totally shorted. If the resistance is infinite even directly across the primary of the power transformer, it may be open or there may be an open thermal fuse underneath the outer layer of insulation wrapping. Also see the section: Comments on Importance of Thermal Fuses and Protectors.

If the fuse blew but resistance is reasonable, try a new fuse of the proper ratings. If this blows instantly, there is still a fault in the power supply or one of its loads. See the section: About Fuses, IC Protectors, and Circuit Breakers.

If these check out, then the problem is likely on the secondary side. One or more outputs may be low or missing due to bad regulator components. A secondary winding could be open though is is less common than primary side failure as the wire (in transistorized equipment at least) is much thicker.

Low or Missing Power Supply Outputs (Non-Switching Type)

Once the line input and primary circuits have been found to be good (or at have continuity and a resistance that is reasonable, the problems is most likely in the secondary side - fuses, rectifiers, filter capacitors, regulator components, bad connections, excess load due to electronic problems elsewhere.

Depending on the type of equipment, there may be a single output of several outputs from the power supply. A failure of one of these can result in multiple systems problems depending on what parts of the equipment use what supply.

Check for bad fuses in the secondary circuits - test with an ohmmeter. (I once even found an intermittent fuse!) Try a new fuse of the same ratings. If this one blows immediately, there is a fault in the power supply or one of its loads. See the section: About Fuses, IC Protectors, and Circuit Breakers. The use of a series current limiting resistor - a low wattage light bulb, for example - may be useful to allow you to make measurements without undo risk of damage and an unlimited supply of fuses.

Locate the large electrolytic filter capacitor(s). These will probably be near the power transformer connections to the circuit board with the power supply components. Test for voltage across each of these with power on. If they are in pairs, this may be a dual polarity supply (+/-, very common in audio equipment). Sometimes, two or more capacitors are simply used to provide a higher uF rating. If you find no voltage on one of these capacitors, trace back to determine if the problem is a rectifier diode, bad connection, or bad secondary winding on the power transformer (the latter is somewhat uncommon as the wire is relatively thick, however).

Dried up electrolytic capacitors will result in excessive ripple leading to hum or reduced headroom in audio outputs and possible regulation problems as well. Test with a scope or multimeter on its AC scale (but not all multimeters have DC blocking capacitors on its AC input and these readings may be confused by the DC level). If ripple is excessive - as a guideline if it is more than 10 to 20% of the DC level - then substitute or jumper across with a good capacitor of similar uF rating and at least the same voltage rating.

If you find voltages that are lower than expected, this could be due to bad filter capacitors, an open diode or connection (one side of a full wave rectifier circuit), or excessive load which may be either in the regulator(s), if any, or driven circuitry.

Disconnect the output of the power supply from its load. If the voltage jumps up dramatically (or the fuse now survives or the series light bulb now goes out or glows dimly), then a short or excess load is likely.

If the behavior does not change substantially, the problem may be in the regulator(s). Transistors, zener diodes, resistors, and other discrete components, and IC regulators like LM317s or 7809s can be tested with an ohmmeter or by substitution. The most common failures are shorts for semiconductors, opens for resistors, and no or low output for ICs.

Where the supply uses a hybrid regulator like an STK5481, confirming proper input and then testing each output is usually sufficient to identify a failure. A defective hybrid regulator will likely provide no or very low output on one or more outputs. Confirm by disconnecting the load. Test with any on/off (logic) control in both states.

Uninterruptible Power Supplies (UPSs) and Power Inverters

CAUTION: reread safety guidelines as portions of these devices can be nasty.

Note: inexpensive UPSs and inverters generate a squarewave output so don't be surprised at how ugly the waveform appears if you look at it on a scope. This is probably normal. More sophisticated and expensive units may use a modified sinewave - actually a 3 or 5 level discrete approximation to a sinewave (instead of a 2 level squarewave). The highest quality units will generate a true sinewave using high frequency bipolar pulse width modulation. Don't expect to find this in a $100 K-Mart special, however.

A UPS incorporates a battery charger, lead-acid (usually) storage battery, DC-AC inverter, and control and bypass circuitry.

Note that if finding a UPS that provides surge protection is an important consideration, look for one that runs the output off of the battery at all times rather than bypassing the inverter during normal operation. The battery will act as a nearly perfect filter in so far as short term line voltage variations, spikes, and noise, are concerned.

A DC-AC power inverter used to run line powered equipment from an automotive battery or other low voltage source is similar to the internal inverter in a UPS.

For a unit that appears dead (and the power has not been off for more than its rated holdup time and the outlet is live), first, check for a blown fuse - external or internal. Perhaps, someone was attempting to run their microwave oven off of the UPS or inverter!

(See the section on: "Fuse post mortems" to identify likely failure mode.)

If you find one - and it is blown due to a short circuit - then there are likely internal problems like shorted components. However, if it is blown due to a modest overload, the powered equipment may simply be of too high a wattage for the UPS or inverter - or it may be defective.

Failures of a UPS can be due to:

1. Battery charging circuit - if the battery does not appear to be charging even after an extended time, measure across the battery with the unit both unplugged and plugged in. The voltage should jump up some amount with power on - when it is supposed to be charging. Disconnect the battery and try again if there is no action - the battery may be shorted totally. Check for blown fuses, smoked parts, and bad connections.

2. Battery - deteriorated or abused lead acid batteries are very common. If the battery will not charge or hold a charge, battery problems are likely. A UPS (or any kind of lead-acid battery powered equipment) that lies idle for a long time (say a year or two) without power to top off the battery will likely result in a dead - not salvageable - battery due to sulfation. Symptoms will be: voltage on battery climbs to more than 2.5 V per cell when first put on charge and even after a long charging period, the battery has essentially no capacity. If the battery voltage is at its nominal value - even when the inverter should be running from it (and there is no or low output), then there is a problem in the inverter or its connections or there is excess load.

3. Inverter - troubleshooting is similar to that required for a switchmode power supply. Common problems: shorted power semiconductors, open fusable resistors, dried up electrolytic capacitors, and bad connections. See the document: Notes on the Troubleshooting and Repair of Small Switchmode Power Supplies. A visual inspection may reveal parts that have exploded or lost their smoke.

4. Line bypass circuit (if used) - check for problems in the controller or its standby power supply, or power switchover components, and bad connections.

Here is some additional information on the basics and troubleshooting of uninterruptable power supplies. Note that the following is from someone with a 230 VAC perspective so some aspects of the line circuitry may not apply to U.S.A. models.

(From: Lex Cunningham (lextron@iinet.net.au).)

UPSs come in all shapes and sizes, from 300 VA units for PCs to 3 phase units rated into the hundreds of kVA for use in industrial applications. The most common type readers of the repair newsgroup will come across will be single phase units with ratings up to 3 kVA. These mainly see use in domestic and commercial applications to provide protection for a single PC, a small network of PCs, or a server.

Types of UPS:

There are basically two types of UPS. With the standby type, the input voltage is switched to the output under normal conditions and the control electronics monitor the incoming line. Should the incoming line fail altogether, fall below a set voltage, or rise above a set voltage, the inverter is powered up to support the load. When the line returns to normal, the inverter is turned off and the line is switched back to support the load. The marketing people use some odd terms for the standby type such as Line Interactive. What this means is that the UPS has Automatic Voltage Regulation of the output voltage. This is achieved by using boost and buck windings on the transformer. These windings are switched as necessary to maintain a relatively constant output voltage, even though the input voltage may be high or low.

The on-line type of UPS uses a dual conversion technique to deliver power to the load. The incoming line is converted to DC and then converted back to AC. The inverter runs continuously, hence the term on-line. These have the advantage of removing all of the line noise and no changeover delay. When the incoming line fails, a DC to DC converter is powered up to provide the DC rail required for the DC to AC inverter.

Power Conversion Techniques:

The standby UPS has two sub classes to describe the method of converting the battery supply to AC. The cheapest method is called quasi sine wave which uses pulse width modulation at the line frequency (50/60 Hz) to maintain the inverter output voltage. The output is basically a square wave of variable duty-cycle depending on the load. This square wave is applied to a transformer to obtain the required output voltage. To a switch mode power supply, the wave shape is not all that important.

The more expensive method is known as true sine wave. Pulse width modulation at 15 to 20 kHz is used to reconstruct a sine wave. This type of UPS is used in situations where square waves would cause overheating of electric motors. These are more complex than quasi sine wave units, and hence come at a higher price.

The on-line UPS uses high frequency PWM techniques and provides a sine wave output. The difference from the standby sine wave type is that the modern on-line inverter works directly at the line output voltage, rather than through a step up transformer.

Safety Considerations:

It can not be stressed enough that all UPS's are potential death traps. The line voltage in any country is lethal. Any voltage higher than around 50 V is considered hazardous.

DC Safety:

UPS's using a single 12 V battery can cause injury. The batteries used can supply large currents if short circuited. It is easy to lose a finger if a ring shorts the battery supply. The risk is that the ring becomes hot, causing cauterisation of the blood vessels. With no blood supply, the only solution is amputation.

The other risks of shorted batteries is the potential for the battery case to split open releasing electrolyte, and flying molten metal.

The DC supply of units in the 2 to 3 kVA range from 48 to 96 V. The 96 V units float the battery bank at 110 V, which will electrocute.

On-line units work at high voltages. In Australia, the nominal line voltage is 240 VAC which when rectified, results in power rails of plus and minus 350 VDC. That is a total of some 700 V.

AC Safety:

When working on UPS's, the use of an earth leakage circuit breaker/residual current detector, or whatever they are known as in your part of the world, has to be considered mandatory.

Other Safety:

Some manufacturers, for cost reasons, do not use line monitoring transformers. Instead, high value resistors are used to divide the line voltage to a value suitable for the control electronics. This results in a machine that is technically totally live. Keep a watch out for these ones and test before touching.

Be aware that the ground clip of an oscilloscope probe is earth. Depending on wiring rules, earth may be bonded to neutral at the main switch/fuse panel. This is true in Australia. Use an oscilloscope with differential inputs designed for the job. A suitable alternative is an add on differential input unit in conjunction with a standard scope. The design presented in Elektor Electronics around 1994 works very well and with a bandwidth of 15 MHz, nothing will be missed.

Battery Changing Procedures:

There are a couple of types of UPS that have a strict battery change procedure. Failure to follow correct procedure results in the destruction of the UPS. Both types come from Lantech of Taiwan. This is not to say that only Lantech machines behave in this way. The ALi range from the mid 90's require the battery to be disconnected, and the reservoir capacitors on the main board discharged using a 220 ohm, 5 W resistor. Before reconnecting the battery, the unit must be plugged into the line to precharge the capacitors. Failure to discharge or precharge the capacitors causes destruction of the inverter output devices. This procedure is noted on a sticker inside the unit.

The current AI-UPS range requires reservoir capacitor precharging using a 1K ohm, 1 W resistor between the battery and the main board, however it is good practice to do the discharge part as well. This procedure is only noted on 19 inch rack mount units. There is no warning on stand alone machines.

Common UPS Faults

- **UPS shuts down in backup mode:**

  The most common fault ever seen is sulphated batteries. The constant charging causes the electrolyte to dry out and the lead plates to become lead sulphate. This results in a battery that has a greatly reduced capacity resulting in the UPS shutting down on line failure. To determine a poor battery, check for swelling of the battery case, or do a load test while monitoring the battery voltage. If the battery voltage falls rapidly to below 12 volts, then it is faulty. Also, if the battery charges rapidly from below 12 volts to 13.8 volts, it is faulty. Always replace all batteries in a bank, or the new one(s) will fail quickly.

- **UPS will not start:**

  Most UPS's will not start unless there is sufficient input voltage. Assuming the fuse is not blown or circuit breaker is good, check the input cutout relay. The coils have been known to burn out.

  Even with an input voltage, the UPS will not start if the battery is flat. This can be caused by battery age, a faulty charger, or running the UPS until low voltage shutdown. If possible program the UPS to shut down at 30% remaining capacity as this increases the life of the battery and ensures there is sufficient power to restart when the line is restored.

  The Best Power (Sola in Oz) range of machines will go into fault mode at power up if an internal fault is detected. Two of the causes are flat batteries or the output relay not switching over. The 510 range has a problem with the output relay not switching over. This is caused by an electrolytic in the battery charger circuit failing. This is associated with the auxiliary winding on the transformer. The capacitor fails leaving the relay with insufficient voltage to switch, the microprocessor detects no output voltage and enters fault mode. Replacing the capacitor with a bipolar type capable of handling the high frequency ripple currents solves the problem.

Some UPS's will not work from their front panel controls as they have been programmed into a certain mode to suit shutdown software. This requires the use of a programming utility from the manufacturer to reprogram the unit.

- **UPS stays in backup mode:**

  Check the line monitoring transformer windings. In units without transformers, check the RF chokes and resistors. This particularly applies to Lantech units.

- **Other faults:**

  All faults can be traced using standard fault finding techniques. If the fault simply can not be found, take the unit to your friendly UPS service tech for an opinion. You will be charged for the work, but then the technician likes to eat as well!

Protection Devices

About Fuses, IC Protectors, and Circuit Breakers

The purpose of fuses and circuit breakers is to protect both the wiring from heating and possible fire due to a short circuit or severe overload and to prevent damage to the equipment due to excess current resulting from a failed component or improper use (i.e., excess volume to loudspeakers).

Fuses use a fine wire or strip (called the element) made from a metal which has enough resistance (more than for copper usually) to be heated by current flow and which melts at a relatively low well defined temperature. When the rated current is exceeded, this element heats up enough to melt (or vaporize). How quickly this happens depends on the extent of the overload and the type of fuse.

Fuses found in consumer electronic equipment are usually cartridge type consisting of a glass (or sometimes ceramic) body and metal end caps. The most common sizes are 1-1/4" mm x 1/4" or 20 mm x 5 mm. Some of these have wire leads to the end caps and are directly soldered to the circuit board but most snap into a fuse holder or fuse clips. Miniature types include: Pico(tm) fuses that look like green 1/4 W resistors or other miniature cylindrical or square varieties, little clear plastic buttons, etc. Typical circuit board markings are F or PR.

IC protectors are just miniature fuses specifically designed to have a very rapid response to prevent damage to sensitive solid state components including intergrated circuits and transistors. These usually are often in TO92 plastic cases but with only 2 leads or little rectangular cases about .1" W x .3" L x .2" H. Test just like a fuse. These may be designated ICP, PR, or F.

Circuit breakers may be thermal, magnetic, or a combination of the two. Small (push button) circuit breakers for electronic equipment are most often thermal - metal heats up due to current flow and breaks the circuit when its temperature exceeds a set value. The mechanism is often the bending action of a bimetal strip or disc - similar to the operation of a thermostat. Flip type circuit breakers are normally magnetic. An electro- magnet pulls on a lever held from tripping by a calibrated spring. These are not usually common in consumer equipment (but are used at the electrical service panel).

At just over the rated current, it may take minutes to break the circuit. At 10 times rated current, the fuse may blow or circuit breaker may open in milliseconds.

The response time of a 'normal' or 'rapid action' fuse or circuit breaker depends on the instantaneous value of the overcurrent.

A 'slow blow' or 'delayed action' fuse or circuit breaker allows instantaneous overload (such as normal motor starting) but will interrupt the circuit quickly for significant extended overloads or short circuits. A large thermal mass delays the temperature rise so that momentary overloads are ignored. The magnetic type breaker adds a viscous damping fluid to slow down the movement of the tripping mechanism.

Fuse Post Mortems

Quite a bit can be inferred from the appearance of a blown fuse if the inside is visible as is the case with a glass cartridge type. One advantage to the use of fuses is that this diagnostic information is often available!

A fuse which has an element that looks intact but tests open may have just become tired with age. Even if the fuse does not blow, continuous cycling at currents approaching its rating or instantaneous overloads results in repeated heating and cooling of the fuse element. It is quite common for the fuse to eventually fail when no actual fault is present.

A fuse where the element is broken in a single or multiple locations blew due to an overload. The current was probably more than twice the fuse's rating but not a dead short.

A fuse with a blackened or silvered discoloration on the glass where the entire element is likely vaporized blew due to a short circuit.

This information can be of use in directly further troubleshooting.

Fuse or Circuit Breaker Replacement

As noted, sometimes a fuse will blow for no good reason. Replace fuse, end of story. In this situation, or after the problem is found, what are the rules of safe fuse replacement? It is inconvenient, to say the least, to have to wait a week until the proper fuse arrives or to venture out to Radio Shack in the middle of the night.

Even with circuit breakers, a short circuit may so damage the contacts or totally melt the device that replacement will be needed.

Four parameters characterizes a fuse or circuit breaker:

1. Current rating - this should not be exceeded (you have heard about not putting pennies in fuse boxes, right?)

(The one exception to this rule is if all other testing fails to reveal which component caused the fuse to blow in the first place. Then, and only then, putting a larger fuse in or jumpering across the fuse **just for testing** will allow the faulty component to identify itself by smoking or blowing its top!) A smaller current rating can safely be used but depending on how close the original rating was to the actual current, this may blow immediately.

2. Voltage rating - this is the maximum safe working voltage of the circuit (including any inductive spikes) which the device will safety interrupt. It is safe to use a replacement with equal or high voltage rating.

3. Type - normal, fast blow, slow blow, etc. It is safe to substitute a fuse or circuit breaker with a faster response characteristic but there may be consistent or occasional failure mostly during power-on. The opposite should be avoided as it risks damage to the equipment as semiconductors tend to die quite quickly.

4. Mounting - it is usually quite easy to obtain an identical replacement.

   However, as long as the other specifications are met, soldering a normal 1-1/4" (3AG) fuse across a 20 mm fuse is perfectly fine, for example. Sometimes a fuse will have wire leads and be soldered directly onto the circuit board. However, your own wires can be carefully soldered to the much more common cartridge type to create a suitable replacement.

Comments on Importance of Thermal Fuses and Protectors

Like a normal fuse or circuit breaker, a thermal fuse or thermal protector provides a critical safety function. Therefore, it is extremely ill advised to just short it out if it fails. Some designs even make this option extra tempting by providing an easy way to bypass even one buried inside a power transformer - using an additional, normally unused terminal.

For testing, it is perfectly acceptable to temporarily short out the device to see if the equipment then operates normally without overheating. However, while these fuses do sometimes just fail on their own, most likely, there was another cause. If you know what it was - you were trying to charge a shorted battery pack, using your window fan to mix cement, or something was shorted externally, then the fuse served its protective function and the equipment is fine. IT SHOULD BE REPLACED WITH THE SAME TYPE or the entire transformer, motor, or whatever it was in should be replaced! This is especially critical for unattended devices. Otherwise, especially with unattended devices, you have a situation where if the overload occurred again or something else failed, the equipment could overheat to the point of causing a fire - and your insurance company may refuse to cover the claim if they find that a change was made to the circuit. And even for portable devices like blow dryers and portable power tools, aside from personal safety should the device malfunction, the thermal protector is there to prevent damage to the equipment itself - don't leave it out!

- Back to AC Adapters and Power Supplies Table of Contents.

Transformers

Common Types of Transformers

A transformer consists of a laminated iron or ferrite core and 2 or more insulated windings that are most often not connected to each other directly. If one set of windings is used as the input for AC power or an audio signal (the 'primary' winding), the voltage appearing on each of the other windings (the 'secondary' winding(s)) will be related by the ratio of the number of turns on each of the windings. However, you don't get something for nothing: The current is related by the inverse of this ratio so the power doesn't change (except due to unavoidable losses).

Transformers are used in nearly every type of electronic equipment both for power and signals, and throughout the electrical distribution network to optimize the voltage/current used on each leg of the journey from the power plant to the user.

The types we are interested in with respect to household appliances, power tools, and consumer electronic equipment are most often use to convert the AC line voltage to some other value, lower or higher:

1. Low voltage power transformer are found in AC wall adapters and electronic equipment as part of their power supplies to generate 1 or more DC voltages to run the device, recharge its batteries, etc. Their outputs are typically between 2 and 48 VAC but almost any other value is possible.

2. High voltage power transformers are found in microwave ovens, old TVs and audio equipment based on vacuum tubes, oil burner ignitions, and some neon signs. Their output can go as high as 15 kV or more.

3. Flyback (or LOPT), inverter, and other more specialized transformers are driven by a high frequency oscillator or chopper in various equipment like TVs and monitors (HV, LV, and other power supplies), PCs and some of their peripherals, electronic flash units. Note that these will NOT operate from the AC line directly and are therefore useless unless driven by a proper electronic circuit.

There are also a couple of other common types of AC line operated transformers used in servicing:

4. Isolation transformers are wound 1:1 so that the output voltage is the same as the input voltage. However, with no direct connection between windings, equipment can be tested with less risk of shock.

5. Variable transformers (or "Variac") allow the output voltage to be adjusted between 0 and full (or slightly above) line voltage which is useful for testing purposes where the behavior of a piece of equipment is being determined.

See the document: Troubleshooting of Consumer Electronic Equipment for more information on these types of transformers.

Testing a Power Transformer

Here are some simple tests to perform where you want to determine if a used (or new) power transformer with known specifications is actually good:

1. Look for obvious signs of distress. Smell it to determine if there is any indication of previous overheating, burning, etc.

2. Plug it in and check for output voltages to be reasonably close (probably somewhat high) to what you expect.

3. Leave it on for awhile. It may get anywhere from just detectable to moderately warm but not to hot to touch and it shouldn't melt down, smoke, or blow up. Needless to say, if it does any of the latter, the tests are concluded!

4. Find a suitable load based on: R = V/I from the specifications and make sure it can supply the current without overheating. The voltage should also not drop excessively between no and full load (but this depends on the design, quality of constructions, whether you got it at Radio Shack :-), etc.

Identifying the Connections on an Unknown Power Transformer

Start with a good multimeter - DMM on the lowest ohms scale or VOM on the X1 resistance range. (You will need to be able to measure down to .1 ohms for many of these.) This will permit you to map the windings.

First, identify all connections that have continuity between them. Except for the possible case of a water soaked transformer with excessive leakage, any reading less than infinity on the meter is an indication of a connection. The typical values will be between something very close to 0 ohms and 100 ohms.

Each group of connected terminals represents one winding. The highest reading for each group will be between the ends of the winding; others will be lower. With a few measurements and some logical thinking, you will be able to label the arrangement ends and taps of each winding.

Once you do this, applying a low voltage AC input (from another power transformer driven by a Variac) will enable you to determine voltage ratios. Then, you may be able to make some educated guesses as to the primary and secondary. Often, primary and secondary windings will exit from opposite sides of the transformer.

For typical power transformers, there will be two primary wires but international power transformers may have multiple taps as well as a pair or primary windings (possibly with multiple taps) for switching between 110/115/120 VAC and 220/230/240 VAC operation. Typical color codes for the primary winding(s) will be black or black with various color stripes. Almost any colors can be used for secondary windings. Stripes may indicate center tap connections but not always.

Note: for safety, use the Variac and another isolated transformer for this.

Here is a more specific example:

> "I recently purchased at a local electronics surplus store at 35volt center tap 2A transformer for a model railroad throttle (power supply). The secondary wires are red-red/yellow-red and I understand how to hook up the secondary in order to get two 17.5 volt sources. My dilemma is the primary. There are SIX black wires (black, black/red, black/blue, black/green, black/yellow, black/grey). Two of the wires were already stripped and I hooked these up to 115 VAC but no voltage on the secondary side. Does anyone have any ideas? I don't know the manufacturer, the transformer is in an enclosed case (no open windings). I also don't know if it has multiple primaries that must be connected or if it has five taps for different input voltages. Any ideas????"

Of course, I assume you did measure on the AC scale on the secondary! :-) Sorry, have to confirm the basics. My natural assumption would also be that the striped wires were the ones you needed.

Here is a suggestion:

1. Use an ohmmeter to determine which sets of primary wires are connected. The resistances will be very low but you should also be able to determine which are just taps as the resistance between them will be very low.

2. Since you already know what the secondary should be, power the secondary from a low voltage AC source like another transformer. Then measure across each pair of primary wires. You should be able to determine which are the main wires and which are the taps.

Using a combination of the above procedures should enable you to pretty fully determine what is going on. I suspect that you have a pair of primary windings that can be connected either series (for 220) or parallel (110) and a tap but who knows. Do the tests. If in doubt, don't just connect it to 110 - you could end up with a melt-down. Post your findings.

Determining Unknown Connections on International Power Transformers

Most likely, you can figure this out if you can identify the input connections.

There will be two primary windings (resistance between the two will be infinite). Each of these may also have additional taps to accommodate various slight variations in input voltage. For example, there may be taps for 110/220, 115/230, 120/240, etc.

For the U.S. (110 VAC), the two primary windings will be wired in parallel. For overseas (220 VAC) operation, they will be wired in series. When switching from one to the other make sure you get the phases of the two windings correct - otherwise you will have a short circuit! You can test for this when you apply power - leave one end of one winding disconnected and measure between these two points - there should be close to zero voltage present if the phase is correct. If the voltage is significant, reverse one of the windings and then confirm.

A multimeter on the lowest resistance scale should permit you to determine the internal arrangement of any taps on the primaries and which sets of secondary terminals are connected to each winding. This will probably need to be a DMM as many VOMs do not have low enough resistance ranges.

It is best to test with a Variac so you can bring up the voltage gradually and catch your mistakes before anything smokes.

You can then power it from a low voltage AC source, say 10 VAC from your Variac or even an AC wall adapter, to be safe and make your secondary measurements. Then scale all these voltage readings appropriately.

Determining Power (VA) Ratings of Unknown Transformers

For a transformer with a single output winding, measuring temperature rise isn't a bad way to go. Since you don't know what an acceptable temperature is for the transformer, a conservative approach is to load it - increase the current gradually - until it runs warm to the touch after an extended period (say an hour) of time.

Where multiple output windings are involved, this is more difficult since the safe currents from each are unknown.

(From: Greg Szekeres (szekeres@pitt.edu).)

Generally, the VA rating of individual secondary taps can be measured. While measuring the no load voltage, start to load the winding until the voltage drops 10%, stop measure the voltage and measure or compute the current. 10% would be a very safe value. A cheap transformer may compute the VA rating with a 20% drop. 15% is considered good. You will have to play around with it to make sure everything is OK with no overheating, etc.

(From: James Meyer (jimbob@acpub.duke.edu).)

With the open circuit voltage of the individual windings, and their DC resistance, you can make a very reasonable assumption as to the relative amounts of power available at each winding.

Set up something like a spread-sheet model and adjust the output current to make the losses equal in each secondary. The major factor in any winding's safe power capability is wire size since the volts per turn and therefore the winding's length is fixed for any particular output voltage.

Determining the Ratings of a Fried Power Transformer

A power transformer can die in a number of ways. The following are the most common:

- Primary open. This usually is the result of a power surge but could also be a short on the output leading to overheating.

  Since the primary is open, the transformer is totally lifeless.

  First, confirm that the transformer is indeed beyond redemption. Some have thermal or normal fuses under the outer layer of insulating tape or paper.

- Short in primary or secondary. This may have been the result of overheating or just due to poor manufacturing but for whatever reason, two wires are touching. One or more outputs may be dead and even those that provide some voltage may be low.

  The transformer may now blow the equipment fuse and even if it does not, probably overheats very quickly.

  First, make sure that it isn't a problem in the equipment being powered. Disconnect all outputs of the transformer and confirm that it still has nearly the same symptoms.

There are several approaches to analyzing the blown transformer and/or identifying what is needed as a replacement:

- If you have the time and patience and the transformer is not totally sealed in Epoxy or varnish, disassembling it and counting the number of turns of wire for each of the windings may be the surest approach. This isn't as bad as it sounds. The total time required from start to dumping the remains in the trash will likely be less than 20 minutes for a small power transformer.

  Remove the case and frame (if any) and separate and discard the (iron) core. The insulating tape or paper can then be pealed off revealing each of the windings. The secondaries will be the outer ones. The primary will be the last - closest to the center. As you unwind the wires, count the number of full turns around the form or bobbin.

By counting turns, you will know the precise (open circuit) voltages of each of the outputs. Even if the primary is a melted charred mass, enough of the wire will likely be intact to permit a fairly accurate count. Don't worry, an error of a few turns between friends won't matter.

Measuring the wire size will help to determine the relative amount of current each of the outputs was able to supply. The overall ratings of the transformer are probably more reliably found from the wattage listed on the equipment nameplate.

If you cannot do this for whatever reason, some educated guesswork will be required. Each of the outputs will likely drive either a half wave (one diode), full wave (2 diodes if it has a centertap), or bridge (module or 4 diodes). For the bridge, there might be a centertap as well to provide both a positive and negative output.

- You can sometimes estimate the voltage needed by looking at the components in the power supply - filter cap voltage ratings and regulators.
- The capacitor voltage ratings will give you an upper bound - they are probably going to be at least 25 to 50 percent above the PEAK of the input voltage.
- Where there are regulators, their type and ratings and/or the circuit itself may reveal what the expected output will be and thus the required input voltage to the regulators. For example, if there is a 7805 regulator chip, you will know that its input must be greater than about 7.5 V (valleys of the ripple) to produce a solid 5 V output.
- If there are no regulators, then the ICs, relays, motors, whatever, that are powered may have voltage and current ratings indicating what power supply is expected (min-max).

Transformer Troubleshooting and Repair

Transformer Fault Diagnosis

Some power transformers include a thermal fuse under the outer layers of insulation. In many cases, an overload will result in a thermal fuse opening and if you can get at it, replacement will restore the transformer to health. Also see the section: Comments on Importance of Thermal Fuses and Protectors.

Where an open thermal fuse is not the problem, aside from bad solder or crimp connections where the wire leads or terminals connect to the transformer windings, anything else will require unwrapping one or more of the windings to locate an open or short. Where a total melt-down has occurred and the result is a charred hunk of copper and iron, even more drastic measures would be required.

In principle, it would be possible to totally rebuild a faulty transformer. All that is needed is to determine the number of turns, direction, layer distribution and order for each winding. Suitable magnet (sometimes called motor wire) is readily available.

However, unless you really know what you are doing and obtain the proper insulating material and varnish, long term reliability and safety are unknown. Therefore, I would definitely recommend obtaining a proper commercial replacement if at all possible.

See the section: Rewinding Power Transformers.

However, DIY transformer construction is nothing new:

(From: Robert Blum (rfblum@worldnet.att.net).)

I have a book from the Government Printing Office . The title is: "Information for the Amateur Designer of Transformers for 25 to 60 cycle circuits" by Herbert B. Brooks. It was issued June 14, 1935 so I do not know if it is still in print. At the time I got it it cost $.10.

(From: Mark Zenier (mzenier@netcom.com).)

"Practical Transformer Design Handbook" by Eric Lowdon. Trouble is, last I checked it's out of print. Published by both Sams and Tab Professional Books.

(From: Paul Giancaterino (PAULYGS@prodigy.net).)

I found a decent article on the subject in Radio Electronics, May 1983. The article explains the basics, including how to figure what amps your transformer can handle and how to size the wiring.

Rewinding Power Transformers

Here is some information and recommendations from people who have successfully repaired power transformers that have self destructed:

(From: colin@rowec.screaming.net.)

DISCLAIMER: There is a safety aspect of mains transformers. Use this information entirely at your own risk.

I have wound and re wound several transformers. When I was first into Electronics (at about 12), I rewound a line output transformer of a colour TV. I reused the wire but I had to re insulate it by suspending it all around the garage and painting it with a special paint I had found. I would never do this again or suggest anyone else do it like this either! but it outlasted the tube.

Since then as an electronics engineer I have wound many SMPS transformers and rewound some working mains transformers to get different voltages.

If you do wind a transformer yourself you need a lot of patience and to be able to keep count of the number of turns (not as easy as it sounds) and strong fingers.

However, the mains transformers that I have come across that have blown up have been beyond repair. This is because the plastic former or bobbin usually melts with the heat that is generated by the fault current that flows when the insulation on the windings gives up. I would not attempt to try and wind a small mains transformer without the coil former as it would be too difficult to SAFELY keep the windings insulated from each other and get the required amount of wire to fit.

If the windings are severely shorted it would seem as though your transformer has suffered this fate. You would definitely have to replace all the windings.

There is of course the problem of finding out what voltage/current the windings were in the first place.

If the machine is only used at one input voltage you may be able to get away with one primary winding (where there were two before - a slight simplification but the wire will need to be slightly thicker - lower by 3 AWG numbers).

Apart from obtaining a direct replacement the best bet would be to find a transformer that has outputs that are the right voltages and sufficient current. This may be tricky and it may not fit inside the case. there are many places that sell of the shelf transformers. maybe you would need two transformers to get the right combination of voltages.

If you are very luck you might get just what you want from a junk shop. or from a piece of junk equipment.

However if you are determined to try to wind a transformer there are several possibilities.

The most critical aspect of winding a mains transformer is the primary winding as the wire used is incredibly fine on small transformers and is easily damaged or even broken and good insulation is of the utmost importance. Also there is a heck of a lot wire and it becomes impracticable unless you are prepared to set up some sort of rig. I would suggest that you consider the alternatives to winding this yourself which are :-

- Buy a kit. Maplin in the UK do these in various sizes. the primary winding comes ready wound, you just need the wire for the secondarys. It comes with the information needed to calculate the number of turns and diameter of wire to use from the voltage and current you need.

- Rewind a healthy transformer. I have done this several times. It is imperative to dismantle the transformer without damaging the primary winding insulation in any way. This is most difficult to do. Normally the 'E' and 'I' laminations are tightly packed into the bobbin and the first one to get out gets really bent up. It is unlikely that you you would be able to do this successfully on a your first try. If it is sealed with a lacquer or worse a hard setting sealant then it is almost impossible. once you have removed the laminations you have to get at the windings you are going to replace. sometimes a two piece plastic cover clips over the bobbin.

You must of course use a transformer that is big enough and has the correct primary voltage. given that the original failed and hand made transformers are never as compact as manufactured ones it would be best to use the biggest transformer that you can possible get to fit. For safety sake only use a modern transformer that is in good condition.

You may well be able to use one or more of the existing windings but you must bear in mind that each winding takes up an amount of space proportional to its current X voltage.

To work out the number of turns and size of wire in the windings you need to know the turns per volt of the new transformer. this can be found by counting one of the secondary windings and dividing by its rated voltage. The number of turns you need is this number times the voltage you want. The size of wire is determined by the current rating. use the wire with the same area per amp as the existing winding. The ends of the windings must be terminated properly. Use enameled copper wire. the enamel might need to be scraped of to enable soldering unless it is the self fluxing type and you have a very hot soldering iron. usually there are tags to solder the ends to.

Also, if it is in something like a tape recorder it most probably needs shielding.

It is up to you to ensure that the finished transformer is safe. The best way to test the insulation is to test with a high voltage (a few kV) between primary and secondary and then between the core and each winding and check there is no leakage current. with mains applied check that there is correct voltages at the outputs. check that the transformer does not get too hot. All transformers get hot, some too hot to touch, but if after several hours its so hot that you skin sticks to it when you touch it it wont last very long !!

There are various places to get the EC wire and junk transformers, a search on the internet would be a good place to start.

(From: Bill Rothanburg (william.rothanburg@worldnet.att.net).)

I've done this. It was more of an intellectual challenge, rather than something practical, but it can be done. Some requirements:

- A transformer which can be easily disassembled. If the transformer is saturated with varnish, expect problems.
- A lot of patience.
- A very good memory.
- A lot of patience.
- Reasonably good mechanical skills.

I had a relatively easy transformer to work with - single primary, dual secondaries. The windings had not been saturated with varnish, so I was able to unwind them COUNTING THE TURNS. Did I mention that this required a great deal of patience? I was able to determine the wire gauge from the old windings.

The transformer had overheated to the point the plastic bobbin was garbage. I was able to fabricate a replacement using fish paper and lots of varnish.

To assist in rewinding I built a "tool" to help - Actually a crank through a piece of wood. The bobbin was held in place by a couple of nuts and spacers. The actual rewinding was the easiest part of the process.

If I were to try this again, I would definitely use a thermal protector in the transformer.

Batteries and Battery Packs

Battery Technology

The desire for portable power seems to be increasing exponentially with the proliferation of notebook and palmtop computers, electronic organizers, PDAs, cellular phones and faxes, pagers, pocket cameras, camcorders and audio cassette recorders, boomboxes - the list is endless.

Two of the hottest areas in engineering these days are in developing higher capacity battery technologies (electrochemical systems) for rechargeable equipment and in the implementation of smart power management (optimal charging and high efficiency power conversion) for portable devices. Lithium and Nickel Metal Hydride are among the more recent additions to the inventory of popular battery technologies. A variety of ICs are now available to implement rapid charging techniques while preserving battery life. Low cost DC-DC converter designs are capable of generating whatever voltages are required by the equipment at over 90% efficiency

However, most of the devices you are likely to encounter still use pretty basic battery technologies - most commonly throwaway Alkaline and Lithium followed by rechargeable Nickel Cadmium or Lead-Acid. The charging circuits are often very simple and don't really do the best job but it is adequate for many applications.

For more detailed information on all aspects of battery technology, see the articles at:

- Sci.Electronics Battery FAQs

Many major battery manufacturers have extensive technical information on their Web sites, though not all of it may be unbiased.

There is more on batteries than you ever dreamed of ever needing. The sections below represent just a brief introduction.

Battery Basics

A battery is, strictly speaking, made up of a number of individual cells (most often wired in series to provide multiples of the basic cell voltage for the battery technology - 1.2, 1.5, 2.0, or 3.0 V are most common). However, the term is popularly used even for single cells.

Four types of batteries are typically used in consumer electronic equipment:

1. Alkaline - consisting of one or more primary cells with a nominal terminal voltage of 1.5 V. Examples are AAA, AA, C, D, N, 9V ('transistor'), lantern batteries (6V or more), etc. There are many other available sizes including miniature button cells for specialty applications like clocks, watches, calculators, and cameras. In general recharging of alkaline batteries is not practical due to their chemistry and construction. Exceptions which work (if not entirely consistently as of this writing) are the rechargeable Alkalines (e.g., 'Renewals'). Advantages of alkalines are high capacity and long shelf life. These now dominate the primary battery marketplace largely replacing the original carbon-zinc and heavy duty types. Note that under most conditions, it not necessary to store alkaline batteries in the 'fridge to obtain maximum shelf life.

2. Lithium - these primary cells have a much higher capacity than alkalines. The terminal voltage is around 3

volts per cell. These are often used in cameras where their high cost is offset by the convenience of long life and compact size. Lithium batteries in common sizes like 9V are beginning to appear. In general, I would not recommend the use of lithiums for use in applications where a device can be accidentally left on - particularly with kids' toys. Your batteries will be drained overnight whether a cheap carbon zinc or a costly lithium. However, for smoke alarms, the lithium 9V battery (assuming they hold up to their longevity claims) is ideal as a 5-10 year service life without attention can be expected.

3. Nickel Cadmium (NiCd) - these are the most common type of rechargeable battery technology use in small electronic devices. They are available in all the poplar sizes. However, their terminal voltage is only 1.2 V per cell compared to 1.5 V per cell for alkalines (unloaded). This is not the whole story, however, as NiCds terminal voltage holds up better under load and as they are discharged. Manufacturers claim 500-1000 charge-discharge cycles but expect to achieve these optimistic ratings only under certain types of applications. In particular it is usually recommended that NiCds should not be discharged below about 1 V per cell and should not be left in a discharged state for too long. Overcharging is also an enemy of NiCds and will reduce their ultimate life. An electric shaver is an example of a device that will approach this cycle life as it is used until the battery starts to poop out and then immediately put on charge. If a device is used and then neglected (like a seldom used printing calculator), don't be surprised to find that the NiCd battery will not charge or will not hold a charge next time the calculator is used.

4. Lead Acid - similar to the type used in your automobile but generally specially designed in a sealed package which cannot leak acid under most conditions. These come in a wide variety of capacities but not in standard sizes like AA or D. They are used in some camcorders, flashlights, CD players, security systems, emergency lighting, and many other applications. Nominal terminal voltage is 2.0 V per cell. These batteries definitely do not like to be left in a discharged condition (even more so than NiCds) and will quickly become unusable if left that way for any length of time.

Battery Chargers

The (energy storage) capacity, C, of a battery is measured in ampere hours denoted a A-h (or mA-h for smaller types). The charging rate is normally expressed as a fraction of C - e.g., .5 C or C/2.

In most cases, trickle charging at a slow rate - C/100 to C/20 - is easier on batteries. Where this is convenient, you will likely see better performance and longer life. Such an approach should be less expensive in the long run even if it means having extra cells or packs on hand to pop in when the others are being charged. Fast charging is hard on batteries - it generates heat and gasses and the chemical reactions may be less uniform.

Each type of battery requires a different type of charging technique.

1. NiCd batteries are charged with a controlled (usually constant) current. Fast charge may be performed at as high as a .5-1C rate for the types of batteries in portable tools and laptop computers. (C here is the amp-hour capacity of the battery. A .5C charge rate for a 2 amp hour battery pack would use a current equal to 1 A, for example.) Trickle charge at a 1/20-1/10C rate. Sophisticated charges will use a variety of techniques to sense end-of-charge. Inexpensive chargers (and the type in many cheap consumer electronics devices) simply trickle charge at a constant current.

   Rapid chargers for portable tools, laptop computers, and camcorders, do at least sense the temperature rise which is one indication of having reached full charge but this is far from totally reliable and some damage is probably unavoidable as some cells reach full charge before others due to slight unavoidable differences in capacity. Better charging techniques depend on sensing the slight voltage drop that occurs when full charge is reached but even this can be deceptive. The best power management techniques use a combination of sensing and precise control of charge to each cell, knowledge about the battery's characteristics, and state of charge.

While slow charging is better for NiCds, long term trickle charging is generally not recommended.

Problems with simple NiCd battery chargers are usually pretty easy to find - bad transformer, rectifiers, capacitors, possibly a regulator. Where temperature sensing is used, the sensor in the battery pack may be defective and there may be problems in the control circuits as well. However, more sophisticated power management systems controlled by microprocessors or custom ICs and may be impossible to troubleshoot for anything beyond obviously bad parts or bad connections.

2. Lead acid batteries are charged with a current limited but voltage cutoff technique. Although the terminal voltage of a lead-acid battery is 2.00 V per cell nominal, it may actually reach more than 2.5 V per cell while charging. For an automotive battery, 15 V is still within the normal range of voltages to be found on the battery terminals when the engine (and alternator) are running.

   A simple charger for a lead-acid battery is simply a stepped down rectified AC source with some resistance to provide current limiting. The current will naturally taper off as the battery voltage approaches the peaks of the charging waveform. This is how inexpensive automotive battery chargers are constructed. For small sealed lead-acid batteries, an IC regulator may be used to provide current limited constant voltage charging. A 1 A (max) charger for a 12 V battery may use an LM317, 3 resistors, and two capacitors, running off of a 15 V or greater input supply.

   Trickle chargers for lead-acid batteries are usually constant voltage and current tapers off as the battery reaches full charge. Therefore, leaving the battery under constant charge is acceptable and will maintain it at the desired state of full charge.

   Problems with lead-acid battery chargers are usually pretty easy to diagnose due to the simplicity of most designs.

Dave's Comments on Building Charger for Small Lead-Acid Batteries

The following applies to the sort of lead-acid batteries found in some camcorders and other portable equipment:

(From: Dave Martindale (davem@cs.ubc.ca).)

The simple way is to build a power supply that outputs 13.8 volts regulated, with a current limit of 0.5 A. 13.8 V can be left connected to the battery forever without damage - this is called a float charge. The 0.5 A current limit protects the battery from drawing too much current and overheating if it's been deeply discharged. This sort of charger will get the battery back up to 80% charge within a few hours, so it's fine for most uses.

However, when designing it, make sure the charger doesn't self-destruct if the input voltage goes away (due to AC power failure) while still connected to the battery. With a standard series regulator, when the input power fails the whole battery voltage gets applied to the base- emitter junction of the output transistor in reverse. Many transistors are only specified to withstand about 6 V reverse base-emitter voltage, so with this design your charger will be toast at the first power failure.

If you want higher-performance charging, there are special charge controller chips that provide 3 or more charge phases. They are:

- Constant current charge at maximum safe current (see battery spec sheet) until the voltage rises to about 14.5 V.
- Constant voltage charge at 14.5 V until the current drops to a fraction of the initial current limit.
- Float charge at 13.65 V after that.

By using the 14.5 V instead of 13.8 V for the initial charge voltage, this type of charger gets the battery back up to 90% charged in considerably less time. But if you only care about charging overnight, you don't need the extra complexity.

On the other hand, NiCd batteries can safely be charged in less than an hour with suitable electronics. Lead-acid simply can't be recharged that fast.

Substituting NiCds for Alkalines

First note that rechargeable batteries are NOT suitable for safety critical applications like smoke detectors unless they are used only as emergency power fail backup (the smoke detector is also plugged into the AC line) and are on continuous trickle charge). NiCds self discharge (with no load) at a rate which will cause them to go dead in a month or two.

For many toys and games, portable phones, tape players and CD players, and boomboxes, TVs, palmtop computers, and other battery gobbling gadgets, it may be possible to substitute rechargeable batteries for disposable primary batteries. However, NiCds have a lower terminal voltage - 1.2V vs. 1.5V - and some devices will just not be happy. In particular, tape players may not work well due to this reduced voltage not being able to power the motor at a constant correct speed. Manufacturers may specifically warn against their use. Flashlights will not be as bright unless the light bulb is also replaced with a lower voltage type. Other equipment may perform poorly or fail to operate entirely on NiCds. When in doubt, check your instruction manual. And, there is a slight, but non-zero chance that some equipment may actually be damaged. This might occur if its design assumed something about the internal resistance of the batteris; the resistance is much lower for NiCds than Alkalines.

Can a Large Electrolytic Capacitor be Substituted for a NiCd?

The quick answer is: probably not. The charger very likely assumes that the NiCds will limit voltage. The circuits found in many common appliances just use a voltage source significantly higher than the terminal voltage of the battery pack through a current limiting resistor. If you replace the NiCd with a capacitor and the voltage will end up much higher than expected with unknown consequences. For more sophisticated chargers, the results might be even more unpredictable.

Furthermore, even a SuperCap cannot begin to compare to a small NiCd for capacity. A 5.5 V 1 F (that's Farad) capacitor holds about 15 W-s of energy which is roughly equivalent to a 5 V battery of 3 A-s capacity - less than 1 mA-h. A very tiny NiCd pack is 100 mA-h or two orders of magnitude larger.

Determining the Actual Capacity of a NiCd Battery Pack

When a battery pack is not performing up to expectations or is not marked in terms of capacity, here are some comments on experimentally determining the A-h rating.

When laying eggs, start with a chicken. Actually, you have to estimate the capacity so that charge and discharge rates can be approximated. However, this is usually easy to do with a factor of 2 either way just be size:

Size of cells	Capacity range, A-h
AAA	.2 - .4
AA	.4 - 1
C	1 - 2
D	1 - 5
Cordless phone	.1 - .3
Camcorder	1 - 3+
Laptop computer	1 - 5+

First, you must charge the battery fully. For a battery that does not appear to have full capacity, this may be the only problem. Your charger may be cutting off prematurely due to a fault in the charger and not the battery. This could be due to dirty or corroded contacts on the charger or battery, bad connections, faulty temperature sensor or other end-of-charge control circuitry. Monitoring the current during charge to determine if the battery is getting roughly the correct A-h to charge it fully would be a desirable first step. Figure about 1.2 to 1.5 times the A-h of the battery capacity to bring it to full charge.

Then discharge at approximately a C/20 - C/10 rate until the cell voltages drops to about 1 V (don't discharge until flat or damage may occur). Capacity is calculated as average current x elapsed time since the current for a NiCd will be fairly constant until very near the end.

NiCd Batteries and the Infamous 'Memory Effect'

Whether the NiCd 'memory effect' is fact or fiction seems to depend on one's point of view and anecdotal evidence. What most people think is due to the memory effect is more accurately described as voltage depression - reduced voltage (and therefore, reduced power and capacity) during use.

(The next section is from: Bob Myers (myers@fc.hp.com) and are based on a GE technical note on NiCd batteries.)

The following are the most common causes of application problems wrongly attributed to 'memory':

1. Cutoff voltage too high - basically, since NiCds have such a flat voltage vs. discharge characteristic, using voltage sensing to determine when the battery is nearly empty can be tricky; an improper setting coupled with a slight voltage depression can cause many products to call a battery "dead" even when nearly the full capacity remains usable (albeit at a slightly reduced voltage).

2. High temperature conditions - NiCds suffer under high-temp conditions; such environments reduce both the charge that will be accepted by the cells when charging, and the voltage across the battery when charged (and the latter, of course, ties back into the above problem).

3. Voltage depression due to long-term overcharge - Self-explanatory. NiCds can drop 0.1-0.15 V/cell if

exposed to a long-term (i.e., a period of months) overcharge. Such an overcharge is not unheard-of in consumer gear, especially if the user gets in the habit of leaving the unit in a charger of simplistic design (but which was intended to provide enough current for a relatively rapid charge). As a precaution, I do NOT leave any of my NiCd gear on a charger longer than the recommended time UNLESS the charger is specifically designed for long-term "trickle charging", and explicitly identified as such by the manufacturer.

4. There are a number of other possible causes listed in a "miscellaneous" category; these include -

   - Operation below 0 degrees C.
   - High discharge rates (above 5C) if not specifically designed for such use.
   - Inadequate charging time or a defective charger.
   - One or more defective or worn-out cells. They do not last forever.

   To close with a quote from the GE note:

   > "To recap, we can say that true 'memory' is exceedingly rare. When we see poor battery performance attributed to 'memory', it is almost always certain to be a correctable application problem. Of the problems noted above, Voltage Depression is the one most often mistaken for 'memory'.....

   This information should dispel many of the myths that exaggerate the idea of a 'memory' phenomenon."

Memory Effect in NiMH Batteries?

The party line is that Nickel-Metal-Hydride batteries do not have any memory effect. Perhaps, perhaps not. See HiMH Batteries, Memory, and Thermal Runaway for one person's test results and other information.

Care and Feeding of NiCds

Here are six guidelines to follow which will hopefully avoid voltage depression or the memory effect or whatever:

(Portions of the following guidelines are from the NiCd FAQ written by: Ken A. Nishimura (KO6AF))

1. DON'T deliberately discharge the batteries to avoid memory. You risk reverse charging one or more cell which is a sure way of killing them.

2. DO let the cells discharge to 1.0V/cell on occasion through normal use.

3. DON'T leave the cells on trickle charge for long times, unless voltage depression can be tolerated.

4. DO protect the cells from high temperature both in charging and storage.

5. DON'T overcharge the cells. Use a good charging technique. With most inexpensive equipment, the charging circuits are not intelligent and will not terminate properly - only charge for as long as recommended in the user manual.

6. DO choose cells wisely. Sponge/foam plates will not tolerate high charge/discharge currents as well as

sintered plate. Of course, it is rare that this choice exists.

Author's note: I refuse to get involved in the flame wars with respect to NiCd battery myths and legends --- sam.

Why There Will Never Actually be Closure on This Topic

(From: Mark Kinsler (kinsler@froggy.frognet.net).)

All of which tends to support my basic operating theory about the charging of nickel-cadmium batteries:

1. Man is born in sin and must somehow arrange for the salvation of his immortal soul.

2. All nickel-cadmium batteries must be recharged.

3. There is no proper method of performing either task (1) or task (2) to the satisfaction of anyone.

Nickel Cadmium Versus Nickel-Metal-Hydride in a Nutshell

NiCds are inexpensive, reliable, and easy to charge, but may suffer from voltage depression (what people call the memory effect) from repeated shallow discharge cycles.

NiMHs have slightly higher capacity and no memory effect but have higher initial cost and are more sensitive to overcharging. Must be used with compatible charger.

Randy's Notes on First Aid for NiCd Battery Packs

CAUTION: Opening these battery packs will of course void any warranty but you knew that. Also, make notes of exactly how the cells and anything else inside is arranged. Improper reassembly can result in damage to equipment and/or risk of overheating should cells short inside the pack due to lack of or misplaced insulation. Under no circumstances should all thermal switches be removed - not only are they a safety device to prevent excessive temperatures but may also be part of the charging circuit. So, if they are removed, your next charge may be your last! I'd highly recommend that all of them be replaced (from another pack as a last resort) and installed in exactly the same positions they were originally.

(From: Randolph Miller (randolph.miller2@verizon.net).)

Many "name brand" camcorder and other similar battery packs contain two or even 3 thermal switches (those rectangular, un-identifiable, wired between the cells). They contain a bimetal strip operating a set of contacts which open at a preset temperature. Often only one of these will fail, resulting in a $40 NiCad that won't charge. Since these little suckers are pricey if ya kind find them, a safe and cheap fix, is to test the thermal switches for continuity (they should be closed at room temp) and remove the defective one. If needed move the other, or at least one, to the mid-point of the cells series. If a battery pack has 8 separate cells, (i.e.: a 9.6 V VHS-C camera pack) the thermal switch should be wired between the 4th and 5th, and as far away from the charging contacts as possible. The extra switches were added as a safety factor but since the average one is designed to open at 87°C, there is no fire hazard so long as the pack is re-sealed after working on it.

A quick fix for a NiCad pack left on the dashboard. Since good ol' solar power can heat a battery pack to the point where the thermal protection can open (and even warp a case) you can be stuck at the soccer game with what seems like dead batteries. The trick is to drop the temp below 87°C. Wrap the battery in plastic so the contacts won't get wet, and stick it in the cooler with the kids lunch and your six-pack. A few minutes and the thermistor should close. letting the batter work normally. Also, if the cord is long enough, never recharge a NiCad inside the car. Place the battery and charger under the car, in the shade, so it doesn't heat quickly and will get a full charge.

Identifying Technology of Unmarked Battery Packs

Since the nominal (rated) voltages for the common battery technologies differ, it is often possible to identify which type is inside a pack by the total output voltage:

- NiCd packs will be a multiple of 1.2 V.
- Lead-acid packs will be a multiple of 2.0 V.
- Alkaline packs will be a multiple of 1.5.

Note that these are open circuit voltages and may be very slightly higher when fully charged or new.

Therefore, it is generally easy to tell what kind of technology is inside a pack even if the type is not marked as long as the voltage is marked. Of course, there are some - like 6 V that will be ambiguous.

Powering LEDs with Batteries

LEDs look like diodes with a high forward voltage drop. Above the that voltage, the incremental resistance is very low and without current limiting, the current would be critically dependent on the exact voltage of the power source. Most of the time, they are spec'd at a particular maximum current and need some means to limit the current to that value based on the input voltage. Some devices may depend on the internal resistance of the batteries to provide the current limiting - this is a poor approach and depends greatly on the type and capacity of the batteries being used. Most common is just a resistor but this provides no regulation and poor efficiency. Better designs (used in LED flashlights) will use a DC to pulse inverter with regulation achieving constant light output regardless of battery state-of-charge and high efficiency. LEDs can usually withstand short high current pulses and this allows the circuit to be designed with low losses.

The specifications for LEDs you see in electronics distributor's catalogs may look the same as those for incandescent lamps but they are not. Incandescent lamps provide their own current limiting; LEDs do not. It's possible to luck out and happen to have a given LED work without current limiting with a particular set of batteries but it hardly an acceptable design approach. Slight variations in battery parameters will result in gross changes in light intensity and possible shortening of life or outright destruction of the LED.

Battery Problem Troubleshooting and Repair

Problems with Battery Operated Equipment

For primary batteries like Alkalines, first try a fresh set. For NiCds, test across the battery pack after charging overnight (or as recommended by the manufacturer of the equipment). The voltage should be 1.2 x n V where n is the number of cells in the pack. If it is much lower - off by a multiple of 1.2 V, one or more cells is shorted and will need to be replaced or you can attempt zapping it to restore the shorted cells. See the section: Zapping NiCds to Clear Shorted Cells. Attempt at your own risk!

If the voltage drops when the device is turned on or the batteries are installed - and the batteries are known to be good - then an overload may be pulling the voltage down.

Assuming the battery is putting out the proper voltage, then a number of causes are possible:

1. Corroded contacts or bad connections in the battery holder.
2. Bad connections or broken wires inside the device.
3. Faulty regulator in the internal power supply circuits. Test semiconductors and IC regulators.
4. Faulty DC-DC inverter components. Test semiconductors and other components.
5. Defective on/off switch (!!) or logic problem in power control.
6. Other problems in the internal circuitry.

NiCd Battery Pack Will Not Hold a Charge

This applies if the pack appears to charge normally and the terminal voltage immediately after charging is at least 1.2 x n where n is the number of cells in the pack but after a couple of days, the terminal voltage has dropped drastically. For example, a 12 V pack reads only 6 V 48 hours after charging without being used.

What is most likely happening is that several of the NiCd cells have high leakage current and drain themselves quite rapidly. If they are bad enough, then a substantial fraction of the charging current itself is being wasted so that even right after charging, their capacity is less than expected. However, in many cases, the pack will deliver close to rated capacity if used immediately after charging.

If the pack is old and unused or abused (especially, it seems, if it is a fast recharge type of pack), this is quite possible. The cause is the growth of fine metallic whiskers called dendrites that partially shorts the cell(s). If severe enough, a dead short is created and no charge at all is possible.

Sometimes this can be repaired temporarily at least by 'zapping' using a large charged capacitor to blow out the whiskers or dendrites that are causing the leakage (on a cell-by-cell basis) but my success on these types of larger or high charge rate packs such as used in laptop computers or camcorders has been less than spectacular. See the section: Zapping NiCds to Clear Shorted Cells.

What is This Thing in my NiCd Battery Pack?

In addition to the NiCd cells, you will often find one or more small parts that are generally unrecognizable. Normally, you won't see these until you have a problem and, ignoring all warnings, open the pack.

If it is a little rectangular silver or plastic box in series with one of the positive or negative terminals of the pack, it is probably a thermostat and is there to shut down the charging or discharging if the temperature of the pack rises too high. (The manufacturer name "Klixon" would be a dead giveaway to identity. Izuzu also makes these things.) If it tests open at room temperature, it is bad. With care, you can safely substitute a low value resistor or auto tail light bulb and see if the original problem goes away or at least the behavior changes. However, if there is a dead short somewhere, that device may have sacrificed its life to protect your equipment or charger and going beyond this (like shorting it out entirely) should be done with extreme care. These may be either mechanical (bimetal strip/contacts) or solid state (Polyfuse(tm) - increases resistance with overcurrent).

If it looks like a small diode or resistor, it could be a temperature sensing thermistor which is used by the charger to determine that the cells are heating which in its simple minded way means the cells are being overcharged and it is should quit charging them. You can try using a resistor in place of the thermistor to see if the charger will now cooperate. Try a variety of values while monitoring the current or charge indicators. However, the problem may actually be in the charger controller and not the thermistor. The best approach is to try another pack.

It could be any of a number of other possible components but they all serve a protective and/or charge related function.

Of course, the part may be bad due to a fault in the charger not shutting down or not properly limiting the current as well.

Zapping NiCds to Clear Shorted Cells

Nickel-Cadmium batteries that have shorted cells can sometimes be rejuvenated - at least temporarily - by a procedure affectionately called 'zapping'.

The cause of these bad NiCd cells is the formation of conductive filaments called whiskers or dendrites that pierce the separator and short the positive and negative electrodes of the cell. The result is either a cell that will not take a charge at all or which self discharges in a very short time. A high current pulse can sometimes vaporize the filament and clear the short.

The result may be reliable particularly if the battery is under constant charge (float service) and/or is never discharged fully. Since there are still holes in the separator, repeated shorts are quite likely especially if the battery is discharged fully which seems to promote filament formation,

I have used zapping with long term reliability (with the restrictions identified above) on NiCds for shavers, Dustbusters, portable phones, and calculators.

WARNING: There is some danger in the following procedures as heat is generated. The cell may explode! Take appropriate precautions and don't overdo it. If the first few attempts do not work, dump the battery pack.

Attempt sapping at your own risk!!!

You will need a DC power supply and a large capacitor - one of those 70,000 uF 40 V types used for filtering in multimegawatt geek type automotive audio systems, for example. A smaller capacitor can be tried as well.

Alternatively, a you can use a 50 to 100 A 5 volt power supply that doesn't mind (or is protected against) being overloaded or shorted.

Some people recommend the use of a car battery for NiCd zapping. DO NOT be tempted - there is nearly unlimited current available and you could end with a disaster including the possible destruction of that battery, your NiCd, you, and anything else that is in the vicinity.

OK, you have read the warnings:

Remove the battery pack from the equipment. Gain access to the shorted cell(s) by removing the outer covering or case of the battery pack and test the individual cells with a multimeter. Since you likely tried charging the pack, the good cells will be around 1.2 V and the shorted cells will be exactly 0 V. You must perform the zapping directly across each shorted cell for best results.

Connect a pair of heavy duty clip leads - #12 wire would be fine - directly across the first shorted cell. Clip your multimeter across the cell as well to monitor the operation. Put it on a high enough scale such that the full voltage of your power supply or capacitor won't cause any damage to the multimeter.

Wear your eye protection!!!

1. Using the large capacitor:

    - Charge the capacitor from a current limited 12-24 V DC power supply.

    - Momentarily touch the leads connected across the shorted cell to the charged capacitor, + to +, - to -. CAUTION: Polarity is critical - do it backwards and you will make the problem worse, probably terminal. There will be sparks. The voltage on the cell may spike to a high value - up to the charged voltage level on the capacitor. The capacitor will discharge almost instantly.

2. Using the high current power supply:

    - Turn on the supply.

    - Momentarily touch the leads connected across the shorted cell to the power supply output, + to +, - to -. CAUTION: Polarity is critical - do it backwards and you will make the problem worse, probably terminal. There will be sparks. DO NOT maintain contact for more than a couple of seconds. The NiCd may get warm! While the power supply is connected, the voltage on the cell may rise to anywhere up to the supply voltage.

Now check the voltage on the (hopefully previously) shorted cell.

If the dendrites have blown, the voltage on the cell should have jumped to anywhere from a few hundred millivolts to the normal 1 V of a charged NiCd cell. If there is no change or if the voltage almost immediately decays back to zero, you can try zapping couple more times but beyond this is probably not productive.

If the voltage has increased and is relatively stable, immediately continue charging the repaired cell at the maximum SAFE rate specified for the battery pack. Note: if the other cells of the battery pack are fully charged as is likely if you had attempted to charge the pack, don't put the entire pack on high current charge as this will damage the other cells through overcharging.

One easy way is to use your power supply with a current limiting resistor connected just to the cell you just zapped. A 1/4 C rate should be safe and effective but avoid overcharging. Then trickle charge at the 1/10 C rate for several hours. (C here is the amp-hour capacity of the cell. Therefore, a 1/10 C rate for a 600 mA NiCd is 50 mA.)

This works better on small cells like AAs than on C or D cells since the zapping current requirement is lower. Also, it seems to be more difficult to reliably restore the quick charge type battery packs in portable tools and laptop computers that have developed shorted cells (though there are some success stories).

My experience has been that if you then maintain the battery pack in float service (on a trickle charger) and/or make sure it never discharges completely, there is a good chance it will last. However, allow the bad cells to discharge to near 0 volts and those mischievous dendrites will make their may through the separator again and short out the cell(s).

Tom's Comments on NiCd Care and Feeding

(From: Tom Lamb (tlamb@gwe.net).)

- Measuring NiCd capacity - I use a very simple/effective system. Put a 2.5 ohm resistor across the contacts of a cheap travel analog clock, which will time the rundown. It is quite consistent for good cells. A good typical AA NiCd will run one hour.

- NiCd zapping - I use a 1 ohm power resistor in series with a car battery, though a series headlight will also work. I charge for about 30 secs or until warm, which will clear the whisker and put in enough charge to see if the cell is salvageable.

Battery Juice and Corroded Contacts

Unless you have just arrived from the other side of the galaxy (where such problems do not exist), you know that so-called 'leak-proof' batteries sometimes leak. This is a lot less common with modern technologies than with the carbon-zinc cells of the good old days, but still can happen. It is always good advice to remove batteries from equipment when it is not being used for an extended period of time. Dead batteries also seem to be more prone to leakage than fresh ones (in some cases because the casing material is depleted in the chemical reaction which generates electricity and thus gets thinner or develops actual holes).

In most cases, the actual stuff that leaks from a battery is not 'battery acid' but rather some other chemical. For example, alkaline batteries are so called because their electrolyte is an alkaline material - just the opposite in reactivity from an acid. Usually it is not particularly reactive (but isn't something you would want to eat).

The exception is the lead-acid type where the liquid inside is sulfuric acid of varying degrees of strength depending on charge. This is nasty and should be neutralized with an alkaline material like baking soda before being cleaned up. Fortunately, these sealed lead-acid battery packs rarely leak (though I did find one with a scary looking bulging case, probably due to overcharging - got rid of that is a hurry).

Scrape dried up battery juice from the battery compartment and contacts with a plastic or wooden stick and/or wipe any liquid up first with a dry paper towel. Then use a damp paper towel to pick up as much residue as possible. Dispose of the dirty towels promptly.

If the contacts are corroded, use fine sandpaper or a small file to remove the corrosion and brighten the metal. Do not an emery board or emery paper or steel wool as any of these will leave conductive particles behind which will be difficult to remove. If the contacts are eaten through entirely, you will have to improvise alternate contacts or obtain replacements. Sometimes the corrosion extends to the solder and circuit board traces as well and some additional repairs may be needed - possible requiring disassembly to gain access to the wiring.

Exploding Batteries - These Things Really Happen

(From: Greg Raines (ghr@ix.netcom.com).)

When I was about 10 years old I was sitting in my dad's driveway in a '65 Plymouth Fury III station wagon while he disconnected the trickle charger from the '67 Fiat in the garage. I heard a pop and saw my dad throw his hands over his face, run to the back door and start kicking it to get someone to open it. Fortunately he wasn't injured. But it was an eye opener. It was probably 30 or below, there was no flame present, and the double garage door was open (this happened in Connecticut). Also in a Fiat 850 sport coupe the battery is in the trunk (front) so there really isn't anything up there that would cause a spark (engine & gas tank in back). So it must have been a spark off of the charger when he pulled it off the terminal (he hadn't unplugged the charger).

Soldering Tabs Onto NiCd Batteries

When replacing NiCd batteries in packs or portable tools, it is often necessary to attach wires to the individual cells. It may be possible to obtain NiCds with solder tabs attached (Radio Shack has these) but if yours do not, here are two ways that work. They both require a (Weller) high wattage soldering gun.

I use a high power Weller (140 W) soldering gun. Use fine sandpaper to thoroughly clean and roughen up the surface of the battery cell at both ends. Tin the wires ahead of time as well. Arrange the wire and cell so that they are in their final position - use a vise or clamp or buddy to do this. Heat up the soldering gun but do not touch it to the battery until it is hot - perhaps 10 seconds. Then, heat the contact area on the battery end while applying solder. It should melt and flow quite quickly. As soon as the solder adheres to the battery, remove the heat without moving anything for a few seconds. Inspect and test the joint. A high power soldering iron can also be used.

Here is a novel approach that appears to work:

(From: Clifford Buttschardt (cbuttsch@slonet.org).)

There is really no great amount of danger spot welding tabs! They usually are made of pure nickel material. I put two sharp pointed copper wires in a soldering gun, place both on the tab in contact with the battery case and pull the trigger for a short burst. The battery remains cool.

(From: mcovingt@ai.uga.edu (Michael Covington).)

Of course! A soldering gun is a source of about 1.5 V at 100 A RMS. Should make a fine spot-welder. You should write that up for QST ("Hints and Kinks") or better yet, send it in a letter to the editor of "Electronics Now" (the magazine I write for).

Battery Related Information

Automotive Power

While it is tempting to want to use your car's battery as a power source for small portable appliances, audio equipment, and laptop computers, beware: the power available from your car's electrical system is not pretty. The voltage can vary from 9 (0 for a dead battery) to 15 V under normal conditions and much higher spikes or excursions are possible. Unless the equipment is designed specifically for such power, you are taking a serious risk that it will be damaged or blown away.

Furthermore, there is essentially unlimited current available from the battery (cigarette lighter) - 20 A or more. This will instantly turn your expensive CD player to toast should you get the connections wrong. No amount of internal protection can protect equipment from fools.

My recommendation for laptop computers is to use a commercially available DC-AC inverter with the laptop's normal AC power pack. This is not the most efficient but is the safest and should maintain the laptop's warranty should something go wrong. For CD players and other audio equipment, only use approved automotive adapters.

How Do Those On-Battery or On-the-Package Battery Testers Work?

There is a graded width resistance element that gets connected when you pinch those two points. It heats up - substantially, BTW. Some sort of liquid crystal or other heat sensitive material changes from dark to clear or yellow at a fairly well defined temperature.

Incidentally, since the current is significant, repeated 'testing' will drain the batteries - as with any proper under-load battery test! This isn't an issue for occasional testing but if the kids figure how to do this....

Personally, I would rather use a $3 battery checker instead of paying for throw-away frills!

Battery Eliminator for Laptop or Appliance with Dead NiCds

Even where you have the AC adapter, it is quite likely that simply removing the (shorted) battery pack will not allow you to use it. This is because it probably uses the battery as a smoothing capacitor. You cannot simply replace the battery with a large electrolytic capacitor because the battery also limits the voltage to a value determined by the number of cells in the pack. Without it, the voltage would be much too high, possibly resulting in damage. You could use N power diodes in series (i.e., N=Vb/.7) to drop the approximate voltage of the battery pack AND a large capacitor but you would be wasting a lot of power in the form of heat.

One alternative is to substitute a regulated power supply with an output equal to the the battery voltage and current capacity found by dividing the VA rating of the normal wall adapter by the battery's nominal terminal voltage (this will be worst case - actual requirements may be less). Connect this directly in place of the original battery pack. Unless there is some other sort of interlock, the equipment should be perfectly happy and think it is operating from battery power!

DISCLAIMER

Careless troubleshooting of a line powered switchmode power supply can result in severe electrical shock or electrocution. This is potentially more lethal than the high voltage section of a TV or monitor due to the high current availability. Even the charged on the main filter capacitors with the unit unplugged can kill.

We will not be responsible for damage to equipment, your ego, county wide power outages, spontaneously generated mini (or larger) black holes, planetary disruptions, or personal injury or worse that may result from the use of this material.

- Back to SMPS Repair FAQ Table of Contents.

Introduction

The switchmode power supply (SMPS)

Until the 1970s or so, most consumer electronic equipment used a basic power transformer/rectifier/filter capacitor type of power supply for converting the AC line into the various voltages needed by internal circuitry. Even regulation was present only where absolutely needed - the high voltage supplies of color TV sets, for example. Remember those old TVs with boat anchor type power transformers? (Of course, if you recall those, you also recall the fond days of vacuum tube sets and the corner drugstore with a public tube tester!)

Switchmode supplies had been commonplace in military and avionic equipment long before they found their way into consumer electronics. I have some DC-DC and DC-AC converter modules from a Minuteman I missile from around 1962 as one example. I suppose that the cost of the switching transistors wasn't as big a deal with a $100 million missile as a $300 TV (even in 1960s dollars).

Nowadays, all TVs, monitors, PCs; most laptop and camcorder power packs; many printers, fax machines, and VCRs; and even certain audio equipment like portable CD players use this technology to reduce cost, weight, and size.

Switchmode power supply repair

Unlike PC system boards where any disasters are likely to only affect your pocketbook, power supplies, especially line connected switchmode power supplies (SMPSs) can be dangerous. Read, understand, and follow the set of safety guidelines provided later in this document whenever working on line connected power supplies as well as TVs, monitors, or other similar high voltage equipment.

Having said that, repairing a power supply yourself may in fact be the only economical option. It is very common for service centers to simply replace the entire power supply board or module even if the problem is a 25 cent capacitor. It may simply not pay for them to take the bench time to diagnose down to the component level. Many problems with switchmode power supplies are easy to find and easy and inexpensive to fix. Not all, but surprisingly many.

This document will provide you with the knowledge to deal with a large percentage of the problems you are likely to encounter with the common small switchmode power supplies found in many types of consumer electronic equipment including PCs, printers, TVs, computer monitors, and laptop or camcorder power packs. It will enable you to diagnose problems and in many cases, correct them as well. With minor exceptions, specific manufacturers and models will not be covered as there are so many variations that such a treatment would require a huge and very detailed text. Rather, the most common problems will be addressed and enough basic principles of operation will be provided to enable you to narrow the problem down and likely determine a course of action for repair. In many cases, you will be able to do what is required for a fraction of the cost that would be charged by a repair center - assuming they would even bother.

Should you still not be able to find a solution, you will have learned a great deal and be able to ask appropriate questions and supply relevant information if you decide to post to sci.electronics.repair. It will also be easier to do further research using a repair text such as the ones listed at the end of this document. In any case, you will have the satisfaction of knowing you did as much as you could before taking it in for professional repair. With your new-found knowledge, you will have the upper hand and will not easily be snowed by a dishonest or incompetent technician.

Most Common Problems

The following probably account for 95% or more of the common SMPS ailments:

- Supply dead, fuse blown - shorted switchmode power transistor and other semiconductors, open fusable resistors, other bad parts. Note: actual cause of failure may be power surge/brownout/lightning strikes, random failure, or primary side electrolytic capacitor(s) with greatly reduced capacity or entirely open - test them before powering up the repaired unit.

- Supply dead, fuse not blown - bad startup circuit (open startup resistors), open fusable resistors (due to shorted semiconductors), bad controller components.

- One or more outputs out of tolerance or with excessive ripple at the line frequency (50/60 Hz) or twice the line frequency (100/120 Hz) - dried up main filter capacitor(s) on rectified AC input.

- One or more outputs out of tolerance or with excessive ripple at the switching frequency (10s of kHz typical) - dried up or leaky filter capacitors on affected outputs.

- Audible whine with low voltage on one or more outputs - shorted semiconductors, faulty regulator circuitry resulting in overvoltage crowbar kicking in, faulty overvoltage sensing circuit or SCR, faulty controller.

- Periodic power cycling, tweet-tweet, flub-flub, blinking power light - shorted semiconductors, faulty over voltage or over current sensing components, bad controller.

In all cases, bad solder connections are a possibility as well since there are usually large components in these supplies and soldering to their pins may not always be perfect. An excessive load can also result in most of these symptoms or may be the original cause of the failure. And don't overlook the trivial: a line voltage select switch in the wrong position or between positions (possibly by accident when moving the supply, particularly with PCs), or damaged.

Repair or replace

Some manufacturers have inexpensive flat rate service policies for power supplies. If you are not inclined or not interested in doing the diagnosis and repair yourself, it may be worthwhile to look into these. In some cases, $25 will get you a replacement supply regardless of original condition. However, this is probably the exception and replacements could run more than the total original cost of the equipment - especially as in the case of most TVs and many computer monitors, where the power supply is built onto the main circuit board.

Nothing really degrades in a switchmode power supply except possibly the electrolytic capacitors (unless a catastrophic failure resulted in a total meltdown) and these can usually be replaced for a total cost of a few dollars. Therefore, it usually makes sense to repair a faulty supply assuming it can be done reasonably quickly (depending on how much you value your time and the down time of the equipment) and, of course, assuming that the equipment it powers is worth the effort. Most replacement parts are readily available and kits containing common service components are also available for many popular power supplies (such as those found in some terminals, MacIntosh and other Apple computers, various brands of video monitors, and some TVs and VCRs).

Where an exact replacement power supply is no longer available or excessively expensive, it may be possible to simply replace the guts if space allows and the mounting arrangement is compatible. For example, for an older full size PC tower, the original power supply may be in a non-standard box but the circuit board itself may use a standard hole configuration such that an inexpensive replacement may be installed in its place.

Alternatively, many surplus electronics distributors have a wide selection of power supplies of all shapes, sizes, output voltages, and current capacities. One of these may make a suitable replacement for your custom supply with a lot less hassle than attempting to repair your undocumented original. It will likely be much newer as well with no end-of-life issues like dried up electrolytic capacitors to deal worry about. Of course, you must know the voltage and current maximum current requirements of each of the outputs in order to make a selection.

For the specific case of SMPSs for standard computers (PC, Macs, workstations, servers), it often doesn't make sense to spend much time or money on repair. The cost of replacement of power supplies for PCs in particular is so low, that just buying a new power supply may be the best course of action. Furthermore, the risk of a faulty repair causing expensive or fatal damage to the mainboard and peripherals including total loss of all data stored on disk, makes repair a risky endeavor unless thorough testing can be performed before installation. However, it won't hurt to check for obvious problems like bad connections. Put the dead one aside and considering trying to repair it if there isn't anything better to do. Realistically, this will be never. :)

Related Information

See the manuals on "Failure Diagnosis and Repair of TVs" and "Failure Diagnosis and Repair of Computer and Video Monitors" for problems specific to that type of equipment. For computer power supplies and other general info, also see: "PC Switchmode Power Supplies". These are all available at this site under the Repair Menu.

Lazar's SMPS Design Corner has many links to switchmode power supply information and suppliers.

Switchmode Power Supplies

Power Supply Fundamentals

A typical line connected power supply must perform the following functions:

- Voltage conversion - changing the 115/230 VAC line voltage into one or more other voltages as determined by application.

- Rectification - turning the AC into DC.
- Filtering - smoothing the ripple of the rectified voltage(s).
- Regulation - making the output voltage(s) independent of line and load variations.
- Isolation - separating the supply outputs from any direct connection to the AC line.

Linear power supplies (LPSs)

A typical linear power supply of the type found in most audio equipment includes a line power transformer which converts the 115/230 VAC 50/60 Hz to other (usually lower) voltages (now that most equipment has done away with vacuum tubes except for CRTs, more on that later). The power transformer also provides the isolation between the load and the line. The outputs are rectified by a diode bridge or other solid state configuration. Filtering is accomplished with electrolytic capacitors and sometimes inductors or resistors arranged as a low pass filter C-L-C (pi) or C-R-C or other configuration.

Where regulation is important - that is, it is desirable for the output voltage to be relatively independent of line or load variations, a regulator stage is added. This may take the form of a Zener diode if the current requirements are modest, discrete transistor circuit, or an integrated 3 terminal regulator like an LM317 (variable), 7805 (+5), or 7912 (-12). There are many more as well as linear regulators for higher voltages such as +115 VDC or +125 VDC for TV power supplies and multiple output (e.g., +5.1 VDC, +12 VDC) hybrid regulators for VCRs.

The regulator circuit essentially compares the output (possibly only one if there are multiple outputs in the same package) with a reference and adjusts the current flow to make the output(s) as nearly equal to the desired voltage as possible. However, a significant amount of power may be lost in the regulator especially under high line voltage/high load conditions. Therefore, the efficiency of linear power supplies is usually quite low - under 50% overall is typical.

Notable characteristics of LPSs are excellent regulation and low output ripple and noise.

What is a switchmode power supply?

Also called switching power supplies and sometimes chopper controlled power supplies, SMPSs use high frequency (relative to 50/60 Hz) switching devices such as Bipolar Junction Transistors (BJTs), MOSFETs, Insulated Gate Bipolar Transistors (IGBTs), or Thyristors (SCRs or triacs) to take directly rectified line voltage and convert it to a pulsed waveform.

Most small SMPSs use BJTs or MOSFETs. IGBTs may be found in large systems and SCRs or triacs are used where their advantages (latching in the on state and high power capability) outweigh the increased complexity of the circuitry to assure that they turn off properly (since except for special Gate Turn Off (GTO) thyristors, the gate input is pretty much ignored once the device is triggered and the current must go to zero to reset it to the off state.)

The input to the switches is usually either 150-160 VDC after rectification of 115 VAC, or 300-320 VDC after doubling of 115 VAC or rectification of 220-240 VAC. Up to this point, there is no line isolation as there is no line connected (large, bulky, heavy) power transformer.

A relatively small high frequency transformer converts the pulsed waveform into one or more output voltages which are then rectified and filtered using electrolytic capacitors and small inductors in a 'pi' configuration C-L-C, or for outputs that are less critical, just a capacitor.

This high frequency transformer provides the isolation barrier and the conversion to generate the multiple voltages often provided by a SMPS.

Feedback is accomplished across the isolation barrier by either a small pulse transformer or opto-isolator. The feedback controls the pulse width or pulse frequency of the switching devices to maintain the output constant. Since the feedback is usually only from the "primary" output, regulation of the other outputs, if any, is usually worse than for the primary output. Also, because of the nature of the switching designs, the regulation even of the primary output is usually not nearly as good both statically and dynamically as a decent linear supply.

DC-DC converters are switchmode power supplies without the line input rectification and filtering. They are commonly found in battery operated equipment like CD players and laptop computers. They have similar advantages to SMPSs in being compact, light weight, and highly efficient.

Description of typical flyback type SMPS

Probably the most common topology for small switchers is the flyback circuit shown below and in Block Diagram of Basic Flyback Switchmode Power Supply.

```
           CR1                             CR2        L :::::

 N o-------------+------------+
```

The input to the supply is the AC line which may have RFI and surge protection (not shown). There may be several inductors, coupled inductors, and capacitors to filter line noise and spikes as well as to minimize the transmission of switching generated radio frequency interference back into the power line. There may be MOV type of surge suppressors across the three input leads (H, N, G). A line fuse is usually present as well to prevent a meltdown in case of a catastrophic failure. It rarely can prevent damage to the supply in the event of an overload, however.

Line rectification is usually via a voltage doubler or diode bridge. One common circuit uses a bridge rectifier as a doubler or normal bridge by changing one jumper. The voltage across the switching transistor is usually around 160-320 V. Some universal supplies are designed to accept a wide range of input voltages - 90-240 VAC (possibly up to 400 Hz or more) or DC - and will automatically work just about anywhere in the world as long as a suitable plug adapter can be found.

When Q1 turns on, current increases linearly in T1 based on the voltage applied and the leakage inductance of T1's primary winding. Little power is transferred to the secondary during this phase of the cycle. When Q1 turns off, the field collapses and this transfers power to the output. The longer Q1 is on, the more energy is stored (until saturation at which point it blows up). Thus, controlling the pulse width of the Q1 on-time determines the amount of power available from the output.

The output rectifier, CR2, must be a high efficiency, high frequency unit - a 1N400X will not work. The pi filter on the output smooths the pulses provided by CR2. Sometimes, a full wave configuration is used with a center tapped transformer secondary.

Note that the transformer, T1, is a special type which includes an air gap in its core (among other things) to provide the inductive characteristics needed for operation in flyback mode.

Multiple output windings on T1 provide for up to a half dozen or more separate (and possibly isolated as well) positive or negative voltages but as noted, only one of these is usually used for regulation.

A reference circuit monitors the main output and controls the duty cycle of the switching pulses to maintain a constant output voltage. (Secondary outputs are not shown in the above schematic.)

R1 is the startup resistor (some startup circuits are more sophisticated) and provides the initial current to the switchmode transistor base. In the old days, SMPS controllers were designed with discrete components. Assuring stable operation is a challenge with any SMPS but particularly with the flyback topology where leaving the drive on for too long will result in transformer core saturation and instant smoke. Nowadays, an IC PWM controller chip is almost always used. The block diagram of a one very popular PWM controller IC is shown below.

Many small SMPSs use opto-isolators for the feedback. An opto-isolator is simply an LED and a photodiode in a single package. As its name implies, an opto-isolator provides the isolation barrier (between the low voltage secondary outputs and the line connected primary) for the feedback circuit. Typically, a reference circuit on the output side senses the primary output voltage and turns on the LED of the opto-isolator when the output voltage exceeds the desired value. The photodiode detects the light from the LED and causes the pulse width of the switching waveform to be reduced enough to provide just the right amount of output power to maintain the output voltage constant. This circuit may be as simple as putting the photodiode across the base drive to the BJT switch thus cutting it off when the output voltage exceeds the desired value. The reference is often a TL431 or similar shunt regulator chip monitoring a voltage divided version of the primary output. When the shunt regulator kicks in, the opto-isolator LED turns on reducing the switchmode transistor drive. There may be an adjustment for the output voltage.

Other designs use small pulse transformers to provide isolated feedback.

Where additional regulation is needed, small linear regulators may be included following the output(s).

There are many other topologies for switching power supplies. However, the basic principles are similar but the detail differ depending on application. The flyback topology described above is one of the most common for small multi-output supplies. However, you may find other types of circuits in TVs and monitors. Some are downright strange (to be polite). I sometimes wonder if engineers are given bonuses based on the uniqueness and difficulty level of understanding their designs!

Advantages of SMPSs compared to LPSs

The benefits provided by implementing switch mode operation are with respect to size, weight, and efficiency.

- Size and weight - since the transformer and final filter(s) run at a high frequency (we are talking about 10 kHz to 1 MHz or more), they can be much smaller and lighter than the big bulky components needed for 50/60 Hz operation. Power density for SMPSs compared to LPSs may easily exceed 20:1.

- Efficiency - since the switching devices are (ideally) fully on or fully off, there is relatively little power lost so that the efficiency can be much higher for SMPSs than for LPSs, especially near full load. Efficiencies can exceed 85% (compared to 50-60% for typical LPSs) with improvements being made continuously in this technology.

Since the advent of the laptop computer, cellular phone, and other portable devices, the importance of optimizing power utilization has increased dramatically. There are now many ICs for controlling and implementing SMPSs with relatively few external components. Maxim, Linear Technology, and Unitrode (now part of Texas Instruments) are just a few of the major manufacturers of controller ICs.

Where are SMPSs used?

Switch mode power supplies are commonly used in computer and other digital systems as well as consumer electronics - particularly TVs and newer VCRs though audio equipment will tend to use linear power supplies due to noise considerations. You will find SMPSs in:

- PCs, workstations, minicomputers, large computers.

- Laptop and notebook computers, PDAs - both internal DC-DC converters and their AC power packs.

- Printers, fax machines, copiers.

- Peripheral and expansion boxes

- X-terminals and video terminals, point of sale registers.

- TVs, computer and video monitors.

- Many VCRs.

- Camcorder AC adapters.

In additional, you will find DC-DC converters which are SMPSs without the AC line connection, internally in an increasing number of consumer and industrial applications including things like portable CD players.

The up side is that they are usually quite reliable, efficient, and cool running.

The down side is that when a failure occurs, it may take out many parts in the supply, though not usually the equipment being powered unless the feedback circuitry screws up and there is no overvoltage protection.

Switchmode Power Supply Troubleshooting

SAFETY

The primary danger to you is from the input side of the supply which is directly connected to the AC line and will have large electrolytic capacitors with 320 V or greater DC when powered (often, even if the supply does not work correctly) and for some time after being unplugged (especially if the power supply is not working correctly but does not blow fuses).

WARNING: The filter capacitors used in many switchmode power supplies can store an amount of energy that can kill - always discharge and confirm this before touching anything.

There is also risk of instantly destroying expensive parts of the supply (and any attached equipment as well) like the switchmode power transistor if your probe should slip and short something either directly or by killing the feedback circuit.

These guidelines are to protect you from potentially deadly electrical shock hazards as well as the equipment from accidental damage.

Note that the danger to you is not only in your body providing a conducting path, particularly through your heart. Any involuntary muscle contractions caused by a shock, while perhaps harmless in themselves, may cause collateral damage - there are many sharp edges inside this type of equipment as well as other electrically live parts you may contact accidentally.

The purpose of this set of guidelines is not to frighten you but rather to make you aware of the appropriate precautions. Repair of TVs, monitors, microwave ovens, and other consumer and industrial equipment can be both rewarding and economical. Just be sure that it is also safe!

- Don't work alone - in the event of an emergency another person's presence may be essential.

- Always keep one hand in your pocket when anywhere around a powered line-connected or high voltage system.

- Wear rubber bottom shoes or sneakers.

- Don't wear any jewelry or other articles that could accidentally contact circuitry and conduct current, or get caught in moving parts.

- Set up your work area away from possible grounds that you may accidentally contact.

- Know your equipment: TVs and monitors may use parts of the metal chassis as ground return yet the chassis may be electrically live with respect to the earth ground of the AC line. Microwave ovens use the chassis as ground return for the high voltage. In addition, do not assume that the chassis is a suitable ground for your test equipment!

- If circuit boards need to be removed from their mountings, put insulating material between the boards and anything they may short to. Hold them in place with string or electrical tape. Prop them up with insulation sticks - plastic or wood.

- If you need to probe, solder, or otherwise touch circuits with power off, discharge (across) large power supply filter capacitors with a 2 W or greater resistor of 5-50 ohms/V approximate value (e.g., for a 200 V capacitor, use a 1K-10K ohm resistor). Monitor while discharging and/or verify that there is no residual charge with a suitable voltmeter. In a TV or monitor, if you are removing the high voltage connection to the CRT (to replace the flyback transformer for example) first discharge the CRT contact (under the insulating cup at the end of the fat red wire). Use a 1M-10M ohm 1W or greater wattage resistor on the end of an insulating stick or the probe of a high voltage meter. Discharge to the metal frame which is connected to the outside of the CRT.

- For TVs and monitors in particular, there is the additional danger of CRT implosion - take care not to bang the CRT envelope with your tools. An implosion will scatter shards of glass at high velocity in every direction. There is several tons of force attempting to crush the typical CRT. Always wear eye protection.

- Connect/disconnect any test leads with the equipment unpowered and unplugged. Use clip leads or solder temporary wires to reach cramped locations or difficult to access locations.

- If you must probe live, put electrical tape over all but the last 1/16" of the test probes to avoid the possibility of an accidental short which could cause damage to various components. Clip the reference end of the meter or scope to the appropriate ground return so that you need to only probe with one hand.

- Use a proper high voltage probe or high voltage meter to measure voltages which are potentially beyond the capabilities of your DMM or VOM - not something cobbled together from 1/4 watt resistors! Note that fault conditions or even testing at *reduced* input voltage may result in greatly excessive voltage on one or more outputs due to lack of regulation.

- It may be possible to perform some of the tests at greatly reduced voltage (e.g., 30 VDC to the chopper instead of 300 VDC) by supplying external power to the controller chip (if used) and injecting base/gate drive from a signal generator. This would greatly reduce the shock hazard as well as equipment damage from a slipped probe or missed faulty component.

- Perform as many tests as possible with power off and the equipment unplugged. For example, the semiconductors in the power supply section of a TV or monitor can be tested for short circuits with an ohmmeter.

- Use an isolation transformer if there is any chance of contacting line connected circuits. A Variac(tm) is not an isolation transformer! The use of a GFCI (Ground Fault Circuit Interrupter) protected outlet is a good idea but will not protect you from shock from many points in a line connected TV or monitor, or the high voltage side of a microwave oven, for example. (Note however, that, a GFCI may nuisance trip at power-on or at other random times due to leakage paths (like your scope probe ground) or the highly capacitive or inductive input characteristics of line powered equipment.) A fuse or circuit breaker is too slow and insensitive to provide any protection for you or in many cases, your equipment. However, these devices may save your scope probe ground wire should you accidentally connect it to a live chassis.

- Don't attempt repair work when you are tired. Not only will you be more careless, but your primary diagnostic tool - deductive reasoning - will not be operating at full capacity.

- Finally, never assume anything without checking it out for yourself! Don't take shortcuts!

Tips on SMPS troubleshooting

The diagnosis of problems in switchmode power supplies is sometimes made complicated due the interdependence of components that must function properly for any portion of the power supply to begin to work. Depending on design, SMPS may or may not be protected from overload conditions and may fail catastrophically under a heavy load even when supposedly short circuit proof. There is particular stress on the switching devices (they are often 800 V transistors) which can lead to early or unexpected failure. Also, SMPS may fail upon restoration of power after a blackout if there is any kind of power spike since turn-on is a very stressful period - some designs take this into account and limit turn on surge.

However, the cause of many problems are immediately obvious and have simple fixes - the blown chopper transistor or dried up main filter capacitor. Don't assume your problem is complex and convoluted. Most are not. You should not avoid attempting a repair just because there is a slight chance it will be more challenging!

A low power (e.g., 25 W) fine tip soldering iron and fine rosin core solder will be needed if you should need to disconnect any soldered wires (on purpose or by accident) or replace soldered components. A higher power iron or small soldering gun will be needed for dealing with larger components. Never use acid core solder or the type used for sweating copper pipes!

CAUTION: You can easily turn a simple repair (e.g., bad solder connections) into an expensive mess if you use inappropriate soldering equipment and/or lack the soldering skills to go along with it. If in doubt, find someone else to do the soldering or at least practice, practice, practice, soldering and desoldering on a junk circuit board first! See the document: Troubleshooting and Repair of Consumer Electronic Equipment for additional info on soldering and rework techniques.

Test equipment

The most valuable piece of test equipment (in addition to your senses) will be a DMM or VOM. These alone will suffice for most diagnosis of faulty components (like shorted semiconductors or open fusable resistors).

CAUTION: If the SMPS (or any other piece of equipment) is capable of producing voltages beyond 1,000 V (or the max range on your meter), make sure you use a proper high voltage probe or high voltage meter - fault conditions could easily result in voltages in the system that are way beyond those that are expected, even if run at reduced input voltage and/or with a series current limiter.

In designs using controller ICs, an oscilloscope comes in handy when there are startup or overcurrent/voltage shutdown or cycling problems. Since everything runs at a relatively low frequency, almost any scope will do.

Incredibly handy widgets

These are the little gadgets and homemade testers that are useful for many repair situations. Here are just a few of the most basic:

- Series light bulb for current limiting during the testing of TVs, monitors, switching power supplies, audio power amplifiers, etc. I built a dual outlet box with the outlets wired in series so that a lamp can be plugged into one outlet and the device under test into the other. For added versatility, add a regular outlet and 'kill' switch using a quad box instead. The use of a series load will prevent your expensive replacement part like a switchmode power transistor from blowing if there is still some fault in the circuit you have failed to locate. (Now, if I would only remember to do this more often!). See the section: The series light bulb trick.

- A Variac. It doesn't need to be large - a 2 A Variac mounted with a switch, outlet and fuse will suffice for most tasks. However, a 5 amp or larger Variac won't hurt. If you will be troubleshooting 220 VAC equipment in the US, there are Variacs that will output 0-240 VAC from a 115 VAC line (just make sure you don't forget that this can easily fry your 115 VAC equipment.) By varying the line voltage, not only can you bring up a newly repaired monitor gradually to make sure there are no problems; you can also evaluate behavior at low and high line voltage. This can greatly aid in troubleshooting power supply problems. WARNING: a Variac is an autotransformer - not an isolation transformer and does not help with respect to safety. You need an isolation transformer as well.

Note: Some SMPS designs require power to be applied instantly to provide the startup voltage to the controller. If this is the case with yours, it won't be possible to bring up the voltage slowly (unless you power that chip separately). However, it should still be possible to run the unit somewhat reduced line voltage. Also, running any SMPS at reduced line voltage is stressful. It may also result in outputs that are not properly regulated and go much higher than normal. Thus, a Variac should be used with caution - with the outputs connected to dummy loads instead of the powered equipment and a series current limiter (e.g., light bulb) in the input.

- Isolation transformer. This is very important for safely working on live chassis equipment like line connected switchmode power supplies (primary side). You can build one from a pair of similar power transformers back-to-back (with their highest rated secondaries connected together. I built mine from a couple of similar old tube type TV power transformers mounted on a board with an outlet box including a fuse. Their secondary high voltage windings were connected together to couple the two transformers together. The unused low voltage windings can be put in series with the primary or output windings to adjust voltage. Alternatively, commercial line isolation transformers suitable for TV troubleshooting are available for less than $100 - well worth every penny.

  There is absolutely no imaginable reason not to use an isolation transformer for troubleshooting SMPSs except possibly for the final test where confirmation is needed that the inrush from a direct line connection (which will have virtually unlimited instantaneous current capability) will not damage the newly repaired supply.

- Variable isolation transformer. You don't need to buy a fancy combination unit. A Variac can be followed by a normal isolation transformer. (The opposite order also works. There may be some subtle differences in load capacity.).

Safe discharging of capacitors in switchmode power supplies

A working SMPS may discharge its capacitors fairly quickly when it is shut off but DO NOT count on this. The main filter capacitors may have bleeder resistors to drain their charge relatively quickly - but resistors can fail and the term 'quickly' may be relative to the age of the universe. Don't depend on them.

The technique I recommend is to use a high wattage resistor of about 5 to 50 ohms/V of the working voltage of the capacitor. This isn't critical - a bit more or less will be fine but will affect the time it takes to fully discharge the capacitor. The use of a current limiting resistor will prevent the arc-welding associated with screwdriver discharge but will have a short enough time constant so that the capacitor will drop to a low voltage in at most a few seconds (dependent of course on the RC time constant and its original voltage).

Then check with a voltmeter to be double sure. Better yet, monitor while discharging.

Obviously, make sure that you are well insulated!

For the power supply filter capacitors which might be 400 uF at 200 V, a 2 K ohm 10 W resistor would be suitable. RC=.8 second. 5RC=4 seconds. A lower wattage resistor (compared to that calculated from V^^2 / R) can be used since the total energy stored in the capacitor is not that great (but still potentially lethal).

The discharge tool and circuit described in the next two sections can be used to provide a visual indication of polarity and charge for TV, monitor, SMPS, power supply filter capacitors and small electronic flash energy storage capacitors, and microwave oven high voltage capacitors.

Reasons to use a resistor and not a screwdriver to discharge capacitors:

- It will not destroy screwdrivers and capacitor terminals.
- It will not damage the capacitor (due to the current pulse).
- It will reduce your spouse's stress level in not having to hear those scary snaps and crackles.

Capacitor discharge tool

A suitable discharge tool for each of these applications can be made as quite easily. The capacitor discharge indicator circuit described below can be built into this tool to provide a visual display of polarity and charge (not really needed for CRTs as the discharge time constant is virtually instantaneous even with a multi-M ohm resistor.

- Solder one end of the appropriate size resistor (for your application) along with the indicator circuit (if desired) to a well insulated clip lead about 2-3 feet long. For safety reasons, these connections must be properly soldered - not just wrapped.
- Solder the other end of the resistor (and discharge circuit) to a well insulated contact point such as a 2 inch length of bare #14 copper wire mounted on the end of a 2 foot piece of PVC or Plexiglas rod which will act as an extension handle.
- Secure everything to the insulating rod with some plastic electrical tape.

This discharge tool will keep you safely clear of the danger area.

Again, always double check with a reliable voltmeter or by shorting with an insulated screwdriver!

Capacitor discharge indicator circuit

Here is a suggested circuit which will discharge the main filter capacitors in switchmode power supplies, TVs, and monitors. This circuit can be built into the discharge tool described above.

A visual indication of charge and polarity is provided from maximum input down to a few volts.

The total discharge time is approximately 1 second per 100 uF of capacitance (5RC with R = 2 K ohms).

Safe capability of this circuit with values shown is about 500 V and 1000 uF maximum. Adjust the component values for your particular application.

(GND Clip)
```

The two sets of 4 diodes will maintain a nearly constant voltage drop of about 2.8-3 V across the LED+resistor as long as the input is greater than around 20 V. Note: this means that the brightness of the LED is NOT an indication of the value of the voltage on the capacitor until it drops below about 20 volts. The brightness will then decrease until it cuts off totally at around 3 volts.

Safety note: always confirm discharge with a voltmeter before touching any high voltage capacitors!

Voltage checkers

Whereas a multimeter is intended to measure voltages (and other things), a checker is used mostly to just produce a quick indication of the presense of voltage, its polarity, and other basic parameters. One use is a quick, but reliable indication of the status of the charge on a BIG capacitor. An, example of a simple version of such a device is the "capacitor discharge indicator circuit" described above.

(From: Ian Field (ionfieldmonitors@ic24.net).)

The version of the checker that I have, also contains a miniature 12 V battery for continuity checking - any resistance less than about 22K will produce some glow. It's handy for quick checks of semiconductor junctions - in general if it produces a slight glow it's leaky, but transistor B/E junctions have an inherent zener voltage, so there is usually some glow. Also schottky-barrier diodes give a reverse leakage glow - this does not mean they're faulty, check the Vf with the diode-check on a DMM before binning! Any zener diode above 10-11 V can be given a quick test for S/C, lower Vz will produce some glow - again check Vf before binning.

These checkers are getting hard to obtain, most of the component stockists here only carry vastly over complicated (and expensive) versions with built-in measurement computer and LCD - these wouldn't last 5 min's around flyback circuitry! Some Automotive accessory shops have a simpler version with no battery - always check that it's stated to be capable of measuring AC or DC at 4 to 380 V before parting with money! The internal circuit should contain the LED's, a 15 ohm resistor to limit the maximum surge current when the PTC is cold and the special PTC film-thermistor. The battery can be added with a button from a VCR front panel - but don't blame me if you kill yourself because you didn't insulate the added components properly! There is a more complicated non-battery version with 2 LED's close to the front of the handle to indicate polarity and a row of LED's along the length of the handle to indicate the voltage-range. This version contains 2 special PTC's and a discrete-transistor bargraph circuit - there might be room to add a battery inside the case. As for the special PTC this is the only place I've seen them - one possibility that might be worthy of looking into is the Siemens PTC SMPSU startup thermistor for TDA4600 control chips, this usually has a series resistor of at least 270 ohms and is more likely to turn-up in European TV set's, but I have seen it in early Matsushita IBM displays and a few others (possibly Tandon) the PTC thermistor is always blue and looks like a very-miniature copy of the Philips white-plastic PTC degauss thermistor.

The series light bulb trick

When powering up a monitor (or any other modern electronic devices with expensive power semiconductors) that has had work done on any power circuits, it is desirable to minimize the chance of blowing your newly installed parts should there still be a fault. There are two ways of doing this: Use of a Variac to bring up the AC line voltage gradually and the use of a series load to limit current to power semiconductors.

Actually using a series load - a light bulb is just a readily available cheap load - is better than a Variac (well both might be better still) since it will limit current to (hopefully) non-destructive levels.

CAUTION: Running any SMPS at greatly reduced line voltage will be stressful for it, especially if the output load is a significant fraction of its full load ratings. In addition, at some range of line voltage, the output regulation may not work properly and the output(s) may go much higher than expected. Use dummy loads in place of the valuable equipment if possible when doing such testing!

What you want to do is limit current to the critical parts - usually the switchmode (chopper) power transistor of an SMPS or horizontal output transistor (HOT) of a TV or monitor. Most of the time you will get away with putting it in series with the AC line. However, sometimes, putting a light bulb directly in the B+ circuit will be needed to provide adequate protection. In that location, it will limit the current to the HOT from the main filter capacitors of line connected power supplies. This may also be required with some switchmode power supplies as they can still supply bursts of full (or excessive) current even if there is a light bulb in series with the AC line.

Actually, an actual power resistor is probably better as its resistance is constant as opposed to a light bulb which will vary by 1:10 from cold to hot. The light bulb, however, provides a nice visual indication of the current drawn by the circuit under test. For example:

- Full brightness: short circuit or extremely heavy load - a major fault probably is still present.
- Initially bright but then settles at reduced brightness: filter capacitors charge, then lower current to rest of circuit. This is what is expected when the equipment is operating normally. There could still be a problem with the power circuits but it will probably not result in an immediate catastrophic failure.
- Pulsating: power supply is trying to come up but shutting down due to overcurrent or overvoltage condition. This could be due to a continuing fault or the light bulb may be too small for the equipment.

Note: for a TV or monitor, it may be necessary (and desirable) to unplug the degauss coil as this represents a heavy initial load which may prevent the unit from starting up with the light bulb in the circuit.

The following are suggested starting wattages:

- 40 W bulb for VCR or laptop computer switching power supplies.
- 100 W bulb for small (i.e., B/W or 13 inch color) monitors or TVs.
- 150-200 W bulb for large color monitors or projection TVs.

A 50/100/150 W (or similar) 3-way bulb in an appropriate socket comes in handy for this but mark the switch so that you know which setting is which!

Depending on the power rating of the equipment, these wattages may need to be increased. However, start low. If the bulb lights at full brightness, you know there is still a major fault. If it flickers or the TV (or other device) does not quite come fully up, then it should be safe to go to a larger bulb. Resist the temptation to immediately remove the series light bulb totally from the circuit at this point - I have been screwed by doing this. Try a larger one first. The behavior should improve. If it does not, there is still a fault present.

Note that some TVs and monitors simply will not power up at all with any kind of series load - at least not with one small enough (in terms of wattage) to provide any real protection. The microcontroller apparently senses the drop in voltage and shuts the unit down or continuously cycles power. Fortunately, these seem to be the exceptions.

What about SMPSs in TVs and monitors?

TVs and monitors have at least one SMPS - the horizontal deflection flyback circuit and may have an additional SMPS to provide the low voltages or the DC for the horizontal output transistor. Most of the theory of operation and troubleshooting techniques apply to these as well. However, manufacturers of TVs and monitors tend to be really creative (can you say, obscure?) when it comes to these designs so a little more head scratching is often necessary to decipher the circuit and get into the mind of the designer. However, the basic failure modes are similar and the same test procedures may be used.

Comments on SMPS capacitor discharging and testing with series loads

(From: Ian Field (ionfieldmonitors@ic24.net).)

At a pinch, discharging BIG electrolytic capacitors with a test lamp (230 V, 60 W in the UK; 115 V, 25 W in series in the US) will do, but if the lamp has blown you are in for a nasty surprise! While I am not criticising the use of spare high-wattage resistors, I tend to find that these get tidied away, so there's none about when you need one!

The lamp sometimes get's used if I can't find an NTC, but I always check with a voltage checker because of the risk! - power resistors can go O/C as well whereas NTC thermistors generally fail S/C - which usually happens as a result of some transient phenomenon such as a lightning-strike near the underground power line.

This is unlikely with the energy dump of discharging an off-line electrolytic (unless the equipment is still powered at the time!). My bench isn't the tidiest in the world, so gadgets tend to get misplaced - including power resistors with added discharge-progress LED indicators. This is where an inrush-suppressor NTC comes into it's own, even without selecting the type - it will discharge a capacitor almost instantaneously with the minimum of arc-burn on the solder pads. Obviously the energy causes some heating - in the case of large electrolytics direct-off-line rectifier smoothing/reservoir the amount of heating is just sufficient to give an idea of the condition of the capacitor - capacitor failure is comparatively rare, so it's not often anticipated and can cause misleading symptoms - so making this double as a routine check occasionally saves a hell of a lot of time!

The trick I have found works even better is to use a NTC inrush-current suppressor thermistor. These items can be salvaged from a scrap monitor or PSU, and careful selection may reveal some types with a "room temperature resistance" of several kohms - with the line-voltage on a capacitor discharging through them, self-heating reduces the resistance to a few ohms. This reduces the welding-sputter as the contact current is only a few milliamps - this rises to a few amperes as the capacitor "dumps" its charge as the NTC resistance fall's with self-heating.

One point I would disagree on is that not all of the many electrolytics need discharging! Most SMPSU's of any appreciable power have high energy electrolytics in the secondary - whether this is expressed as high voltage or high current. In the case of monitors, the post PWM-B+ rail has a large storage electrolytic which can do appreciable damage in the event that line-drive failure has prevented use of it's energy. The NTC thermistor method helps here; after "dumping" the line voltage electrolytics - the NTC is at a lower resistance and ready for following up on the lower charge electrolytics.

There is a point concerning "test-lamp dummy loads" this has more to do with monitors than SMPSU boxes. As well as the suggested use to limit inrush current to a safe value on SMPSU boxes - I also use this method on line-O/P stages especially to verify that flyback-transformer failure was not the original cause of B+PWM or SMPSU blow-up. Recently I have been caught-out a few times because some "energy-star" designs are so efficient that the inrush current of the lamp itself is ample to cause catastrophic damage! The UK 220/230 V 60 W test lamp I have here has a calculated operating resistance of 806.7/881.7 ohms compared to a measured cold resistance of about 67 ohms so the PTC effect of the filament tends to limit the advantage!

To clarify my comment on confirming whether a faulty flyback transformer has damaged the B+PWM; older circuits use a MOSFET buck-regulator, in which S/C failure of the MOSFET feeds unregulated B+ to the line-O/P stage - This invariably destroys the HOT and sometimes the transformer, but either could as easily be the original cause. In any event - bypassing the B+PWM MOSFET via the test lamp passes just enough current to see if the transformer is operable - with the price of replacements, very few quotes are accepted - so it's well worth making sure before ordering an expensive replacement or doing too much repair work! More recently, the trend has been for flyback - step up B+ regulators. When the B+ MOSFET fails S/C it simply stalls the main SMPSU (sometimes destroying the rectifier!). Since this type of B+PWM is step-up, the operability of the flyback transformer can be checked by simply removing the S/C MOSFET. The most recent designs appear to be based on semi-resonant SMPSU topology - they resemble buck-regulator PWM controllers, but the PWM MOSFET is at chassis potential and the transformer primary is at full PSU-rail, the line-O/P transistor is between the two with the drive transformer connected to provide an emitter-coupled blocking oscillator configuration, to add "regen" to the base drive. The boost diode often includes the buck-regulators "ringing-choke" in the "net inductive component" that it recovers energy from! As the later configuration most closely resembles the buck-regulator type, the test lamp is required to confirm transformer operability - but the weird and wonderful circuit arrangements can make it lots of fun working out where to connect it!

A voltage checker that I find indispensable is the Steinel Master check 3 from; Steinel GmbH & Co. (KG Dieselstrabe 80-86 D-4836 Hertzebrock 1, Germany). The version I have consists of a pair of "inverse-parallel" LED's in series with a metal-film PTC thermistor on a tiny ceramic tube former - this has a very low thermal inertia so the PTC thermistor limits the current to a safe value for the LED's for any applied voltage between 4 & 380 V the combination of 2 LED's give a clear indication of AC or DC polarity. When this checker is used around SMPSU's, you can clearly see the effect of minority carrier transition time losses in the rectifiers, because the leading-edge of the waveform pushes the rectifiers Vf well in excess of 0.7 V for the minority carrier injection delay - before the rectifier begins to conduct. Where a PSU rectifier has two electrolytics and a choke in a Pi filter, the checker will often reveal negative transients on the electrolytic closest to the rectifier - which is a clear sign of capacitor ESR failure.

SMPS failure modes

Also see the section: Sounds that SMPSs make.

SMPS fail in many ways but the following are common:

- Faulty primary-side components. Rectifier diodes, filter capacitor(s), MOVs, and other parts located before the switchmode (chopper) transistor(s) may short due to a surge or lightning, or for no apparent reason. Main fuse will blow instantly.

  Symptoms: Totally dead supply, fuse blows instantly (vaporizes or explodes) even if switchmode transistor is removed unless a fusable resistor has blown to protect the fuse. :) Test all components on line side of high frequency transformer for short circuit failures with a multimeter.

- Shorted switchmode transistor - may take out additional parts such as fusable flameproof resistors in collector or emitter circuits of bipolar transistors or source or drain circuits for MOSFETs as well as gate components like the 15 or 18 V protection zener. Main fuse will blow unless protected by fusable resistors and one or more of them blows first.

  Symptoms: Totally dead supply, fuse blows instantly (vaporizes or explodes unless fusable resistor has opened). Measuring across C-E or D-S of switchmode transistor yields near zero ohms even when removed from circuit.

- Shorted rectifier diodes in secondary circuits - these are high frequency high efficiency diodes under a fair amount of stress.

  Symptoms: In a very basic supply without overcurrent protection, the failure of one or more of these diodes may then overload the supply and cause a catastrophic failure of the switchmode power transistor (see above) and related components. Thus, these should be checked before reapplying power to a supply that had a shorted switchmode transistor.

  On short circuit protected supplies, the symptom may be a periodic tweet-tweet-tweet or flub-flub-flub as the supply attempts to restart and then shuts down. Any power or indicator lights may be blinking at this rate as well.

  Test with an ohmmeter - a low reading in both directions indicates a bad diode. Sometimes these will test OK but fail under load or at operating voltage. Easiest to replace with known good diodes to verify diagnosis. Rectifiers either look like 1N400X type on steroids - cylinders about 1/4" x 1/2" (example: HFR854) or TO220 packages (example: C92M) with dual diodes connected at the cathode for positive supplies or the anode for negative supplies (the package may include a little diagram as well). These may either be used with a center-tapped transformer, or simply parallel for high current capacity. If in doubt, remove from the circuit and test with the ohmmeter again. If not the output used for regulation feedback, try the supply with the rectifier removed. As noted, a test with an ohmmeter may be misleading as these rectifiers can fail at full voltage. When in doubt, substitute a known good rectifier (one half of a pair will be good enough for a test).

- Bad startup circuit - initial base (gate) drive is often provided by a high value, high power resistor or resistors from the rectified AC voltage. These can simply open for no good reason.

  Symptoms: In this case the supply will appear totally dead but all the semiconductors will check out and no fuses will blow. Check the startup resistors with an ohmmeter - power resistors in the AC line input section. WARNING: there will be full voltage on the main filter capacitor(s) - 1X or 2X peak or around 160 or 320 VDC depending on design. Discharge before probing.

- Dried up capacitors - either input or output side.

Symptoms: The main filter capacitor may dry up or open and cause the output to be pulsing at 60 (50) or 120 (100) Hz and all kinds of regulation problems. Measure voltage across main filter capacitor(s). If the reading is low and drops to a much lower value or 0 instantly upon pulling the plug, then one of these capacitors may be open or dried up. If you have an oscilloscope, monitor for ripple (use an isolation transformer!!). Excess ripple under moderate load is an indication of a dried up or open capacitor.

In extreme cases, a main filter capacitor with greatly reduce capacity or that is totally open may result in failure of the switchmode transistor and a dead supply that blows fuses or fusable resistors. Therefore, it is always a good idea to test the electrolytic capacitors whenever repairing a SMPS that has blown its switchmode transistor.

Capacitors in the low voltage section may fail causing regulation problems. Sometimes there are slew rate limiting capacitors which feed from the primary output to the regulator controller to limit initial in-rush and overshoot. A failure of one of these may mess up regulation at the very least. For example, excess leakage may reduce the output of the main output (and as a consequence, all the others as well).

Where a controller like a UC3842 is used, a failure of the capacitor on its Vcc pin may result in a aborted startup or cycling behavior as it is starved for juice each time it pulses the switchmode power transistor:

(From: John Hopkins (bugs71@ptdprolog.net).)

> "I have encountered a bad cap (10uf 35v) on the Vcc input of a UC3842 IC in the power supply. Turn unit on, get very short burst of power supply output, then nothing. Every time the 3842 output a pulse, it ran out of VCC. Small part, big problem."

In almost all cases, when in doubt parallel a known good capacitor of similar capacitance and at least equal voltage rating (except for these slew rate limiting capacitors where substitution is the only sure test).

For Panasonic (and other) VCR power supplies, it is common - almost assured after a few years - that one or more the output filter capacitors commonly fail and replacing all of them, while perhaps a brute force solution, will fix a whining supply or one having bad regulation or noise. However, check the semiconductors as well before applying power. See the section: Panasonic VCR SMPS.

- Bad connection/cold solder joints - as with all other mass produced power systems (including TVs and monitors), cracked or defective solder connections are very common especially around the pins of high power components like transformers, power resistors and transistors, and connectors.

  These are particularly common with portable equipment. Universal AC adapters for camcorders and laptop computers are often abused to the point of failure. Large components like the line filter choke and high frequency transformer are prone to crack the solder bond at their pins or even break loose from the circuit board.

  Symptoms: almost any kind of behavior is possible. The unit may be erratic, intermittent, or totally dead. Visually inspect the solder side of the circuit board with a bright light and magnifying glass if necessary. Gently prod or twist the circuit board with an insulating stick to see if the problem can be made to change. Note that a one-time intermittent can blow many components so inspecting for intermittents is a really good idea even you believe that all bad components have been replaced.

- Regulation problems - outputs high or low.

  Symptoms: voltage has changed and adjustment pot if one exists has no effect or is unable to set voltage to proper value. Check components in the feedback regulator, particularly the opto-isolator and its associated circuitry. A weak opto-isolator may allow for excessive output voltage. A shorted photodiode in the opto-isolator may prevent startup. An open photodiode may lead to a runaway condition. WARNING: probe these circuits with care both because of the safety issues but also since any slip of the probe may lead to a runaway condition and catastrophic failure of the switchmode transistor and its related parts as well as damage to any attached equipment.

Note that the high frequency transformer does not make the top 10 list - failure rates for these components are relatively low. You better hope so in any case - replacements are usually only available from the original manufacturer at outrageous cost.

Most other parts are readily available from places service parts distributors like MCM Electronics as well as general electronics distributors like DigiKey and Mouser.

Rebuild kits are available for many common supplies used in VCRs, monitors, terminals. See the section: Repair parts sources.

Also, while it is tempting to suspect any ICs or hybrid controllers since it is thought that replacements are difficult and expensive to obtain, these parts are pretty robust unless a catastrophic failure elsewhere sent current where it should not have gone. And, ICs at least, are usually readily available.

Sounds that SMPSs make

Most switchmode power supplies when operating normally produce little or no detectable sound. The switching frequencies are usually well above the range of human hearing, but your dog or pet dolphin might be driven nuts!

However, under various fault conditions, and sometimes when lightly loaded, there may be tell-tail audible indications of the SMPS's state of happiness. The cause may be in the SMPS itself or its load.

1. Tweet-tweet-tweet or chirp-chirp-chirp (sometimes flub-flub-flub) - Short circuit or current overload. This is usually an indication of a shorted secondary-side rectifier and/or if in a TV or monitor using an SMPS, a shorted horizontal output transistor. The power supply is in a repeating cycle attempting to start up, being dragged down by the overload, and shutting down.

2. High pitched, but audible, whine - Excessive load. Like (1), this may be caused by shorted components. For example, a common failure a Panasonic VCR power supply is for the 18 V zener diode across the 15 V output to short due to dried up electrolytic capacitors. The result in an overload and whine, but usually not a catastrophic failure of anything else.

Which of (1) or (2) actually present will depend on the particular design of the SMPS and the severity of the overload. If the design uses a hard SCR crowbar, an overvoltage condition may trigger one of the symptoms!

3. Tick-tick-tick - Too little or no load. In a TV or monitor using an SMPS, this is likely due to a lack of horizontal drive or a blown fuse or fusable resistor in the horizontal deflection system. The power supply is in a repeating cycle of starting up, being unable to limit the regulated voltage to a safe value, and shutting down. Attempting to power up an SMPS without an adequate dummy load may result in these symptoms.

4. Hissing or white noise - possibly from inductors - this may be normal under certain conditions:

   (From: Charlie Allen (charlie.allen@usa.net).)

   > "Some switchmode power supply inductors will make a hissing or white noise sound, typically when the circuit is lightly loaded and running in a "pulse skip" or PFM mode. I have heard it on many DC/DC circuits. You could try removing the coil and pouring in some epoxy."

General SMPS troubleshooting approach

The following sections provide a set of guidelines for attacking SMPS problems. Those in the next 5 paragraphs are common to SMPS using both discrete and integrated controllers:

1. First, determine that it is not something trivial like a blown fuse due to a legitimate overload (that has since been removed). I have a SCSI peripheral box that will blow its SMPS fuse if the SCSI cable is inserted live.

2. Categorize the problem into: startup problem, catastrophic failure, incorrect outputs, or excessive ripple or noise.

3. Determine what the proper output voltages should be. Identify the main (regulated) output.

4. Disconnect the supply from the equipment it is powering if possible. This will prevent the possibility of expensive damage should the output voltages soar to stratospheric levels for some reason. If this is not possible, you will need to be extra careful - always use a Variac to bring up the input slowly and monitor the main output at all times.

   Note: Some SMPS designs require power to be applied instantly to provide the startup voltage to the controller. If this is the case with yours, it won't be possible to bring up the voltage slowly (unless you power that chip separately). However, it should still be possible to run the unit somewhat reduced line voltage.

   CAUTION: Running any SMPS at greatly reduced line voltage will be stressful for it, especially if the output load is a significant fraction of its full load ratings. In addition, at some range of line voltage, the output regulation may not work properly and the output(s) may go much higher than expected. Use dummy loads in place of the valuable equipment if possible when doing such testing!

5. Determine an appropriate load for the outputs (if not connected to the equipment). A typical SMPS will want a minimum of 5% to 20% of full load current at least on the main output to regulate properly. Others may not need any load - it depends on the design or they may have an internal load. Here are some typical load currents:

   - VCR - 0.2 A on +5 V and +12 V outputs.
   - PC - 2 A on +5 V, 1 A on +12 V. A dual beam auto head light works well.
   - Monitor - 0.2 A on +60 V to +120 V output.
   - Typical 40 W switcher = 1 A on +5 V and +12 V.

Troubleshooting SMPSs using discrete controllers

The following paragraphs apply mainly to SMPSs using discrete circuitry (no ICs) for pulse width control. For those using integrated controller chips, see the next section: Troubleshooting SMPSs using integrated controllers.

- Startup problems - check the power on the switchmode transistor and work back from there if there is none. Check for open fusable resistors in the return as well. Determine if there is startup base/gate drive. Check for open startup resistors, bad connections, blown parts in the controller circuitry.

- Blows fuses - check primary side components, switchmode transistor(s), and all other semiconductors for shorts. Then check for open fusable resistors and bad connections. Finally, check the electrolytic capacitors for reduced capacity and leakage.

- Power cycling - monitor current and voltage sensing signals to determine if they are actually signaling a fault. Open or out of tolerance resistors may result in incorrect sensing. With the series light bulb and/or Variac, disable each of these inputs by bypassing the appropriate components. If one of these experiments prevents the cycling behavior, either that circuit has a faulty component or the controller circuit is not functioning properly.

- Regulation or ripple/noise problems - check main HV filter capacitor and other filter capacitors for decreased value or opens. Check regulation components including shunt regulators and zener diodes.

Troubleshooting SMPSs using integrated controllers

Since there are usually several fault conditions that can result in an aborted startup or cycling behavior, the basic troubleshooting procedure needs to be modified when dealing with SMPS using controller ICs like the UC3840 or UC3842.

Also see the section: Typical controller ICs found in small switchmode power supplies for descriptions of two common integrated controller ICs.

The following paragraphs apply to SMPSs using integrated controllers. For those using discrete components only (no ICs), see the previous section: Troubleshooting SMPSs using discrete controllers.

- Startup problems - check the power on the switchmode transistor and work back from there if there is none. Check for open fusable resistors in the return as well. Check for power to the controller. Determine that no fault condition inputs have abnormal voltages during startup. Check for drive out of the controller IC and see if it reaches the switchmode transistor. You will probably need to power cycle the line input and monitor each of the relevant signals as you do so. (It may not be possible to bring up the voltage slowly with a Variac if the startup circuit uses capacitive or inductive coupling to generate the intial supply voltage for the controller chip. However, a Variac can still be used to run it at reduced voltage if this is the case.) Determine if the supply is shutting down abnormally due to a legitimate or bogus over-current or over-voltage condition or is never actually starting up due to a lack of a voltage or a stuck-at fault on a sense line. Monitor its power to determine if it is stable during startup - a bad capacitor or diode could result in insufficient or decreasing voltage which causes the controller to give up.

  CAUTION: Running any SMPS at greatly reduced line voltage will be stressful for it, especially if the output load is a significant fraction of its full load ratings. In addition, at some range of line voltage, the output regulation may not work properly and the output(s) may go much higher than expected. Use dummy loads in place of the valuable equipment if possible when doing such testing!

  Powering the controller separately may aid in troubleshooting of these and related problems. This will decouple the chopper drive from the voltage usually derived via a winding on the high frequency transformer to power the controller once the supply is running.

- Blows fuses - check primary side components, switchmode transistor(s), and all other semiconductors for shorts. Then check for open fusable resistors and bad connections. There is a chance that a blown transistor took out the controller chip as well. Under normal conditions, controllers like the UC3840 or UC3842 should current limit on a PWM cycle-by-cycle basis. Therefore, a blown fuse indicates a failure of either the switchmode transistor, controller or both.

- Power cycling - First make sure you are providing the minimum load if one is required. Many SMPSs will cycle on overvoltage if there is none. Some may blow up! Assuming the load conditions are normal, monitor current and voltage sensing and Vcc inputs to controller to determine which, if any, are at fault. Open or out of tolerance resistors may result in incorrect sensing. Check for faulty reference setting components like zener diodes. With the series light bulb and/or Variac, disable each of the sense inputs by bypassing the appropriate components. If one of these experiments prevents the cycling behavior, either that circuit has a faulty component or the controller IC's input characteristics have changed and it will need to be replaced. It should be possible to determine if these sensing reference levels are correct from the controller specifications and thus should be ignored by the controller as within normal limits.

- Regulation or ripple/noise problems - check main HV filter capacitor and other filter capacitors for decreased value or opens. Check regulation feedback components to controller including any reference voltage output and zener diodes. Determine if the controller is responding to error voltage. If possible, monitor both error and PWM drive signals on a dual trace scope.

Initial post-repair testing

Once defective parts have been replaced, if possible remove the normal load from the supply if you have not already done so just in case it decides to put excessive voltage on its outputs and replace with a dummy load. For a multiple output supply, the most important output to have a load on is the one that is used for regulation but some modest load on all the outputs is preferred. You should be able to determine a suitable value by considering the application. For something like a VCR, a few hundred mA on the main output is probably enough. This would require something like a 25 ohm 2 W resistor for a 5 or 6 volt output or 50 ohm 5 W resistor for a 12 volt output (depending on which is the primary output). For a PC power supply, a couple of amps may be needed - a 2 or 3 ohm 15 W resistor on the +5 output. The minimum load is sometimes indicated on the specification sticker. In the case of a TV or monitor, disconnecting the load may not be possible (or at least, easy).

If available, use a Variac to bring up the input voltage slowly while observing the main output. You should see something at about 50% of normal input voltage - 50 or 60 V for a normal 115 VAC supply. With a small load, the output should very quickly reach or even exceed its normal value. Regulation at very low line voltage may be far off - this is often normal. Just make sure you're using dummy loads so your equipment can't be damaged.

Note: Some SMPS designs require power to be applied instantly to provide the startup voltage to the controller. If this is the case with yours, it won't be possible to bring up the voltage slowly (unless you power that chip separately. So, if nothing happens when doing this, don't panic - it may be a feature, not a bug. :) It should still be possible to run the unit somewhat reduced line voltage on the Variac.

If you do not have a Variac, put a light bulb in series with the line (this is desirable in any case). Use a 100 W bulb for a TV or PC, 40 W for a VCR typical. The light bulb should limit the current to a non-destructive value long enough to determine whether everything is OK. It may not permit normal operation under full load, however. When power is first applied, the light bulb will flash briefly but may just barely be glowing once the output has stabilized. If it is fairly bright continuously, there is likely still a problem in the supply. See the section: The series light bulb trick.

Once you are finished, save your schematic and notes for the future. For example, multiple models of VCRs even from different manufacturers use the same basic design, maybe even the same supply.

Some general switchmode power supply repair comments

Any time the switchmode transistor requires replacement, check all semiconductors for shorts and fusable resistors for opens. even if you locate what is thought to be **the** problem early on. Multiple parts often fail and just replacing the transistor may cause it to fail as a result of something else still being bad. In particular, check primary side electrolytic capacitors for reduced capacity or opens. These conditions can result in a blown switchmode transistor as it attempt to supply adequate current during the troughs of the rectified high voltage DC. It only takes a few more minutes. For other problems like an open startup resistor this excessive caution is unnecessary as these are usually isolated failures. However, if any dried up electrolytics are found, it is good practice to test them all - or just replace them all since the cost and time will be minimal. As they say, 'peas in a pod fail at nearly the same time'.

It is often helpful to trace the circuit by hand if a service manual is not available. You will gain a better understanding of this supply and be able to put the knowledge to use when the next one shows up on your bench - there is a lot of similarity even between different manufacturers. A bright light behind the circuit board may help to make the foil runs and jumpers more visible. The only difficult part will be determining how the transformer windings are hooked up. An ohmmeter will help but even if you cannot entirely determine this, just make a note. For most purposes, the exact topology of the windings is not critical for diagnostic procedures.

Periodic power cycling problems

These are of the form: tweet-tweet-tweet or flub-flub-flub or some other similar variation. Any LEDs may be flashing as well and in the case of something like a monitor or TV, there may be HV static or even a partial raster in synchrony with the sounds. These types of problems are more common with sophisticated implementations - the simple ones just blow up!

As noted elsewhere, shorted secondary components are a very likely cause of this behavior. These include diodes, capacitors, and overvoltage SCRs. The fact that there is some output suggests that the main switchmode (chopper) transistor is working. There would likely be no output at all if it were bad.

Note that an underloaded supply may be cycling due to overvoltage and there may actually be nothing wrong! Many SMPSs require a minimum load to maintain stability and to provide proper regulation. This is typically 20 percent of maximum on the primary output (the one which drives the feedback loop). However, minimum loads may also be needed on other outputs depending on design. The only way to be sure is to check the manufacturer's specs.

Other possibilities for periodic or pulsing outputs:

1. One of the diodes is failing at volage - quite possible. As long as you do not remove both from the output that is used for feeback, it should be safe to take them out one at a time and then substitute for the one remaining in the feedback voltage. Use a Variac and series light bulb when testing in this manner and constantly monitor the main output.

2. Some other cause of excessive current - shorted capacitor, transformer (though not likely), etc.

3. Faulty current sense circuit - open or increased value resistor.

4. Faulty voltage sense circuit - detecting overvoltage or regulation defective and it is shutting down (correctly).

5. Faulty component in the startup circuit. This could be a bad diode, resistor, or even an electrolytic capacitor that has changed value or is open at low voltage (when the controller is just waking up).

6. Faulty controller IC (if applicable).

Testing a SMPS without startup drive

Where an SMPS doesn't start and it isn't obvious why, it might help to drive the chopper from an external signal source to see what then works. The only time this is really practical is where a single transistor or MOSFET is used - generating a push-pull waveform probably isn't worth it.

This will always be a risky procedure both for you and the power supply. The switching frequency is likely unknown but for these tests you can assume it is in the 10 to kHz range. You can reduce the risk somewhat (to the supply at least) by using a series light bulb load and/or running on reduced line voltage. The most important thing to avoid is putting in an excessively long drive pulse which will result in the high frequency transformer saturating, huge amounts of current, and likely a dead transistor and possibly other parts if there is nothing to limit the current. If you have the option, start with a narrow pulse waveform to minimize on-time and don't push your luck! :)

Similarly, where a power supply attempts to start but cycles or shuts down, consider powering the controller chip from a separate supply to eliminate any issues of the transformer derived voltage that normally runs it after startup.

Components Found in Switchmode Power Supplies

Common, unusual, and strange

Most of the components used in switchmode power supplies are common and easily identified. However, some may be unfamiliar and unrecognizable. Others could be totally custom parts - ASICs or hybrid circuits - developed specifically for a particular model or product line. However, these rarely fail despite your temptation to blame them specifically *because* locating a replacement is difficult and most likely expensive.

Common components like transistors, diodes, capacitors, and resistors, can usually be tested with a multimeter at least for total failure. Also see the documents: "Testing of Bipolar Transistors with a VOM or DMM" and "Testing Capacitors with a Multimeter and Safe Discharging".

Of course, with catastrophic failures, no equipment beyond your eyeballs and nose may be needed.

Switchmode (chopper) transistors and other semiconductors

Also see the document: Basic Testing of Semiconductor Devices.

- Bipolar power transistors (often BU or 2SC/2SD numbers) - high voltage power types are used for the main switchmode (chopper) transistor.

Test for shorted and open junctions. These are the most common failures for the power transistors. Partial failure where there is some leakage or various parameters change value are unlikely.

Substitution of a transistor with at least equal voltage and current ratings should be fine for testing as long as you use a series light bulb to limit the current should something still be wrong elsewhere in the circuit. A not-exact match may run hotter than normal. Always use a heatsink.

- Power MOSFETs (2SK numbers) - many newer supplies are using these rather than the bipolar type. In some ways they are more robust but testing is more difficult.

  Testing for shorts is still possible but anything beyond the "moist finger test" requires additional equipment than a multimeter. However, the original problem did not blow a fuse or fusable resistor, if the MOSFET is not shorted, there is an good chance that it is still fine and you should look elsewhere for the problem. It may be a problem with the startup circuit or controller. There is also usually a 15 or 18 V zener across G-S for protection. This may blow when the MOSFET dies.

Note: if your supply produces any output (say, more than 10% of rated voltage), it is unlikely that the chopper transistor is bad as it must be working to some extent and, as noted, these usually blow totally.

- Small bipolar transistors - these may be found in feedback and control functions.

  Test for shorted and open junctions with a multimeter. Substitute with similar known good transistor is best, however. I have seen little silicon transistors that had developed enough leakage to prevent a 400 W supply from coming up!

- Diodes and rectifiers - a bridge or set of 2 or 4 discrete diodes is usually used for the AC line rectification and/or doubling. High efficiency and/or fast recovery types are used in the secondary side for rectification of the various output voltages. These may look like normal axial lead diodes or may be combined in pairs inside TO220 type packages.

  Test for shorted and open junctions. However, sometimes, diodes will only fail with full voltage in-circuit but test good with a multimeter.

  Replacements for the primary side rectifiers are very inexpensive and readily available. If the unit blows fuses with the switchmode transistor and main filter capacitors pulled, the rectifiers may indeed be bad.

  It is usually safe to remove secondary rectifiers one at a time to see if the supply will come up. As long as you do not remove all diodes for the output that provides the feedback for the regulation, this should be relatively low risk. (However, do this with a dummy load - not your expensive laptop computer just in case.) Even removing those diodes is usually safe if you can power the supply using a Variac since you will be able to limit the input (while monitoring the main output) should the outputs go overvoltage.

- SCRs - small SCRs may be found in the overvoltage protection circuitry of some supplies. Note that SCR type of crowbars are used across the output as a way to guarantee that an overvoltage condition will kill the output regardless of the reason for the overvoltage condition. Hopefully, the supply's overcurrent protection will kick in rather than having the supply blow up. This is not always the case, unfortunately.

  Test for shorts if output on which SCR is connected is not coming up. Remove the SCR. Now, using a Variac to bring up the voltage slowly, see if the relevant output is going over voltage, is still clamped at a low level, or is the correct voltage (under load). A momentary overvoltage spike at turn-on could also trip the crowbar. This could be due to a faulty inrush/slew rate limiting circuit.

- TL431 or similar shunt regulator IC - either a TO92 or 8 pin DIP. Has 3 active terminals - A, C, and R. Current will flow from C to A if R-A is greater than 2.5 V.

  Test for shorts but substitution is best. However, with care (using a Variac AND series light bulb to limit the input current, it is possible to determine if the circuit in which these are connected is working. Short across TL431 - supply should either turn off or run at greatly reduced output. Remove the TL431 - there should be no regulation - outputs should continue to climb as Variac is increased. By monitoring input to TL431 it should be possible to determine if it is doing its job.

- Optoisolator - either a 4 or 6 pin DIP or a 4 pin cylindrical object. This provides the regulator feedback across the isolation barrier. Replacements are readily available.

  Test by putting 10-20 mA through LED and measuring decrease in resistance of reverse biased photodiode. However, this will not identify a weak optoisolator. Swapping is best.

Capacitors (filter and bypass)

- Filter capacitors - electrolytic type are used for filtering of the rectified (possibly doubled) AC line input and for filtering of the various outputs of the power supply.

  If no capacitor checker is available, test for opens, shorts, and leakage with a multimeter. For electrolytics, this is straightforward. Inspect the capacitor for any discoloration, a bulging case, or other evidence of trauma.

  An ESR meter is a convenient device for rapidly checking the health of electrolytic capacitors. The ESR (Effective Series Resistance) of a capacitor increases as the capacitor deteriorates ('dries up'). Even a capacitor that tests good on a capacitor checker may not work properly due to excessive ESR.

  When in doubt, the best approach is to substitute a known good capacitor of at least equal working voltage and similar uF rating.

  Also see the document: Capacitor Testing, Safe Discharging and Other Related Information.

  (From: Steve (libertytek@aol.com).)

  > "When you find a position that eats electrolytic caps, replace them but add a parallel .22 to .47 uF ceramic monolithic.
  >
  > Whenever these crappy caps are used with even small high frequency currents passing through them, they break down chemically causing other failures also. Even the "high ripple current" rated caps won't tolerate what they should and are often rated at 1,000 - 2,000 hours.
  >
  > I also often find too little heat sinking and will add more surface to improve cooling."

- Bypass Capacitors - high quality plastic dipped or rectangular molded capacitors as part of RFI filter. These rarely fail.

Test for shorts - your multimeter will probably not be able to detect the small capacitance. Substitute if in doubt.

Note that many of these are special high quality low loss types with regulatory approval for use across the power line in the line filter. Exact replacements are required for safety.

Resistors (normal and flameproof), NTC thermistors, MOVs

- Resistors - test for correct value with a multimeter. If measured in-circuit, value may read low if shunted by other components. If a higher than normal reading is obtained in-circuit, the resistor is bad. Metal film types like to go open circuit - especially very high value resistors.

  Startup resistors in particular tend to go open-circuit resulting in a dead supply but no blown fuses or fusable resistors. These are usually high value (100K typical) medium wattage and run hot since they are across the full rectified line voltage.

- Flameproof or fusable resistors (They are the same) - these are often designated 'FR'. They will look like power resistors but will be colored blue or gray, or may be rectangular ceramic blocks. They should only be replaced with flameproof resistors with identical ratings. They serve a very important safety function: they cannot catch fire when overheated and will open rather than changing value which implements an overload protection function.

  These usually serve as fuses in addition to any other fuses that may be present (and in addition to their function as a resistor, though this isn't always needed). If an FR type resistor has blown, you probably have shorted semiconductors that will need to be replaced as well. Check all the transistors and diodes in the power supply with an ohmmeter. You may find that the main switch mode transistor has decided to turn into a blob of solder - dead short. Check everything out even if you find one bad part - many components can fail or cause other components to fail if you don't locate them all. Check resistors as well, even if they look OK.

  The most common location for these in a small SMPS is in the return circuit of a the switchmode transistor. However, they may be in the power feed as well. The value may be a fraction of an ohm but can be larger.

  In TVs and monitors, these are often found in the hot power feed to the main low voltage power supply and in various secondary supply feeds as well. For the main supply, they will be 5-25 W rectangular ceramic power resistors. For the secondary supplies, they may be the 1/2-2 W blue or brown tubular variety.

  Test for opens. Those in the return circuits are usually very low value - a fraction of an ohm to a few ohms - if in the return of the switchmode (chopper) transistor. The type in the power feeds may be anywhere from a fraction of an ohm to several K ohms depending on the circuit load.

  For testing ONLY, a normal resistor may be substituted but the proper replacement MUST be installed before returning the supply to service.

  Since they function as fuses, flameproof resistors should not be replaced with higher wattage types unless specifically allowed by the manufacturer. These would not blow at the same level of overload possibly resulting in damage to other parts of the circuitry and increasing the risk of fire.

- MOVs - Metal Oxide Varistors - look like brightly colored plastic coated disk capacitors but not marked with capacitance. These are surge suppressors. A severe surge or lightning strike may obliterate one or more of these. There will usually be either 1 between the Hot and Neutral or 3 across H, N, and safety ground.

If they are visibly damaged in any way, just remove (for now) or replace. Test with an ohmmeter - resistance should be nearly infinite.

- NTC resistors (thermistors) - Negative Temperature Coefficient resistors act as inrush surge limiters. There may be one or two of these in series with the AC input. These are a high value when cold but drop to a low value once they heat up due to current flow into the supply. These often look like fat black disk capacitors.

  Test when cold and hot (use a hot air gun or hair dryer if not in-circuit). Resistance should drop from 10s of ohms to a very low value.

Transformers and inductors

- High frequency transformers - these include the switchmode power transformer and any feedback (toroidal or E-I core type) transformers.

  The main transformer which provides line isolation and generates the multiple output voltages from the 150-320 VDC input rail. These are usually custom wound for each model power supply and replacements are only available from the manufacturer. However, some distributors will stock replacements for a few TVs and computer monitors.

  Testing for opens is usually easy since connections to the input (chopper) and output rectifiers are fairly obvious. However, feedback windings may be involved and these are not readily determined without a schematic or tracing the circuit (and, possibly not even then.) The good news is that failures of these transformers is less common than one might fear.

  Some supplies use small transformers for feedback rather than optoisolators. These can be tested for opens but rarely cause problems. There may also be transformers in series with the input that can be similary tested.

  Identifying shorted turns requires a 'ring test' or measurement of the Q. See the document: Testing of Flyback (LOPT) Transformers.

- Control/standby power transformers - used to provide power to the controller of some units when the main chopper is idle. These may be damaged by a power surge, usually with an open primary winding. Test with an ohmmeter. A shorted winding will result in overheating.

- Inductors - test for opens. Identifying shorted turns requires a 'ring test' or measurement of the Q. See the document: Testing of Flyback (LOPT) Transformers.

  AC line input inductors can just be bypassed if they test open.

  Output 'pi' filter inductors rarely fail but if you suspect one, just remove it and jumper across the pads for testing - ripple just won't be quite as good.

- Coupled Inductors - used as part of the Pi type RFI filter in the AC input circuit. These look like small transformers but the windings are in series with the AC line. There are usually 1 or 2 of these on better supplies and they are very reliable.

Test for opens. Identifying shorted turns requires a 'ring test' or measurement of the Q. See the document: Testing of Flyback (LOPT) Transformers. These inductors can just be removed and bypassed during testing if they are open since they only affect input line noise filtering.

Fans

Many small SMPSs don't have any fans built in but expect there to be a fan or fans elsewhere in the equipment designed draw air over the power supply. Most computer power supplies do have a fan inside - and these are high failure items due to how cheaply they are made.

A bad or tired fan, or even clogged air filters, can result in overheating and outright failure, or at the very least, increased stress on components and reduced life expectancy. Thus, periodic maintenance is highly recommended. Inspection of the fan(s) and filter(s) should be one of the first steps in any testing procedure.

The most common problem with fans is dry/gummed up/worn bearings. Ball bearings are rarely found in PC power supplies (the manufacturer saved 25 cents). Even on expensive workstation computers, mediocre fans may be used (Sun Microsystems had to replace a whole bunch of fans on state-of-the-art Ultra-Sparc systems because of bad bearings). Quick test: With the power off, give the fan a spin. If it continues to coast for at least a couple of seconds, the bearings are probably good. If it stops instantly, they are gummed up. If in doubt, replace the fan with a good quality ball bearing type. It's really not worth attempting to disassemble and oil the bearings unless you have nothing better to do.

Fan motors do go bad but this is much less common than bad bearings. With modern brushless DC motors, one phase could be defective resulting in sluggish operation and/or failure to start if stopped in just the wrong position.

On more sophisticated equipment with temperature sensing to adjust fan speed, the speed control circuitry could also be bad.

WARNING: Replacement of the fan on SMPSs requires access to the interior. Make sure the equipment is unplugged and the large filter capacitors are fully discharged before doing anything inside the case - both for your safety and to prevent damage to the supply.

For more on fans, fan motors, and lubrication, see the document: Notes on the Troubleshooting and Repair of Small Household Appliance and Power tools.

(From: Clive Cooper (clpc@cooperware.com).)

I spent 3 days searching for a problem on a SMPS. It turned out to be a simple fault that eluded me for some time.

The SMPS worked fine for about 10 minutes and then the output voltages dropped slowly and eventually the supply went dead.

It turned out that the fan, although it appeared to be working fine was only getting 60% of the supply voltage it needed. This was due to a faulty temperature sensor that just told the fan that the supply was cold even when it was hot.

Conclusions: A fan that is blowing is not necessarily blowing what it should be blowing and the fact that it seems to be working doesn't mean its working at maximum efficiency.

Items of Interest

Panasonic VCR SMPS

The same power supply design is used with minor variations in a wide variety of Panasonic (and clone) VCRs from the 1980s and 1990s (and may continue to this day). Depending on the specific model, there may slightly different output voltages and number of outputs but the general organization is identical. These use discrete components throughout with feedback from the primary output (5 to 5.2 V depending on model) using an optoisolator to essentially short out the drive to the main chopper transistor (Q1) when the output equals the desired voltage. The most common problems found with any of these supplies is dried up electrolytic capacitors. Generally, the first to go will be C16 and C17 on the +5.1 VDC line and/or C21 in the feedback path (actual part type and number may vary slightly with model). Symptoms will be either that the primary output is somewhat low (4 to 4.5 VDC) or that the supply has gone overvoltage and blown the protection zener (D15) resulting in a high pitched whine as the chopper struggles to drive current into a short circuit (this usually doesn't damage any other parts if caught in a reasonably timely manner). If any capacitor related problems are found, it is a good idea to replace all the electrolytics in the supply. Model specific capacitor kits as well as total rebuild kits are available from places like Studio Sound Service and MCM Electronics.

The Panasonic VCR power supply schematic is available in both PDF and GIF format:

Typical controller ICs found in small switchmode power supplies

Here is some information on the Unitrode UC3840 programmable off-line PWM controller and its simplified cousin, the UC3842. These are typical of the types of sophisticated inexpensive integrated SMPS controller ICs that are now readily available.

* Unitrode Datasheets gets you Unitrode's power conversion controllers (more than 40 different devices!).

  Or, from the Philips site:

* UC3842 Datasheet

* UC3842 Application Note

The information below is just a summary.

These devices generate the PWM pulse control to the switchmode (chopper) transistor as well as various fault sensing and other control functions.

Parts such as these are now found in many small switchmode power supplies and provide much more precise control during startup and normal operation, and better handling of fault conditions compared to most implementations using discrete circuitry.

However, they also result in additional head scratching when troubleshooting since many faults or incorrectly detected faults can shut down the unit or cause a power cycling type of behavior. Therefore, a datasheet for the controller chip will prove essential. In many cases a scope will be needed to monitor the various sense, control, and drive signals. A systematic troubleshooting approach must be used to eliminate power, startup, sensing, and control components one at a time once obvious shorted or open parts or bad connections have been eliminated from consideration.

Unitrode UC3840 programmable off-line PWM controller

Features of the Unitrode UC3840 include:

1. Fixed frequency operation set by user selected components.
2. A variable slope ramp generator for constant volt-second operation. providing open-loop line regulation and minimizing or in some cases, even eliminating the need for feedback control.
3. A drive switch for low current start-up off of the high voltage line.
4. A precision reference generator with internal over-voltage protection.
5. Complete over-voltage, under-voltage, and over-current protection including programmable shutdown and restart.
6. A high current single-ended PWM output optimized for fast turn-off of an external power switch.

The following pin descriptions for the Unitrode UC3840 were derived from a Unitrode application note. Errors in interpretation are quite possible.

```
Pin 1: Compensation         Error amplifier (op amp) compensation network.

Pin 2: Start/U.V. lockout   This comparator performs three functions.  With
                            an increasing voltage, it generates a turn-on
                            signal at a start threshold. With a decreasing
                            voltage, it generates an under-voltage fault
                            signal at a lower level separated by a 200uA
                            hysteresis current.  At the under-voltage
                            threshold, it also resets the Error Latch if
                            the Reset Latch has been set.

Pin 3: OV sense             Over-voltage input from power supply output(s).

Pin 4: Stop (Ext stop)      External logic signal to inhibit power.

Pin 5: Reset                External logic signal to reset error condition
                            caused by (1) over-voltage, (2) over-current, (3)
                            input under-voltage detect, (4) external stop.
```

Pin 6: Current threshold	This voltage input sets the over-current trigger levels for the internal comparators.
Pin 7: Current sense	This is the pulse-by-pulse PWM current control. The input is a voltage taken across a series resistor in the switchmode transistor's return. There are two internal comparators with a difference in threshold of 400 mV. The one with the lower threshold limits the current for each PWM cycle. The one with the higher threshold sets the error flop-flop and shuts down the supply if its threshold is ever exceeded.
Pin 8: Slow start	This input limits the maximum PWM duty cycle. During power-on, an RC delay can therefore control the rate at which the output ramps up. The final value limits the maximum PWM duty cycle during normal operation.
Pin 9: Rt/Ct	R and C determine the constant PWM oscillator frequency.
Pin 10: Ramp	Ramp generator output.
Pin 11: Vi sense	This voltage is normally derived from the DC input and controls the slope of the ramp.
Pin 12: PWM output	This is the drive signal to the switchmode transistor. This is an open collector output and will normally be used in conjunction with the Driver bias (Pin 14) signal to provide total drive to the switchmode transistor.
Pin 13: Ground	Signal and drive common.
Pin 14: Driver bias	Supplies drive current to external power switch to provide turn-on bias and pullup during normal operation. Disabled for shutdown if the Error Latch is set.
Pin 15: Vcc	UC3840 chip supply derived from the DC input rail during startup and secondary winding on high frequency transformer during normal operation.
Pin 16: 5 V reference	Stable voltage reference (output) for regulation control.
Pin 17: Inv input	Error amplifier inverting input.
Pin 18: Non inv input	Error amplifier non-inverting input. The difference between the inputs on Pins 17 and

18 control PWM duty cycle. These will generally be derived by comparing the main output with the desired voltage reference.

Unitrode UC3842 off-line PWM controller

The UC3842 provides the necessary functions to implement an off-line fixed frequency current mode control schemes with a minimal external parts count. Note how most of the pin functions are subsets of those found in the more sophisticated UC3840. The UC3842 retains most of the features of the UC3840 but requires fewer external components and comes in a much smaller package (8 vs. 18 pins).

The following pin descriptions for the Unitrode UC3842 were derived from a Unitrode application note. Errors in interpretation are quite possible.

```
Pin 1: Compensation           Error amplifier (op amp) compensation network.

Pin 2: Vfb                    Error amplifier (non-inverting) input for
                              regulation feedback.

                              This input is used to control PWM duty cycle
                              and is normally derived from the main regulated
                              output voltage.  It is similar in function to
                              The non-inverting input, Pin 18, of the UC3840.

Pin 3: Current sense          This is the pulse-by-pulse PWM current control.
                              The input is a voltage taken across a series
                              resistor in the switchmode transistor's return.

Pin 4: Rt/Ct                  R and C determine the constant PWM oscillator
                              frequency.

Pin 5: Ground                 Signal and drive common.

Pin 6: PWM output             This is the drive signal to the switchmode
                              transistor.  It uses a totem pole output which
                              has a high current drive capability both high
                              and low.

Pin 7: Vcc                    UC3842 chip supply derived from the DC input rail
                              during startup and secondary winding on high
                              frequency transformer during normal operation.

Pin 8: 5 V reference          Stable voltage reference (output) for regulation
                              control.
```

Description of UC3842 startup operation and cycling problems

Depending on the particular circuit design, a variety of fault conditions can result in cycling or shutdown of an SMPS controlled by a chip like the UC3842. And, an underloaded supply may be cycling due to overvoltage!

In addition to the overload condition described below, a dried up electrolytic capacitor on the Vcc line can also result in this cycling behavior since it is unable to hold up the voltage between output pulses. In addition, the sense inputs can trigger shutdown. In all, an often complex difficult to understand and troubleshoot situation - sometimes too much so for its own good!

(Portions from: Yves Houbion (yves.houbion@fundp.ac.be).)

Pin 7 is the power supply (Vcc). The oscillator inside the 3842 begins to work above 16 V on Vcc and stops working when this voltage drops below 11 V. With a stopped oscillator, the current consumption is very low, around 1 mA; with a working oscillator, the current is much higher, about 12 mA. (The specific voltages and currents are typical values for one particular version of the 3842 and can vary from device to device and depending on model.)

Vcc is generally powered in two ways: a high value power (startup) resistor connected to the main bridge (e.g., +300V) and a from a winding off the transformer (via a rectifier/filter capacitor). The value of the startup resistor is selected such that there is more than 16 V with 1 mA but less than 11 V at 12 mA. So the oscillator can't continue to work with only the startup resistor supplying power.

Suppose we apply AC power to the supply. The +300V comes on. First, the 3842 consumes only 1 mA, Vcc reaches 16 V, and the oscillator starts up. If all is well (no overloads), the transformer provides the necessary 12 mA current to maintain Vcc at more than 11 V.

However, if the transformer is overloaded, Vcc falls under 11 V and the oscillator stops working. The current decreases to 3 mA, the voltage increase (coming from the +300V) the oscillator start again, ad-infinitum.

Tweet-tweet-tweet....

Switching between 115 VAC and 230 VAC input

Assuming it is not a wide compliance 'universal type', a common way to do this is with a jumper (or switch) in the line input circuitry below (also shown in Typical SMPS Input Voltage Select Circuit):

```
              D1
AC o-----+----|>|-------+---------+-----o DC (+)
        ~|    D2        |+        |
         +----|<|----+  |       +_|_
              D3     |  |     C1 ---
         +----|>|----|--+       - |
         |    D4     |    +--o-o--+     +320 VDC to chopper
AC o---+-+----|<|----+ -  |  J1   |
       |~            |    |     +_|_
       +-------------|----+   C2 ---
                     |          - |
                     +------------+-----o DC (-)
```

- With the jumper, J1, installed, the circuit is a voltage doubler for use on 115 VAC. (D3 and D4 never actually conduct because they are always reverse biased.)
- With the jumper, J1, removed, the circuit is a simple bridge rectifier for use on 230 VAC.

Changing the input voltage of a switchmode power supply

Would it be possible to modify a power supply designed for operation on 120 VAC for use overseas where the power is 240 VAC?

I don't advise it. There are many factors involved in changing a power supply unless it is designed for dual voltage or autoswitching. They saved a few cents if it is not easily switched, what can I say?

The problem is that it is probably a flyback converter and these are pretty finicky about changes. In addition to the caps, and switching transistor, the transformer would probably saturate at the higher voltage unless the switching frequency were also doubled. Getting these things to work normally without blowing up is touchy enough. To change one without a thorough understanding of all the design parameters would be really risky.

Going the other way may be more realistic if (and this is a big if) you will not be running at anywhere near full capacity. Many switchmode power supplies will run on much lower than their rated input voltage. However, regulation may be poor and the switchmode transistor will need to be passing much higher current to maintain the same power output. To maintain specifications could require extensive changes to the circuitry and replacement of the switchmode transistor and possibly transformer and other parts as well. Again, I do not recommend this.

Use a small stepup or stepdown transformer instead. The only exceptions are:

- If there are clearly marked jumpers to select the input voltage.

- You can reverse engineer enough of the input circuitry to add/remove the needed connection with confidence.

  CAUTION: As they say in wood-working: "Measure twice, cut once". Make sure you are dealing with the correct jumper AND you are going the right way (increasing or decreasing as needed). If the manufacturer didn't include this feature, there may be a good reason!

- The supply is clearly marked as being autoswitching or having universal power input.

Also see the secton: "Switching between 115 VAC and 230 VAC input".

Slightly modifying the output voltage of a PC power supply

Surplus PC power supplies are widely available and inexpensive. However, what do you do if 5 V isn't exactly what you need for a project?

(From: Winfield Hill (hill@rowland.org).)

Some of the PC power supplies I've dissected do have pots, by they have a limited voltage-adjustment range. One interesting thing, every design used a TL431 chip, which is a 3-pin TO-92 regulating IC, as the voltage reference and opto-feedback component. Find this chip and trace out the resistors connected to it to determine which part to change to make a higher voltage.

But, watch out for the SCR over-voltage circuit in some supplies. This is usually set to trip around 6 to 6.5 volts, and its trip point would need to be modified as well.

As far as the step-down transformer turns ratio, there's little trouble one will encounter here, because the power supply is no doubt designed to function properly with reduced AC line voltages. The penalty one will pay for turning up the output voltage is a higher minimum AC voltage.

In most designs, the +12 and -12 V supplies merely track the 5V supply, and are not separately regulated. They may soar to higher voltages anyway if unloaded, but will be additionally increased in voltage by the ratio of 5V output increase. Even though the rating of the 5V electrolytic may not be exceeded, and still have a sufficient safety margin, this may not be the case for the 12 V outputs. So that issue should be examined as well.

Finally, a reminder for any reader tempted to break open the box and start experimenting. Voltages of up to 320 V are present, so be careful. Know what you're doing. For safety, stay away from open supplies when plugged in, or always keep one hand behind your back when probing. Remember a the AC bridge and HV DC and flyback transformer portion of all these supplies is operating straight from the AC line, so don't connect the ground of your oscilloscope to any of that circuitry. A battery-operated multimeter is best.

Use of surge suppressors and line filters

Should you always use a surge suppressor outlet strip or line circuit? Sure, it shouldn't hurt. Just don't depend on these to provide protection under all circumstances. Some are better than others and the marketing blurb is at best of little help in making an informed selection. Product literature - unless it is backed up by testing from a reputable lab - is usually pretty useless and often confusing.

Line filters can also be useful if power in you area is noisy or prone to spikes or dips.

However, keep in mind that most well designed electronic equipment already includes both surge suppressors like MOVs as well as L-C line filters. More is not necessarily better but may move the point of failure to a readily accessible outlet strip rather than the innards of your equipment if damage occurs.

Very effective protection is possible through the use of a UPS (Uninterruptible Power Supply) which always runs the equipment off its battery from the internal inverter (not all do). This provides very effective isolation power line problems as the battery acts as a huge capacitor. If something is damaged, it will likely be the UPS and not your expensive equipment. Another option is to use a constant voltage transformer (SOLA) which provides voltage regulation, line conditioning, and isolation from power spikes and surges. Manufacturers of these products may even provide equipment damage warranties which will reimburse for surge damage to the powered equipment while using their products. I am not sure how one proves that the UPS was being used at the time, however!

It is still best to unplug everything if the air raid sirens go off or you see an elephant wearing thick glasses running through the neighborhood (or an impending lightning storm).

GFCI tripping with monitor (or other high tech equipment)

Ground Fault Circuit Interrupters (GFCIs) are very important for minimizing shock hazards in kitchens, bathrooms, outdoors and other potentially wet areas. They are now generally required by the NEC Code in these locations. However, what the GFCI detects to protect people - an imbalance in the currents in the Hot and Neutral wires caused possibly by someone touching a live conductor - may exist safely by design in 3 wire grounded electronic equipment and result in false tripping of the GFCI. The reason is that there are usually small capacitors between all three wire - Hot, Neutral, and Ground in the RFI line filters of computer monitors, PCs, and printers. At power-on and even while operating, there may be enough leakage current through the capacitors between Hot and Ground in particular to trip the GFCI. Even for ungrounded 2 wire devices, the power-on surge into inductive or capacitive loads like switching power supplies may falsely trip the GFCI. This is more likely to happen with multiple devices plugged into the same GFCI protected outlet especially if they are controlled by a common power switch.

Therefore, I do not recommend the use of a GFCI for computer equipment as long as all 3 wire devices are connected to properly grounded circuits. The safety ground provides all the protection that is needed.

Why do power supplies seem to fail after a power outage?

Startup is the most stressful time for a typical switchmode power supply. The output filter capacitors as well as the load must be driven while the input voltage is changing - possibly wildly. With careful design, these factors can be taken into consideration. Not all power supplies are designed carefully or thoroughly tested under all conditions. When power is restored, surges, dips, brownouts, and multiple on-off cycles are possible. This is why it is always recommended that electronic equipment be unplugged until power has been restored and is stable.

Supplies that are autoselecting with respect to input power are vulnerable to voltages at an intermediate value between their low and high ranges. At some values, they may autoselect the incorrect input range:

(From: Mike Diack (moby@kcbbs.gen.nz).)

A subject dear to my heart due to a recent unpleasant experience - Was using a Picturelel videoconference ISDN codec on a job when, because of a powerline fault, the line voltage dropped to 170 volts. The PicTel has a big Onan switchmode PSU which is autoswitching between 100-120 and 200-240 volts. It got confused, and (regrettably) chose the former.... with very smelly results.

Moral: turn off things with cunning PSUs when brownouts occur (oh yes the airconditioner units got very hot and tripped out, too)

Buzzing or other sounds from SMPSs

Two common causes are (1) loose transformer (or other cores) vibrating at a subharmonic of the switching frequency and (2) dried up electrolytic capacitors (primary side) introducing 120 Hz hum under load.

(From: Ray Hackney (rhackney@unicomp.net).)

Simplistically speaking, the sound comes from something moving.

With non switch mode power supplies (SMPS), it may be ferrous material (like a metal cover) being drawn toward the power transformer. That's obvious since pushing on the cover will soften the hum. The frequency is usually 60Hz or 120Hz.

The only time you should hear a "noise" from a SMPS is during a period of "unstable" operation (i.e. their "loop" isn't stable and in regulation.) That's why you may hear them "chirp" or whistle when you first turn them on or off. It may also indicate a PC type power supply that's overloaded. In years gone by, I've seen a quiet PC become a whistler after having a new, big (30 meg, full height!) hard disk added. Sometimes the pitch of the whistle would change depending on what parts of the system were being accessed or what software was being executed. (Usually, when the old Intel AboveBoard was being accessed in this '286, the audible pitch was lower indicating greater current draw.)

For all power supplies, it may be the windings on the "magnetics" (inductor or transformer). If they're not wound tightly and secured they can vibrate. Many video monitors exhibit this problem when their flyback transformer emits a whistle. It may be the windings themselves moving or the winding assembly may be loose on the core.

Sometimes the capacitors in a SMPS will emit sound. Caps in SMPS' frequently have high AC current levels. If the supply is supposed to have what's known as "continuous current" and goes into "discontinuous current" mode, the capacitor plates get stressed pretty heavily and move in the capacitor body (but only with some types). Since the SMPS will go into and out of discontinuous mode at a rate < 10kHz, it's audible. I've run into this on breadboards I've built for 200W and 2.5kW SMPS'.

Cool electrolytics - temperature rating versus ESR

(From: Jeroen H. Stessen (Jeroen.Stessen@philips.com).)

Electrolytic capacitors like to be kept cool! If there's anything that these capacitors can't stand, it's heat. It causes them to dry out.

Electrolytic capacitors exist in (at least) two different temperature ratings: 85 C and 105 C. The latter are obviously more temperature resistant. Unfortunately they also tend to have a higher ESR than their 85 C counterparts. So in an application where the heat is due to I^2 * ESR dissipation, the 105 C type may actually be a *worse* choice! If the heat is due to a nearby hot heatsink then 105 C is indeed a better choice.

When better may be worse

ESR is usually something to be minimized in a capacitor. However, where the original design depended (probably by accident) on a certain ESR, this may not always be the case:

(From: Lee Dunbar (dunbar@unitrode.com).)

Substitutions of low ESR caps into circuits which had lousy caps is not always the good idea that it appears to be.... Caution is advised, as low ESR caps will not limit surge currents.

The circuits' series impedance drops (compare substituted capacitors ESR when new with the original capacitor's ESR was when it was a new capacitor), which, in turn, lets the surge magnitude rise, the higher currents destroy can semiconductors and other components.

I guess what the industry needs is a good capacitor cross reference guide for aluminum electrolytics!

Alan's SMPS troubleshooting technique

(From: Alan Liefting (aliefting@ihug.co.nz).)

1. Replace all faulty components and check all semiconductors and resistors.

2. Remove switching MOSFET or disconnect its supply voltage.

3. Connect variable DC PSU to main secondary voltage (one which is monitored).

4. Connect an oscilloscope to the gate of the switching MOSFET. As the DC voltage from the external PSU is increased to the value of what the SMPS output should be, a change in the mark-space ratio of the PWM

waveform can be observed. Only a small change in the supplied voltage around the SMPS output voltage is required to observe the effect as the power supply attempts to regulate.

If the supplied voltage is increased further the PWM waveform will cease as the control circuit will detect an overvoltage.

With this technique the whole power supply can be tested without fear of destroying MOSFETs and it can be determined if the SMPS is regulating to the correct voltage (if known!).

This will not work with all SMPS's. It depends on the design.

John's notes on SMPS repair

(From: John Croteau (croteau@erols.com).).

Switchmode power supply repairs can be difficult. The problem is manufacturers don't usually give you an easy test set up. They should tell you if it will run at no load or what dummy load to use. Secondly they should tell you what voltage or resistance to use to replace the opto-isolator (or transformer) for that load. The SMPS hot side is a high frequency oscillator whose 'on time' is varied by feedback supplied through the opto-isolator. The troubleshooting procedure should normally be in this order.

1. First eliminate external causes such as shorts or no load as the cause of the shutdown.

2. Eliminate the secondary side shorted diodes, capacitors, etc.

3. After eliminating overloads on the outputs check the DC supply to the power device.

4. Check the bias coming from the feedback. Trace the bias supplied by the feedback and try to determine what is the correct bias for that situation (usually no power same as start-up).

   - If the bias is as on the schematic then troubleshoot the hot (primary) side as any oscillator.

   - If the bias is wrong and there is no short on the output then concentrate on why the feedback doesn't supply the expected voltage to bias the scillator on.

5. If you work on many of the same type SMPS:

   - Determine the normal load and make a dummy load.

   - Determine the value of resistance that is created at the output of the opto-isolator (hint: use Ohm's law). Then remove one leg of the output of the opto-isolator and replace it with a resistor as calculated.

   By using a fixed load and cutting out the feedback it is very easy to troubleshoot. Don't forget to check the voltages and waveforms in your test set-up and record them for future reference.

Russell's comments on SMPS repair

(From: Russell Houlton (71101.2454@CompuServe.com))

I wanted to pass on some comments on repair of switchmode power supplies. I've fixed a few myself.

1. I see quite a few where the filter capacitors have failed. Not all electrolytic capacitors are the same. You should get capacitors that are rated for high frequency service. Use of "normal" caps that one finds in the local electronics stores are likely to go bad in about a year. Not something a professional who values his reputation wants to see happen. In fact, I suspect that some manufacturer fail to understand this and use the wrong caps causing common failures in their units. Especially units that may be subjected to use in warmer areas. I see this mostly with specialized devices rather then mass consumer items.

   I highly recommend the Panasonic HFS series cap that can be bought from DigiKey (and other places I'm sure). These unit are specially designed for good size as well as use in switching supplies. They are also rated for 105 degrees C as opposed to the more common 85 degrees C temperature rating. I have never had to replace a HFS cap I installed, where I've had to replace "common" caps in repair situations. (No I don't sell the HFS or have stock in DigiKey, I'm just passing some info that has worked well for me.) (Note: The HFS series caps have been discontinued by Panasonic. They recommended using the EEU-FC (FC series) as a replacment. --- Sam.)

2. SMPS usually try to regulate one of the output voltages by using the switcher, usually it's the output with the most power, but might be the one that's most voltage critical. If the filter caps go bad in the main output voltage, the auxiliary output voltages will go high. The SMPS may also start to make high-pitched sounds as the ripple messes with the feedback system. The aux output voltages may go so high that the secondary regulator may go into foldback to protect itself. I found this out the hard way. It's really something that can kick you in the pants because normally one would not check the 5V supply if the problem seems to be a bad 23.5 V regulator.

3. Noisy (whining or buzzing) SMPSs that still work tend to be either bad main output voltage capacitors or bad electrolytics in the power oscillator circuit. See the section: Buzzing or other sounds from SMPSs.

4. Most SMPSs have also have a *minimum* power draw requirement from their loads. This is especially true of the main output voltage. If not enough power is drawn from the supply, the supply may not be stable and can not supply full power on the auxiliary voltages. An example of this is using a 250 W PC power supply just to drive a disk drive. Without the heavy 5 V power draw of a motherboard, the supply may not start up reliable or provide the needed 12 V power for the hard drives.

5. I've also seen cases where one of the voltage doubler caps will open up causing failure in one of the switching transistor(s). It will short out a single transistor unit, but in a dual switching unit, the transistor associated with the good cap will over-work itself and open. An easy way to test is to remove the other switching transistor (in a dual unit) and apply power for 2 seconds. (Take all prudent precautions for working around a live and open unit!) Disconnect power and use your voltmeter to check the voltage across each of the caps. They should discharge at a roughly equal rate. A bad cap will lose all it's voltage in less then 2 seconds. A good cap will hold it's charge much longer.

6. Lastly, some unit that have the switch mode power supply in the same enclosure as the CRT will have a sync signal that comes from the horizontal flyback transformer. This keeps the SMPS in sync with the display so that the small magnetic fields that are created by the SMPS don't create a wavy pattern on the screen. Something to remember if a newly re-assembled unit shows a window screen like interference pattern on the display.

Bob's description of how a typical PC power supply works

(From: Bob Wilson (rfwilson@intergate.bc.ca).)

I really suggest you refer to a handbook on basic switchmode power supply design for the nitty-gritty.

I have a schematic of a 200 Watt PC power supply, and I assure you that there are enough cost-saving clever shortcuts in the design, that unless you know a fair amount about the design of switchers, it will just totally and completely baffle you.

Nearly all 200 W PC power supplies are *identical* knock offs of one-another (except for the power-good comparator section). The transformer has a +5 V output which is what is regulated. It also has a +12 V output and a -12 V output. The -5 V output is derived from the -12 V output using a 7905 regulator. All transformer outputs are related in voltage by the transformer turns ratio. The power supply topology is a Half Bridge, which normally requires a "buck section" in each output (namely an inductor, catch diode and capacitor). To vastly improve the cross regulation between windings, a common core is used to wind all the 3 output inductors on.

Basically, however, a 200 W PC power supply is a half-bridge design, with a bridge-type voltage doubler in front which simply rectifies 220 V, or doubles 110 V to 220 V. So the thing is basically a 220 Volt design.

The controller is typically a TI TL494 that operates off the output of the supply. This means that in order to start, there must already be an output voltage present! How they do this is really really clever, and also extremely confusing. The power transformer is itself, self oscillating. This generates a rudimentary output voltage that allows the thing to bootstrap up to normal operation, and the controller chip to take over.

The +12 Volt output is what is used to power the PWM chip. Thus, the supply runs off its own output. This is done to eliminate the need for troublesome opto-coupler feedback. To boot itself up (after all, there is no initial +12 V to allow itself to start), the driver transformer is modified (very cleverly) to form part of a blocking oscillator. Thus the unit initially self oscillates in a crude fashion until there is enough voltage on the +12 V output to allow the PWM to start, which then swamps out the self oscillation and normal operation commences.

Since the controller resides on the output side of the transformer, the drive to the 2 half-bridge NPN bipolar transistors is by a driver transformer (a direct connection cannot be made because the transistors are on the primary side).

Frequency of operation is 50 kHz, which is low by today's standards, but this means lower cost transformer winding (Litz wire is not needed, for example).

Steve's comments on PC power supply operation and repair

(From: Steve Bell (service@bell-electronics.freeserve.co.uk).)

There are not normally schematics available for PC power supplies.

If the PC's are very old, some service manuals included the PSU schematics - but these will be very very old, like the early Apricot that used the Astec AC9335, the Olivetti XT, and some PC's that ran CPM like the LSI Octopus.

Most AT class computers never had schematics available for their power supplies, the manufacturers simply intended them to be swapped out. Schematics were produced by the power supply manufacturers for companies such as Compaq, Sun Microsystems etc, but these where only released to their authorized service centres. These are far and few between and sign non disclosure agreements, so schematics are not available to anyone else. I used to work for one such company, they repaired all of Sun's power supplies from throughout Europe.

Here in the UK, and also in the USA, if a 'standard' AT or ATX power supply fails it's often cheaper to replace. Many PC power supplies aren't standard - we repair many from Compaq, Elonex, HP, Apple, Sun etc that are non standard and can be repaired far cheaper than the manufacturers exchange unit. Also in many countries a swap out isn't available or can be costly.

Even without schematics power supplies can be repaired. The same type of circuitry repeats itself. Older power supplies often used the TL494C pwm IC, newer use the UC3842/3/4/5 series driving MOSFETs. Some older still used the NE5560, SG3524 etc., many didn't use a PWM IC, but instead discrete components. Data sheets on the IC's used are very useful.

Considering the 'standard' 200 W AT PSU, these usually use 2 T0220 power transistors, and at power on a resistor, usually around 270 - 330 K turn on the top transistor, and current flows in the inverter transformer. A winding on the secondary supplies a voltage that is rectified and smoothed to feed the PWM IC and its drivers. These then drive the 2 transistors via a transformer and the power supply is running. The 5 V output voltage is then sensed and fed back to the PWM IC to maintain regulation. Most faults on these types of power supplies involve the high value resistors failing associated with the inverter transistors, the transistors and associated components, bridge rectifier shorted - also check inrush thermistor for cracks or pinholes. Secondary rectifiers can fail, and electrolytic caps can fail if the fan stops. The PWM circuitry can always be fed with an external DC supply and checked independently.

The other type of power supply, less common in older power supplies, uses the UC3842 series PWM IC driving a single MOSFET. This IC sits on the primary side, so its ground is floating high. An isolating transformer is needed when scoping anything on the primary, with the scope ground clip to primary ground.

Sourcing substitute components isn't normally difficult. I'd start by obtaining some decent transistor, diode and MOSFET data books so you can relate faulty parts to what's available locally.

If the power supplies are all 200 W, a simple resistive load will suffice for testing made from large ally clad resistors on a substantial heat sink. These will toast when running for longer, so will need fan cooling - a cheap desk fan is sufficient. If you are going to be repairing a lot of varying power and type over a prolonged period, it may be better to build an active load. This is basically banks of 2N3055's (for 5V & 3.3V) and 2N3773 (for 12 V upwards) in series with low value power resistors than can have their conduction varied and current monitored by other circuitry. You simply have a lead for each power supply type you test/repair. Also don't forget to check the PG o/p on the power supply.

PC power supply information (pinouts, testing and non-standard uses)

When testing or operating a common PC (computer) power supply without being connected to its mainboard and peripherals, a substitute load must be provided. This would be the case if you wanted to determine whether a supply was good or wanted to use the supply for other purposes.

To test the supply, you want to:

- Remove all of the (expensive) stuff - mainboard, drives, etc. Unplug all of the power supply connectors.
- Provide a dummy load to +5 and +12 outputs.
- Typical (but not always) color codes for PC power supplies:

    - Red: +5, Yellow: +12, Black: Gnd (Probably case as well).
    - White: -5, Blue: -12, Orange: Power_good (output).

  (Some newer supplies may have a +3.3 output as well which may be green).

- PC power supplies (as well as most other switchers) need a minimum load on +5 and possibly on +12 as well. An amp (e.g., 5 ohms on +5) should be enough.

  I use an old dual beam auto headlight. It adds a touch of class as well to an otherwise totally boring setup. :-) You can also use auto tail light bulbs or suitable power resistors or old disk drives you don't really care about (you know, those boat anchors).

- There are no sense lines. There is a 'Power_Good' line which is an output from the power supply to the mainboard and can be ignored unless you want to connect it to an indicator to let you know all the outputs are within specs (it may need a pullup and I don't know its drive capability).

- Pinout for the standard PC and clone connector (some companies like Compaq do NOT use this type of connector, however.). Black (Gnd) wires together for the P8 and P9 connectors when installed to mainboard.

```
      J8: Pin 1 = Power_Good   J9: Pin 1 = Gnd
          Pin 2 = +5               Pin 2 = Gnd
          Pin 3 = +12              Pin 3 = -5
          Pin 4 = -12              Pin 4 = +5
          Pin 5 = Gnd              Pin 5 = +5
          Pin 6 = Gnd              Pin 6 = +5
```

  Note: for an XT only, J8-Pin 1 is Gnd, J8-Pin 2 is no connect.

- The peripheral connectors are: Pin 1: +12, Pin 2 and 3: Gnd, Pin 4 = +5.

Safe PC power supply loading

PC power supplies are often ideal for other purposes but the required loads represent wasted power. So, it would be nice to be able to eliminate them. Unfortunately, it probably isn't easy to modify a PC power supply so less/no load is needed for regulation. However, it is worth testing a supply to see how low you can actually go on the loads - many WILL regulate the +5 with no load on the +12 but probably not the reverse. While 20 percent load is often recommended, 5 percent or less may work just fine. And, some don't need any additional loads on either output (they will probably include a minimal load resistor internally).

CAUTION: Usually, a PC power supply will just shut down with too little load. However, some may be much more unhappy. Thus attempting to determine a safe minimum load does entail some risk of letting the smoke out.

The reason that you need a load is that the PWM controller can't do down to really small duty cycles needed for low loading. The design would need to be changed and differs from unit to unit.

Typical PC and ATX power supply schematic

- Domaci Stranka's Web Site has a reverse engineered 200 W ATX PC Power Supply. (Local copy of diagram: Schematic of Typical ATX Power Supply.)

- Tecknik.net has several PC and an ATX power supply under "Circuits". (The ATX supply is the same one as above.)

Notes on ATX power supply testing

You don't need a fancy "mainboard simulator" or "special ATX test tool" to run an ATX power supply on the bench.

(From: Stefan Krommes (stkro@gmx.net).)

There is a wire (Power_Supply_On) on the ATX connector that will turn on the main supply when pulled low. This color of that wire is mostly labeled on the side of the supply - or (as with fortron supplies) it is the one that is not labeled (green). If you look on top of the ATX connector as if it was plugged into the board the wire in question is the 4th from the right hand side on the top row (where there is the clip) - a look into your mainboard manual might give you a visual idea since the ATX connector is often depicted there with pins labeled.

As said if you fire up your supply it would be wise to load it. Check the label on the supply and load the main +5V and +12 V line to about 15-20% of their max. current capability. - Some automotive bulbs (headlight, brakelight, etc.) come handy not only for the 12 V but for the main 5 V line too. Below about 20% load there is the chance of the supply not regulating the voltage properly but it should start.

The 5 V standby line does not need any load - it should read a clean 5 VDC as soon as the supply is plugged in and the mains power switch is switched on.

The main supply should get on-line as soon as the Power_Supply_On wire gets pulled to ground and the voltages should measure within 5% if loaded to about 20% of maximum power.

(From: Sam.)

CAUTION: I have seen one case where an ATX supply actually blew up without a load using this "hot wire" technique. I don't know if there was already a problem with the unit or it really absolutely required a load. But almost immediately after grounding the green wire, multiple electrolytic caps on the secondary side exploded and spilled their guts, one of the MOSFETS shorted, and *then* the power fuse blew. :(It may be that the designers of this supply in their infinite wisdom assumed that since power is enabled via the mainboard, there would never be a circumstance where there wouldn't be at this that as a load!

(From: Arthur Jernberg (stubbie45@hotmail.com).)

Here is the pinout for an ATX mainboard:

Left to right: First row voltage; Second row current/color:

```
[+3.3V] [+5V] [+12V] [-12V] [-5V] [+5VSB] [COM] [P-ON] [PG]
 [14A]  [22A]  [9A]   [1A]  [.5A]  [PUR]  [BLK] [GRN]  [GRY]
```

(From: Sam.)

IMPORTANT CAUTION: Apparently, Dell, who has followed industry standards in most respects, changed the ATX power supply pinout on their PCs sometime in 1998 and may still be using this proprietary pinout. See: Dell Proprietary (Non-Standard) ATX Design. Since there is absolutely no valid technical reason for doing this, one can only assume it is due to some, shall we say, shady business decision to prevent people from going to a third party for upgrades or replacement mainboards or power supplies. Worse, installing a non-Dell power supply with a Dell mainboard will result in a destroyed power supply and possible damage to the mainboard. Thanks Dell. :(It's straightforward though not trivial to change the power supply pinout back to standard (but it isn't a matter of just moving pins around in the connector since the number of wires for some signals has also changed). But there should be no need. Companies should compete by selling a better product, not a closed system.

Detailed Procedure for ATX Power Supply Fault Diagnosis

Before blaming the power supply, make sure the outlet is live, the main power switch (if any) is on, and that any line voltage select switch hasn't changed position or shifted to an intermediate position accidentally (possibly when moving the PC).

(From: Petrus Bitbyter" (p.kralt@hccnet.nl).)

I have written a set of notes on repairing ATX power supplies. It follows below and should contain all you need (and more) to decide whether your power supply has gone or not.

First of all read the document: SAFETY and the general information on SMPS repair elsewhere in this document.

Most of the times the fault is found between the mains connection and the transformer(s).

1. In the most simple cases only the fuse is blown. After replacing this fuse, connect the PS to the mains using the series light bulb trick.

   - If the bulb burns brightly, you know that the old fuse had a good reason to quit, so the case is not simple anymore. The first thing you have to do now is to find the short circuit. The most suspected components are the mains rectifier, the filter capacitors and one or more of the power transistors. Use eyes, nose and an ohmmeter to find scene of the crime. Remove and check the suspected components. Replace defective components except for the power transistors at this time. It makes no sense to continue until you fixed the short circuit

   - If the fuse is good but the PS still dead, you can start to check the voltages.

2. Check the voltage between pin 3 and pin 9 of the ATX to mainboard connector. This should be +5 VDC. If not you have to check the voltages on the mains side. Otherwise it will be wise to check the voltages on the mains side as well (Steps 3 to 5). Then continue reading up to Step 12, not to miss some explanation. Continue at Step 12.

3. The AC pins of the mains rectifier should show the mains AC voltage. If not you may have an interrupted trace or mains filter.

4. Between plus and minus of this rectifier you should find about +310 VDC or +325 VDC depending on your mains voltage. I call it the primary power voltage.

5. If not you may have a faulty mains rectifier.

6. If the voltage is much lower (analog meter) or jumping around (digital meter), the large filter capacitors (e.g., 470 uF, 200 V) are also suspected.

7. Both filter capacitors mentioned above are in series. The midpoint should be at half the primary power voltage. If it is not, the mains rectifier, the filter capacitors and the parallel resistors (parallel to the capacitors) may be defective. Another suspect is a third capacitor (typically 1 uF, 250 V) that leads from the midpoint to a transformer.

Explanation: ATX PSs usually has three power transistors at the mains side. One is connected to a small transformer, the other two connected to a larger transformer. You can recognize the pair of transistors best by finding the emitter of one of them connected to the collector of the other. First you have to deal with the one transistor and the small transformer. (Go to Step 8 if you removed this transistor already.)

6. Check the voltage on the collector of the transistor.

   - If this voltage is zero or very low there may be an interruption between the collector and the primary power voltage.

   - If this voltage is below the primary power voltage or jumping, there seems to be switching activity. You can check this with an AC voltmeter on a secondary coil of the transformer. The reading will not be correct, but if you find an AC voltage you have to continue checking the secondary rectifier and regulator.

   - If this voltage is the primary power voltage the transistor is not conducting (open or not being driven).

7. Check the voltage on the base of the transistor. If this voltage is less than 0.6 V, the startup resistor may be defective. Otherwise, the transistor may be gone (most likely.)

8. Disconnect the PS from the mains and take the safety precautions to discharge the capacitors.

9. Remove the suspected transistor and check it with an ohmmeter or a transistor checker. Most of the times you will have to provide a new transistor. (Beware! Even a transistor that looks good under test conditions may malfunction in the actual circuit.) This is also the time to remove, check and replace other fried, exploded or discolored components near the transistor/transformer combination.

10. Re-power the PS using the series light bulb.

    - If the lamp is burning brightly you have a short circuit in your PS. Most likely your (new) power transistor is conducting due to too high a continuous base current. You have to dive deeper into this part of the circuit until you find the cause of this problem.

    - If the lamp is dim or not burning at all you can re-check the voltage between pin 3 and pin 9 of the mainboard connector. Finding +5 VDC, you can continue. Otherwise you have to restart your investigation of the small transformer/one power transistor part of the circuit. (Step 6.) It makes no sense to continue until this part of the PS functions correctly.

11. Disconnect the PS from the mains when you are done so far.

Explanation: For the next part of the repair procedure you have to provide some load to the PS. This is simply because of some PSs will not function well without load. You may use an (old) main board. Someone ever told me he uses 12 V car bulbs, one on the +5 VDC and another on the +12 VDC outputs. I prefer a huge and heavy old harddrive. Those old basalt blocks (we use to strengthen our dikes) consume a lot of energy. The one I use, provided enough load for all the PSs I ever repaired.

12. Replace the power transistors you may have removed earlier. Reconnect the PS to the mains using the series light bulb. Check the voltage between pin 3 and pin 9 of the main board connector. Connect pin 14 of the main board connector to pin 13. This will switch on the main part of the PS, the part with the two power transistors and the large transformer.

    - If your loads start to work, check the voltages of the several power connectors. When they have the correct values your PS is on air again. Check it out by removing the series light bulb.

    - If (even after removing the series light bulb) some but not all of the values are correct, you have a problem. You have to investigate the failing voltages from the secondary coil of the transformer till the connector. Quite a challenge.

    - If the light bulb is burning brightly you have a short circuit. Most likely your power transistors are gone so you have to check (and almost sure replace) them and their surrounding components, especially the start resistors. Pay special attention to the freewheel diodes (between the collector and the emitter of the power transistors.) Don't forget to disconnect the PS and to discharge the filter capacitors first! When you are done, restart at Step 12.

    - If your lamp is dim or dark but your load does not work you may have defective or blocking power transistors. A fault on the secondary side of the transformer is another possibility.

13. Search for switching activity on the secondary coils of the transformer using an AC meter.

    - If you don't find AC voltage you have to check the voltages on the power transistors.

    - If you find an AC voltage you most likely have a defective rectifier, filter capacitor or regulator at the secondary side. Disconnect from the mains, discharge the filter capacitors and try to find the failing components with an ohmmeter. You will have to remove the rectifiers from the board prior to testing because of the secondary coils have only few windings of thick wire so they are the shortest shortcuts as far as your ohmmeter concerns. Another trick is to use a controllable power supply. Connect it to the point where the removed rectifier was connected to its filter capacitor. Beware of the polarity! Power on both PSs and increase the voltage of your controllable PS to the level of normal operating of your defective PS. The regulator that sucks to much current with respect to the light load will be the main suspect. You have to go deeper into the circuit of this regulator if you want to repair it. Another challenge.

14. Check the voltages on the power transistors. The collector of one of them should be at the primary power voltage, the emitter of the other should be at the common. The remaining collector and emitter are tied together and should be at half the primary power voltage.

    - If you can't find the primary power voltage at a collector you have an interruption. Maybe a bad soldering or the like.

    - If no emitter is connected to common you also have an interruption.

- If the tied collector-emitter is not at half the primary power voltage you most likely have defective power transistors. (In my experience they always die together.) Disconnect, discharge and remove, check and replace the power transistors and their surrounding components. Restart at Step 12.
- If the tied collector-emitter is at half the primary power voltage you can check the base-emitter voltage of the power transistors. If they are less than 0.6 V you may be lucky and find only defective start resistor(s) and/or other base circuit components. But most of the times a defective base circuit will kill its transistor which in turn will kill its neighbor. So you will have to replace them all.

Of course, this story does not cover all possible faults of PC-power supplies, but I only once failed to repair a PS using this scheme.

War stories - the Boschert 2-stage SMPSU

(From: Tony Duell (ard@p850ug1.demon.co.ku).)

In case you have been lucky enough not to have come across the beast, the basic idea is:

1. Rectify/smooth mains, giving 340V DC.
2. Put that into a non-isolated step-down switching converter using a fat power transistor, a freewheel diode and an inductor. The control IC for this is a 723 (!) with feedback applied via an optocoupler from the secondary side. Oh, and there's a current-limit shutdown from a 0R15 resistor in series with the 'load' (section 3, etc). The output of this stage is about 150V
3. The output of that feeds a pair of transistors that run as a free-running push/pull oscillator. That drives the primary of the main chopper transformer (which provides isolation from the mains).
4. The secondaries of that transformer are rectified to provide output voltages. There's a feedback to (2) as described, and also a crowbar.

Now for the failure mode (seen it happen):

1. The first chopper goes short-circuit because it feels like it. The 150 VDC line jumps to 340 VDC (remember, no isolation, and the inductor/transistor are in series from the 340 VDC line to the 150V line).
2. The crowbar fires, shorting the output. The primary-side current goes up as well.
3. The overcurrent trip operates, and the 723 tries to shut down. It removes the drive from the *first* chopper. But that's shorted, so removing the drive doesn't do a darn thing.
4. The 2 transistors in the push/pull circuit short as well.
5. Rectified mains is now connected acros : 3 shorted transistors, a few small windings (oscillator feedback transformer, inductor, etc), and the 0R15 resistor. The latter explodes.
6. 340 VDC is now applied across the connections of the ex-0R15 resistor. A few small transistors and the 723 expire, along with some PCB tracks.

7. The fuse (10 A, FF blow) fails.

Repairing that was an entertainment. I still have my photocopy of the schematic with all the dud components circled!

Capacitors, startup, and low voltage testing

(From: Kevin Beeden (kevin.beeden@rrl.co.uk).)

I was fighting with a Hitachi PSU (SP-13A unit from UK VT-F860E VCR).

Symptoms: Following line power disconnect, wouldn't start up. Traced circuit, found broken Tr in LV side, replaced, no good. No gate drive. Trouble figuring gate drive cct. Applied 30 VDC to HV side and drove gate from 10 kHz signal generator (5 V squarewave via 1K resistor). The MOSFET switcher was okay, output active but won't start. Startup drive is via a 1 uF, 250 V cap. Can't see any drive on gate when power applied from cold. Read these notes. Doh! Capacitor gone open circuit. Replace cap and now get gate drive until output settles.

I was happily surprised to find that the circuit worked off of 30 VDC, as I'm not keen on debugging live mains or 400 VDC! This may be a top tip for fellow debuggers. I simply connected 30 VDC to the post-rectification smoothing cap, hit the gate with the signal generator, and away it went. Note: this is under no load conditions; the PSU was removed from the VCR.

I also found a devious little component masquerading as a resistor. It appears to actually be back-to-back (Schottky? 1V3) diodes and a 220 ohm resistor in some series or parallel arrangement. Marked externally as 220R, identical appearance to other resistors.

Why is the main fuse rating so big?

On a typical SMPS (or piece of equipment like a TV, monitor, or VCR using an SMPS), the nameplate current rating may be much much smaller than the fuse rating (or equivalently, the nameplate power rating may imply a much smaller current). Why is this the case?

There are actually many reasons for the fuse to be much larger than the maximum current specified on the nameplate. Some of these include:

1. The peak current during power on is actually much higher due to the degauss coil and charging of the SMPS caps.

2. ?The power factor is much smaller than unity for a typical SMPS and this increase the average current - which is what the fuse sees.

3. The fuse for the SMPS is really there to protect against catastrophic failure so it can be much larger than the average expected current. If that fuse blows, it's usually the result of the failure of the main chopper transistor, not a slight overload (for which the SMPS should shut down).

Replacing the fuse with a smaller one really won't make the equipment any safer but may result in nuisance blowing.

---

Service Information

Advanced troubleshooting

If the solutions to your problems have not been covered in this document, you still have some options other than replacement.

(Also see the related document: Troubleshooting and Repair of Consumer Electronic Equipment.

Manufacturer's service literature: Service manuals may be available for for your equipment. Once you have exhausted other obvious possibilities, the cost may be well worth it. Depending on the type of equipment, these can range in price from $5-100 or more. Sometimes, these may even be free (yes, even in this day and age where you have to pay for free air at your local gas station!) Some are more useful than others. However, not all include the schematics so if you are hoping to repair an electronic problem try to check before buying.

Inside cover of the equipment: TVs often have some kind of circuit diagram pasted inside the back cover. In the old days, this was a complete schematic. Now, if one exists at all for a monitor, it just shows part numbers and location for key components - still very useful.

Sams Photofacts: These have been published for over 45 years mostly for TVs and radios. There are some for VCRs and a few for some early PC monitors and other pre-Jurassic computers. However, for the power supplies in TVs, there will nearly always be a Sams with complete schematics.

Whatever the ultimate outcome, you will have learned a great deal. Have fun - don't think of this as a chore. Electronic troubleshooting represents a detective's challenge of the type hat Sherlock Holmes could not have resisted. You at least have the advantage that the electronics do not lie or attempt to deceive you (though you may beg to differ at times). So, what are you waiting for?

SMPS info and datasheets on-line

Many companies now have very extensive information available via the World Wide Web. Here are a few company sites:

* International Rectifier
* Lambda Semiconductors
* Maxim Integrated Products
* SGS-Thomson
* Unitrode Corporation

The following site has a variety of information and links to SMPS related sites:

* SMPS Design by Jerrold Foutz.

References on SMPS technology and troubleshooting

There is a nice detailed article on PC power supply repair from Nuts and Volts Magazine on-line at: PC Power Supply Repair by T. J. Byers. This is probably a good place to start if you are specifically interested in the common PC power supply. It looks like this article is pre-ATX but most of the information still applies.

Also see the document: PC Switchmode Power Supplies.

Texas Instruments has an application note which is sort of the "short" version of SMPS repair. See: Off-Line SMPS Failure Modes PWM Switchers and DC-DC Converters.

Here are some suggested books with information relating to SMPS and DC-DC converter design, testing, troubleshooting, repair, etc.:

1. Power Supplies, Switching Regulators, Inverters & Converters, 2nd Edition.
   Irving Gottlieb
   TAB Books, 1994
   ISBN 0-8306-4404-0

2. Modern DC-to-DC Switchmode Power Converter Circuit
   Rudolf P. Severns and Gordon E. Bloom
   Van Nostrand Reinhold
   ISBN 0-442-21396-4

3. Principles of Solid State Power Conversion
   Ralph E. Tarter
   Howard W. Sams & Co., Inc.
   ISBN 0-672-22018-0

4. Advances in Switched-Mode Power Conversion
   R.D. Middlebrook & Slobodan Cuk
   Contact: TeslaCo, Pasadena, CA 91107 (last known address)

5. Simplified Design of Switching Power Supplies
   John D. Lenk
   Butterworth-Heinemann
   ISBN 0-7506-9821-7.

6. Power Electronics, 2nd ed.
   B.W. Williams
   McGraw-Hill, 1992
   ISBN 0-07-070439-2

7. Switching Power Supply Design
   Abraham Pressman, Second Edition
   McGraw-Hill, 1998

    Whittington, Flynn and Macpherson published
    Research Studies Press, Ltd.
    ISBN 0-863-80203-6

In addition, many smeiconductor manufacturers publish extensive information on switchmode technology. Mostly, this is in connection with their product lines but will also contain a lot of general information. Much of this is available on Internet via the World Wide Web. Companies include: Maxim, Linear Technology, and Unitrode.

(From: OneStone (OneStone@bigpond.com).)

"Try the Linear Technologies Website.

Look for their App notes:

- AN25 Switching regulators for Poets.
- AN19 LT1070 Design manual
- AN29 Some thoughts on DC-DC converters
- AN30 Switching regulator circuit collection.
- AN31 Linear Circuits for digital systems.

Then try one of their new data sheets, such as the LT1370, for some modern circuit configurations, such as SEPIC converters. The above APP notes are all contained in their Linear Applications handbook, Volume 1, 1990. If you are a designer they also have a CD-ROM available, which includes some switcher and filter design software. It's a bit limited, but a great starting point if you don't need to stretch the boundaries."

For diagnosing power problems in TVs and Computer or Video monitors, here is one book that includes many illustrations and case histories.

17. Troubleshooting and Repairing Solid State TVs
    Homer L. Davidson
    2nd Edition, 1992
    TAB Books, Inc.
    Blue Ridge Summit, PA 17214

(From: Ernst C. Land, Jr. (a6mech@ionet.net) and Mark Zenier (mzenier@eskimo.com or mzenier@netcom.com).)

The September 1996 (VOL. 17 NO. 9) issue of Nuts & Volts Magazine has a great article on theory, troubleshooting, and repair of PC power supplies. Their web site is: http://www.nutsvolts.com.

When you get there, click on [more], then [back issues]

Parts information

I have found one of the most useful single sources for general information on semiconductors to be the ECG Semiconductors Master Replacement Guide, about $6 from your local Philips distributor. STK, NTE, and others have similar manuals. The ECG manual will enable you to look up U.S., foreign, and manufacturer 'house' numbers and identify device type, pinout, and other information. Note that I am not necessarily recommending using ECG (or other generic) replacements if the original replacements are (1) readily available and (2) reasonably priced. However, the cross reference can save countless hours searching through databooks or contacting the manufacturers. Even if you have a wall of databooks, this source is invaluable. A couple of caveats: (1) ECG crosses have been known to be incorrect - the specifications of the ECG replacement part were inferior to the original. (2) Don't assume that the specifications provided for the ECG part are identical to the original - they may be better in some ways. Thus, using the ECG to determine the specifications of the parts in your junk bin can be risky.

Other cross reference guides are available from the parts source listed below.

Information sources on the Internet

Many manufacturers are now providing extensive information via the World Wide Web. The answer to you question may be a mouse click away. Perform a net search or just try to guess the manufacturer's home page address. The most obvious is often correct. It will usually be of the form "http://www.xxx.com" where xxx is the manufacturers' name, abbreviation, or acronym. For example, Hewlett Packard is hp, Sun Microsystems is sun, Western Digital Corp. is wdc. NEC is, you guessed it, nec. It is amazing what is appearing freely accessible via the WWW. For example, monitor manufacturers often have complete information including detailed specifications for all current and older products. Electronic parts manufacturers often have detailed datasheets and application notes for their product offerings.

Here is a non-commercial Web site that has some information and sample circuits (not necessarily tested!) on using Maxim parts in various DC-DC converter applications as well as a bunch of links to relevant SMPS chip manufacturers:

- Maxim Pirate Applications Web Site

Interchangeability of components

The question often arises: If I cannot obtain an exact replacement or if I have a monitor, TV, or other equipment carcass gathering dust, can I substitute a part that is not a precise match? Sometimes, this is simply desired to confirm a diagnosis and avoid the risk of ordering an expensive replacement and/or having to wait until it arrives.

For safety related items, the answer is generally NO - an exact replacement part is needed to maintain the specifications within acceptable limits with respect to line isolation, X-ray protection and to minimize fire hazards. Typical parts of this type include flameproof resistors, some types of capacitors, and specific parts dealing with CRT high voltage regulation. However, during testing, it is usually acceptable to substitute electrically equivalent parts on a temporary basis. For example, an ordinary 1 ohm resistor can be substituted for an open 1 ohm flameproof resistor to determine if there are other problems in the the SMPS chopper before placing an order as long as you don't get lazy and neglect to install the proper type before considering the repair complete.

For other components, whether a not quite identical substitute will work reliably or at all depends on many factors. Some deflection circuits are so carefully matched to a specific horizontal output transistor that no substitute will be reliable.

Here are some guidelines:

1. Fuses - same type (usually normal or fast blow), exact same current rating and at least equal voltage rating. I have often soldered a normal 3AG size fuse onto a smaller blown 20 mm long fuse as a substitute.

2. Resistors, capacitors, inductors, diodes, switches, potentiometers, LEDs, and other common parts - except for those specifically marked as safety-critical - substitution as long as the replacement part fits and specifications should be fine. It is best to use the same type - metal film resistor, for example. But for testing, even this is not a hard and fast rule and a carbon resistor should work just fine.

3. Rectifiers - many of these are high efficiency and/or fast recovery types. Replacements should have equal or better PRV, Imax, and Tr specifications. However, the AC input bridge can usually be replaced with anything with at least equal voltage and current ratings.

4. Main filter capacitor(s) - use replacements with at least equal working voltage and similar uF rating. For testing, even something with half the capacity will be fine. For the final replacement bigger is not always better and even using a smaller one (uF) will be fine as long as you are not running the supply near full load capacity. Use of a higher temperature rated capacitor than the original may be desirable as its life may have been shorteded by a hot environment. This practice will never hurt.

5. Transistors and thyristors (except SMPS choppers or HOTs) - substitutes will generally work as long as their specifications meet or exceed those of the original. For testing, it is usually OK to use types that do not quite meet all of these as long as the breakdown voltage and maximum current specifications are not exceeded. However, performance (like regulation specifications) may not be quite as good. For power types, make sure to use a heatsink.

6. SMPS chopper (or horizontal output) transistors - exact replacement is generally best but except for very high performance monitors, generic HOTs that have specifications that are at least as good will work in many cases. Make sure the replacement transistor has an internal damper diode if the original had one. For testing with a series light bulb, even a transistor that doesn't quite meet specifications should work well enough (and not blow up) to enable you to determine what else may be faulty. The most critical parameters are Vceo/Vcbo, Ic, and Hfe which should all be at least equal to the original transistor. I have often used by favorite BU208D as a temporary substitute for other HOTs and SMPS (chopper) transistors. Make sure you use a heatsink (with insulating washer if applicable) and thermal grease in any case - even if you have to hang the assembly with a cable-tie to make it fit.

   Also see the section: Replacement power transistors while testing.

The following are usually custom parts and substitution of something from your junk box is unlikely to be successful even for testing: flyback (LOPT) and SMPS transformers, interstage coils or transformers, microcontrollers, and other custom programmed chips.

Substituting entire circuit boards and other modules from identical models is, of course, possible and an excellent troubleshooting aid even if it is only used to confirm or identify a bad part. However, if the original failure was catastrophic, you do run some risk of damaging components on the substitute circuit board as well.

Replacement power transistors while testing

During testing of horizontal deflection circuits or switchmode power supplies, particularly where the original failure resulted in the death of the HOT or chopper, overstress on replacement transistors is always a possibility if all defective components have not be identified.

Therefore, using a part with better specifications may save you in the long run by reducing the number of expensive blown parts. Once all other problems have been located and repaired, the proper part can be installed.

However, this is not always going to work. In a TV and especially a high performance monitor, the HOT may be closely matched to the drive and output components of the deflection circuits. Putting in one with higher Vce, I, or P specifications may result in overheating and failure due to lower Hfe.

Where possible, a series load like a light bulb can be used limit the maximum current to the device and will allow you to power the equipment while checking for other faults. Some designs, unfortunately, will not start up under these conditions. In such cases, substituting a 'better' device may be the best choice for testing.

(From: Glenn Allen (glenn@manawatu.gen.nz).)

I been repairing SMPS of all types but when I started on those using MOSFETs I was blowning a few of them when replaced because something else was faulty.

Ever since I have been using a BUZ355 on a heat sink I haven't blown it. It is rated at 800 V, 6 A, and 220 W. it is a

TO218 case bigger than a T0220. It seems the higher ratings allows you to do repair where as a something like a 2SK1117 or MTP6N60 will just blow.

Testing of replacement chopper transistors

The following is useful both to confirm that a substitute replacement chopper transistor is suitable and that no other circuit problems are still present. However, this will not catch single shot events that may blow the transistor instantly without any increase in temperature.

It was written with TV and monitor horizontal output transistors in mind but applies to the switchmode/chopper transistors found in line powered SMPSs as well.

(From: Raymond Carlsen (rrcc@u.washington.edu).)

After installing a replacement HOT in a TV set or monitor, I like to check the temperature for awhile to make sure the substitute is a good match and that there are no other problems such as a weak H drive signal. The input current is just not a good enough indicator. I have been using a WCF (well calibrated finger) for years. For me, the rule of thumb, quite literally, is: if you can not hold your finger on it, it's running too hot, and will probably fail prematurely. Touching the case of the transistor or heat sink is tricky....

Metal case transistors will be connected to the collector and have a healthy pulse (>1,200 V peak!) and even with plastic case tab transistors, the tab will be at this potential. It is best to do this only after the power is off and the B+ has discharged. In addition, the HOT may be hot enough to burn you.

A better method is the use of an indoor/outdoor thermometer. I bought one recently from Radio Shack for about $15 (63-1009). It has a plastic 'probe' on the end of a 10' cable as the outdoor sensor. With a large alligator clip, I just clamp the sensor to the heat sink near the transistor and set up the digital display near the TV set to monitor the temperature. The last TV I used it on was a 27" Sanyo that had a shorted H. output and an open B+ resistor. Replacement parts brought the set back to life and the flyback pulse looked OK, but the transistor was getting hot within 5 minutes... up to 130 degrees before I shut it down and started looking for the cause. I found a 1 uF 160 volt cap in the driver circuit that was open. After replacing the cap, I fired up the set again and monitored the heat sink as before. This time, the temperature slowly rose to about 115 degrees and stayed there. I ran the set all day and noticed little variation in the measurement. Test equipment doesn't have to cost a fortune.

Repair parts sources

For general electronic components like resistors and capacitors, most electronics distributors will have a sufficient variety at reasonable cost. Even Radio Shack can be considered in a pinch.

However, for modern electronic equipment repairs, places like Digikey, Allied, and Newark do not have the a variety of Japanese semiconductors like ICs and transistors or any components like flyback transformers or degauss Posistors.

See the document: Major Service Parts Suppliers for some companies that I have used in the past and others that have been recommended.

In addition, specifically for VCR SMPS repair:

- Studio Sound Service
  Fax: 1-812-949-7743

Email: studio.sound@datacom.iglou.com.

Rebuild kits for many popular VCR switchmode power supplies, VCR parts, some components. They will be happy to identify specific VCR part numbers as well based on model and description as well.

Introduction

Scope of This Document

When problems develop in the horizontal deflection/high voltage subsystems of TVs or monitors (or even modern oscilloscopes and other CRT displays), the flyback transformer (or line output transformer for those on the other side of the Lake) is often a suspected cause. This is due in part to the fact that it is usually the most expensive and hard to find replacement part in the unit and because flybacks are often less well understood than other more common components.

This document addresses the operation and testing of flyback (LOPT) transformers: What they are, how they fail, why they fail, and how to test them. For more information on horizontal deflection systems, see the document: TV and Monitor Deflection Systems.

- Back to Flyback Testing Table of Contents.

Safe Troubleshooting of Flyback Transformers

WARNING: Read, understand, and follow the recommendations in the document: Safety Guidelines for High Voltage and/or Line Powered Equipment before attempting any TV or monitor repairs.

In particular, before touching or probing the flyback or circuitry in its vicinity:

- Unplug the equipment!!!
- Measure the voltage on B+ feed to the flyback and discharge the main filter capacitors if necessary.
- If going near the HV output, focus, or screen connections, discharge the CRT capacitance as well.

For specific information on safety for your equipment, see the documents: Notes on the Troubleshooting and Repair of Computer and Video Monitors or Notes on the Troubleshooting and Repair of Television Sets as appropriate.

- Back to Flyback Testing Table of Contents.

Flyback (LOPT) Transformers

What Does the Flyback (LOPT) Transformer Do?

The typical flyback or Line OutPut Transformer (LOPT) consists of two parts (you may also encount the term IHVT - Integrated High Voltage Transformer):

1. A special transformer which in conjunction with the horizontal output transistor/deflection circuits boosts the B+ (120 V typical for a TV) of the low voltage power supply to the 20 to 30 kV for the CRT as well as provides various secondary lower voltages for other circuits.

   A HV rectifier turns the high voltage pulses into DC and the CRT capacitance smooths it. The HV may be developed from a single winding with many many turns of wire or a lower voltage winding and a diode-capacitor voltage multiplier.

The various secondary voltages power the logic, tuner, video signal, vertical deflection circuits, and CRT filaments. In fact, with many TV designs, the only power not derived from the flyback is for the keep-alive circuitry needed to maintain channel memory and provide startup drive to the horizontal deflection/high voltage system.

2. A voltage divider that provides the focus and screen supplies. The pots are in this divider network - and these things fail resulting in poor focus, uncontrolled brightness, or fluctuating focus and/or brightness. A total short could also result in failure of other components like the horizontal output transistor. The focus and screen are generally the top and bottom knobs, respectively. In some TVs, the focus and screen divider and/or controls are external to the flyback and susceptible to dust and problems particularly on damp days.

How is a Flyback Transformer Different than a Regular Transformer?

While the following is not always strictly true for TV and monitor flyback transformers, it is a nice overview:

(From: Sivasankar Chander (siva@bond.bocaraton.ibm.com).)

1. The main difference between a flyback transformer and a regular transformer is that a flyback transformer is designed to store energy in its magnetic circuit, i.e., it functions like a pure inductor, whereas a regular transformer is designed to transfer energy from its primary to secondary and to minimize stored energy.

2. A flyback transformer in its simplest form has current flowing either in its primary, or in its secondary (but not both at the same time). (This is more complicated in practice because of finite turn-off times for transistors and diodes, need for snubber circuits, etc).

3. The reluctance of the magnetic circuit of a flyback transformer is usually much higher than that of a regular transformer. This is because of a carefully calculated air-gap for storing energy (it's an inductor).

4. The voltages applied to a flyback transformer on the primary side are almost always rectangular (pulsed) whereas regular transformers usually have sinusoidal voltages applied to them.

5. The currents flowing through either side of a flyback transformer are either increasing or decreasing linear sawtooths, whereas a regular transformer usually has sinusoidal currents.

6. Finally, due to the properties of core materials, flyback transformers are most conveniently operated in the range from 10^3 to 10^6 Hz, whereas regular transformers have a much wider range, from a few Hz to 10^12 Hz.

I may have succeeded in confusing you beyond redemption, so the best recourse for you would be to read any introductory textbook on switching power supplies for a more comprehensive picture.

The Origin of the Term, 'Flyback'

In the U.S. (possibly all of North America), the transformer that generates the high voltage in a TV, monitor, or other CRT based equipment, is called the 'flyback' or 'flyback transformer'. Most everywhere else in the world, it is either LOPT (Line OutPut Transformer) or simply LOT, or as noted IHVT - Integrated High Voltage Transformer (which is actually the most accurate term for modern units).

The term 'flyback' probably originated because the high voltage pulse that charges the CRT capacitance is generated by the collapse of the magnetic field in the core of the transformer during the short retrace period - when the electron beam in the CRT 'flies back' to the start of a new scan line. The flux in the core changes slowly during scan and is abruptly switched in polarity by the HOT turning off during the flyback or retrace period.

Many off-line switchmode power supplies and DC-DC converters are also of the 'flyback' type with energy transferred to their output circuits mainly during the same time in the cycle - but there is no CRT involved. Indeed, these high frequency ferrite transformers - which generally look like regular transformers often of E-I core construction - may also be referred to as flybacks in transformer company catalogs.

LOPT and LOT derive from the fact that it is the line scan circuit that is involved and the transformer is in the output stage.

I still think flyback is much more quaint! :-).

Of course, others have their own definition:

(From: Sam Riner (riner@inet2000.com).)

When I was about 12 I touched the wire coming from the FBT on the picture tube, this was a BIG floor model TV, and I flew about five feet backwards. I know this isn't the real history for the name but for many years I believed it was.

A Little History

So, how far back does the use of a flyback based high voltage go?

(From: Henry van Cleef (vancleef@netcom.com).)

A flyback HV supply was a feature of the 1946 RCA 630 and GE 801 sets. They used either an 807 or 6BG6 horizontal output tube, 6W4 damper, 1B3 rectifier.

The prewar TV's (yes, TV's were made and for sale before the NTSC standard was approved in 1941) generally used a 60 Hz. transformer and 2X2 similar to circuits used in RCA and Dumont oscilloscopes of the 1930's.

Zworykin/Morton "Television" (Wiley, 1940) has schematics and a project home-brew TV set using an 81 tube for the HV off a standard power transformer. Of course, to follow your way around this book, you have to know vacuum tube theory and a lot of physics reasonably well, but it is an historical gold mine.

(From: Brad Thompson (Brad_Thompson@pop.valley.net).)

Some of the early TV sets used an RF oscillator to generate the high voltage for electrostatic-deflection CRTs: a typical tube lineup might include a 6V6 oscillator and 1B3 (or 1X2) rectifier.

Why is the Deflection and High Voltage Combined?

One of the main reasons that TVs and many monitors are designed with horizontal deflection driven flybacks is simply economics - it provides a cheap way to get the high voltage and many or most of the other voltages for the set with minimal hardware. (High quality computer monitors sometimes use a separate high voltage supply so that the horizontal deflection is then used just for deflection to reduce interactions between changing scan rates and the HV.) A side benefit is that if the horizontal deflection dies, the HV power supply voltage goe with it and prevents the CRT phosphors from burning do to undeflected high intensity beam.

The use of the horizontal frequency rather than the AC line frequency of 50 or 60 Hz allows the power supply components to be small and light compared to a line operated power transformer and filter capacitors.

Flyback Construction

While details can vary somewhat, all flybacks consist of a set of windings on a gapped ferrite core. High voltage diodes and resistive dividers (often with adjustment pots) for focus and screen (G2) may also be present.

A typical flyback includes the following components:

- Drive winding - for a line powered TV, there will be perhaps a hundred turns of medium gauge (e.g., AWG #26) wire. For low voltage powered, it may only be a dozen turns of thicker wire. This is what is connected in series with the B+ to the horizontal output transistor in a TV or monitor.

- High voltage winding - several thousand turns. This winding may be split into several series sections with a high voltage rectifier for each or could be a single winding. An alternative is provide a lower voltage winding and use a voltage multiplier (diode-capacitor ladder) to boost this to that required by the CRT. Very fine wire (e.g., AWG #40) will be used for the high voltage winding. The high voltage lead to the CRT is fed from the highest voltage output of the rectifier or multiplier.

  Some TV and monitor designs use a physically separate (external - not part of the flyback transformer) voltage multiplier. In this case, the flyback high voltage winding will generate 6 to 10 kVAC and the multiplier will boost this typically 3X or 4X to 20 to 30 kVDC. The focus and screen (G2) network will generally be part of the multiplier module in this case.

- Resistive divider network for focus and screen (G2). This will probably be fed from only one of the series connected windings (if used). Often, there are adjustments for focus and screen right on the flyback. The outputs from this divider may be connected to pins in the base of the flyback or have their own separate leads which connect to the CRT socket/board.

- Auxiliary windings - anywhere from a couple of turns (for the CRT filament) to several hundred turns (for a boost source). These supply various voltages for the typical TV or monitor - CRT filament, logic power, analog power, boost source (where the flyback does not include its own screen supply), etc. The gauge of these windings will depend on the current requirements of each output. They are connected to solder pins at the base of the flyback.

- Ferrite core - consisting of two C shaped pieces clamped together with either a spring arrangement or studs and nuts. There will be a gap of a fraction of a mm provided by a set of spacers between the two C sections.

Most modern flybacks have all the windings on the same leg of the core. The drive winding and auxiliary windings will be wound and separately insulated under the high voltage winding. The high voltage winding will consist of many layers which have insulating material (i.e., mylar) between them.

The other components will be mounted in a separate part of the assembly and the entire unit is then potted in an Epoxy type filler. Part of the core is generally accessible - often one entire leg.

A flyback is not an ordinary transformer. The ferrite core contains a gap. Energy is stored in the magnetic field of the core during scan as the current is ramping up. Energy is also coupled to certain secondary outputs during scan. However, energy for the high voltage (HV) is coupled to the its secondary windings almost entirely when the primary current is shut off at the end of the scan (probably the source of the name flyback because it is during the retrace of the electron beam).

Which type of coupling is in effect depends on the direction of the rectifiers on the secondary side of the flyback:

```
                   _  _
                    \/                                   _/\_
    B+ ------+    +----|>|-----+---o +V1  B+ ------+    +----|>|-----+---o +HV
            o )::( o  Scan     |                  o )::(   Flyback   |
              )::(  Rectifier _|_                   )::(  Rectifier _|_
              )::(            ---                   )::(            ---
              )::(             |                    )::(             |
        _/\_  )::(             |              _/\_  )::( o           |
   HOT ------+    +------------+         HOT ------+    +------------+
                              _|_                                   _|_
                               -                                     -
```

Here, V1 is just a typical example of an auxiliary supply derived from a scan rectifier and HV is the best known example of the use of a flyback rectifier.

Note that the ratio of the number of turns for each winding *cannot* be used to calculate expected output voltages since the rate of collapse of the magnetic field (determined by the design of the horizontal output circuit) affects this.

The gap is critical to the proper operation and is usually determined by some plastic spacers. CAUTION: mark each one and replace them in exactly the same position if you disassemble the core for any reason.

Why You Don't Want to Fabricate Your Own Flyback or Rebuild a Bad One

Attempt to disassemble a flyback and you will understand why I don't recommend this unless the entire future of the explored *and* unexplored universe depends on the effort! You need specialized equipment to just wind the high voltage coil.

This isn't something you can do by hand in your basement and the only problem isn't the several thousand turns of nearly invisible wire used in a typical flyback. To sustain the high voltages without arcing and to minimize the interwinding capacitance, the high voltage winding is constructed as many individual layers - perhaps 50 layers in all - of 50 turns each using super fine wire (#40 typical - thinner than a human hair). Each layer must be wound perfectly flat with all wires side-by-side and then individually insulated with mylar tape. Just breathing on such wire will practically break it let alone wrapping several thousand turns in perfect order!

The other parts: drive and low voltage windings, focus and screen divider network, and high voltage rectifiers must be assembled with the high voltage winding and CRT leads and then the entire affair is potted in Epoxy.

Forget it - you have better things to do than spend a week on a transformer!

---

Flyback Failure and Testing

Why do flyback Transformers Fail?

While flyback transformers can on occasion be blown due to a failure elsewhere in the TV or monitor's power supply or deflection circuits, in most cases, they simply expire on their own. Why?

Flybacks are wound with many layers of really really fine wire with really really thin insulation. This entire assembly is potted with an Epoxy resin which is poured in and allowed to cure.

In some ways, these are just short circuits waiting to happen.

Flybacks get hot during use and this leads to deterioration of the insulation. Any imperfections, nicks, or scratches in the insulation or trapped air bubbles and impurities in the Epoxy fill material contribute to failure. Temperature cycles and manufacturing defects result in fine cracks in the Epoxy potting material reducing the insulation breakdown particularly in the area of the high voltage windings, rectifiers, and focus/screen divider network. They also physically vibrate to some extent. A whole bunch of other factors are also no doubt important.

Once a breakdown - sparking or arcing - develops, it is usually terminal.

It is amazing they last as long as they do with the stresses they are under.

How Do Flyback Transformers Fail?

Flybacks fail in several ways:

1. Overheating leading to cracks in the plastic and external arcing. If there is no major damage to the windings, repair may be possible. However, arcing from the windings punctures their very thin insulation so that shorted windings may already have developed. Even if the windings are currently in good condition, long term reliability of any such repairs is questionable.

   Nonetheless, it doesn't hurt to try cleaning and coating with multiple layers of high voltage sealer, corona dope, or even plastic electrical tape (preferably as a temporary repair though I have gotten away with leaving this in place permanently). If possible, moving the point to which the flyback is arcing further away (i.e., a piece of metal or another wire) would also help.

   (The following from: Tom Riggs (thriggs@mail.netusa1.net))

   For sealing flyback transformers, I have found that silicone sealer has worked very well. I used the clear variety, though others will probably work as well. I have heard of burn through with corona dope. (Author's note: make sure you allow ample time for the silicone sealer to setup completely - or else it will breakdown instantly - at least 24 hours. Also, some types (those that smell like vineger - acetic acid - as they cure may result in corroded wiring in the long term).

2. Cracked or otherwise damaged core will effect the flyback characteristics to the point where it may not work correctly or even blow the horizontal output transistor and other expensive parts like the low voltage regulator or switchmode power supply. If the core can be reconstructed so that no gaps (other than the required ones where the two halves join) are present and clamped and/or glued in place, it should be possible to perform testing without undue risk of circuit damage but consider a replacement flyback as a long term solution.

3. Internal shorts in the FOCUS/SCREEN divider network, if present. One sign of this may be arcover of the FOCUS or SCREEN spark gaps on the PCB on the neck of the CRT.

4. Internal short circuits in the windings.

5. Open windings.

More than one of these may apply in any given case. As noted, temporary repair, at least, is sometimes possible for failures (1) and (2). For failures (3) to (5) replacement is usually the only alternative.

- Back to Flyback Testing Table of Contents.

Basic Testing

Initial Tests Using Your Senses and Perhaps a Multimeter

First, perform a careful visual inspection with power off. Look for cracks, bulging or melted plastic, and discoloration. Look for bad solder connections at the pins of the flyback as well. If the TV or monitor can be powered safely, check for arcing or corona around the flyback and in its vicinity, or at the sparkgaps or gas tube protectors on the CRT neck board.

Next, perform ohmmeter tests for obvious short circuits between windings, much reduced winding resistances, and open windings. Don't neglect to check between the CRT HV connector (suction cup) and the pins on the base. This should measure infinity.

For the low voltage windings, service manuals may provide the expected DC resistance (Sams' Photofact, for example). Sometimes, this will change enough to be detected - if you have an ohmmeter with a low enough scale. These are usually a fraction of an ohm. It is difficult or impossible to measure the DC resistance of the HV winding since the rectifiers are usually built in. The value is not published either.

WARNING: Make sure you have the TV or monitor unplugged and confirm that the main filter capacitor is discharged before touching anything as the flyback is usually connected to this point, perhaps directly! If you are going to remove or touch the CRT HV, focus, or screen wires, discharge the HV first using a well insulated high value resistor (e.g., several M ohms, 5 W) to the CRT ground strap (NOT signal ground).

Measurements that are much less than the published values likely indicate a partially shorted winding. However, a difference of 10% may not be at all significant. Higher than normal readings might simply indicate that a design change was made. Yes, I know, hard to believe they would not have informed you of this! For example, various versions of the flyback used in the Apple MAC Plus - 157-0042A,B,C - are functionally similar but have minor variations in winding parameters. It is not known what effects this would have but they are interchangeable at least for testing.

Of course, any continuity between separate windings is definitely a fault.

Partially short circuited windings (perhaps, just a couple of turns) and sometimes shorts in the focus/screen divider will drastically lower the Q and increase the load the flyback puts on its driving source with no outputs connected. It is these types of failures, not detectable by simple ohmmeter tests or visual inspection, which the techniques described in the sections under "Advanced testing" address.

While less common, I have seen shorts between the CRT HV connector and the low voltage windings on the base of the flyback. This implies a breakdown of the Epoxy potting material probably due to thermally induced microcracks or poor quality manufacturing. Once a small arc develops, it rapidly carbonizes the material around it further reducing the resistance. These rarely heal themselves and thus show up as obviously low resistance readings using an ohmmeter. It is an easy test and can be performed without removing the flyback. Discharge the CRT HV (though this will probably be dead) and just remove the connector from the CRT.

It is also possible that various types of flyback faults can damage other circuitry (beyond taking out the horizontal output transistor and its associated parts). For example, a sudden short between the CRT HV connector and a low voltage winding or a short between two low voltage windings could conceivably blow solid state components powered from the flyback. This damage will generally not be apparent until the flyback is replaced. Therefore, if shorts are detected in the flyback, it is worth testing some of the components in the vicinity and vice-versa.

The Process of Elimination

Before attempting the more advanced tests suggested below, there may be ways of being more certain that your flyback is the problem component. The following assumes that running the TV or monitor with the suspect flyback results in an excessive load on the low voltage (B+) power supply blowing a fuse (or attempting to blow a fuse - excessively bright series light bulb). The B+ likely drops from its normal 65 VDC to 140 VDC or more (depending on the actual TV or monitor and mode) to some low value like 25 VDC when measured on the low voltage power supply side of the flyback drive winding. (Measuring at the HOT can result in all sorts of weird readings due to the pulse nature of the waveform and is not recommended - especially when everything is working properly - 1,500 V pulses!).

- Disconnect all the secondary loads from the suspect flyback including the CRT. Connect only the drive (B+ and HOT).

  Power up the TV or monitor (preferably with a series light bulb or on a Variac.

  If the B+ now climbs to a more normal value, a problem with the HV (CRT short) or one of the secondary loads is indicated. Connect each of these up one a time (or test individual components) to localize the fault. The flyback is likely good.

- Remove the suspect flyback and connect just the HOT and B+ to the drive winding of a known good flyback for a similar size TV or similar type of monitor (as appropriate). It may be close enough to keep the drive circuitry happy.

  Power up the TV or monitor (preferably with a series light bulb or on a Variac.

  If the B+ now climbs to a more normal value, a problem with the original flyback is indicated. However, more thorough testing may be desirable to be absolutely certain.

  If you do this regularly, keeping a selection of 'flyback simulators' - just the drive windings and cores may be desirable.

- Back to Flyback Testing Table of Contents.

Advanced Testing

When the Basic Tests Don't Reveal Anything

Also see the section: Flyback Testing Equipment.

There are several ways of testing flybacks (assuming you do not actually have special test equipment for this purpose). Here are two possibilities. The first is easier if you have a scope but the second is more fun.

Method 1

The following technique, called a 'ring test', works for flybacks, chopper transformers, motors, mains transformers, deflection yoke windings, VCR video and other magnetic heads, and other transformers, coils, or inductors.

However, note that it can miss certain problems like open windings (if they are not used for the test) as well as shorts or opens that occur only when the flyback is driven near full voltage. Thus, do the basic tests FIRST and don't assume that the flyback is 100 percent good just because it passes the ring test (though the likelihood of this is very high).

(Portions from: Gabe (ggabe@mcs.com).)

This is called a 'ring test' and is the method often used by commercial flyback (or other coil/transformer) testers. The theory is that a faulty flyback (which cannot be found by simple resistance measurements) will have shorted turns in one of the coils. In such a case, the 'Q' of the transformer is greatly reduced. If excited by an impulse, a faulty transformer will resonate with a highly damped oscillation while a good one will decay gradually.

1. Connect a high quality capacitor across one winding of the suspect device. Hope for a resonant frequency of a few kHz. You may need to select the capacitor value for best results. I have found that a capacitor in the .001 uF to 1 uF (non-polarized) will usually be satisfactory.

   Note that it doesn't matter whether the excitation is applied to the shorted winding or any other one. However, you should avoid trying to connect the generator to one of the very small windings like those for the CRT filament which may only have 2 or 3 turns.

2. Apply a pulse waveform to the parallel resonant circuit. In 1960, most scopes had a 'sync out' on the timebase that provided a few 10s of volts at enough current for this. A circuit in "Television" magazine a couple of years ago used a BU508, a 12 V power supply, and a small oscillator built from a 4011 chip. A function generator or a 555 timer based circuit will also make a satisfactory stimulous. Also see the section: Flyback Testing Equipment.

3. Look at the waveform across the resonant circuit with a 'scope. A good unit will give a nicely decaying oscillation, of at least a few cycles, possibly 10's of cycles. If there is a shorted turn *anywhere* in the device, the oscillations will be seriously damped, and you'd be lucky to see 2 complete cycles. Experience and/or comparison with a known good device will tell you what to expect.

```
                              Scope
              _                 o
 Pulse or   _| |_               |      Device under Test
 function o---------------------+-----------+    +---
Generator                       |            )::(
                 High Quality  _|_           )::(     All other
                 Non-polarized ---           ):: +--- windings
                     Capacitor  |            ):: +--- left open
                                |            )::(
   Ground o---------------------+-----------+    +---
```

(From: James Elliott (jelliott@stlnet.com).)

I tried the Q evaluation method using the 100 volt CAL voltage pulse from a Tektronix scope. It worked best when I used a series 200 pF capacitor. I got maybe 100 pulses before it decayed to zero. If I shorted two of the primary pins, the decaying pulse train went to zero almost immediately. So it works!

I thought of another method. The Q of a resonant circuit is equal to the center frequency divided by the half power bandwidth. I applied an audio generator through a 22k resistor, found the peak frequency, then went off that frequency to .707 of that amplitude. Double this would be the bandwidth. I got Q's of 26 and 16 for two I tried. (Editor's note: This appears to be a valid approach.)

Method 2

The circuit below excites the flyback in much the same way as in normal operation. The only caution is that this tester probably does not put enough stress on the flyback to find an intermittent that fails only under full operating conditions. However, most flyback failures are solid - once a short develops, there is a meltdown of sorts and it is there to stay.

You will require a 12 V power source of at least 2 or 3 amps capacity (regulation is not important - I just use a simple transformer, rectifier, filter capacitor type of power supply).

The circuit is shown below. None of the component values are critical.

```
+12     Q1   +----------------+
 o           |                 )::
 |       B |/ C                )::         <-- Flyback Under Test -->
 |  +------|    2N3055         )::

               110        27     _|_
               2W         5W      -
```

Note: if the circuit does not start oscillating at about 5 volts or less, interchange the two feedback connections to the transistor bases.

The tester is just a chopper feeding the salvaged core from an old flyback (I removed the inductance control spacers for this core). The drive (5T+5T) and feedback (2T+2T) coils can be wound from hookup wire (#14-#20) and well insulated with plastic electrical tape. Connect the center taps directly to the coils - do not bring out a loop of wire. Make sure all the turns of each coil are wound in the same direction. Wind the feedback coil directly on top of the drive coil. The secondary of this core is a 10 turn well insulated coil similar to the other two wound on the opposite side of the ferrite core.

You will need to remove the suspect flyback from the TV or monitor. Another 10 turn coil is wound on the suspect flyback core anywhere it will fit. Connect one end of this coil to one end of the 10 turn coil on your old flyback core. Use a wire nut or twist together securely. Provide an easy way of connecting the other ends momentarily - a pushbutton comes in handy.

Make sure you locate the HV return lead on the flyback and use that as the return for the arc. Otherwise, you may puncture the insulation when the high voltage finds it own path to ground.

Identifying the High Voltage Return on a Flyback

It is essential that this be correctly connected or else the high voltage *will* find a suitable path to ground - and it may not do the other circuitry any good!

There are several approaches that can be taken - possibly in combination:

- Process of elimination - the HV return will often be an isolated pin on the flyback not connected to anything else. Therefore, if you test between all combinations of pins on the flyback (removed from the circuit board) and find a pin that appears open to all other pins but is connected to a pad on the circuit board, it is quite likely the HV return.
- Check all connections on the circuit board and identify those that go to ground. One of these flyback pins will be the HV return. It will do no harm to connect them all to ground during testing.
- Use a 100 VDC or greater power supply and high value resistor, say 100K. Connect the power supply negative output through this resistor to the HV lead on the flyback (suction cup connector):

```
                    100K
       PS- o--------/\/\--------+--------o CRT (suction cup) connector on flyback
                                |
                                o
                                -
     100 VDC           Measure voltage here
```

```
                                                  +
                                                  o
                                                  |
      PS+ o---------------------+--------o Probe to pins on base of flyback
```

Check each pin on the base of the flyback with the probe. Touching the return pin will result in the voltage reading dropping to perhaps 50 or 60 volts. This is the forward voltage drop across the high voltage rectifier stack inside the flyback. All other pins will result in it remaining at the supply voltage (except for the ground connection to the F/G2 divider if it is separate - then it may drop a fraction of a volt). Note that if you cannot locate the HV return, your flyback may indeed be defective; it may have an internal bad connection, open HV rectifier, or burnt out HV winding. Or, if other pins drop the voltage, you may have already found shorts in the flyback!

Method 2 Testing Procedure

Once everything is wired and double checked, turn on the juice.

- If the flyback is good, then with the coils connected there will be several kV at its output - enough to create a small arc (1/8" typical, up to 1/2" for color flybacks).

- The load imposed on the oscillator will be modest (the frequency increases in response to load).

If there are any shorted windings, then there will be no significant HV output and the load on the oscillator will increase dramatically.

- If you get arcing or corona from *under* the flyback - at the pins - either did not locate the correct HV return or there is a short inside resulting in HV arcing internally to the low voltage windings.

I have used this 'tester' on a dozen or so flybacks. It has never been wrong (though I have opted not to believe it and gotten screwed).

Other Flyback Testing Procedures and Comments

Here is a Web site with some notes on flyback testing procesures:

- Noahtech Flyback Testing Page

They have other useful information related to monitor repair as well.

(From: Terry (terwes1@juno.com).)

I first check for HOT shorts, secondary supply overloads, and everything else, disconnecting the flyback windings to any suspect circuits as I go. So, if I get to the following test, pretty much all connections to the flyback are now open anyway. Next, I perform "The Loop Test":

1. Ring the transformer at the HOT primary winding. You don't need fancy signal generators to inject a signal. Even the 60 Hz AC secondary from a 6 volt filament transformer will work, although you date yourself if you have one in your shop. (Note: I expect that the 6 VAC transformer works in this case because the core of the flyback saturates pretty quickly at this low frequency resulting in sharp edges to produce the ring pulse - I would rather use a 555 timer or pulse generator --- Sam.)

2. Scope any flyback secondary for the little ringing pulse. Observe the number of cycles in the damped pulse.

3. Run a small piece of wire around one post of the ferrite core and short the two ends of the wire together (loop).

4. If the number of damped cycles doesn't reduce dramatically then the transformer already has a *single turn short*

or *worse*. It's bad. There is little change because Q is already greatly reduced by the existing short in the failed flyback, even one turn. If it does reduce dramatically, then you've just strongly affected Q by introducing your own single turn short, so the flyback is OK. What is "dramatically"? Try out a few known good and bad ones and find out for yourself. :)

This *should* work in-circuit but any defective (heavy load, etc) circuit on any flyback lead will reduce Q, so you have to eliminate these other possibles anyway. It is my experience that the flyback almost always leaves physical evidence of its demise. If I don't see it, I check everything else before I try this loop test. I rarely have to use it.

I just love it when the $encore guys call to tell me I need $2000 worth of test equipment to reliably test horizontal circuits. When I tell 'em how I do it, they're pretty much speechless. Some are fascinated. Those are the ones who should switch from sales to tech.

(From: Wild Bill (kwag98@tcis.net).)

There are numerous instruments which will check certain flyback/IHVT parameters, and not others. Thorough testing can only be accomplished with several instruments. As far as I know, there is no single instrument which will test all parameters.

Testing for internal faults includes continuity, shorts, shorted turns, winding-to-winding and winding to core leakage, the HV rectifier (multiplier) stack, focus-screen divider (and internal spark gap), and a drive pulse input - relative proportional output test. And after all of the above tests, the device might still break down at the actual circuit working voltages/temperatures.

The minimum tests should include ohms, leakage, and ringing. An open in the HV winding can't be detected with an ohmmeter if the xfmr contains a HV rectifier stack. as the ohmmeter won't provide the necessary voltage to bias the rectifiers. A well designed (fairly inexpensive) leakage tester can provide the necessary voltage to check this.

(From: Jurb6005 (jurb6005@aol.com).)

I test flybacks by clipleading a beefy old TO3 horizontal output transistor into the circuit. This tests it at the actual operating voltage and will show all faults. Believe it or not, this also works on sets that use a GCS (Gate Control Switch, GTO SCR?) like the 2SG264 and 613. If you use it on one of these sets it may get hot, but it will run long enough to test things. (Even a 'beefy old HOT' may not survive certain faults. --- Sam.)

Also, on sets that use a linear regulator (not a switchmode power supply or regulator) there is usually a ballast resistor. If you simply leave the shorted regulator disconnected, it will run through the ballast and viola! You can non-destructively test the circuit.

These methods are especially good if you are writing the estimate, you need not solder anything in!

---

Additional Flyback Testing and Service Information

Flyback Testing Equipment

Sencore and others sell test equipment that includes the 'ring test' or similar capabilities built in. For the professional, these are well worth the expense.

However, the hobbyist could probably purchase lifetime TV replacements for the cost of once of these fancy gadgets.

Bob Parker (of ESR Meter fame) has now designed an inexpensive, easy to use LOPT/Flyback Tester avaiilable through Dick Smith Electronics. Information is available at:

- Bob Parker's FBT Page

Other flyback testers are described at:

- Kephart's FBT Page
- VAAG FBT Page

Various electronics magazines have published construction articles for various types of simplified versions of these devices. Here is a pointer to one such article:

The "Think Tank" column of Popular Electronics, December, 1998, provides information on a unit for testing inductors and transformers (including flybacks) which displays characteristics on an oscilloscope.

(Portions from: Tony Duell (ard@p850ug1.demon.co.uk).)

The February 1998 issue of 'Television' magazine, has a simple circuit for an LOPT (Line Output Transformer - flyback transformer) tester.

It uses a TBA920 chip as an oscillator, driving a BUT11AF which supplies the primary of the LOPT. The voltage developed across this winding (the back EMF when the transistor is turned off) is shown on a DMM. There's also a 'scope point to look at the waveform produced.

Another chip or an oscillator constructed from discrete transistors can be substituted for the TBA920. Some possibilities: 555 timer or MC1391, or a multivibrator can be built from 2N3904s.

However, there are a few errata in the article:

1. The supply voltage is 12 V as mentioned in the text, not 2 V as shown on the schematic.

2. The peak amplitude given in fig. 3 of 8 V should be after the divider network, not at the transformer itself.

3. There is a capacitor shown from pin 13 (decoupling) which almost certainly should be a bypass to ground, not to the collector of the drive transistor.

Quickie In-Circuit Flyback Tests

Note: Larry has 'beta tested' Bob Parker's (of ESR meter fame) flyback tester described at: http://www.ozemail.com.au/~bobpar/fbt.htm.

(From: Larry Sabo (sabo@storm.ca).)

Checking out flybacks can be frustrating and very time consuming without a good tester.

Now, it just takes me a second to check for ringing on the HOT collector. No ringing? Check the HOT with a DVM for shorts. No shorts? Unsolder all flyback legs except the primary winding and check for rings again. No rings? Shorted turns in the flyback!

Bob's estimate that 20% of faulty flybacks have internal leakage or arcing, or bad HV diodes, seems about right. And an LC102 (tester) won't catch these either :-). I've found that about half of these show up with a low resistance measurement between the EHT cap and ground.

Sometimes scoping the output at the EHT cap shows unrectified ringing but stray capacitance probably accounts for that.

Other times, it's clearly rectified, so go figure. As a last resort, I resort to Sam's chopper to wrestle the hold-outs to the ground, but it takes a bit of time to remove the flyback and put 10-15 turns around the core. The ringer has also helped me isolate a defective yoke, which explained why things wouldn't ring.

Anyway, I think Bob's tester is a great little unit and am glad I have had the opportunity to test it--and keep the prototype! :-)

(From: John Robertson (jrr@flippers.com).)

I use an audio signal generator set it to about 15 kHz and a scope or AC voltmeter on one of the output windings.

Connect the generator to the leads that the horizontal output transistor and ground use (out of circuit, use HOT and B+ leads --- sam). You should see on the scope a reasonably nice waveform similar to the input. If you are using a voltmeter, you should get approximatly the correct ratio output voltage relative to the original voltages. So if your generator puts out 10 VAC and the original HV input levels were 100 VDC, then the voltage levels should be about 1/10th of the original. I do this in-circuit, and try to get a square wave as the source, but the theory is consistant.

(From: Quick Fix (iradg@guru.nu).)

If you don't don't repair that many TVs, the cheapest way to check a FBT is to connect its primary winding in series with the yoke (low side) of a working set. If the picture shrinks a few inches on both sides evenly and with no ringing or jail bars, your FBT is good. You can even measure the high voltage on your FBT with this method.

Testing for Bad High Voltage Diodes

A single diode failure would be tough to find if it is in series with other diodes (as is typical on larger flybacks) as it would only be a problem when run near full output. However, this sort of failure is unlikely.

General diode failure (shorts) would probably not be detected with the sorts of tests described above or with typical flyback testing equipment. Actually, a simple ohmmeter test between the HV output and return might suffice! If this doesn't reveal anything, I suggest the following:

One possible way to test for this would be to attach a high voltage capacitor between the HV output and return of the flyback. If the diodes are good, the tester's excitation should then charge this cap up (watch out - the voltage might get to be quite high!). While charging, this load will make the flyback fail any ring test. Once charged, it should pass. However, if the diodes are shorted, I would expect the flyback to test bad as the cap will continue to present an AC load on the output and never charge properly.

I haven't tried this, however, so no guarantees.

(From: dB King ((netrekker@pdq.net).)

Sencore Z-Meters are capable of applying sufficient bias to check those diodes for forward conduction and reverse leakage. Forward conduction should be confirmed first to rule out an open -- almost all multimeters will always show open HV diodes due to their limited voltage output.

Indispensable for capacitor tests as well. I dunno how I got by w/o mine! They also have built-in yoke/flyback ringer. :)

Quite expensive. You might wanna try to find a used one.

Why Do All Flyback Transformers Seem to be Unique?

(Most of these comments also apply to SMPS high frequency transformers.)

Of all the components in a monitor or TV, the flyback is very likely to be a unique part. This is not so much due to the high voltage winding and/or HV multipler but rather related to its usual function as the source of multiple secondary power supply voltages used by various tuner, deflection, video, and audio subsystems. In addition, inductance, capacitance, pin configuration, and HV, focus, and screen outputs must be compatible.

ECG and similar companies do have a line of generic FBTs and should have a catalog/cross reference for these similar to the one for semiconductors. See the section: Replacement Flyback Transformers.

However, FBTs are where the designers of TVs and monitors can be really creative. After all, specifying the flyback windings gives them complete freedom to pick the number and types of secondary voltages! Your chances of picking up something off the street so-to-speak and expecting it to fit anything you have ever owned - or ever will own - isn't great.

(From: an engineer at a TV manufacturer).

We have one guy whose mission in life is doing exactly that... (and specifing HOT's too).

Besides specifying auxiliary secondaries you can also specify an overturn on the primary (for deflection coils which would otherwise require a >1500 V HOT) and influence the tuning of the EHT secondary, to determine the EHT internal impedance. And finally you might specify a built-in EHT capacitor or bleeder resistor and various types of clicked-on potmeter modules (perhaps with a second focus voltage for DAF).

Typical Flyback Schematic

This diagram shows a typical flyback that might be found in a direct view color television or computer monitor. Resistances are included for illustrative purposes only and may be quite different on your flyback!

The high voltage section on the right may actually be constructed as a voltage multiplier rather than a single winding with multiple HV diodes. The rectifiers or multiplier, and/or focus/screen divider may be external to the flyback transformer in some models.

Flyback transformers used in black-and-white TVs and monochrome computer monitors do not have a focus and screen divider network. Older ones do not include a high voltage rectifier either - it is external.

The ferrite core of a flyback transformer is constructed with a precision gap usually formed by some plastic spacers or pieces of tape. Don't lose them if you need to disassemble the core. The ferrite core is also relatively fragile, so take care.

The focus and screen divider network uses potentiometers and resistors (not shown) with values in the 10s to 100s of M ohms so they may not register at all on your multimeter. The high voltage rectifiers (CR1 to CR3 on this diagram) are composed of many silicon diodes in series and will read open on a typical VOM or DMM.

Note that there is no standardization to the color code. However, the fat wire to the CRT is most often red but could also be black. Of course, you cannot miss it with the suction cup-like insulator at the CRT anode end. The focus and/or screen connections may also be to pins rather than flying leads.

```

Replacement Flyback Transformers

Unfortunately, you cannot walk into Radio Shack and expect to locate a flyback for your TV or monitor. It is unlikely the carrots at the counter will even know what a flyback is or recognize one if it hit them over the head (wherever that would be on a carrot). They will probably attempt to sell you a 6.3 V power transformer :-). Fortunately, there are other options:

- Original manufacturer - most reliable source but most expensive. Older models may not be available. This may be the only option for many TVs and monitors - particularly expensive or less popular models.

- Electronics distributors - a number of places including MCM Electronics, Dalbani, Premium Parts, and Computer Component Source, sell replacement flybacks. See the document: Notes on the Troubleshooting and Repair of Computer and Video Monitors for contact info. Many of these are actually original parts and are designated as such. However, there may be no way of knowing and you may end up with something that isn't quite compatible (see below). Thus, unless the catalog listing says 'original part', these may be no better than the sources below.

  Here is one apperently just for flybacks:

  - Component Technologies, 1-888-FLYBACK or 1-800-878-0540. email: fbtxformer@aol.com.

  and one that is mostly for flybacks:

  - CRC Components, 1-800-822-1272.

  some others:

  - Data Display Ltd, Canadian sub of CCS, 1-800-561-9903.
  - EDI (Electro Dynamics, Inc.) NY, 1-800-426-6423.
  - Global Semiconductors, 1-800-668-8776, Toronto.

  And, here's one for your semi-antique (1950s) needs:

  - Linear Electronics, Walthan, MA. Phone: 1-617-894-7300, Fax: 1-617-894-8890. (They also have vacuum tubes.)

- Generic replacements - these are sometimes available. ECG, NTE, ASTI, HR Diemen, for example, offer a line of replacement flybacks. Some of these sites include a cross reference to their replacement based on TV or monitor model and/or the part or house number on the flyback:

    - NTE (NTE Electronics, Inc)
    - ECG (Philips)
    - ASTI (ASTI Magnetics)
    - Flybacktransformer
    - Cactus Technology Corp.

  However, these may be of lower quality or not be quite compatible with your original. In an effort to minimize the number of distinct flyback models, some corners may be cut and one-size-fits-many may be the rule resulting in all sorts of problems. Here are a couple of possibilities:

    - The number of turns on one or more windings may not quite match your original meaning there will be lower or higher voltages from certain outputs and/or drive conditions (current, resonance) may be affected.

    - There may even be extra or missing connections - pins on the bottom or flying leads. It is essential to determine what must be done to make the flyback work in your equipment *before* applying power. Extra connections may need to be grounded or connected to some other points in the circuit. If this is not done, operation may not be correct or other parts may blow as current from these unconnected pins finds its own way to ground.

    - The flyback may simply be defective due to bad quality control, part number confusion, or mismarking. Internal circuitry such as the focus and screen(G2) divider could be improperly wired, configured for a different model, or omitted entirely. Such defects can be very tough to identify.

  Thus, marginal or erratic behavior might result from generic replacements greatly complicating your troubleshooting since without careful measurements there is no way of knowing whether the problem is due to the new flyback or a fault that still exists elsewhere. For some actual experiences, see the section: Cheap Flybacks - Beware.

(From: a-freak@freenet.de.)

HRdiemen is a manufacturer of replacement line output transformers and have several thousand types available. But the nicest thing is their online database where they have pinout and internal schematics including typical voltages of every of these transformers. Just type your original letters/numbers into the search box, then you get the replacement transformer type and a link to its internal construction.

Very helpful if you want to "recycle" an old transformer for a new circuit.

Javascript must be enabled for this to all happen automagically. If you prefer to work without javascript (like me, to avoid ad banners and other doubtful background activities), you can also directly access http://www.hrdiemen.es/data/esquemas/HR7491.gif or whatever number your transformer has.

Cheap flybacks - Beware

There have been reports of inexpensive replacement flybacks resulting in a variety of strange symptoms. I do not know how likely it is to have problems with these. In most cases, I would expect the replacement to drop right in and perform perfectly. However, I have heard of occasionally difficulties. I do not know which, if any, of the companies listed above sell such incompatible devices. However, it would be worth checking before buying if possible.

Here are several examples of incompatibility problems:

(From: Petercoe (petercoe@aol.com).)

There is some good and some bad to these flybacks. One thing I noticed is that the competition has caused the price of the name brands to drop.

However, these flybacks may not work right in all cases. I know I had to modify a circuit in a Sony to get the set to work right after using a low priced replacement. I also had a Goldstar which would only work with the original flyback."

(From: Michael Caplan (cy173@freenet.carleton.ca).)

The FBTs that I tried (three samples in two generic brands available here in Canada) all seem to be missing the required internal voltage divider. This was confirmed by comparison with a new oem Sony part. The OEM part exhibits the proper resistance measurement. It is through this resistance that the Hold Down voltage is derived. "No resistance = no Hold Down voltage", as far as I can see."

(From: Dave Moore (penguin@datastar.net).)

I recently put a cheapo sub flyback Hitachi P/N 243384 in a Hitachi model CT2647 26" tv.

Apart from inadequate horizontal deflection, the TV exhibited ringing like jail bar shadows on the left side of the screen and a bright area with retrace lines showing from top to bottom down the middle of the of the screen. At first I thought that this was the classic bad B+ filter to the crt board phenomena. But nope, filter good.

So I figured that it had to be a bad filter in the brightness limiter or to the video circuits. A quick round about with my trusty DS ESR meter did sniff out a weak cap in what seemed to be the brightness limiter circuit. Did this cure the problem? As John Belushi would say: Noooooooooooo. Well I recalled a similar problem that I had encountered while experimenting with the screen voltage on a Zenith TV. At one point I had removed a small disk capacitor on the screen supply trying to unload the shorted screen supply. Well the problem turned out to be the picture tube and after I cleared the screen short I noticed a similar phenomena to the one that I was presently experiencing (the bright area in the middle of the screen from top to bottom with retrace lines).

Well after I reconnected the little disk capacitor the problem went away. So!! I thinks to myself: The little disk cap on this Hitachi I'm working on must be bad. Well lo and behold - there is no disk cap on the hitachi. No place for one either. It was designed to not need one apparently.

So I put a .01 uf 1400 volt disk cap (cause it was handy) on the screen and voila! End of jail bars and retrace lines in middle of screen. I can only assume that the cheapie flyback was the cause. This makes me wonder if the lack of horizontal width might be symptomatic of this "cheapie" flyback also. I'll probably just parallel some capacitance on the HOT since I don't have much width to make up. I already adjusted B+ to the High Voltage section and at full clockwise position of the control the picture doesn't open up all the way. I left the control at mid position and played the set for a couple of hours. Everything's running cool.

(From: Gregory Danner (gdanner@advancenet.net).)

As far as "generic" flybacks, be prepared to do some slight adapting as far as mechanical installation. Sometimes new ones aren't the same diameter and height, and don't fit with existing metal support brackets, which may have to be cut away or bent. Sometimes the pins that go through the circuit board aren't aligned quite right, and may have to be bent and adjusted slightly to fit the board. Screen and focus controls may not be in the same physical position on the new flyback. But, overall, I would say that most of the generic flybacks I've used have worked out OK electronically.

Introduction

Scope of This Document

TVs and most computer and video monitors depend on the use of similar (at least in concept) circuit configurations to generate several outputs:

* Current waveform required in the deflection yoke coils of the CRT for linear sweep of the electron beam to create a high quality (geometry and linearity) picture. This is close to a sawtooth but not quite.
* CRT High voltage (20 to 30 kV or more) required to accelerate the electron beam and provide high brightness

and sharp focus, as well as other related voltages - focus and screen (G2).

- Various auxiliary power and signals for other subsystems of the equipment (low voltage, CRT filament, feedback, etc.).

This document addresses the basic principles of operation of these types of deflection systems. While most people with any familiarity with TV or monitor operation or repair have some vague idea of how these circuits work (probably just enough to be dangerous), many are incorrect or at least very incomplete.

Most of this information applies to the horizontal deflection which operates at the higher frequency in a raster scan display (except for peculiar rotated portrait formats where the functions of the horizontal and vertical scan are interchanged.

Equipment which utilizes this circuitry includes TV (direct view as well 3-CRT and light valve projection types), computer and video monitors, tube based video cameras (e.g., vidicon), and other magnetically deflected CRT devices.

Vertical deflection circuits are much less complex due to the lower scan rate (e.g., 50 to 120 Hz V as compared to 15.734 kHz H for an NTSC TV or up to 120 kHz or more for a high resolution computer monitor). Most of the control and output drive circuitry is contained in a special vertical chip in modern equipment.

Deflection System Safety

The deflection components of an operating TV or monitor contains substantial power with high voltages and high currents. This circuitry in many TVs and some monitors is directly line connected (no isolation). There are often large high voltage filter capacitors on the B+ supply and these may retain a lethal charge for some time after the plug is pulled. The CRT HV capacitance can also retain a dangerous charge - possibly for weeks!

Read, understand, and follow the recommendations in the document: Safety Guidelines for High Voltage and/or Line Powered Equipment before attempting any TV or monitor repairs. See the specific documents: Notes on the Troubleshooting and Repair of Television Sets or Notes on the Troubleshooting and Repair of Computer and Video Monitors as appropriate for your equipment.

Horizontal Deflection System Fundamentals

How Does the Horizontal Deflection Circuit Work?

Although there are many variations, the basic operation of the horizontal deflection/high voltage power supplies in most TVs, monitors, and other CRT displays is very similar.

For understanding the working of the deflection circuit regard the flyback transformer as an inductor. The airgap stores energy, some of which may be tapped off during flyback by secondary rectifiers (e.g., vertical deflection, signal circuits, and high voltage supplies) and non-rectified loads (e.g., filament supply) but these have hardly any influence on the basic working principles.

The scenario described below is only true in the steady state - the first few scans are different because the picture tube capacitance is still discharged. This represents a short-circuit at the secondary side of the flyback. It prevents proper demagnetizing, hence the core will go into saturation (unless special soft-start measures have been taken, like a B+ supply that comes up slowly). Generally, a hard start of the line deflection circuit represents a very heavy load on the HOT. This will happen after a picture tube flashover or if the B+ is connected suddenly (due to intermittent contact) and can mean instant death to the HOT due to secondary breakdown. See the section: More on HOT Failure.

Basic Deflection Circuit Operation

The following description is only the basics. For more information, see the article by David Sharples in "Electronics World", June 1996.

A very simplified circuit is shown below - many components needed to create a practical design have been omitted for clarity. First concentrate only on the portion of the schematic shown below to the left of the yoke components:

```
                         B+
                          o
                          |
                          +
                           )::
                Part of T2 )::
                   Flyback )::
                   Primary )::
                           )::
                          +
                          |
                          +-------+---------+----------+
                          |       |         |          |
         Horizontal       |       |         |          +
           Drive          | C     |         |           )::    (Horizontal
             T1       B |/      __|__      _|_          ):: L2  Deflection
         --+    +-------|       _/_\_      ---          )::     Yoke - HDY)
    Driver  )::(        |\        |   D1    | C1       +
    Stage   )::(     Q1   | E     | Damper  | Snubber _|_ C2
    (not    )::(     HOT  |       |         |         --- S-correction
     shown  )::(          |       |         |          |
         --+    +---------+---+---+---------+----------+
                             _|_
                              -
               B+ Return (may not be signal ground)
```

The current in the flyback primary and collector of the HOT are *not* equal. The horizontal deflection yoke, damper diode, HOT collector, snubber HV capacitor(s), and flyback primary all connect to the same point. We begin our adventure at the end of the scan - retrace - when the flyback period begins:

1. At the end of scan, current is flowing through the flyback primary to the HOT, Q1. At the start of the flyback period, Q1 turns off. (This must be done in a controlled manner - not just a hard shutoff to minimize stresses on the HOT - but that is another story). Since current in an inductor (the primary of the flyback has inductance) cannot change instantaneously, the current is diverted into the snubber capacitor, C1. The inductance of the flyback primary (T2) and C1 forms a resonant circuit so that the voltage climbs on C1 as the current goes down.

At its peak, this voltage will be 1000 V to 1500 V.

2. C1 now begins to discharge in reverse through the primary of T2 (back into the B+ supply - the filter capacitor will stabilize the B+ output) until its voltage (also C-E of the HOT) reaches 0.

3. If there were no damper diode (D1), this voltage would go negative and continue to oscillate as a damped sinusoid due to the resonant circuit formed by T2 and C1 (and the other components). However, D1 turns on as the voltage goes negative and diverts the current through it clamping the voltage near 0 (-Vf for the diode).

   Note that the damper diode D1 may have been built into the HOT T2 in the case of an inexpensive or small screen TV or even some monitors that don't have any circuitry for E/W correction.

   Steps (1) to (3) have accomplished the flyback function of quickly and cleanly reversing the current in T2 (and, as we will see, the deflection yoke as well). The full flyback (and yoke current) are now flowing through the forward biased damper diode, D1.

4. At the beginning of scan, the damper diode (forward biased) carries the bulk of the current from the yoke and flyback. The nearly constant voltage of the B+ across T2 results in a linear ramp of current now through the damper diode since it is still negative and decreasing in magnitude.

5. At approximately mid-scan, the current passes through zero and changes polarity from minus to plus. As it does so, the damper diode cuts off and the HOT picks up the current (with a voltage drop of +VCEsat). Current is now flowing out of the B+ supply.

   The base-drive to the HOT must have been switched on before this point! Timing is not very critical as long as it happens between the end of the flyback and the zero crossing of the summed current. The location of the zero crossing depends on the secondary load, notably the beam current. Larger beam current requires that the HOT be switched on earlier. The designer has to do some optimizing here...

6. During the second half of the scan, the HOT current ramps up approximately linearly. This is again due to the nearly constant voltage of B+ across the inductance of the flyback primary.

7. Near the end of scan, the HOT turns off and the cycle repeats.

   The HOT has a storage time between 3 us and 7 us, thus the base-drive is switched off earlier, in a controlled way to properly remove the charge carriers from the collector region in the HOT. The peak amplitude of the base current and the way it is decreased determine the ultimate dissipation in the HOT and are thus subject of heavy optimization. This is hampered by the fact that there is much spread in HOT parameters.

Thus, the current in the flyback (ignoring the yoke components) is a nearly perfect sawtooth. The ramp portion is quite linear due to the essentially constant B+ across the flyback primary inductance. The current waveform can be easily viewed on an oscilloscope with a high frequency current probe. See the section: Probing TV and Monitor Yoke Signals.

The voltage across the C-E of the HOT is a half sinusoid pulse during the flyback (scan retrace) period and close to zero at all other times (-Vf of the damper diode during the first half of scan; +VCEsat for the HOT during second half of scan).

Caution: Without a proper high frequency high voltage probe, it is not possible or safe to observe this point on an oscilloscope with full B+. However, where the equipment can be run on a Variac, this clean pulse waveform can be observed at very reduced B+. Excessive ringing or other corruption would indicate a problem in the flyback, yoke, or elsewhere.

Normally you would use a 100:1 probe suitable for 2 kV peak. You could always make your own voltage divider out of a couple of suitable resistors and use a regular 10:1 or 1:1 probe. Beware that also the capacitive division ratio must be correct because the line frequency is high enough to make it relevant.

The current through Q1+D1 is several amperes peak-peak. There's a lot of power circulating here, making this a *dangerous* circuit in every way!

The Deflection Yoke Connection

So, you ask: "Why can't the yoke just be placed in series or parallel with the flyback primary?". After all, the current is a nice sawtooth. Isn't that what we want?

There are several reasons including:

- The desired yoke current is not quite a sawtooth but includes two major corrections: S and E/W (described below). These cannot be applied easily with such a configuration.

- The flyback also generates the HV and secondary output voltages and the primary current might then be affected by these and change as a function of beam current (picture brightness) or audio level (although feeding the audio amplifiers from LOT windings is not common anymore).

Note that some TVs and monitors cut off power to the horizontal deflection circuits if the yoke connector is removed. This is a separate interlock and not a result of the B+ flowing through the yoke. Its purpose is to protect the circuitry and the CRT. With no deflection, the very bright spot in the center of the screen would quickly turn into a very dark permanent unsightly blemish. With appropriate precautions to avoid this costly situation, it is possible to power a monitor or TV with the yoke winding(s) disconnected to determine if a defective yoke is messing up the deflection system operation. See the documents: Notes on the Troubleshooting and Repair of Computer and Video Monitors or Notes on the Troubleshooting and Repair of Television Sets for additional information.

The yoke is placed across the C-E of the HOT in series with a capacitor (S-correction) and other components which in effect form a variable power supply (analogous to the constant B+) which is used to compensate for the various problems of scanning a nearly flat screen.

What are S and E/W or N/S Correction?

These terms actually refer to the various corrections to deal with what is normally called scan linearity and pincushion distortion. Most larger TVs and nearly all high quality monitors will have various user and internal controls to optimize the corrections for each scan rate (multiscan monitors).

And yes, E/W/N/S stand for directions. :)

Because the screen of most CRTs is relatively flat (even those not advertized as flat) and the electron gun is relatively close, any picture tube will naturally have serious linearity problems and pincushion distortion if there were no corrections applied. Near the *edges* and *corners* of the screen the spot will move faster because the same angular speed translates to a larger linear speed. This is simple trigonometry.

There are 3 ways of correcting N/S:

1. The design of the deflection coil (distribution of the windings). This is cheap and robust but it requires a huge design effort. Also, if for some reason the glue that holds the wires together gets soft then the geometry and convergence may be affected.

2. With permanent magnets. After the tube has been built it is switched on and some magnets are stuck on the back to improve geometry, convergence and or landing. This is very difficult but relatively cheap. I would expect it in better monitors.

3. With active N/S correction. A line-frequency complex waveform is injected as current into the raster deflection coil. This allows arbitrary correction of N/S waveforms, within the limitations of the waveform generator and the bandwidth of the system. This can be easy to adjust, or not, depending on the design, and it is most expensive of all. I would expect it in workstation monitors.

As for problems with N/S geometry, if there is an active circuit at all, then it would correct only 4-way symmetrical errors, so you would expect an error in all 4 corners. I don't know of any circuits that would affect only 1 corner. A magnet might affect only 1 corner, it might have dropped. A coil might have softened in 1 corner, due to heat. That would be beyond repair, I guess. But it is not very likely either. My guess is that the error has always been there, from the start and it was just noticed!

S-Correction Circuit Operation

The first correction to apply, in both directions, is S-correction. By simply putting a capacitor in series with each coil, the sawtooth waveform is modified into a slightly sine-wave shape (the top and bottom are somewhat squashed). This reduces the scanning speed near the edges. Linearity over the two main axis should now be good.

When we add in the yoke components (only the horizontal deflection coil and S-correction capacitor or S-cap are actually shown above) conditions are only slightly more complex:

First, consider what would happen if instead of the S-cap, the yoke were connected to B+ like the flyback. In this case, the total current would divide between the flyback primary and the yoke. It would still be a sawtooth as described above. Of course, component values would need to be changed to provide the proper resonant circuit behavior.

That's called 'tuning of the flyback capacitor', to achieve the proper duration of the flyback pulse, matching the blanking time of the video signal, and to achieve the proper peak flyback voltage, matching the Vces specification of the HOT with a reserve of about 20%. That's two conditions, requiring two degrees of design freedom. There are 3 freedoms: supply voltage, flyback capacitor and yoke inductance.

With the S-cap and yoke wired as shown above, the inductance of the yoke and S-cap form a low pass filter such that voltage on the S-cap will be a smoothed version of the pulses on the HOT collector (similar in effect to the B+ feeding the flyback but not a constant value). The average value of the S-cap voltage will be positive.

The S-capacitor together with the yoke inductance forms a resonant circuit whose frequency is tuned lower than the line frequency. It has the effect of modifying the sawtooth current into a sine-wave shape. This is called 'S-correction'. It reduces the scanning speed at the left and right edges of the screen.

The value of the S-cap can be selected so that the voltage varies in such a way as to squash the current sawtooth by the appropriate amount to largely compensate for the fact that the electron beam scans a greater distance with respect to deflection angle near the edges of the screen.

Think of it this way: When the scan begins, the yoke current is at the maximum value in the direction to charge the S-cap. The voltage across the S-cap is causing the current to decrease but the S-cap is also gaining charge so the rate of decrease is increasing. At the time the current passes through 0, the S-cap is charged to its maximum. The current now reverses direction retracing its steps. Got that! :-). This is another example of a portion of a resonant circuit. The voltage on the S-cap is varying by just the right amount to compensate for the geometry error.

Many CRTs, especially the flatter ones, have a need for geometry correction that goes beyond simple S-correction. Most tubes need inner pin-cushion correction, which is also called "dynamic S-correction". It is an adaptation of the diode modulator circuit, which is only found with tubes that need E/W (pin-cushion) correction in the first place. See the section: N/S and E/W Correction Circuit Operation.

Some tubes need more S-correction only at the extreme edges, this is called "higher-order S-correction". This requires another resonant circuit, tuned to a higher frequency, which is more difficult to implement. Most sets will not have such circuit.

Many tubes in the USA (with only 100 degrees deflection angle) are "raster-correction-free" so they will not have much correction circuitry other than basic S-correction. There will be no diode-modulator for E/W-modulation. Such sets will have larger remaining errors that tubes (with 110 degrees deflection angle) that need active correction to begin with.

For multiscan monitors, S-caps must be selected for each scan range since the timing varies with scan rate. These are only approximate corrections but good enough for most purposes. MOSFET or relay circuits take care that for each range of scanning frequencies the correct combination of S-correction capacitors is selected.

As an example, consider a multiscan monitor which supports VGA (31.4 kHz, 800x600 at 56 Kz (35 kHz), and 800x600 at 60 Hz (38 kHz):

For good geometry between 31, 35 and 38 kHz, two discrete values for the S-cap is barely enough. Actually a 3rd value optimized for 35 kHz would be better. If there is only one S-cap and it is optimized for 38 kHz, then at 31 kHz you will be using a too large angle of the sine (of the resonant frequency between the S-cap C and the deflection coil inductance). Possibly even > 180 degrees, making the current fold back. Apart from an obvious geometric distortion, there is also increased risk of HOT failure because you're operating too close to the resonant frequency.

Applications of CRTs in TVs are a lot less critical than computer monitors, so don't expect too much of them. It is simply not worth the money until more critical applications like WebTV come along. The market is not willing to pay for corrections to problems that most people would never notice (with typical TV pictures).

N/S and E/W Correction Circuit Operation

Then remain the N/S and E/W errors, meaning that near the corners the scanning speed is still too large.

To a large extent the N/S errors can be corrected by a suitable yoke coil design. For smaller tubes (90 to 100 degrees types) this is also possible for E/W errors. For larger tubes (110 degrees) or high quality tubes, electronic E/W correction is required. This is the well-known pincushion.

E/W correction is modulation (which implies multiplication) as a function of vertical beam position. The amplitude of the horizontal deflection current is modulated with a parabola waveform which is derived from the vertical deflection circuit. This squeezes the top and bottom lines back into the left and right screen borders.

N/S correction (if any) is a method of injection - addition of a high frequency waveform (harmonics of the line frequency) to the low-frequency field-deflection waveform.

This requires costly nasty circuitry which is better avoided.

This is how the diode modulator for E/W correction works:

```

            -
       B+ Return (may not be signal ground)
```

The deflection supply B+ gives a constant voltage Vb. At the output of the E/W amplifier there is a variable voltage Vm. Because there can not be an average voltage over any coil, the average voltage over the deflection circuit (L2 + C2) is Vb-Vm. The scanning width is proportional with this voltage Vb-Vm. By modulating Vm as a field-frequency parabola which is higher for the top and bottom lines it is achieved that the scanning width is reduced for the corners of the screen.

The required field-parabola waveform is derived from the field deflection circuit. Amplitude and DC-level are adjustable, for correcting pin-cushion distortion and setting the screen width. EHT is *not* influenced !

The E/W amplifier usually has a PNP emitter follower only, because it must only sink current and dissipate a bit of power. The coils L3 and L4 take care that the E/W amplifier sees no line-frequency. The "bridge" components L3 and C5 resemble the deflection coil with its S-correction capacitor and carry the large amplitude alternating current. L3+C5 are tuned to approximately the same frequency as L2+C2.

C1, C3 and C4 must be tuned so that EHT is independent of Vm and peak voltage over D2+C2 is high enough but not too high when Q2 is off. C4 is usually a small ceramic capacitor of approx. 1 nF mounted close to the HOT Q1, it also suppresses EMI. Flyback capacitors are critical components. Wrong types may overheat and burn. Bad contacts here or elsewhere in the deflection circuit may arc and also cause fire.

There are many variants to this circuit, e.g. for dynamic S-correction. Multi-sync monitors need added circuitry to make the EHT independent of the line frequency (if there is not a separate EHT supply, that is).

If the E/W modulator fails then you will see that the top and bottom lines will be much too wide. There are several parts that could have failed. It's usually not too difficult to find why there's no parabola. If you have partial loss of E/W modulation, notably in the extreme corners, then you should suspect the tuning of the 3 flyback capacitors that belong to the diode modulator circuit. That's a specialist job...

S-Correction Problems

- An open S-cap will result in no horizontal deflection - a vertical line.
- A shorted S-cap will likely load down the B+ possibly resulting in a blown fuse or other power supply components.
- An S-cap that changed value (or in the case of a multiscan monitor, selected to be the wrong value) will result in distortion at the left and right sides of the screen:
  - Too low: picture will be squashed towards edges.
  - Too high: picture will be stretched towards edges.

  Note that this is not the same as what is commonly called linearity which would likely affect only one side or gradually change across the screen.

Horizontal Linearity Correction

Since there is non-zero resistance associated with the components (mainly coil losses) in the yoke circuit (yoke winding, ESR of S-cap, etc.) the world is not quite as ideal as one would hope. Without compensation, this resistance would result in non-linearity of the picture - it would tend to be squashed on the right side as the resistance saps energy from the yoke circuit.

The waveform becomes a damped sinewave, which will be 'undamped' by restoring energy during the flyback.

One way to deal with this is to add a magnetically biased saturable inductor in series with the horizontal deflection yoke. This is called the linearity coil.

Its core is magnetically biased near the point of saturation such that the inductance decreeases with increasing current and this helps to stretch the right hand side of the scan. In other words, during the scan the coil saturates so that the inductance decreases. At the end of scan there is practically no voltage left over the linearity coil so that the deflection coil gets maximum voltage.

E/W Correction Problems

The common name for the adjustments is likely to be 'Pincushion Amp' and 'Pincushion Phase'. They are controlling the E/W correction circuits.

Pincushion Amp adjusts the amplitude of the correction signal.

Pincushion Phase adjusts where the correction is applied on the vertical scan.

- Failure of the E/W correction circuit will result in very noticeable pincushioning distortion of the vertical edges.
- Excessive E/W correction will result in barrel distortion of the vertical edges.
- A bad power supply derived from the flyback could also result in similar symptoms due to ripple or lack of power to the pincushion circuitry.

Differences Between N/S and E/W Correction Implementation

While the desired effects are symmetric - modulate the amplitude of one component of the deflection circuit (H or V) by the other (V or H), the implementations will differ substantially. The reasons should be obvious: The line frequency is much higher than the field frequency.

E/W correction is easy: the lower frequency modulates the higher frequency. This reduces to simple amplitude modulation. Well, simple in principle. The line circuit is a high-energy circuit. For this purpose the diode modulator circuit has been invented. It allows an energy exchange between the line deflection circuit and a pseudo deflection circuit.

N/S correction is difficult: the higher frequency modulates the lower frequency. It *can* be done with sort-of amplitude modulation by using a 'transductor'. This is not a transformer but a component with 2 coils and a saturable core where the (line frequency) current through 1 coil modulates the inductance of the other coil. If there are tuned parts in the circuit then the correction will be highly sensitive to line frequency variations.

It can also be done with a regular transformer, by injecting a strong signal (from an amplifier) with line frequency components into the field deflection circuit.

Either way, it's an expensive solution which should be avoided by designing the deflection coils in such a way that the picture tube needs no active N/S correction.

Several types of auxiliary power may be obtained from the flyback, somewhat as a byproduct of the deflections system operation. These may provide DC (using high speed rectifiers and small filter capacitors), or AC. Although not always well known, the coupling factor with the primary is decent for a flyback transformer and so there can be scan rectifiers as well as flyback rectifiers in the same system - and often are. Refer to the diagram, below:

- Scan power is obtained during the forward stroke as with a 'normal' transformer. Energy is transferred while the HOT/damper diode is conducting. The output rectifier is oriented so that current flows during scan time. (Dots on the transformer winding match.)

The scan rectifiers make no use of the stored magnetic energy, they load the primary directly during the scan part. They do not cause an increase of the stored magnetic energy so a heavy load is not a problem.

- Flyback power is obtained from the stored energy in the flyback transformer's inductance when the HOT shuts off. The output rectifier is oriented so that current flows at flyback time. (Dots on the transformer windings oppose.)

  The flyback rectifiers on the other hand (especially the EHT) draw from the stored magnetic energy. When the secondary load increases, the magnetization current will also increase. Ultimately this will cause saturation of the ferrite core. Excess beam current is a common cause for this and should be avoided by the beam current limiter. The advantage of a flyback rectifier is that it provides 7 times more volts per winding than a scan rectifier.

- AC power (usually only for the filament or a feedback signal) flows during both scan and flyback.

```

```

Here, V1 is just a typical example of an auxiliary supply derived from a scan rectifier and HV is the best known example of the use of a flyback rectifier. Since the deflection system runs at 15 kHz or higher, fast recovery diodes must be used as rectifiers. However, at these frequencies, the uF ratings of the filter capacitors can be quite small compared to power line (50/60 Hz) based systems.

EHT (High Voltage) Generation

The EHT (Extra High Tension or HV to the CRT) is generated from a secondary winding on the flyback transformer having several thousand turns of very fine wire. Being a flyback supply, the actual output voltage is many times what would be calculated based on turns ratios alone. The HV rectifier consists of a stack of silicon diodes with a total PIV rating of 50 kV or more.

Because the flyback pulse is so narrow, the rectifier diode will conduct only a short time. Thus the peak current in the winding will be quite high, resulting in a significant voltage drop when loaded. The internal impedance of the EHT source is in the order of 1 MOhm, so with a load of e.g. 1 mA the EHT will drop 1000 V = -3%. Usually the EHT voltage is far from stable, 10% drop is quite normal.

If the EHT voltage drops, then the electrons will be accelerated less and will move through the deflection field at a lower velocity. As a result they will be easier to deflect by the magnetic field, and the picture size will grow. Without special measures, brighter pictures will be larger. The measure is to feed some EHT information or beam current information to the deflection circuits, reducing the deflection current amplitude a bit for bright pictures. For horizontal deflection this is done by the E/W modulator. This is called anti-breathing.

Sets with raster correction free picture tubes don't have an E/W modulator. There the correction may be done by means of a power resistor in series with the B+ supply. A large beam current causes more power consumption, this lowers the B+ supply voltage and thus reduces the line deflection current. That also reduces the EHT even further, but the deflection current has a stronger effect on the picture width than the EHT. Better methods exist too.

The EHT information is also used to protect the flyback transformer from overload. As the load increases, the average primary current rises. Ultimately it may reach a level where the transformer core may go into saturation. This causes large peak currents in the HOT which might lead to destruction. To prevent this, some EHT information is fed to the contrast controller, to automatically reduce the picture brightness whenever the white content is too much. This is called the average beam current limiter.

A failure in the video path, like a video output amplifier stuck at 0 V, causes a high beam current that will not react to the contrast controller. In that case the beam current limiter will not work and the set should switch off automatically, usually within a few seconds after applying power. When the cathodes heat up, you'll see an even picture with diagonal retrace lines and then it will switch off.

The Difference Between the Ideal and the Real

Don't expect to find the circuits shown above staring you in the face when you get your Sams' Photofact or service manual. There are a semi-infinite number of variations on this basic theme. Some of them will, to put it mildly, appear quite obscure (or to put it more positively, creative) at first.

You may see all sorts of additional passive components as well as transformers for generating additional voltages not provided by the flyback. There may be diodes in places you would think would be impossible. Therefore, to really understand even approximately how each design works may require some head scratching but the basic operation of them all seems to be very similar.

Horizontal Output Transistor (HOT) Information

Why are There So Many Different HOTs?

I find it fascinating (ok, well at least interesting) that after 20 years of designing totally solid state TVs and monitors, HOTs have not become jelly bean parts. Why does every new design insist on a unique HOT? I don't believe this is simply due to increased requirements like wider deflection angles or (for computer monitors) higher scan rates.

Actually there is still some progress going on :-).

TV's for Europe DO get higher scan rates, you know. Our entire high-end range runs on 31250 Hz. Sets with VGA capability often run even higher. 100 Hz HDTV was supposed to run on 62500 Hz but that is a big technological problem as you might imagine.

Larger screen sizes (32" 16:9, 33" 4:3) do tend to have less sensitive deflection coils, so the peak-peak amps go up. Combined with the higher scan rate this often means that some new transistor must be found, even if it is only a higher rated selection from an existing type. There are also 1700 V Vce types next to the regular 1500 V.

And in USA it is known that setmakers (like ourselves) have standard transistors marked with a different type number, to prevent repairmen from putting in just any would-be replacement type. For a fact, it IS risky to put in the wrong replacement, the faulty drive conditions may destroy it early. So try and avoid this.

To comfort you, the BU508 is still widely used!

HOT Specs and Substitution

Refer the article on deflection circuit design by David Sharples (Electronics World & Wireless World, June 1996).

Every line transistor has its own requirements for:

- Amount of base drive current, especially the Ib at end-of-scan.
- Waveform of base drive current (rising, steady, falling)
- Speed of reduction base drive current at switch-off.

The most effort goes into the optimization of the magnitude of the base drive current. The problem is: gain spread. In the ideal world, all transistors would come from the factory with exactly the same gain. In the real world, this isn't the case - it isn't even close. You have to find *one* optimum drive so that neither the high-gain nor the low-gain type will dissipate too much power taking into consideration the variations in other circuit components as well. There used to be other spread factors influencing the dynamic transistor parameters but fortunately, these have been mostly eliminated by better process control.

- Overdriving causes a slow switch-off behavior, some collector current keeps flowing during the beginning of the flyback and will cause dissipation.

- Underdriving causes bad saturation, the collector voltage will start to rise before the flyback should start. This too causes dissipation.

Either condition is easily observed with an oscilloscope, a current probe and a 1:100 voltage probe (be sure to calibrate it for high frequency response!).

The dissipation as a function of the base drive current is a more-or-less parabolic function with a global minimum. The minimum will be different for high-gain and low-gain types. By measuring the curves for both extreme types and combining them, an optimum drive for the random type will be found, with a figure for the worst-case dissipation.

All this will only be true if you insert a device which is a member of the population spread for which you optimized the base drive. If you just insert a random other device (different type, same type but different brand, same type and brand but much older/newer batch) then all bets are off. Dissipation may be way too high, with early failure as a result (and possibly a distorted picture geometry due to excess damping of the waveform).

It is certainly not possible to substitute a standard HOT (BU508) in place of a more advanced type (in >> 15 kHz applications like a monitor). It is also a very bad idea to substitute a BU508 in place of a much lighter type like a BUT11 (used in <= 17" sets). It will fail!

With horizontal output transistors, it is *not* true that 'bigger is better'. If you substitute a heavier transistor (more amps, more volts, more watts, faster switching, whatever) for a lighter one, then there is a very big chance that it will fail earlier, not later. The reason is that the drive conditions will now be wrong (most likely underdrive) and the transistor will overheat from too high conduction losses (Ic * Vce,sat). So do yourselves a favour and get a correct replacement type.

If cost weren't an issue, transistors and other parts could be hand selected (and some are in any case). But, you wouldn't be able to buy a monitor for $200 if that were required!

Is there a Universal HOT Replacement for TVs?

WARNING: As noted elsewhere in this document, the following approach is much less likely to work with long term (or even more than a few millisecond) reliability in high performance computer monitors.

(From: Chris Jardine (cjardine@wctc.net).)

I shouldn't say this, but, the TV repair shop I worked for a number of years ago stocked 1 universal Horizontal Output Transistor 2SC1308K or NTE238. This worked in almost every set out there that used a transistor and not SCR's (RCA, etc.). This may not be the best way of substituting, but, these 2 part numbers seem to have fairly high gain, power capability, voltage ratings, current ratings, etc. These characteristics made it a good substitute and when you buy 100 at a time you would get a really good price.

This may not work in your case, but, my $.02

Is There a Universal HOT Replacement for Monitors?

> "Would anyone like to comment on BU508's, they should be to the same spec. and born equal. My experience has been that different manufacturers BU508's behave differently. One make will fry and last about 3 weeks, put in a different make, no circuit change, and it runs cool, and is still running 3 years later. Price doesn't seem to be a guide, a $1 one may run cool and have no mfr. code, while a branded one might cost a lot more and run hot."

Yes, here you have the problem exactly!

There is such a thing as component spread. Base drive must be optimized for the whole range of gain within a type. That range can be so large that at the limits of the spread the dissipation can still be too large. The reason is that the device with the largest gain will be overdriven, causing a tail in the current at switch-off, whereas the device with the smallest gain will be underdriven, causing it not too saturate enough. Each condition can be easily viewed on the 'scope. By varying the base drive you can minimize dissipation.

Normally one basedrive is set for the entire population, accepting the variation in dissipation and its upper limit. Sometimes the variation is so large that this will not be acceptable. But this is unlikely for a BU508 in a 16 kHz application. Substituting it with a similar type from a different brand with different parameter spread may indeed cause it to dissipate too much and thus fail early. This has nothing to do with price or quality, just with a different optimum base drive. If base drive has been optimized for a brand with low parameter spread then it can be that the heatsink may have correctly been selected smaller...

Since you live in the UK, you should definitely read David Sharples' article in Electronics World (was it June 1996 ?). He literally optimizes base drive for a living.

Typical Types of HOTs Used in Monitors

```
14", SVGA (38 kHz)           A-types: BU2508AF, 2SC4830,  2SC5148.

                             D-types: BU2508DF, 2SC4762,  2SC4916,  2SC5149,
```

```
                                    2SC4291,  2SC5250.

15", XVGA (64 kHz)           A-types: BU2520AF, BU2522AF, 2SC3885A, 2SC3886A,
                                      2SC4757,  2SC4758,  2SC5129,  2SC4438,
                                      2SC4770,  2SC4743,  2SC5067,  2SC5207,
                                      2SC5251,  2SC5002.

                             D-types: BU2520DF, 2SC3892A, 2SC3893A, 2SC4531,
                                      2SC4763,  2SC4124,  2SC4769,  2SC5296,
                                      2SC4742,  2SC4744,  2SC4927,  2SC5003.

                           C
                           o                      C o--+--+
                           |                           |  |
                         |/                          |/  _|_
                    B o--|                 B o--+--------|   /_\ Dd
                         |\                     |        |\    |
                           |                    |   Rd     |   |
                           o                    +--/\/\----+--+--o E
                           E

                 A-Type without damper      D-Type with Damper
```

Note that transistors with built-in damper diodes also are likely to have a base to emitter resistor of about 50 ohms - keep this in mind when testing a HOT with a multimeter - that 50 ohm resistor will look like a shorted junction on the diode test scale.

In nearly all the above cases, the devices will plug-in substitute for each other within a category.

For designs with larger screen sizes (and higher frequencies) the device selection is not so straightforward as some designs which split the horizontal deflection and high voltage generation circuitry.

Continuous dissipation is hardly ever the cause of failure. Failure is usually due to some infrequent transient condition. For multi-frequency monitor designs of 1991-1994 mode-change was/is a big killer. When repairs are made it is wise to cycle through a mode-change sequence. Delays of about 1 min. between changes should be used, shorter delays can cook the device.

- As a rule, once an engineer has a bad experience with mode change he takes greater care in the small-signal circuitry of his next design. This has led to mode change, in general, becoming more benign in the last couple of years. However, in Taiwan & Korea there is a high turn round of engineering staff and some, shall we say, less than perfect designs do still reach production.

- To "cook" a device by mode changing would take at least 30 mins. of continuous changing with a delay of about 20 seconds between each change.

- If a device fails during such a sequence the old spit test is good indicator of why a device fails. That is, a drop of spit on the HOT immediately after failure can tell us a lot: if it sizzles, then the device has probably cooked, if it doesn't then the device failed instantly after one stressful cycle. Frontiers of technology it is isn't but it is a useful technique.

- If you do get failures which haven't been caused by the HOT "cooking" I have no easy solution, sorry!

- Winfield Hill's comments reflect the experiences of many. School physics teaches that bipolar's are current driven and MOSFET's are voltage driven. In practice, of course, this is a gross over-simplification. A MOSFET in deflection would, as we say in the north of England, have to be a "bloody big bugger". For example, a 1500V MOSFET that behaved as a BU2508 would have to be nearly twice the size and at least twice the price. Getting 10V on all the gate cells of such a big chip requires a lot of charge to be injected (i.e., current) and then removed (reverse current); much like a bipolar drive.

Varieties of BU508 HOTs

(From: J. G. Simpson (ccjs@cse.bris.ac.uk).)

BU508 series seem to come in a number of variants, I haven't sorted out the specification for each listed variant, but have found that it's worth trying replacements by different manufacturers. Also if the device is on a grounded piece of metal as heatsink try adding another radiator (twisted vane is my preference). Some TV manufacturers introduce post production mods to change resistance values to provide more drive into the base, this may be in the base or emitter. Scope the waveform for parasitic high frequency oscillation and check that the waveform looks clean. Check voltage rails, supply and derived, and that the set is not over scanning. Check all the components around the horizontal output stage, it may be the manufacturer. had a duff batch of some component (often a capacitor that goes OC) that keeps failing which then stresses the BU508.

Why Do Apparently Similar or Better HOTs Sometimes Run Hot and Blow?

It is often surprising that replacing a horizontal output transistor with one that has overall better specifications does not work out - it may run hot and fail.

There is more to characterizing a transistor than just maximum voltage, current, and power dissipation.

One important parameter is current gain: Too low a gain for a particular operating point may result in incomplete turn-on during scan resulting in high dissipation. You want the transistor to be in the fully saturated state. A larger HOT is more likely to have a lower current gain.

If you read the app notes put out by the manufacturers like Motorola you will also find that fast turn off based drive (negative step) is actually not what you want since this traps excess carriers in the high resistivity collector region which leads to continued conduction and heating. The ideal waveform also provide adequate drive during scan but not excessive overdrive and is thus an increasing ramp to account for the increasing collector current during scan.

Characteristics like this are not dealt with by the basic specs but can differ substantially among otherwise similar transistors.

Also see the section: HOT Specs and Substitution.

Storage Time of HOTs

Storage time differs between transistor types, there's parameter spread within a type (lower Hfe gain gives shorter storage time and v.v.) and it depends on load (higher beam current or larger deflection amplitude due to E/W modulation gives shorter storage time).

Variations in storage time would translate into horizontal position errors of the picture. That's why the base-drive to the HOT is generated by a PLL that measures the phase of the output of the HOT, which is the flyback pulse at the collector. This PLL is called the PHI-2. It keeps a constant phase relation between the sync at the input and the flyback pulse. As a result, you will see the base-drive pulse shifting in time as a function of HOT load, this is normal.

Most deflection processors generate a base-drive pulse with a constant duty-cycle. This means that also the switch-on moment of the HOT will vary with the load. This makes it extra difficult to optimize the base-drive because there is only a limited time interval where the HOT may be switched on and that interval is shorter with high beam current load. On-time is typically between 50% and 55%, depending on the IC.

The feedback of the flyback pulse to the PHI-2 PLL is not perfect because the shape of the pulse distorts as a function of beam current. This will give a dynamic geometry error. It is compensated by feeding a certain amount of EHT information to the PLL.

Typical HOT Dissipation

Just measuring the actual power dissipation in a HOT is not trivial due to the nasty shapes of the voltage and current waveforms. You can't do this with your DMM! A couple of ways of doing this are:

- Monitor the voltage and current waveforms for the HOT. Integrate the instantaneous measured V*I over the duration of one scan line and multiply by the horizontal scan rate.
- Mount the HOT and a fixed power resistor on identical heat sinks so that their thermal enviroments are the same. Then, adjust the current through the resistor (and thus its power dissipation) so that the temperature rise of the heat sinks for the two are equal.

Here are some measured values for TV HOTs with optimized drive:

(From: David, a Philips application engineer).

```
14-21", 16 kHz: About 1 W      (some have the HOT running in free-air)
21-36", 16 kHz: Less than 2 W  (some new large CRT's only need 9 A p-p)
25-36", 32 kHz: Less than 4 W  (dissipation really is prop. to frequency)
```

I am sure I don't need to tell you that the dissipation varies with the type of HOT used and the drive.

Why MOSFETs are Not Generally Used for HOTs

One would think that with a MOSFET's high impedance voltage drive and other desirable characteristics, they would have displaced bipolar transistors for horizontal deflection circuits. Why not?

True, a MOSFET is much much much easier to drive. In modern switched-mode power supplies they reign, rightfully so. They are effective and rugged.

But in line deflection things are not so easy. I'll give you 4 reasons:

1. The flyback pulse is regularly 1200 V peak, allowing for margins you need a 1500 V device. There are few or no FETs available for that. In a small set, a 1000 or 1200 V device may be usable. With effort, the deflection circuit impedance may be re-scaled for greater current and lower voltage.
2. The conduction losses (Vds = Id * Rds) of a FET are quite high, this not only is wasteful dissipation but it also affects the linearity of the picture (it's a damped sine-wave, going slower and slower).

3. For the same power losses a FET needs a much bigger silicon area, also FETs are made in a more advanced process, with IC-like features, this translates directly into greater cost! They are several times more expensive.

4. A FET has no storage time, hence it has no storage-time modulation, which is a disadvantage because that would help to improve the natural stability of the control of the phase of the line deflection.

And these are just some major reasons, there are minors too. We have looked into it time and again and still the bipolar wins!

Optimizing Base Drive for HOTs

It is interesting that the problem of base drive optimization receives a fair bit of attention, either for allowing a (non-compatible) replacement HOT to survive or for rebuilding a fixed frequency monitor to a different scan frequency. I wish there was an easy way to teach the average hobbyist a method to do this himself.

The recipe itself isn't all to difficult: mostly we change the value of the power resistor that feeds the line drive circuit until the temperature of the HOT heatsink is at minimum. Too much basedrive current increases the switching losses, too little basedrive current increases the conduction losses. The optimum is somewhere in the middle. All you need is a handful of power resistors and a thermometer on the heatsink.

If you need to optimize for a general HOT type (as opposed to one single sample) then you kindly ask the manufacturer to provide some limit case samples (lowest and highest hFE found) and find a basedrive that satisfies both extremes. Of course you must select a slightly larger heatsink. So far so good. The difficult bit is when you find that you need to change other components in the drive circuit as well, like the spread inductance of the driver transformer, a damping resistor, a duty cycle of a drive signal etc. And of course you may find that the HOT you planned to use is entirely unsuitable for this application ...

Anyway, it's never a case of just 'drive it hard'.

What is This Diode Across My HOT?

It is called a damper diode and is essential to proper operation of the TV's or monitor's horizontal deflection as well as to the continued life and happiness of the HOT. Using an HOT with an internal damper is OK even if there is a separate one in the circuit. The other way around (leaving it out entirely) will likely result in instant - i.e., single scan - destruction of the HOT. This is because in modern deflection system designs, the damper carries the horizontal yoke current for a significant portion of the scan. If it is not present, the HOT will be forced to try to eat this current - in reverse - across C-E.

The damper is a special high voltage fast recovery type of diode - a 1N400x type will not work in its place.

BTW, many of these HOTs have a D after the part number to indicate that they have the internal damper and include a B-E resistor (which may confuse transistor testing) of about 50 ohms. However, the D is not a sure indication of an internal damper - nor is its absence an indication of a lack thereof. The entire part number must be checked to be sure.

What is This Funny Capacitor (or Capacitors) Across My HOT?

These may go by the name flyback, high voltage, snubber, or deflection capacitors. When the HOT is shut off, the current flowing in the inductance of the flyback primary and horizontal deflection yoke cannot be stopped instantly. These capacitors provide a place for this current to go and is part of a tuned circuit (in combination with the flyback and yoke) which needed to accomplish the flyback function.

If this capacitor is open or missing, excessive flyback voltage will result probably killing the HOT. If the HOT does not fail, the result will likely be greatly increased high voltage. Should the X-ray protection circuitry not shut down the deflection, there could be internal or external arcing and/or destruction of components like the flyback or tripler.

For proper operation and continued safety, only proper exact replacements should be used for these parts.

- Back to Deflection Systems Table of Contents.

Horizontal Output Transistor Failure and Testing

HOTs Keep Blowing (or Running Excessively Hot)

Unfortunately, these sorts of problems are often difficult to definitively diagnose and repair and will often involve expensive component swapping.

You have just replaced an obviously blown (shorted) horizontal output transistor (HOT) and an hour (or a minute) later the same symptoms appear. Or, you notice that the new HOT is hotter than expected:

Would the next logical step be a new flyback (LOPT)? Not necessarily.

If the set performed normally until it died, there are other possible causes. However, it could be the flyback failing under load or when it warms up. I would expect some warning though - like the picture shrinks for a few seconds before the poof.

Other possible causes:

1. Improper drive to horizontal output transistor (HOT).

   - A too weak drive (or a HOT with a too low Hfe) causes Vce(sat) to be too large, giving conduction losses.

   - A too strong drive (or a HOT with a too high Hfe) causes it to switch off too slowly, giving switching losses.

   Base drive should be optimized to balance between these 2 losses. Check driver and HOT base circuit components. Dried up capacitors, open resistors or chokes, bad connections, or a driver transformer with shorted windings can all affect drive waveforms.

2. Excessive voltage (B+) on HOT collector - check low voltage regulator (and line voltage if this is a field repair), if any.

3. Defective safety/flyback capacitors or damper diode around HOT. (Though this usually results in instant destruction with little heating).

4. New transistor not mounted properly to heat sink - probably needs mica washer and heat sink compound.

5. Replacement transistor not correct or inferior cross reference. Sometimes, the horizontal deflection is designed based on the quirks of a particular transistor. Substitutes may not work reliably.

   Well, you can always *try* to optimize the base drive by changing the value of the power resistor that feeds the drive circuit at the primary of the drive transformer. But you're on your own here! Clearly label what you have done or else your name will be mud if the unit ever needs to be repaired by someone else in the future.

6. And, of course, bad connections in the drive or output circuitry can be the cause of almost any sort of failure! The HOT should not run hot if properly mounted to the heat sink (using heatsink compound). It should not be too hot to touch (CAREFUL - don't touch with power on - it is at over a hundred volts with nasty thousand volt spikes and may be line connected - discharge power supply filter caps first after unplugging). If it is scorching hot after a few minutes, then you need to check the other possibilities.

   However, it is possible that the deflection circuit is just poorly designed in the first place and it has always run hot (though it is unlikely to have always been scorching hot). There is no way to know for sure without a complete analysis of the circuit - not something that is a realistic possibility. In this case, the addition of a small fan may make a big difference in HOT survival.

   It is also possible that a defective flyback - perhaps one shorted turn - would not cause an immediate failure and only affect the picture slightly. This would be unusual, however. See the document: Testing of Flyback (LOPT) Transformers.

   Note that running the set with a series light bulb may allow the HOT to survive long enough for you to gather some of the information needed to identify the bad component.

Base Drive and Hot HOTs

One common cause of a HOT running excessively hot is wrongly dimensioned base drive. This may be due to problems in the drive circuit due to bad components (often a capacitor) or as a result of poor design. There is usually easy evidence if you look at the rising edge of the collector voltage. If it rises too early, before the end of the scan, then the transistor is underdriven and there will be excess conduction losses. If it rises too late, or rather when there is still a lot of collector current during the flyback, then the transistor is overdriven and there will be excess switching losses. The condition can be varied by playing with the power resistor that supplies the line drive circuit. It would be appropriate to vary this as a function of parameter spread within one type of transistor. This is not necessary for 16 kHz deflection because there is sufficient margin for error.

Other deviations may be due to an inappropriate waveform of the base current. It should not fall too quickly because the HOT needs time for recombination of electron-hole pairs. This is typical of high voltage transistors which have a very wide and high-impedance collector-base region, difficult to control. Setting this right is the one-time responsibility of the TV designer. It can be disturbed by a wrong transistor substitution of course, so check whether a correct type has been mounted. That's what I mean when I say that a bigger HOT is not better. A BU508 requires a totally different base drive from a BUT12.

Also see the section: Optimizing Base Drive for HOTs.

HOTs Blowing at Random Intervals

The HOT may last a few months or years but then blow again.

However, a combination of mode switching, loss of sync during bootup, running on the edge of acceptable scan rates, and frequent power cycles, could test a monitor in ways never dreamed of by the designers. A TV may suffer from similar failures due to repeated power cycling, video input selection, or channel changing. It may take only one scan line that is too long to blow the HOT. Newer horizontal processor chips are quite smart about preventing HOT killing signals from reaching the horizontal driver but they may not be perfect.

On the other hand, the cause may be along the lines of those listed in the section: HOTs Keep Blowing (or Running Excessively Hot) and just not as obvious - blowing in a few days or weeks instead of a few seconds but in this case, the HOT will likely be running very hot even after only a few minutes.

Another possible cause for random failures of the HOT are bad solder connections in the vicinity of the flyback and HOT (very common due to the large hot high power components) as well as the horizontal driver and even possibly the sync and horizontal oscillator circuits, power supply, or elsewhere.

Preventing Random HOT Failures

As noted above, a bigger HOT is not necessarily the answer. A selection of the same HOT for 1700 V breakdown voltage may help but is not an option outside the design lab. Sometimes very exotic HOT type numbers occur, which are really a selection from a standard type, used for statistical failure analysis.

A separate EHT supply (only in the most expensive monitors) would also help to save the deflection transistor, but might kill its EHT twin. Of course, not an option in the field.

Soft-start circuits make a biiig difference, but are an inherent part of the design, not an afterthought.

The chance of failure may also be a function of an unspecified transistor parameter, so sometimes the mere swapping of a HOT may solve it permanently.

And, if in the unlikely event it is an EMI problem (like a cellular phone lying on top or the set) then obviously the cause must be eliminated. A layout change is a better remedy but out of reach of a repair shop.

More on HOT Failure

> "I'm sure this has been discussed before, but I have worked on several monitors lately with shorted HOT's, replacing that one part has fixed all of them, and I have not had a reoccurrence yet. Does something cause HOT's to blow, or do they just short occasionally for no reason?"

Actually, we know fairly well why HOTs blow, at least in television. They almost always fail from secondary breakdown, not from average dissipation. Secondary breakdown occurs instantly if the combination of voltage and current is too high, even for only 1 line period.

Usually this happens due to a hard-start condition of a flyback converter. In case of a CRT display this usually applies to the high voltage output which is loaded by the built-in capacitance of the tube. When the FBT starts to charge that capacitance it sees a short-circuit. This causes the core of the FBT to go into saturation and the primary current rises to a multiple of what it should be.

When the HOT switches off such a large current it breaks down. That is, some HOTs break down. Most are better than spec and survive. If it survives the first hard start it will likely survive many.

Such situation occurs most likely after a picture tube flashover, when the EHT capacitance has been shorted. After about 3 line periods the current through the HOT becomes too high. Only a soft-start method can really prevent it but it is a bit hard to design a circuit.

Other causes for HOT failure may be false drive pulses, e.g. due to a bad sync input (not likely for a monitor with a slow line PLL) or due to EMI. It should not happen, but it will. Some manufacturers have better designers than others. Ahem...

Saga on Swapping of HOTs

(From: Malik (M.Dad@mmu.ac.uk).)

The prologue:

I have in for repair a Tatung monitor model CM14UAE. Originally it was dead this fault was quickly remedied by replacing the line output transistor which was 'dead short', causing the power supply to shut down.

Now the transistor I replaced seems to get a hell of a lot hotter than it should, when it gets to a certain temperature after about half an hour the width begins to collapse at which point I quickly switched off. If I switched off for a few seconds and back on again I would get the width back but again it quickly began to collapse.

Things you need to know:

The LOP stage is independent from the EHT transformer. i.e. there is a separate transformer for the EHT (and A1 supplies etc) with its own transistor and a separate line output only transformer with its own transistor.

I have also tried substituting the efficiency diode, still no joy. I have also replaced the EW transistor and its driver.

To me it seems that the transistor is not being switched properly, although the waveforms do look OK.

Original line output device 2SC3893A, which I replaced with a BU508DF (European equivalent according to the books. I also tried a 2SC3883 which used for the same job in other SVGA monitors. Both give the same problem,

I will be trying to get the original transistor in case this is the problem but I don't think it will make a difference.

And the conclusion:

Anyway after all that headache I finally received through the post the original 2SC3893A. I fitted this and left the monitor on test. Sigh of relief, the problem has gone away.

It seems the timing on this device differs from all the others I tried. The transistor runs at a reasonable temperature even after a few hours use.

The moral of this story is, use original line output transistors. Unless you are 100% sure the replacement works in its place. Don't rely too much on equivalent books, these should be used as a guide. The book I looked at specified the BU508DF as a direct replacement for a 2SC3893A, but as I know now it doesn't work properly.

The HOT should not run too hot to touch. If the replacement sizzles, it won't last long and is probably deficient in some specification. If the monitor or TV appears to work normally otherwise, try an exact replacement HOT if available before swapping other expensive parts like the flyback (LOPT). For testing, however, a substitute can usually be used - with a series light bulb and Variac.

Brief Comments on Testing the HOT

For a TV or monitor with no blown fuses that will not start, here are two quick checks to see if the HOT is good and has power and drive:

- HOT tests - check across each pair of pins for shorts (preferably removed from the circuit board). No junction should measure less than 50 ohms or so. Lower readings almost certainly indicate a bad HOT. If in-circuit, however, the reading between base and emitter will be near zero due to the secondary of the driver transformer. See the document: Basic Testing of Semiconductors. Don't be confused by internal damper diodes and B-E resistors.

- Power - measure across the collector to emitter with a multimeter (with the HOT removed or if there is no deflection, this is safe with it in place). There should be solid B+, typically about 100 to 160 V (for TVs, 115 VAC sets - possibly higher for 220 VAC sets), 60 to 170 V or higher for auto-scan monitors. If this is missing, either there is a problem with the power supply or the emitter fusable resistor has blown (probably in addition to the HOT) and there is no return for your voltmeter. If it is pulsing, the power supply may be cycling on overvoltage - the HOT may be good in this case but there is no base drive.

- Drive: put an oscilloscope on the base - there should be pulses around .7 V for most of the scan and probably going negative a couple volts at least for retrace. Specific timing will depend on the actual scan rate. If drive is weak or missing, If drive is weak or missing, determine how it is derived as there may be a problem in the startup power supply or deflection IC.

WARNING: Use an isolation transformer for the oscilloscope tests (and whenever you are probing a TV in general)!!! This part of the circuit, in particular, is usually line connected. See the document: Safety Guidelines for High Voltage and/or Line Powered Equipment.

Testing of Replacement HOTs

The following is useful both to confirm that a substitute replacement HOT is suitable and that no other circuit problems are still present. However, single scan line anomalies (particularly when changing channels and/or where reception is poor with a TV or when switching scan rates and/or when no or incorrect sync is present with a monitor) resulting in excessive voltage across the HOT and instant failure are still possible and will not result in an HOT running excessively hot.

- Function - Confirm that the monitor or TV behaves EXACTLY as you expect. Look for any sign of changes in picture width and other aspects of geometry that might indicate a less than happy horizontal deflection system.

- Temperature - After letting the unit run for a while, unplug the unit and confirm that the voltage on the HOT collector is near zero (discharge the power supply filter capacitors if it is not) and see how hot the HOT is. Note: Unplugging without switching of off may result in the capacitors discharging faster if the unit has a soft (logic controlled) on/off switch. Careful, the HOT may be really hot - start at the far end of the heat sink and work your way towards the transistor case. Obviously, a temperature probe (insulated!) would be better as it would be able to make measurements while the HOT is powered. You can also use a cheap thermometer for this purpose - attach its sensor to the heat sink near the HOT.

(From: Raymond Carlsen (rrcc@u.washington.edu).)

After installing a replacement HOT in a TV set or monitor, I like to check the temperature for awhile to make sure the substitute is a good match and that there are no other problems such as a weak H drive signal. The input current is just not a good enough indicator. I have been using a WCF (well calibrated finger) for years. For me, the rule of thumb, quite literally, is: if you can not hold your finger on it, it's running too hot, and will probably fail prematurely. Touching the case of the transistor or heat sink is tricky....

Metal case transistors will be connected to the collector and have a healthy pulse (>1,200 V peak!) and even with plastic case tab transistors, the tab will be at this potential. It is best to do this only after the power is off and the B+ has discharged. In addition, the HOT may be hot enough to burn you.

A better method is the use of an indoor/outdoor thermometer. I bought one recently from Radio Shack for about $15 (63-1009). It has a plastic 'probe' on the end of a 10' cable as the outdoor sensor. With a large alligator clip, I just clamp the sensor to the heat sink near the transistor and set up the digital display near the TV set to monitor the temperature. The last TV I used it on was a 27" Sanyo that had a shorted H. output and an open B+ resistor. Replacement parts brought the set back to life and the flyback pulse looked OK, but the transistor was getting hot within 5 minutes... up to 130 degrees before I shut it down and started looking for the cause. I found a 1 uF 160 volt cap in the driver circuit that was open. After replacing the cap, I fired up the set again and monitored the heat sink as before. This time, the temperature slowly rose to about 115 degrees and stayed there. I ran the set all day and noticed little variation in the measurement. Test equipment doesn't have to cost a fortune.

Oscillation or Ringing at HOT Base?

> "Could this be happening because I'm using the wrong HOT?"

At these relatively low frequencies your scope probe is probably not suspect, although you should keep loops small and not underestimate the effect of high dV/dt inside the line transformer.

First, how do we know if the oscillations were already there with the original HOT ? I suppose you have never measured that ...

Second, it is NEVER a good idea to replace a HOT with just any other type because there can be significant differences which are not at all visible in the spec. Even for specialists it's quite difficult to optimize the drive conditions for a new HOT type. You're on your own here.

Third, some oscillations are normal because the inductance of the base drive transformer does form part of a damped resonant circuit. Usually these oscillations show after switching OFF the HOT and they can be a problem if the negative Vbe is insufficient during the flyback pulse and the transistor might be turned back on, which would kill it. As a rule of thumb, Vbe should be -2 V during flyback, but there are exceptions. Depending on the HOT type, some damping resistor may have to be applied. I've never heard of oscillations during HOT ON.

If the collector waveforms (V and I) seem OK and the HOT does not overheat then maybe you shouldn't worry too much. But do check at high beam current too (max. brightness on a white picture) because then the HOT must be switched on earlier to provide the magnetizing current to the line transformer too.

(From: Alan McKinnon (a.mckinnon@pixie.co.za).)

I've run into this kind of thing several times recently on different sets, this is what I've found:

1. Do you have a damper resistor (about 30 or so ohms) across B-E of the HOT. It can go open circuit, causing weird stuff.

2. Check the supply feed resistor into the transformer of the line drive circuit. These can go high, especially

if it's a high value resistor dropping a supply of 120 odd volts down to 30 or so.

3. Check all small resistors and caps in the line drive circuit, take then out and measure them, in circuit reading are funny in this area.

4. Try a new drive transformer.

Additional Deflection System Information

Web Resources on Deflection Systems

Here is an article originally from Sencore: Understanding the TV Horizontal Output Stage. I have archived it at Sam's Copy of Sencore's Understanding the TV Horizontal Output Stage in case the link dies. While specifically written for television sets, most of it also applies to monitors.

Why are Nearly All Horizontal Driver Circuits Transformer Coupled?

Almost every TV and monitor in the universe uses a small high frequency transformer to couple the drive signal from the horizontal oscillator to the horizontal output transistor base. There are several reasons why this is so popular:

- One (probably secondary) reason is that this provides one of the isolation barriers between a line-connected HOT and flyback primary and the signal circuits of the TV.

- A more important rational is that a transformer is nice easy way of impedance matching the horizontal driver circuit (100s to 1000s of ohms) to the few ohm input impedance of the horizontal output transistor base which requires upwards of several amps for proper drive. A typical driver transformer may be in the 5-10:1 turns ratio representing 25-100:1 impedance ratio.

- A byproduct of all this is that it is unlikely for a faulty driver stage to kill the HOT. Unlikely but not impossible.

However, there are apparently some smaller TVs that use a direct coupled drive scheme but these are definitely the exception.

S-Correction Circuits on Multi-Scan Monitors

(Quoted text from a curious but frustrated tinkerer/technician.)

> "Hi there. Recently, I've encountered this circuit (or ones similar to it) several times in VGA monitors and I'd like to know what it's purpose is.

The IRF620's are N channel Enhancement Mode MOSFETs.

8. The connection at this point is to the HOT collector via the horizontal deflection yoke (HDY), width, and linearity coils."

You will probably find that 0, 1, or 2 of the MOSFETs will be turned on (S0, S1 set to ground or +15 V (typical) depending on the scan rate. This would introduce varying amounts of S-correction (E/W) depending on the horizontal scan rate.

The diodes are probably for clamping and protection. The MOSFETs are used as switches. You, in effect, get 1, 2, or 3 x .64 uF between the yoke return (the point marked '*') and ground.

This circuit is from an auto-scan computer monitor where it switches the effective S-correction capacitor to one of 3 possible values depending on scan rate.

Note that this approach is used both in multi-scan and auto-scan monitors. The multi-scan (largely obsolete technology though still used in some specific applications) has two or more discrete line frequencies and the auto-scan has a whole range of available frequencies. You would not guess this from the discrete switching of the S-correction capacitors. Obviously, the S-correction is optimized only for 3 frequencies and approximated for all others. This is generally good enough (even) for auto-scan.

The internal diodes anti-parallel to the MOSFET (A to S, K to D) are important to set the DC voltage over the extra S-capacitors to a reasonable value before they are first switched in. At lower line frequencies the extra capacitors are permanently switched on.

For each given scan frequency there is only one correct value for the S-correction capacitor. If you limit your circuit to only 3 discrete values (like 0.64, 1.28 and 1.92 uF) then the horizontal geometry can be optimized for only 3 scan frequencies.

Somewhere between these 3 frequencies there will be 2 switch-over points where more S-correction capacitance is added by the switches. Generally, around these border frequencies the geometry will be worst (because whatever the position of the switch, there will be an error one way or the other) and it would be wise to switch over near some little-used frequencies and thus optimize for the much-used frequencies like 31, 38, 48 and 64 kHz. For the other scan frequencies, the geometry will then be only approximately correct. Luckily, S-correction is not very critical.

For any given scan frequency, the position of the MOSFET switches is constant: either on or off. These are not used in a switched mode.

There *will* be one or two other MOSFET switches that switch at a line scan rate in order to take care of the correct dependency of the (average) supply voltage and E/W voltage in function of the scan frequency.

There is a difference in the horizontal deflection circuit of a TV versus an auto-scan monitor. In the diode bridge of a TV, the deflection circuit is in the upper half of the bridge and the "bridge circuit" is in the lower half of the circuit. The E/W amplifier *sinks* current from the centre node (and dissipates). The VB supply voltage is constant.

In the diode bridge of a auto-scan monitor, the deflection circuit is in the lower half of the bridge. This makes the S-correction capacitor grounded and thus easier variable (without need for level shifters, opto-couplers, etc). The E/W amplifier *sources* current into the centre node. The VB supply voltage is made variable, linearly proportional to the line frequency, by means of a switched-mode down-converter topology. The same topology is also used for the E/W amplifier, which now actually delivers power to the circuit. With this topology you can have a constant (even regulated) EHT and a constant deflection current amplitude, independent of the line frequency.

> "In another similar monitor, this circuit had completely self-destructed and taken out a few other things too (fire). The monitor shuts down immediately unless the HOT is disabled or connections A, B, and C are *all* broken (no other combination works). It almost seems like it's used to accommodate or change the horizontal frequency for different video modes. For some reason, the monitor is now powering up so seems like it might be an intermittent short somewhere."

By disconnecting A,B,C you effectively take the coils of the horizontal deflection yoke (HDY) out of the circuit. By disabling the line transistor (HOT) there remains only DC voltage over the bridge- and S-correction capacitors. Either way there is no voltage over the HDY. I would suspect a short or arcing in the deflection coil. Just a wild guess, though.

There is enough energy present in the deflection circuit (also in the HDY) to create a very nice fire, let there be no doubt about that. A loose contact in series with this circuit is potentially fatal.

More on Horizontal Driver Circuits

Usually, the primary voltage is *constant* when the driver transistor is ON and thus the HOT is OFF. Then when the driver switches OFF, the stored magnetic energy switches the HOT to ON.

This is called non-simultaneous base drive, which is most common. The primary voltage that you see then is mostly a transformed version of the secondary voltage, over the series base impedance. The voltage at HOT=ON is not forced from the primary side.

Usually the "cold" side of the primary of the driver transformer is connected via a power resistor and filtering electrolytic capacitor to the B+. The R determines the average voltage and thus the base drive current. Higher R means less base drive and vice-versa. Varying the value of this resistor is the first choice for minimizing the power dissipated in the HOT.

The filtered DC voltage at the cold side is (typically) a little over 1/2 * V(B+). Then when the driver switches off the voltage at the hot side (of the primary) will be higher, but typically not higher than V(B+). But how high exactly is a coincidence.

Why do Some Monitors Fail if Driven at the Wrong Horizontal Frequency?

I think it *should* not have failed. It is the purpose of the deflection processor to guard that the line deflection never runs at a forbidden frequency. It is possible that such protection is not good enough, that when the PLL is not in lock it might generate a very irregular line drive. That can prove to be immediately fatal to a line transistor. All it takes is one line length that is too long, followed by a flyback pulse that is too high, and it's all over. Second breakdown, terminal.

Trying a too high line frequency is usually not harmful, generally your EHT will be too low and your deflection current amplitude too. The HOT might eventually die from overheating due to bad drive conditions, but otherwise any decent monitor should be able to withstand it. In the better cases it simply refuses to sync on an illegal frequency.

1. While increasing the frequency of the horizontal drive *all other factors being equal* should not result in HOT death, all other factors are not always equal. The sync circuits may select an improper set of voltages, the drive waveform (as mentioned) may be insufficient, etc.

2. The sync may lock to a submultiple so the drive may be at 1/2 H resulting in a too long on-time and poof.

As noted, this can be a one shot affair - absolutely no warning. My recommendation remains to attempt if at all possible to obtain the specs for any monitor you intend to use.

Tweaking the Deflection Rates in a Fixed Frequency Monitor

Pulling a fixed frequency monitor by more than a few percent will likely be a problem. I know this is not the answer you were looking for but getting a new inexpensive video card may be a better solution.

If not, you are looking for an adjustment called horizontal oscillator, horizontal frequency, or horizontal hold. If you do tweak, mark everything beforehand just in case you need to get back to the original settings. There is some risk - changing it too far may result in damage either immediate or down the road - I have no idea.

Here is a discussion about modifying a monitor to run at other scan rates than for which it was originally designed (in this case, a lower one):

> "I would like to convert IBM XGA2 (39.4 kHz JH) monitors (9515, 9518) to work at VGA (31.4 kHz H) rates.
>
> I have the schematics, and with datasheets/application notes from chipmakers' websites altering the scan-frequencies and the mode-switching logic has been relatively straightforward.
>
> That's as regards the 'small-signal' bits (and frame output), to leave a 39.4 kHz scan for 75 fps graphics and provide 31.5 kHz for the 400-line DOS text (VGA startup) mode, and 350-line graphics.
>
> *But* the HOTs blow up at 31.5 kHz: after a while in the first of a number of 9515s, almost instantly in 9518. The corpses and heatsinks are very hot, as in 'high temperature' as well as function :-(("

Blowing up the HOT after minutes is due to bad base drive, or (much more rare) due to LOT core saturation. Blowing up a HOT immediately is due to too high collector pulse.

> "The base drive looks fine on a 'scope as regards holding the HOTs (or now an experimentally-substituted forward diode) firmly saturated for the longer 'on' time, and then sharply/cleanly

> turning them off."

There's more to a good base drive than just 'looking fine' on a scope. The aim is to minimize the dissipation in the HOT. This requires just the right amount of base current and reducing it in a particular manner at the end of each line. (A process that we call 'de-holing', removing all the holes from the high-impedance collector region, this must not go too fast.)

- Too little base drive current will cause the collector voltage to start rising too early, before the beam has reached the right end of the screen. The HOT goes out of saturation too early, causing dissipation.

- Too much base drive current will cause the collector current to reduce too slowly during the beginning of flyback. The HOT goes out of saturation too late, also causing dissipation.

Usually for lower line frequency you need a bit more base drive.

> "I have only a rather vague mental picture of how a LOPT works. I think that, as a load on the HOT, it is almost purely inductive from turn-on (though not from the EHT-generating turn-off)."

If there are secondary scan-voltage rectifiers then they add to the load during (beam) scan. Otherwise it is always inductive. During flyback, the flyback capacitor and the secondary flyback rectifiers cause the characteristic flyback pulse shape.

> "Hence I suppose that the longer 'on' period allows the current to increase to a higher (and destructive) level."

Not the higher current in itself is destructive, but the increased magnetic energy is. During flyback, 1/2*L*I^2 is converted to 1/2*C*V^2 in the flyback capacitor. More energy means more voltage over the HOT. Over 1500 V peak it will be destroyed immediately.

> "If magnetic saturation were to be reached, it would even look more like a dead short than an inductance."

That's true, but it occurs mainly due to excess beam current. Secondary flyback load causes the primary scan current to rise.

> "My questions are twofold: (1) how correct is my understanding?"

Fair enough. You can get a fair idea by running simulations with ideal circuit models. But to understand what happens inside a HOT you need very advanced models. Which don't even exist (yet)!

> "(2) More to the point, what solution is there?"

You're doing a good job guessing. I'll let you continue.

> "One that springs to mind is to reduce the voltage of the HOT's supply, something like proportionally to the increase in 'on' time, so that the peak current is back to what it is at the higher frequency."

Exactly. Peak current and more importantly peak voltage, because then also the EHT will be kept constant.

> "This would be a non-trivial task, both to provide a second voltage (at quite high current) and to switch between them."

Maybe not trivial but a lot easier than you think.

> "Though some multi-frequency monitors have such multiple (switched) supplies, I don't think all do: what alternatives can be adopted? How does one calculate in this area, or is it (unfortunately) a matter of having LOPTs intended for the purpose?"

The LOPT must be optimized for the higher line frequency and the corresponding short flyback duration. For lower line frequencies, you want to reduce the B+ voltage so that it is proportional to the line time. This is in fact very easy if you use a switched-mode down-converter (is that called a 'buck'?) and you make the on-time of the switch *constant*. Now the line frequency may be varied over a wide and continuous range. This gives near constant EHT too.

On other monitors, a voltage determined by the detected scan rate is returned to the power supply in place of the usual zener reference to adjust its output.

You can use an extra filter coil to provide constant B+ to the line deflection circuit or you can use the LOPT primary for that. There are some subtle problems with which I will not bother you.

It may be necessary to reduce base drive current for line frequencies beyond a certain value.

The 'only' other thing left to do is to keep geometry correct for the various display modes. Mainly by switching in more or less S-correction capacitance (using FETs or even relays).

Don't assume that you will be able to re-invent the multi-scan monitor on your own. I think you will find that you have insufficient resources to do that.

Honestly.

That's quite a difference (a factor of 2.6)! Forget it. That's more work than even an expert would be willing to spend on a single prototype. Usually the lower impedance is intended for a higher line deflection frequency, so that requires a total redesign.

I don't know of any simple impedance transformation trick to operate the coil at a regular line frequency (with up-transformed impedance) except for sinewave deflection where I once succeeded in doing that. But this is sawtooth deflection, not so easy. Sorry.

Yoke and Interlocks

> **"I was asked a question today that I never thought of much before. If you remove the yoke (unplug it) from a TV or monitor is the high voltage still present and if so can this cause damage to the set. Thanks"**

The answer is an unqualified maybe on all counts.

Some have an interlock so you lose power to the deflection/set if the yoke is unplugged - found that out on a Magnavox chassis that would not do anything without the yoke connections.

Those that continue to have power may result in damage - at the very least, if the HV is present, you will be drilling a hole in the center of the screen since deflection will be absent. The horizontal deflection will be detuned possibly resulting in overheating, excess HV, etc.

If you do try this, I recommend using a Variac and carefully monitoring the CRT for presense of a very bright spot (which will turn into a very dark spot quite quickly) as well as an excessively hot HOT.

BTW, disconnecting the yoke may be desirable to troubleshoot a horizontal deflection/high voltage if the yoke is suspect. If the yoke is loading the deflection output due to shorted turns, disconnecting it may allow high voltage to come up - just go slow and nothing will blow.

(From: Stefan Huebner (Stefan_Huebner@rookie.fido.de).)

Some yoke plugs have a jumper wire to remove +B from the flyback when pulling it. But this may still damage the SMPS since they are not all build for running without a minimum load. Some yoke plugs only have the four yoke wires connected; in those sets HV will build up when the plug is pulled and you may even destroy something in the flyback area (most likely the HOT) because the horizontal deflection yoke is an essential part of the flyback circuitry (exception: some monitors, foe example Eizo, which have separate HOTs for the flyback and the horizontal yoke).

Why the Yoke is Needed to Keep the Horizontal Deflection System Happy

If you unplug the yoke (even if there is no interlock), while the system may still work to some extent, performance will be poor. High voltage will be reduced and parts may overheat (and possibly blow up).

- **One reason to do this at all is as a quick test to determine if the yoke is defective. While the resulting waveforms will not be totally correct, they should be much better than with a shorted yoke installed and there may be enough HV to get a spot on the screen. Caution: It may be quite bright. See the documents: Notes on the Troubleshooting and Repair of Computer and Video Monitors or Notes on the**

Troubleshooting and Repair of Television Sets for more info and precautions.

- Another more fun reason is if it is desired to use the flyback subsystem of a defunct TV, monitor, or computer terminal as a stand-alone high voltage power supply - but details are left as an exercise for the highly motivated (and cautious!) student. See the document: Salvaging Interesting Gadgets, Components, and Subsystems for more exciting details.

WARNING: High voltages and possibly line voltage present at HOT, yoke, flyback outputs, and elsewhere!

Of course, just removing the yoke doesn't work. The flyback capacitor is tuned for the presence of both inductances: line transformer and deflection coil. If you remove the deflection coil then the remaining primary transformer inductance is about 5 times as large. So, rule-of-thumb, you would have to decrease the flyback capacitor by a factor of approximate 5. But that's not all:

Without the deflection coil, a lot less current runs through the horizontal output transistor. So, in all likelihood, it will now be overdriven. So you need to reduce the basedrive. But that's not all:

If you remove the picture tube capacitance and the deflection coil then all peak energy demand must be delivered from the primary winding of the line transformer. Even the shortest peak load will cause saturation. The parallel deflection coil will at least lend some temporary energy, and the picture tube capacitance does an even better job. A good high-voltage source without the benefit of a deflection coil is more expensive...

If you *must* get rid of the 'ugly' deflection coil, then you may want to replace it with an equivalent 'pretty' coil. But:

- It must be able to carry the peak current without saturation (a deflection coil has such a huge air gap that it can not possibly ever saturate, but a smaller coil can).

- It must have a low enough dissipation so you might have to wind it with litz-like wire (multi-stranded isolated), do not underestimate the losses in high-frequency coils, mostly due to skin- and proximity-effect.

- Yes, it can be done, good luck.

And you might want to add a discrete high-voltage capacitor. How to isolate the wiring (corona discharge!) is left as an exercise to the reader... (We pot them in convenient blocks).

Probing TV and Monitor Yoke Signals

Due to the particular nature of the signals on the deflection yoke, special techniques must be used to safely view them on a scope. Note that the following also applies to some extent to deflection signals in tube-type video cameras and other similar devices as well.

You cannot put a ground clip on either pole of the line yoke, because one side carries the flyback pulses which are approx. 1000 Vpp and the other side carries the S-correction voltage which may be 100 V average with a (?) 50 Vpp line parabola. Both signals are at line frequency (15.75 kHz and up). You need a 100:1 oscilloscope probe for the 1000 Vpp signal! The field coil carries lower voltages (order of 50 Vpp max) and at field frequency (50 to 120 Hz).

Usually you connect the scope ground to a large heatsink, unless that carries a warning label that it is not grounded... ALWAYS check first to identify a proper ground and use an isolation transformer for safety since even this may not be the same as the power line ground.

If you have a current probe for your scope, this can be used to monitor the various current waveforms. I have used my Tektronix current probe to view the yoke current on TVs. The rendition of the horizontal deflection current waveform is quite good. However, the vertical suffers from severe distortion due to the low frequency cutoff of this probe.

You can build a not-very-fantastic (but quite usable) current problem using a split ferrite core of the type used on keyboard and monitor cables (preferably one that snaps together). The following will work:

- Wrap seven turns of insulated wire around one half of the core.

- Solder a 2.2 ohm resistor across the two leads to act as a load.

- Connect to the vertical input of your scope via a coaxial cable or probe.

You can experiment with the number of turns and load resistor value for best results.

To use your fabulous device, insert one and only one of the current carrying wires inside the ferrite core and clamp the two halves together.

For a typical TV horizontal deflection yoke, this results in about a .3 V p-p signal. The shape was similar to that from my (originally) expensive Tektronix current probe. Enjoy the show! Due to its uncompensated design, this simple probe will not work well (if at all) for low frequency signals.

Breathing Compensation

Breathing is a change in picture size caused by a variation of the EHT voltage due to varying beam current loading. The EHT has a typical output impedance of (approx.) 1 M Ohm. Average beam current varies between 0 and 2 mA, so the voltage drops by 2 kV (from 30 kV), or worse. At lower EHT, the electron beam is easier to deflect, so the picture size will increase.

Brighter picture -> higher beam current -> lower EHT -> larger picture. That's the law of physics.

The breathing can be compensated by decreasing the deflection current amplitude as a function of the beam current. A voltage called "EHT-info" is generated from the beam current as delivered by the line transformer. This is fed to the deflection circuit for feed-forward correction. For horizontal deflection this means feeding it to the East-West modulator.

And here's the catch for you Americans: many USA sets don't have an East-West modulator! Most picture tubes (for the USA) with 90 or 100 degrees deflection don't need (much) pin-cushion correction, so there is no fundamental need for the East-West modulator and so there is also no correction possibility for the anti-breathing. There are other options for corrections, like creating a deliberate higher output impedance for the V+ deflection supply etc., but these are passive measures which will lack accuracy.

Sets with 110 degrees deflection angle (common in Europe) will need active East-West correction and should also perform adequate anti-breathing. Although that is still difficult enough, I should know...

The LD/DVD "Video Essentials" contains test pictures to check your breathing performance. It advises you a simple counter- measure: reduce the beam current by lowering the contrast setting ! This will also improve the sharpness (less spot blooming) and increase the lifetime of the picture tube (less burn-in of the phosphors). But you need to darken the room because the picture will obviously be much darker... (http://www.videoessentials.com/)

Circuit Simulation of the Deflection System?

If it were that easy... You could use any regular circuit simulation like Spice or Microcap. The real problem is in obtaining the device models, particularly the horizontal output transistor and the line transformer. Initially you could start with ideal components (switch, inductor) and see if you've got the basic component values right. That will give you some basic insight into the working of the circuit, but it is then that the real fun starts. For example, storage time modulation of the HOT is essential for the Phi-2 PLL response... I don't think you will find any realistic device models for power transistors, so you will have to breadboard and actually measure...

Jurb's Comments on HOT Troubleshooting

(From: JURB6006 (jurb6006@aol.com).)

The base current is hard to read, but the HDT (Horizontal Drive Transistor) collector waveform can give you a readable picture of it. When you put a scope probe on the base of the HOT, the reading is almost useless, it tells you more about a parameters of the HOT than whether or not it has sufficient drive.

The reason for this phenomenon is the same as the reason they use a transformer to drive the HOT in the first place. A complimentary pair of transistors would do the job just fine, as long as they don't need the isolation. If the chassis uses an SMPS, it would be cheaper except for one thing. The HOT itself.

Even though the transformer steps down quite a bit, it is still a current source. As many linear amplifying stages we see using discreet components, the fact that a bipolar transistor device is current driven gets obscured.

The HDT collector voltage waveform can tell many things. When the base of the HOT is disconnected it will become what looks like the upper left quadrant of a circle. When loaded with that junction it looks more like a square wave. There is a hump at the beginning of the top, maybe about a 120 kHz component, that's the lag of the base current through whatever components and stray inductance. Then the top roses at a slower rate, that's when the collector current is ramping in the HOT.

Without linearity problems, it's probably turning on good enough. A good piece of the on time of the HOT is during trace. The major problem I have found is the turnoff time. Apparently if enough forward bias is applied, a pretty good negative spike is developed for turnoff of the HOT. If you can scope the HOT collector, you will see this as a rounding of the end of the pulse. When that top of about a 70 Khz sine wave hits the baseline, you want a sharp corner on it. If that part of the waveform is rounded, the HOT will fail. (transistor)

The only effect this has on the raster, if you can underscan it you can see a slight compression at the left side. Also depending on the exact design of the H sweep circuit, you might not even see that, and even if you had spikes between the pulses, the pincushion circuit might isolate them enough so you don't see it in the raster.

Horizontal Deflection Circuit from Small TVs and Monitors

(From: Carlos Marques (c_finos@hotmail.com).)

This is another common horizontal deflection system, used mainly in small TVs and monitors. This method of horizontal deflection has a high value decoupling non-polar capacitor (4.7 uF typically) across the HOT in series with the yoke. The collector of the HOT is also connected to the FBT, at a tap which joins two windings. One of the windings connects to the positive supply, and the other connects to a diode which is connected to ground. Sometimes this diode has a small capacitor in parallel with it. I have seen this configuration many times, and I don't understand it very well, mainly the flyback process.

DISCLAIMER

Working inside a CRT-based television set, or computer or video monitor can be lethal from line-connected and high voltage power supplies as well as CRT implosion. Read and follow ALL of the safety guidelines found in Safety Guidelines for High Voltage and/or Line Powered Equipment and the section: SAFETY, below. If in doubt about your abilities or experience, leave repair and internal adjustments to a professional.

We will not be responsible for damage to equipment, your ego, county wide power outages, spontaneously generated mini (or larger) black holes, planetary disruptions, or personal injury or worse that may result from the use of this material.

Introduction

Television at the crossroads

Television in substantially its present form has been with us for nearly 50 years. It is a tribute to the National Television Standards Committee (NTSC) that the color television standards agreed upon in the early 1950s have performed remarkably well making quite efficient use of valuable radio spectrum space and the psychovisual characteristics of the human eye-brain system. However, HDTV (High Definition TV) will supplant and ultimately replace the current standards. We will all come to expect its superior resolution, freedom from noise and ghosting, and pure CD sound. Yet, the perceived quality of TV broadcasts and cable will never likely be the major issue with most consumers. Content will continue to be the biggest problem.

It is likely that in roughly 15 years, HDTV - digitally processed and transmitted as 1s and 0s - will completely replace the current system. Acceptance in the marketplace is by no means assured but with the merging of TV and computers - with the Internet as a driving force - it would seem that the days of the stand-alone analog TV set are numbered.

Television receiver fundamentals

The basic color television receiver must perform the same functions today as 40 years ago. (Since B/W is a subset of the color standard, most references in this document will be for color except as noted). A studio video monitor includes all of the functions of a television receiver except the tuner and IF (which rarely fail except for bad connections or perhaps lightning strikes to the antenna or cable connection). Therefore most of the repair information in this document is applicable to both TVs and studio monitors. Modern computer monitors share many similarities with TVs but the multisync and high scan rate deflection circuitry and more sophisticated power supplies complicates their servicing.

As of this writing, the majority of TVs are still based on the Cathode Ray Tube (CRT) as the display device. Tiny pocket sets, camcorder viewfinders, and the like have started using LCD (Liquid Crystal Display) panels but these are still inferior to the CRT for real time video. There has always been talk of 'the picture on the wall' display and these are now appearing as large screen plasma panel displys but their cost is still high compared to even projection TVs using CRTs. The reason is simple economics - it is really hard to beat the simplicity of the shadow mask CRT. Of course, prices will drop as the technology matures.

Projection - large screen - TVs, on the other hand, are able to take advantage of a novel development in integrated micromachining - the Texas Instruments Inc. Digital Micromirror Device (DMD), now called DLP for "Digital Light Processing". This is basically an integrated circuit with a tiltable micromirror for each pixel fabricated on top of a static memory - RAM - cell. This technology would permit nearly any size projection display to be produced and would therefore be applicable to HDTV. Since it is a reflective device, the light source can be as bright as needed. This technology is already appearing in commercial high performance projectors and is competing for use in totally digital movie theaters to replace the film projector and has begun appearing in high-end consumer projection TV sets - yet.

> (From: Kurk MacKay (kurk_mackay@telus.net).)
>
> "DMD TVs have been on the marketplace for about a year now. The DMD is more commonly referred to as DLP (Digital Light Processing) in the marketplace. From what I've heard Samsung has had a DLP TV on the consumer marketplace as of last year in the US and this year here in Canada. My boss was looking at buying one so we went around to view them. The picture quality looks to be between the LCD projection and Plasma. I believe the current Samsung uses a color wheel but they are working on a three color independent system.
>
> For more info or if you want to buy one, see DLP TV Showcase."

As noted, the plasma panel flat screen display has been around for several years in high-end TVs, typically in the 42 inch diagonal range. However, they are very expensive ($5,000 to $15,000 as of Winter, 2003), and their life expectancy may be limited due to the gradual degradation of the active pixel cells - which occurs faster than for a CRT. The physical resolution is also still low enough that visible discrete pixels may be objectionable to some viewers. However, there is little doubt that this or a similar technology will eventually replace the direct view CRT and 3-tube projection TVs in the mid to large screen sizes in the not too distant future.

The remainder of this document concentrates on CRT based analog TVs since these still dominate the market and realistically, these are the only type where there is a good chance of repair without access to specialized test equipment and parts. I wouldn't recommend any sort of attempt at repair of flat screen TVs or monitors - no matter what the size - beyond checking for bad connections, dead power supplies, or other obvious problems. The chance of success is vanishingly small and it's very likely that even with great care, damage could occur to the panels or circuitry.

TV repair

Unlike VCRs or CD players where any disasters are likely to only affect your pocketbook, TVs can be dangerous. Read, understand, and follow the set of safety guidelines provided later in this section whenever working on TVs, monitors, or other similar high voltage equipment.

If you do go inside, beware: line voltage (on large caps) and high voltage (on CRT) for long after the plug is pulled. There is the added danger of CRT implosion for carelessly dropped tools and often sharp sheetmetal shields which can injure if you should have a reflex reaction upon touching something you should not touch. In inside of a TV or monitor is no place for the careless or naive.

Having said that, a basic knowledge of how a TV set works and what can go wrong can be of great value even if you do not attempt the repair yourself. It will enable you to intelligently deal with the service technician. You will be more likely to be able to recognize if you are being taken for a ride by a dishonest or just plain incompetent repair center. For example, a faulty picture tube CANNOT be the cause of a color television only displaying shows in black-and-white. The majority of consumers probably do not know even this simple fact. Such a problem is usually due to a bad capacitor or other 10 cent part.

This document will provide you with the knowledge to deal with a large percentage of the problems you are likely to encounter with your TVs. It will enable you to diagnose problems and in many cases, correct them as well. With minor exceptions, specific manufacturers and models will not be covered as there are so many variations that such a treatment would require a huge and very detailed text. Rather, the most common problems will be addressed and enough basic principles of operation will be provided to enable you to narrow the problem down and likely determine a course of action for repair. In many cases, you will be able to do what is required for a fraction of the cost that would be charged by a repair center.

Should you still not be able to find a solution, you will have learned a great deal and be able to ask appropriate questions and supply relevant information if you decide to post to sci.electronics.repair. It will also be easier to do further research using a repair text such as the ones listed at the end of this document. In any case, you will have the satisfaction of knowing you did as much as you could before taking it in for professional repair. With your new-found knowledge, you will have the upper hand and will not easily be snowed by a dishonest or incompetent technician.

Repair or replace

If you need to send or take the TV to a service center, the repair could easily exceed half the cost of a new TV. Service centers may charge up to $50 or more for providing an initial estimate of repair costs but this will usually be credited toward the total cost of the repair (of course, they may just jack this up to compensate for their bench time).

TV prices have been dropping almost as fast as PC prices. Therefore, paying such prices for repair just may not make sense. Except for picture tube problems, most TV faults can be corrected without expensive parts, however. Keeping a 5 year old TV alive may be well worthwhile as basic TV performance and important features have not changed in a long time.

If you can do the repairs yourself, the equation changes dramatically as your parts costs will be 1/2 to 1/4 of what a professional will charge and of course your time is free. The educational aspects may also be appealing. You will learn a lot in the process. Thus, it may make sense to repair that old clunker for your game room or beach house. (I would suggest the kid's room but most TV watching just rots the brain anyhow so a broken TV may be more worthwhile educationally than one that works.)

- Back to TV Repair FAQ Table of Contents.

TV Receivers 101

Subsystems of a television set

A TV set includes the following functional blocks:

1. Low voltage power supply (some may also be part of (2).) Most of the lower voltages used in the TV may be derived from the horizontal deflection circuits. Sometimes, there is a separate switching power supply but this would be the exception. Rectifier/filter capacitor/regulator from AC line provides the B+ to the switching power supply or horizontal deflection system. Degauss operates off of the line whenever power is turned on (after having been off for a few minutes) to demagnetize the CRT.

2. Horizontal deflection. These circuits provide the waveforms needed to sweep the electron beam in the CRT across and back some 15,734 times per second (for NTSC). The horizontal sync pulse from the sync separator locks the horizontal deflection to the video signal.

3. Vertical deflection. These circuits provide the waveforms needed to sweep the electron beam in the CRT from top to bottom and back 60 times per second (for NTSC). The vertical sync pulse from the sync separator locks the vertical deflection to the video signal.

4. CRT high voltage (also part of (2).) A modern color CRT requires up to 30 kV for a crisp bright picture. Rather than having a totally separate power supply, nearly every TV on the planet derives the HV (as well as many other voltages) from the horizontal deflection using a special transformer called a 'flyback' or 'Line OutPut Transformer (LOPT) for those of you on the other side of the lake.

5. Tuner, IF, AGC, video and audio demodulators. Input is the antenna or cable signal and output are baseband video and audio signals. There is usually someplace inside the TV where line level video and audio are present but it may not be accessible from the outside of the cabinet unless you paid for the more expensive model with the A/V option. Very often, the tuner is a shielded metal box positioned on the bottom right (as viewed from the front) separate from the main circuit board. Sometimes it is on the main circuit board. The IF section may be in either place.

   On older or cheap TVs with a knob tuner, this is usually mounted to the front panel by itself. There are usually separate boxes for the VHF and UHF tuners.

6. Chroma demodulator. Input is the baseband video signal. Outputs are the individual signals for the red, green, and blue video to the CRT.

7. Video drivers (RGB). These are almost always located on a little circuit board plugged directly onto the neck of the CRT. They boost the output of the chroma demodulator to the hundred volts or so needed to drive the cathodes of the CRT.

8. Sync separator. Input is baseband video. Output is horizontal and vertical sync pulses to control the deflection circuits.

9. Audio amplifier/output. The line level audio is amplified to drive a set of speakers. If this is a stereo TV, then these circuits must also perform the stereo demultiplexing.

10. System control. Most modern TVs actually use a microcontroller - a fixed program microcomputer to perform all user interface and control functions from the front panel and remote control. These are becoming increasingly sophisticated. However, they do not fail often. Older TVs use a bunch of knobs and switches and these are prone to wear and dirt.

Most problems occur in the horizontal deflection and power supply sections. These run at relatively high power levels and some components run hot. The high voltage section is prone to breakdown and arcing as a result of hairline cracks, humidity, dirt, etc.

The tuner components are usually quite reliable unless the antenna experiences a lightning strike. However, it seems that even after 20+ years of solid state TVs, manufacturers still cannot reliably solder the tuner connectors and shields so that bad solder connections in these areas are common even in new sets.

Why projection TVs are not just normal TVs in big boxes

In order to achieve the necessary brightness with a large display format, three separate monochrome CRTs are used with optics to combine the three images properly at the screen. This creates an entire set of additional problems in design.

(From: Jeroen H. Stessen (Jeroen.Stessen@philips.com).)

The average projection TV has about twice as many parts as its direct-view counterpart. Some of the extra parts are essential for projection because CRT projection tubes require dynamic convergence. The other extra parts have to do with the fact that a more expensive TV also should have some extra features, like Dolby ProLogic sound, a satellite tuner and such.

Generally, the electronics are based on a standard chassis that is also used for direct-view CRT television. Even the deflection circuits require minor adaptations at most. The high-voltage circuit is different because the EHT, focus and G2 voltages must be distributed over 3 CRTs. So this requires a special high-voltage part, which also includes an EHT capacitor and bleeder.

There will be 3 CRT panels with video amplifiers. Because of the extremely high brightness, projection tubes will burn the phosphor screen immediately in fault conditions so a protection circuit is essential.

And last but certainly not least, there is the dynamic convergence panel. The heart is a waveform generator IC, often of a Japanese brand but nowadays there's also a digital variant by Philips. The old-fashioned way requires many many potentiometers to program the waveforms. Then there's 5 or 6 convergence amplifiers and a corresponding extra power supply. And usually this is where the single deflection circuits are distributed to the 3 CRTs. At the same time the deflection currents are sensed for the protection circuits.

Designing a PTV from a DVTV requires several man-years of work. In the factory, a special corner is devoted to the assembly. There you'll find specially educated people and the speed of the assembly line is a lot lower than usual. It requires many more adjustments, e.g. 3 optical and 3 electrical focus adjustments and then convergence.

For more information on TV technology

The books listed in the section: Suggested references include additional information on the theory and implementation of the technology of television standards and TV receivers.

Philips/Magnavox used to have a very nice on-line introduction to a variety of consumer electronics technologies. Although their site has disappeared - and even people who work for them have no clue - I have now recovered several of the articles including those on TVs, VCRs, camcorders, satellite reception, and connections. See the Introductory Consumer Electronics Technology Series.

Also see:

- NTSC Television Tutorials by Williamson Labs has many diagrams with a bit of text on their site. It looks like they are really trying to sell stuff including a CDROM but the graphics are worth checking out.

On-line tech-tips databases

A number of organizations have compiled databases covering thousands of common problems with VCRs, TVs, computer monitors, and other electronic equipment. Most charge for their information but a few, accessible via the Internet, are either free or have a very minimal monthly or per-case fee. In other cases, a limited but still useful subset of the for-fee database is freely available.

A tech-tips database is a collection of problems and solutions accumulated by the organization providing the information or other sources based on actual repair experiences and case histories. Since the identical failures often occur at some point in a large percentage of a given model or product line, checking out a tech-tips database may quickly identify your problem and solution.

In that case, you can greatly simplify your troubleshooting or at least confirm a diagnosis before ordering parts. My only reservation with respect to tech-tips databases in general - this has nothing to do with any one in particular - is that symptoms can sometimes be deceiving and a solution that works in one instance may not apply to your specific problem. Therefore, an understanding of the hows and whys of the equipment along with some good old fashioned testing is highly desirable to minimize the risk of replacing parts that turn out not to be bad.

The other disadvantage - at least from one point of view - is that you do not learn much by just following a procedure developed by others. There is no explanation of how the original diagnosis was determined or what may have caused the failure in the first place. Nor is there likely to be any list of other components that may have been affected by overstress and may fail in the future. Replacing Q701 and C725 may get your equipment going again but this will not help you to repair a different model in the future.

Please see the document: On-Line Tech-Tips Databases for the most up to date compilation of these resources for TVs, VCRs, computer monitors, and other consumer electronic equipment.

CRT Basics

Note: Most of the information on TV and monitor CRT construction, operation, interference and other problems. has been moved to the document: TV and Monitor CRT (Picture Tube) Information. The following is just a brief introduction with instructions on degaussing.

Color CRTs - shadow masks and aperture grills

All color CRTs utilize a shadow mask or aperture grill a fraction of an inch (1/2" typical) behind the phosphor screen to direct the electron beams for the red, green, and blue video signals to the proper phosphor dots. Since the electron beams for the R, G, and B phosphors originate from slightly different positions (individual electron guns for each) and thus arrive at slightly different angles, only the proper phosphors are excited when the purity is properly adjusted and the necessary magnetic field free region is maintained inside the CRT. Note that purity determines that the correct video signal excites the proper color while convergence determines the geometric alignment of the 3 colors. Both are affected by magnetic fields. Bad purity results in mottled or incorrect colors. Bad convergence results in color fringing at edges of characters or graphics.

The shadow mask consists of a thin steel or InVar (a ferrous alloy) with a fine array of holes - one for each trio of phosphor dots - positioned about 1/2 inch behind the surface of the phosphor screen. With most CRTs, the phosphors are arranged in triangular formations called triads with each of the color dots at the apex of the triangle. With many TVs and some monitors, they are arranged as vertical slots with the phosphors for the 3 colors next to one another.

An aperture grille, used exclusively in Sony Trinitrons (and now their clones as well), replaces the shadow mask with an array of finely tensioned vertical wires. Along with other characteristics of the aperture grille approach, this permits a somewhat higher possible brightness to be achieved and is more immune to other problems like line induced moire and purity changes due to local heating causing distortion of the shadow mask.

However, there are some disadvantages of the aperture grille design:

- weight - a heavy support structure must be provided for the tensioned wires (like a piano frame).

- price (proportional to weight).

- always a cylindrical screen (this may be considered an advantage depending on your preference.

- visible stabilizing wires which may be objectionable or unacceptable for certain applications.

Apparently, there is no known way around the need to keep the fine wires from vibrating or changing position due to mechanical shock in high resolution tubes and thus all Trinitron monitors require 1, 2, or 3 stabilizing wires (depending on tube size) across the screen which can be see as very fine lines on bright images. Some people find these wires to be objectionable and for some critical applications, they may be unacceptable (e.g., medical diagnosis).

Degaussing (demagnetizing) a CRT

Degaussing may be required if there are color purity problems with the display. On rare occasions, there may be geometric distortion caused by magnetic fields as well without color problems. The CRT can get magnetized:

- if the TV or monitor is moved or even just rotated.

- if there has been a lightning strike nearby. A friend of mine had a lightning strike near his house which produced all of the effects of the EMP from a nuclear bomb.

- If a permanent magnet was brought near the screen (e.g., kid's magnet or megawatt stereo speakers).

- If some piece of electrical or electronic equipment with unshielded magnetic fields is in the vicinity of the TV or monitor.

Degaussing should be the first thing attempted whenever color purity problems are detected. As noted below, first try the internal degauss circuits of the TV or monitor by power cycling a few times (on for a minute, off for at least 20 minutes, on for a minute, etc.) If this does not help or does not completely cure the problem, then you can try manually degaussing.

Note: Some monitors have a degauss button, and monitors and TVs that are microprocessor controlled may degauss automatically upon power-on (but may require pulling the plug to do a hard reset) regardless of the amount of off time. However, repeated use of these 'features' in rapid succession may result in overheating of the degauss coil or other components. The 20 minutes off/1 minute on precedure is guaranteed to be safe. (Some others may degauss upon power-on as long as the previous degauss was not done within some predetermined amount of time - they keep track with an internal timer.)

Commercial CRT Degaussers are available from parts distributors like MCM Electronics and consist of a hundred or so turns of magnet wire in a 6-12 inch coil. They include a line cord and momentary switch. You flip on the switch, and bring the coil to within several inches of the screen face. Then you slowly draw the center of the coil toward one edge of the screen and trace the perimeter of the screen face. Then return to the original position of the coil being flat against the center of the screen. Next, slowly decrease the field to zero by backing straight up across the room as you hold the coil. When you are farther than 5 feet away you can release the line switch.

The key word here is ** slow **. Go too fast and you will freeze the instantaneous intensity of the 50/60 Hz AC magnetic field variation into the ferrous components of the CRT and may make the problem worse.

WARNING: Don't attempt to degauss inside or in the back of the set (near the CRT neck. This can demagnetize the relatively weak purity and convergence magnets which may turn a simple repair into a feature length extravaganza!

It looks really cool to do this while the CRT is powered. The kids will love the color effects (but then lock your degaussing coil safely away so they don't try it on every TV and monitor in the house!).

Bulk tape erasers, tape head degaussers, open frame transformers, and the "butt-end" of a weller soldering gun can be used as CRT demagnetizers but it just takes a little longer. (Be careful not to scratch the screen face with anything sharp. For the Weller, the tip needs to be in place to get enough magnetic field.) It is imperative to have the CRT running when using these whimpier approaches, so that you can see where there are still impurities. Never release the power switch until you're 4 or 5 feet away from the screen or you'll have to start over.

I've never known of anything being damaged by excess manual degaussing as long as you don't attempt to degauss *inside* or the back of the set - it is possible to demagnetize geometry correction, purity, and static converence magnets in the process! However, I would recommend keeping really powerful bulk tape erasers-turned-degaussers a couple of inches from the CRT.

If an AC degaussing coil or substitute is unavailable, I have even done degaussed with a permanent magnet but this is not recommended since it is more likely to make the problem worse than better. However, if the display is unusable as is, then using a small magnet can do no harm. (Don't use a 20 pound speaker or magnetron magnet as you may rip the shadow mask right out of the CRT - well at least distort it beyond repair. What I have in mind is something about as powerful as a refrigerator magnet.)

Keep degaussing fields away from magnetic media. It is a good idea to avoid degaussing in a room with floppies or back-up tapes. When removing media from a room remember to check desk drawers and manuals for stray floppies, too.

It is unlikely that you could actually affect magnetic media but better safe than sorry. Of the devices mentioned above, only a bulk eraser or strong permanent magnet are likely to have any effect - and then only when at extremely close range (direct contact with media container).

All color CRTs include a built-in degaussing coil wrapped around the perimeter of the CRT face. These are activated each time the CRT is powered up cold by a 3 terminal thermister device or other control circuitry. This is why it is often suggested that color purity problems may go away "in a few days". It isn't a matter of time; it's the number of cold power ups that causes it. It takes about 15 minutes of the power being off for each cool down cycle. These built-in coils with thermal control are never as effective as external coils.

Note that while the monochrome CRTs used in B/W and projection TVs and mono monitors don't have anything inside to get magnetized, the chassis or other cabinet parts of the equipment may still need degaussing. While this isn't likely from normal use or even after being moved or reoriented, a powerful magnet (like that from a large speaker) could leave iron, steel, or other ferrous parts with enough residual magnetism to cause a noticeable problem.

See the document: TV and Monitor CRT (Picture Tube) Information for some additional discussion of degaussing tools, techniques, treatments for severe magnetization from lightning strikes, and cautions.

TV Placement And Preventive Maintenance

General TV placement considerations

Proper care of a TV does not require much. Following the recommendations below will assure long life and minimize repairs:

- Subdued lighting is preferred for best viewing conditions but I will not attempt to tell you how to arrange your room!

- Locate the TV away from extremes of hot and cold. Avoid damp or dusty locations if possible. (Right you say, keep dreaming!)

- Allow adequate ventilation - TVs use more power than any of your other A/V components. Heat buildup takes its toll on electronic components. Leave at least 3 inches on top and sides for air circulation if the entertainment center does not have a wide open back panel. Do not pile other components like VCRs on top of the TV if possible (seebelow).

- Do not put anything on top of the TV that might block the ventilation grill in the rear or top of the cover. This is the major avenue for the convection needed to cool internal components.

- If possible, locate the VCR away from the TV. Some VCRs are particularly sensitive to interference from the TV's circuitry and while this won't usually damage anything, it may make for less than optimal performance due to RF interference. The reverse is sometimes true as well.

  In addition, modern VCRs are NOT built like the Brooklyn Bridge! The weight of a TV or stereo components could affect the VCR mechanically, messing up tape path alignment or worse.

- If possible, locate your computer monitor away from the TV. Interaction of the electromagnetic fields of the deflection systems may result in one or both displays jiggling, wiggling, or vibrating.

- Locate loudspeakers and other sources of magnetic fields at least a couple of feet from the TV. This will minimize the possibility of color purity or geometry problems.

- Make sure all input-output video and audio connections are tight and secure to minimize intermittent or noisy pictures and sound. Use proper high quality cable only long enough to make connections conveniently.

- Finally, store video cassettes well away from all electronic equipment including and especially loudspeakers. Heat and magnetic fields will rapidly turn your priceless video collection into so much trash. The operation of the TV depends on magnetic fields for beam deflection. Enough said.

Preventive maintenance

Preventive maintenance for a TV is pretty simple - just keep the case clean and free of obstructions. Clean the screen with a soft cloth just dampened with water and at most, mild detergent. DO NOT use anything so wet that liquid may seep inside of the set around the edge of the picture tube - you could end up with a very expensive repair bill when the liquid shorts out the main circuit board lurking just below. If the set has a protective flat glass faceplate, there is usually an easy way (on newer sets with this type of protection) of removing it to get at the inner face of the CRT. Clean both the CRT and the protective glass with a soft damp cloth and dry thoroughly. If you have not cleaned the screen for quite a while, you will be amazed at the amount of black grime that collects due to the static buildup from the high voltage CRT supply.

In really dusty situations, periodically vacuuming inside the case and the use of contact cleaner for the controls might be a good idea but realistically, you will not do this so don't worry about it.

Warning about using a TV as a computer or video game display

> "I remember a while back (about 10 years) most home computers used to hook up to televisions. I seem to

> remember them having some effect on the TV though. I think they made the TV go blurry after a while. I was just wondering what these computers used to do to the televisions to mess them up like that. I thought a TV signal was a TV signal."

The problem was screen burn. Since computers of that era were mostly text and video games tended to use fixed patterns for scenery, patterns tended to be burned into the phosphor such that they were noticeably darker and less sensitive in those areas. This was exacerbated by the tendency to run those devices at very high brightness levels.

Modern computers and video games should not be nearly as much of a risk since the displays are so much more varied and dynamic. Nevertheless, setting the brightness at a moderate level would be prudent.

However, projection sets with their much higher intensity CRTs may still be susceptible to screen burn and the manufacturer will likely NOT cover the cost of repairs. There is probably a disclaimer to this effect in the warranty.

TV Troubleshooting

SAFETY

TVs and computer or video monitors are among the more dangerous of consumer electronic equipment when it comes to servicing. (Microwave ovens are probably the most hazardous due to high voltage at high power.)

There are two areas which have particularly nasty electrical dangers: the non-isolated line power supply and the CRT high voltage.

Major parts of nearly all modern TVs and many computer monitors are directly connected to the AC line - there is no power transformer to provide the essential barrier for safety and to minimize the risk of equipment damage. In the majority of designs, the live parts of the TV or monitor are limited to the AC input and line filter, degauss circuit, bridge rectifier and main filter capacitor(s), low voltage (B+) regulator (if any), horizontal output transistor and primary side of the flyback (LOPT) transformer, and parts of the startup circuit and standby power supply. The flyback generates most of the other voltages used in the unit and provides an isolation barrier so that the signal circuits are not line connected and safer.

Since a bridge rectifier is generally used in the power supply, both directions of the polarized plug result in dangerous conditions and an isolation transformer really should be used - to protect you, your test equipment, and the TV, from serious damage. Some TVs do not have any isolation barrier whatsoever - the entire chassis is live. These are particularly nasty.

The high voltage to the CRT, while 200 times greater than the line input, is not nearly as dangerous for several reasons. First, it is present in a very limited area of the TV or monitor - from the output of the flyback to the CRT anode via the fat HV wire and suction cup connector. If you don't need to remove the mainboard or replace the flyback or CRT, then leave it alone and it should not bite. Furthermore, while the shock from the HV can be quite painful due to the capacitance of the CRT envelope, it is not nearly as likely to be lethal since the current available from the line connected power supply is much greater.

Safety guidelines

These guidelines are to protect you from potentially deadly electrical shock hazards as well as the equipment from accidental damage.

Note that the danger to you is not only in your body providing a conducting path, particularly through your heart. Any involuntary muscle contractions caused by a shock, while perhaps harmless in themselves, may cause collateral damage - there are many sharp edges inside this type of equipment as well as other electrically live parts you may contact accidentally.

The purpose of this set of guidelines is not to frighten you but rather to make you aware of the appropriate precautions. Repair of TVs, monitors, microwave ovens, and other consumer and industrial equipment can be both rewarding and economical. Just be sure that it is also safe!

- Don't work alone - in the event of an emergency another person's presence may be essential.

- Always keep one hand in your pocket when anywhere around a powered line-connected or high voltage system.

- Wear rubber bottom shoes or sneakers.

- Don't wear any jewelry or other articles that could accidentally contact circuitry and conduct current, or get caught in moving parts.

- Set up your work area away from possible grounds that you may accidentally contact.

- Know your equipment: TVs and monitors may use parts of the metal chassis as ground return yet the chassis may be electrically live with respect to the earth ground of the AC line. Microwave ovens use the chassis as ground return for the high voltage. In addition, do not assume that the chassis is a suitable ground for your test equipment!

- If circuit boards need to be removed from their mountings, put insulating material between the boards and anything they may short to. Hold them in place with string or electrical tape. Prop them up with insulation sticks - plastic or wood.

- If you need to probe, solder, or otherwise touch circuits with power off, discharge (across) large power supply filter capacitors with a 2 W or greater resistor of 100 to 500 ohms/V approximate value (e.g., for a 200 V capacitor, use a 20K to 100K ohm resistor). Monitor while discharging and verify that there is no residual charge with a suitable voltmeter. In a TV or monitor, if you are removing the high voltage connection to the CRT (to replace the flyback transformer for example) first discharge the CRT contact (under the suction cup at the end of the fat HV wire). Use a 1M to 10M ohm 5 W or greater wattage (for its voltage holdoff capability, not power dissipation) resistor on the end of an insulating stick or the probe of a high voltage meter. Discharge to the metal frame which is connected to the outside of the CRT.

- For TVs and monitors in particular, there is the additional danger of CRT implosion - take care not to bang the CRT envelope with your tools. An implosion will scatter shards of glass at high velocity in every direction. There are several tons of force attempting to crush the typical CRT. While implosion is not really likely even with modest abuse, why take chances? However, the CRT neck is relatively thin and fragile and breaking it would be very embarrassing and costly. Always wear eye protection when working around the back side of a CRT.

- Connect/disconnect any test leads with the equipment unpowered and unplugged. Use clip leads or solder temporary wires to reach cramped locations or difficult to access locations.

- If you must probe live, put electrical tape over all but the last 1/16" of the test probes to avoid the possibility of an accidental short which could cause damage to various components. Clip the reference end of the meter or scope to the appropriate ground return so that you need to only probe with one hand.

- Perform as many tests as possible with power off and the equipment unplugged. For example, the semiconductors in the power supply section of a TV or monitor can be tested for short circuits with an ohmmeter.

- Use an isolation transformer if there is any chance of contacting line connected circuits. A Variac(tm) is not an isolation transformer! The use of a GFCI (Ground Fault Circuit Interrupter) protected outlet is a good idea but will not protect you from shock from many points in a line connected TV or monitor, or the high voltage side of a microwave oven, for example. (Note however, that, a GFCI may nuisanse trip at power-on or at other random times due to leakage paths (like your scope probe ground) or the highly capacitive or inductive input characteristics of line powered equipment.) A fuse or circuit breaker is too slow and insensitive to provide any protection for you or in many cases, your equipment. However, these devices may save your scope probe ground wire should you accidentally connect it to a live chassis.

- Don't attempt repair work when you are tired. Not only will you be more careless, but your primary diagnostic tool - deductive reasoning - will not be operating at full capacity.

- Finally, never assume anything without checking it out for yourself! Don't take shortcuts!

Warning about disconnecting CRT neck board

Some manufacturers warn against powering a TV or monitor CRT without the CRT neck board connected. Apparently, without something - anything - to drain the charge resulting from the current flow due to residual gas ions inside the CRT, the shortest path may be through the glass neck of the tube to the yoke or from the pins outside the CRT to whatever is nearby. There aren't many ions in a modern CRT but I suppose a few here, a few there, and eventually they add up to enough to cause a major disaster at least on some CRTs.

This is probably not a problem on small CRTs but for large ones with high high voltages and high deflection angles where the glass of the neck is very thin to allow for maximum deflection sensitivity, the potential does exist for arcing through the glass to the yoke to occur, destroying the CRT.

There is really no way to know which models will self destruct but it should be possible to avoid such a disaster by providing a temporary return path to the DAG ground of the CRT (NOT SIGNAL GROUND!!) via the focus or G2 pins preferably through a high value high voltage rated resistor just in case one of these is shorted.

This probably applies mostly to large direct-view TVs since they use high deflection angle CRTs but it won't hurt to take appropriate precautions with video and computer monitors as well.

Troubleshooting tips

Many problems have simple solutions. Don't immediately assume that your problem is some combination of esoteric complex convoluted failures. For a TV, it may just be a bad connection or blown fuse. Remember that the problems with the most catastrophic impact on operation like a dead TV usually have the simplest solutions. The kind of problems we would like to avoid at all costs are the ones that are intermittent or difficult to reproduce: the occasional interference or a TV that refuses to play 'StarTrek Voyager'.

If you get stuck, sleep on it. Sometimes, just letting the problem bounce around in your head will lead to a different more successful approach or solution. Don't work when you are really tired - it is both dangerous (especially with respect to TVs) and mostly non-productive (or possibly destructive).

Whenever working on precision equipment, make copious notes and diagrams. You will be eternally grateful when the time comes to reassemble the unit. Most connectors are keyed against incorrect insertion or interchange of cables, but not always. Apparently identical screws may be of differing lengths or have slightly different thread types. Little parts may fit in more than one place or orientation. Etc. Etc.

Pill bottles, film canisters, and plastic ice cube trays come in handy for sorting and storing screws and other small parts after disassembly. This is particularly true if you have repairs on multiple pieces of equipment under way simultaneously.

Select a work area which is wide open, well lighted, and where dropped parts can be located - not on a deep pile shag rug. The best location will also be relatively dust free and allow you to suspend your troubleshooting to eat or sleep or think without having to pile everything into a cardboard box for storage.

Another consideration is ESD - Electro-Static Discharge. Some components (like ICs) in a TV are vulnerable to ESD. There is no need to go overboard but taking reasonable precautions such as getting into the habit of touching a **safe** ground point first.

WARNING: even with an isolation transformer, a live chassis should **not** be considered a safe ground point. When the set is unplugged, the tuner shield or other signal ground points should be safe and effective.

A basic set of precision hand tools will be all you need to disassemble a TV and perform most adjustments. These do not need to be really expensive but poor quality tools are worse than useless and can cause damage. Needed tools include a selection of Philips and straight blade screwdrivers, socket drivers, needlenose pliers, wire cutters, tweezers, and dental picks. For adjustments, a miniature (1/16" blade) screwdriver with a non-metallic tip is desirable both to prevent the presence of metal from altering the electrical properties of the circuit and to minimize the possibility of shorting something from accidental contact with the circuitry. A set of plastic alignment tools will be useful for making adjustments to coils and RF transformers.

A low power (e.g., 25 W) fine tip soldering iron and fine rosin core solder will be needed if you should need to disconnect any soldered wires (on purpose or by accident) or replace soldered components. A higher power iron or small soldering gun will be needed for dealing with larger components.

CAUTION: You can easily turn a simple repair (e.g., bad solder connections) into an expensive mess if you use inappropriate soldering equipment and/or lack the soldering skills to go along with it. If in doubt, find someone else to do the soldering or at least practice, practice, practice, soldering and desoldering on a junk circuit board first! See the document: Troubleshooting and Repair of Consumer Electronic Equipment for additional info on soldering and rework techniques.

For thermal or warmup problems, a can of 'cold spray' or 'circuit chiller' (they are the same) and a heat gun or blow dryer come in handy to identify components whose characteristics may be drifting with temperature. Using the extension tube of the spray can or making a cardboard nozzle for the heat gun can provide very precise control of which components you are affecting.

For info on useful chemicals, adhesives, and lubricants, see "Repair Briefs, an Introduction" as well as other documents available at this site.

Program to aid in diagnosing TV set problems

I haven't actually tried this so no warranties. :)

(From: Joe Janecka a0010631@airmail.net).)

I cranked out a little program for diagnosing TV problems and posted it at:

- TV Diagnostics Page.

It's not the complete answer, but it can get you started.

Test equipment

Don't start with the electronic test equipment, start with some analytical thinking. Your powers of observation (and a little experience) will make a good start. Your built in senses and that stuff between your ears represents the most important test equipment you have.

However, some test equipment will be needed:

- Multimeter (DMM or VOM) - This is essential for checking of power supply voltages and voltages on the pins of ICs or other components - service literature like the Sams' Photofacts described elsewhere in this document include voltage measurements at nearly every circuit tie point for properly functioning equipment. The multimeter will also be used to check components like transistors, resistors, and capacitors for correct value and for shorts or opens. You do not need a fancy instrument. A basic DMM - as long as it is reliable - will suffice for most troubleshooting. If you want one that will last for many years, go with a Fluke. However, even the mid range DMMs from Radio Shack have proven to be reliable and of acceptable accuracy. For some kinds of measurements - to deduce trends for example - an analog VOM is preferred (though some DMMs have a bar graph scale which almost as good).

- Oscilloscope - While many problems can be dealt with using just a multimeter, a 'scope will be essential as you get more into advanced troubleshooting. Basic requirements are: dual trace, 10-20 MHz minimum vertical bandwidth, delayed sweep desirable but not essential. A good set of proper 10X/1X probes. Higher vertical bandwidth is desirable but most consumer electronics work can be done with a 10 MHz scope. A storage scope or digital scope might be desirable for certain tasks but is by no means essential for basic troubleshooting.

  I would recommend a good used Tektronix (Tek) or Hewlett Packard (HP) scope over a new scope of almost any other brand. You will usually get more scope for your money and these things last almost forever. Until recently, my 'good' scope was the militarized version (AN/USM-281A) of the HP180 lab scope. It has a dual channel 50 MHz vertical plugin and a delayed sweep horizontal plugin. I have seen these going for under $300 from surplus outfits. For a little more money, you can get a Tek 465 or 465B (newer version but similar specifications) 100 Mhz scope ($200 to $600, sometimes cheaper on eBay or elsewhere but there is more risk than buying from a reputable dealer). I have now acquired a Tek 465B and that's what I use mostly these days. The HP-180 is still fine but I couldn't pass up a really good deal. :) The Tek 465/B or other similar model will suffice for all but the most demanding (read: RF or high speed digital) repairs.

- A video signal source - both RF and baseband (RCA jacks). Unless you are troubleshooting tuner or video/audio input problems, either one will suffice. RF sources include a pair of rabbit ears or an outdoor antenna, a cable connection, or a VCR with a working RF modulator. This will be more convenient than an antenna connection and will permit you to control the program material. In fact, making some test tapes using a camcorder or video camera to record static test patterns will allow you full control of what is being displayed and for how long.

- Color bar/dot/crosshatch signal generator. This is a useful piece of equipment if you are doing a lot of TV or monitor repair and need to perform CRT convergence and chroma adjustments. However, there are alternatives that are almost as good: a VHS recording of these test patterns will work for TVs. A PC programmed to output a suitable set of test patterns will be fine for monitors (and TVs if you can set up the video card to produce an NTSC/PAL signal. This can be put through a VCR to generate the RF (Channel 3/4) input to your TV if it does not have direct video inputs (RCA jacks).

Incredibly Handy widgets

These are the little gadgets and homemade testers that are useful for many repair situations. Here are just a few of the most basic:

- Series light bulb for current limiting during the testing of TVs, monitors, switching power supplies, audio power amplifiers, etc. I built a dual outlet box with the outlets wired in series so that a lamp can be plugged into one outlet and the device under test into the other. For added versatility, add a regular outlet and 'kill' switch using a quad box instead. The use of a series load will prevent your expensive replacement part like a horizontal output transistor from blowing if there is still some fault in the circuit you have failed to locate.

- A Variac. It doesn't need to be large - a 2 A Variac mounted with a switch, outlet and fuse will suffice for most tasks. However, a 5 amp or larger Variac is desirable. If you will be troubleshooting 220 VAC equipment in the US, there are Variacs that will output 0-240 VAC from a 115 VAC line (just make sure you don't forget that this can easily fry your 115 VAC equipment.) By varying the line voltage, not only can you bring up a newly repaired TV gradually to make sure there are no problems but you can also evaluate behavior at low and high line voltage. This can greatly aid in troubleshooting power supply problems. Warning: a Variac is not an isolation transformer and does not help with respect to safety. You need an isolation transformer as well.

- Isolation transformer. This is very important for safely working on live chassis equipment. Since all modern TVs use a line connected power supply, it is essential. You can build one from a pair of similar power transformers back-to-back (with their highest rated secondaries connected together. I built mine from a couple of similar old tube type TV power transformers mounted on a board with an outlet box including a fuse. Their high voltage windings were connected together. The unused low voltage windings can be put in series with the primary or output windings to adjust voltage. Alternatively, commercial line isolation transformers suitable for TV troubleshooting are available for less than $100 - well worth every penny.

- Variable isolation transformer. You don't need to buy a fancy combination unit. A Variac can be followed by a normal isolation transformer. (The opposite order also works. There may be some subtle differences in load capacity.).

CAUTION: Keep any large transformer of this type well away from your monitor or TV. The magnetic field it produces may cause the picture to wiggle or the colors to become messed up - and you to think there is an additional problem!

- Degaussing coil. Make or buy. The internal degaussing coil salvaged from a defunct TV doubled over to half it original diameter to increase its strength in series with a 200 W light bulb for current limiting will work just fine. Or, buy one from a place like MCM Electronics - about $15 for one suitable for all but the largest TVs. Also, see the section: Degaussing (demagnetizing) a CRT.

Safe discharging of capacitors in TVs and video monitors

It is essential - for your safety and to prevent damage to the device under test as well as your test equipment - that large or high voltage capacitors be fully discharged before measurements are made, soldering is attempted, or the circuitry is touched in any way. Some of the large filter capacitors commonly found in line operated equipment store a potentially lethal charge.

This doesn't mean that every one of the 250 capacitors in your TV need to be discharged every time you power off and want to make a measurement. However, the large main filter capacitors and other capacitors in the power supplies should be checked and discharged if any significant voltage is found after powering off (or before any testing - the CRT capacitance in a TV or video monitor, for example, can retain a dangerous or at least painful charge for days or longer!)

The technique I recommend is to use a high wattage resistor of about 5 to 50 ohms/V of the working voltage of the capacitor. This isn't critical - a bit more or less will be fine but will affect the time it takes to fully discharge the capacitor. The use of a current limiting resistor will prevent the arc-welding associated with screwdriver discharge but will have a short enough time constant so that the capacitor will drop to a low voltage in at most a few seconds (dependent of course on the RC time constant and its original voltage).

Then check with a voltmeter to be double sure. Better yet, monitor while discharging (not needed for the CRT - discharge is nearly instantaneous even with multi-M ohm resistor).

Obviously, make sure that you are well insulated!

- For the main capacitors in a TV or monitor power supply which might be 400 uF at 200 V, this would mean a 5K, 10W resistor. RC = 2 seconds. 5RC = 10 seconds. A lower wattage resistor can be used since the total energy in not that great. If you want to be more high tech, you can build the capacitor discharge circuit outlined in the companion document: Capacitor Testing, Safe Discharging, and Other Related Information. This provides a visible indication of remaining charge and polarity.

- For the CRT, use a several M ohm resistor good for 30 kV or more (or a string of lower value resistors to obtain this voltage rating). A 1/4 watt job will just arc over! Discharge to the chassis ground connected to the outside of the CRT - NOT SIGNAL GROUND ON THE MAIN BOARD as you may damage sensitive circuitry. The time constant is very short - a ms or so. However, repeat a few times to be sure, then use a shorting clip as these capacitors have a way of recovering a painful charge if left alone - there have been too many stories of painful experiences from charge developing for whatever reasons ready to bite when the HV lead is reconnected.

  Note that if you are touching the little board on the neck of the CRT, you may want to discharge the HV even if you are not disconnecting the fat red wire - the focus and screen (G2) voltages on that board are derived from the CRT HV.

  WARNING: Most common resistors - even 5 W jobs - are rated for only a few hundred volts and are not suitable for the 25 kV or more found in modern TVs and monitors. Alternatives to a long string of regular resistors are a high voltage probe or a known good focus/screen divider network. However, note that the discharge time constant with these may be a few seconds. Also see the section: Additional information on discharging CRTs.

  If you are not going to be removing the CRT anode connection, replacing the flyback, or going near the components on the little board on the neck of the CRT, I would just stay away from the fat red wire and what it is connected to including the focus and screen wires. Repeatedly shoving a screwdriver under the anode cap risks scratching the CRT envelope which is something you really do not want to do.

Again, always double check with a reliable voltmeter!

Reasons to use a resistor and not a screwdriver to discharge capacitors:

1. It will not destroy screwdrivers and capacitor terminals.

2. It will not damage the capacitor (due to the current pulse).

3. It will reduce your spouse's stress level in not having to hear those scary snaps and crackles.

Additional information on discharging CRTs

You may hear that it is only safe to discharge from the Ultor to the Dag. So, what the @#$% are they talking about? :-).

(From: Asimov (mike.ross@juxta.mnet.pubnix.ten).)

'Dag' is short for Aquadag. It is a type of paint made of a graphite pigment which is conductive. It is painted onto the inside and outside of picture tubes to form the 2 plates of a high voltage filter capacitor using the glass in between as dielectric. This capacitor is between .005uF and .01uF in value. This seems like very little capacity but it can store a substantial charge with 25,000 volts applied.

The outside "Dag" is always connected to the circuit chassis ground via a series of springs, clips, and wires around the picture tube. The high voltage or "Ultor" terminal must be discharged to chassis ground before working on the circuit especially with older TV's which didn't use a voltage divider to derive the focus potential or newer TV's with a defective open divider.

CAUTION: The Dag coating/springs/clips/etc. may not be the same as signal ground on the mainboard. Discharging to that instead could result in all sorts of expensive blown components. Discharging between the CRT anode cap and Dag should be low risk though it is best to use a HV probe or properly rated high value resistor.

For more details, see the document: [TV and Monitor CRT (Picture Tube) Information](#).

Removing the CRT HV connector

WARNING: Make sure the CRT has been discharged FIRST!

The rubber part is usually not glued down so it can be lifted rather easily. However, there may be some silicone type grease between the rubber boot (that looks like a suction cup) and the CRT glass to seal out dust.

A metal clip with a spring keeping it spread out attaches inside the button.

While there are a variety of types of clips actually used, pushing the connector to one side and/or squeezing it in the appropriate direction (peel up one side of the rubber to inspect) while gently lifting up should free it. Probably :-).

The clip (when removed) and CRT button look sort of like this:

```
                       ||======= HV Cable
                       /\
               Clip   |  |
          (Removed)  _|  |_
                                (No DAG coating in vicinity of HV connector)
        ____________.-    -.____________
  CRT   ____________|______|____________ Glass
                  Metal Button
```

Replacement is done in reverse order!

This isn't rocket science and excessive force should not be needed! :-)

Safe troubleshooting techniques for line powered TVs

TVs are particularly dangerous with respect to troubleshooting due to the fact that a substantial portion of their circuitry - sometimes all of it - is directly line connected. Even if your are working in a totally unrelated area like the sound circuits, awareness of the general design and location of the line-connected circuits can prove to be a life saver.

These designs may take several forms:

> Separate switchmode power supply (SMPS). In this case, only the primary side of the power supply is line connected. The remainder of the TV is usually isolated from the line by the high frequency transformer and

feedback device (transformer or optoisolator) of the switchmode power supply.

1. On-board SMPS - a portion of the circuitry on the mainboard is directly line-connected. In the best case, this is restricted to the area around the power cord connections and well marked on both top and bottom but don't count on it. Again, the rest of the TV may be isolated but avoiding hazardous areas is more difficult especially in cramped quarters.

2. Flyback derived power supply - a non-isolated linear (usually) power supply provides B+ to the horizontal deflection (and startup circuit). All other system power is derived from secondary windings on the flyback transformer. Similar comments to (2) above apply.

(1) to (3) may be found in TVs with A/V inputs and outputs.

4. Full hot chassis - a bridge rectifier/filter capacitor/linear regulator provides some voltages including B+. The flyback secondaries provide the remaining voltages. All share a common return which is at the intersection of two of the diodes of the bridge rectifier. There is no isolation.

   This type of design will usually not be found in a TV where there are external connections (other than the RF antenna/cable connector which can be capacitively isolated and you may actually get an AC reading or even sparks between the RF shield and an earth ground due to this capacitance.)

   WARNING: Never attempt to add A/V inputs or outputs to such a TV as the signals and shields will be electrically live.

   However, some TVs with A/V inputs/outputs actually had a live chassis and used an isolated means of coupling the signals from/to the external jacks:

   (From: Bill Coffel (bc@datamix.com).)

   The late 70's and early 80's Sony CVM 1250/1750/2150 (12"/17"/21") monitors (TV) have a HOT chassis. In fact they are kV-1201/1701/2101 TV sets in larger cabinet With a 3 prong plug!!!! The inputs and outputs are isolated via opto couplers and transformers on an additional circuit board (about 6" by 8" and powered by a small transformer) the connector panel is the only part grounded via the third prong.

   If someone thinks its not a live chassis they are in for quite a shock.

Always use an isolation transformer, whatever kind of design is used in the equipment you are troubleshooting. There are very few situations in which an isolation transformer will hurt. If you use it automatically, you will never have a chance to screw up.

Identify the appropriate ground point (return) for your multimeter or scope. These should be marked in the Sams' Photofact or service manual. There may be several such returns such as: non-isolated, signal, and CRT. Selecting the wrong one - even momentarily connecting to it - can ruin your whole day.

If you are not using an isolation transformer (a no-no), connecting your scope to the wrong ground point can result in (1) blown fuses and/or blown parts, and a very dangerous situation and (2) readings that don't make sense generally with distorted power line frequency signals of high amplitude.

- Use the non-isolated ground (A) (with your isolation transformer on the TV *only* for measurements of voltage on the line-connected power supply.

- Use the signal ground (B) for all measurements of tuner, IF, video, and sound circuits.

Whenever you get a reading or waveform that is grossly wrong, confirm that you are using the proper ground point! Note that failures of fusable resistors in the *return* of the HOT or power supply chopper or elsewhere can also result in points that should be near ground floating at unexpected voltage levels.

The general arrangement of components for a typical TV using a linear B+ supply with isolated auxiliary supplies for the signal circuits is shown below including the (linear) line-connected power supply, horizontal deflection output (drive, horizontal output transistor, flyback), and a typical Aux power supply output.

```
    Line fuse   Main bridge                            Part of flyback
          _      rectifier    +----------+  B+           transformer
    H o--_ --+------|>|---+---|          |-----------------+            Aux 1
             |            |   | Filter,  |                  ):: +--|>|--+--o
             |  +---|>|---+   | REG, etc.|                  )::(       _|_
  115 VAC    |  |             |          |                  )::(       ---
             +--|---|<|---+   +----------+             +---+ ::(        |
                |         |         |     H-drive      |        +-------+ B
 +-> N o---------+---|<|---+---------+   transformer  |/ C             __|__
 |                                A _|_       || +----|    Horizontal   -_-
 +-> G - Power line earth ground   ///        ||(     |\ E Output      Signal
        via building wiring         ^        ||(       |  Transistor  ground
                                    |        || +------+  (HOT)
                                    '               A _|_
                             Non-isolated return --> ///
                              (connected points)
```

For this power supply, what if?:

1. You connect your scope ground clip to the non-isolated ground (A) and you are *not* using an isolation transformer?

   Answer: you blow the line fuse and/or melt your scope probe ground lead. Other parts may be damaged as well. In effect, you have just shorted across the bottom diode of the bridge.

2. You attempt to monitor a video signal with your scope ground connected to the non-isolated ground (A)?

   Answer: you see only a highly distorted power line waveform of roughly 100 V p-p In effect, you are measuring across one of the diodes of the bridge rectifier, stray capacitance, etc.

The series light bulb trick

When powering up a TV (or any other modern electronic devices with expensive power semiconductors) that has had work done on any power circuits, it is desirable to minimize the chance of blowing your newly installed parts should there still be a fault. There are two ways of doing this: use of a Variac to bring up the AC line voltage gradually and the use of a series load to limit current to power semiconductors.

Actually using a series load - a light bulb is just a readily available cheap load - is better than a Variac (well both might be better still) since it will limit current to (hopefully) non-destructive levels.

What you want to do is limit current to the critical parts - usually the horizontal output transistor (HOT). Most of the time you will get away with putting it in series with the AC line. However, sometimes, putting a light bulb directly in the B+ circuit will be needed to provide adequate protection. In that location, it will limit the current to the HOT from the main filter capacitors of line connected power supplies. This may also be required with some switchmode power supplies as they can still supply bursts of full (or excessive) current even if there is a light bulb in series with the AC line.

Actually, an actual power resistor is probably better as its resistance is constant as opposed to a light bulb which will vary by 1:10 from cold to hot. The light bulb, however, provides a nice visual indication of the current drawn by the circuit under test. For example:

- Full brightness: short circuit or extremely heavy load - a fault probably is still present.

- Initially bright but then settles at reduced brightness: filter capacitors charge, then lower current to rest of circuit. This is what is expected when the equipment is operating normally. There could still be a problem with the power circuits but it will probably not result in an immediate catastrophic failure.

- Pulsating: power supply is trying to come up but shutting down due to overcurrent or overvoltage condition. This could be due to a continuing fault or the light bulb may be too small for the equipment.

Note: for a TV or monitor, it may be necessary (and desirable) to unplug the degauss coil as this represents a heavy initial load which may prevent the unit from starting up with the light bulb in the circuit.

The following are suggested starting wattages:

- 40 W bulb for VCR or laptop computer switching power supplies.
- 100 W bulb for small (i.e., B/W or 13 inch color) TVs.
- 150 to 200 W bulb for large color or projection TVs.

A 50/100/150 W (or similar) 3-way bulb in an appropriate socket comes in handy for this but mark the switch so that you know which setting is which!

Depending on the power rating of the equipment, these wattages may need to be increased. However, start low. If the bulb lights at full brightness, you know there is still a major fault. If it flickers or the TV (or other device) does not quite come fully up, then it should be safe to go to a larger bulb. Resist the temptation to immediately remove the series light bulb totally from the circuit at this point - I have been screwed by doing this. Try a larger one first. The behavior should improve. If it does not, there is still a fault present.

Note that some TVs and monitors simply will not power up at all with any kind of series load - at least not with one small enough (in terms of wattage) to provide any real protection. The microcontroller apparently senses the drop in voltage and shuts the unit down or continuously cycles power. Fortunately, these seem to be the exceptions.

Getting inside a TV

You will void the warranty - at least in principle. There are usually no warranty seals on a TV so unless you cause visible damage or mangle the screws, it is unlikely that this would be detected. You need to decide. A TV still under warranty should probably be returned for warranty service for any covered problems except those with the most obvious and easy solutions. Another advantage of using warranty service is that should your problem actually be covered by a design change, this will be performed free of charge. And, you cannot generally fix a problem which is due to poor design!

Getting into a TV is usually quite simple requiring the removal of anywhere from 4 to 16 Philips or 1/4" hex head screws - most around the rear edge of the cabinet or underneath, a couple perhaps in the middle. Disconnect the antenna and/or antenna or cable wiring first as it may stay with catch on the rear cover you are detaching. Reconnect whatever is needed for testing after the cover is removed.

As you pull the cover straight back (usually) and off, make sure that no other wires are still attached. Often, the main circuit board rests on the bottom of the cover in some slots. Go slow as this circuit board may try to come along with the back. Once the back is off, you may need to prop the circuit board up with a block of wood to prevent stress damage and contact with the work surface.

Most TVs can still be positioned stably on any of three sides (left, right, bottom) even without the rear cover. However, some require the cover for mechanical strength or to not easily fall over. Be careful- larger TVs, in particular, are quite heavy and bulky. Get someone to help and take precautions if yours is one of the unstable variety. If need be, the set can usually safely be positioned on the CRT face if it is supported by foam or a folded blanket.

Reassemble in reverse order. Getting the circuit board to slide smoothly into its slots may take a couple of attempts but otherwise there should be no surprises.

Specific considerations before poking around inside a TV or monitor

Both electrical and mechanical dangers lurk:

- Main filter capacitor(s). This is the most dangerous (not the HV as you would expect). Fortunately, these capacitors will normally discharge in a few minutes or less especially if the unit is basically working as the load will normally discharge the capacitors nearly fully as power is turned off. With TVs, the main filter capacitor is nearly always on the mainboard. Monitors are more likely to have a separate power supply module.

  However, you should check across this capacitor - usually only one and by far the largest in the set - with a voltmeter and discharge as suggested in the section: Safe discharging of capacitors in TVs and video monitors if it holds more than a few volts (or wait longer) before touching anything.

  Some of these are as large as 1,000 uF charged to 160 V - about 13 w-s or a similar amount of energy as that stored in an electronic flash. This is enough to be potentially lethal under the wrong circumstances.

- High Voltage capacitor formed by the envelope of the CRT. It is connected to the flyback transformer by the fat (usually red) wire at the suction cup (well, it looks like one anyhow) attached to the CRT. This capacitor can hold a charge for quite a while - weeks in the case of an old tube type TV!

  If you want to be doubly sure, discharge this also. However, unless you are going to be removing the HV connector/flyback, it should not bother you.

  The energy stored is about 1 w-s but if you touch it or come near to an exposed terminal, due to the high voltage, you will likely be handed *all* the energy and you *will* feel it. The danger is probably more in the collateral damage when you jump ripping flesh and smashing your head against the ceiling.

  Some people calibrate their jump based on voltage - about 1 inch/V. :-).

  There will be some HV on the back of the circuit board on the neck of the CRT but although you might receive a tingle but accidentally touching the focus or screen (G2) pins, it is not likely to be dangerous.

- CRT implosion risk. Don't hammer on it. However, it is more likely that you will break the neck off the tube since the neck is relatively weak. This will ruin your whole day and the TV or monitor but will likely not result in flying glass everywhere. Just, don't go out of your way to find out.

- Sharp sheet metal and so forth. This is not in itself dangerous but a reflex reaction can send your flesh into it with nasty consequences.

Dusting out the inside of a TV

The first thing you will notice when you remove the cover is how super dusty everything is. Complements to the maid. You never dreamed there was that much dust, dirt, and grime, in the entire house!

Use a soft brush (like a new paintbrush) and a vacuum cleaner to carefully remove the built up dust. Blowing off the dust will likely not hurt the TV unless it gets redeposited inside various controls or switches but will be bad for your lungs - and will spread it all over the room. Don't turn anything - many critical adjustments masquerade as screws that just beg to be tightened. Resist the impulse for being neat and tidy until you know exactly what you are doing. Be especially careful around the components on the neck of the CRT - picture tube - as some of these are easily shifted in position and control the most dreaded of adjustments - for color purity and convergence. In particular, there will be a series of adjustable ring magnets. It is a good idea to mark their position in any case with some white paint, 'white out', or a Magic Marker so that if they do get moved - or you move them deliberately, you will know where you started.

Troubleshooting a TV with the mainboard disconnected

There are times when it is desirable to remove the chassis or mainboard and work on it in a convenient location without having to worry about the equipment which will simulate the critical functions but this is rarely an option for the doit-yourselfer.

My approach is usually to do as much work as possible without removing the main board and not attempt to power it up when disconnected since there are too many unknowns. Professionals will plug the chassis into a piece of equipment which will simulate the critical functions.

Note that if you have a failure of the power supply - blown fuse, startup, etc., then it should be fine to disconnect the CRT since these problems are usually totally unrelated. Tests should be valid.

However, if you really want to do live testing with the main board removed, here are some considerations. There are usually several connections to the CRT and cabinet:

- Deflection yoke - since the horizontal coils are part of the horizontal flyback circuit, there could be problems running without a yoke. This could be anything from it appearing totally dead to an overheating or blown horizontal output transistor. There may be no problems. Vertical and any convergence coils may or may not be problems as well.

- CRT video Driver board - pulling this should not usually affect anything except possibly video output and bias voltages.

- CRT 2nd anode - without the CRT, there will be no capacitor to filter the high voltage and you would certaily want to insulate the HV connector **real** well. I do not know whether there are cases where damage to flyback could result from running in thie manner, however.

- Front panel controls - disconnecting these may result in inability to even turn the set on, erratic operation, and other unexpected behavior.

- Degauss - you just won't have this function when disconnected. But who cares - you are not going to be looking at the screen anyhow.

- Remote sensor - no remote control but I doubt that the floating signals will cause problems.

- Speakers - there will be no audio but this should not cause damage.

If you do disconnect everything, make sure to label any connectors whose location or orientation may be ambiguous. Most of the time, these will only fit one way but not always.

TV Adjustments

These include both controls accessible to the user (and often not understood) as well as internal adjustments that may need to be touched up due to the aging of components or following a repair.

User picture adjustment

For general viewing, subdued lighting but not total darkness is probably best. However, for most dramatic impact, a darkened environment may be preferred. Make the following adjustments under the expected viewing conditions.

Tune to a strong channel or play a good quality tape.

Turn the brightness, contrast, and color controls all the way down. Center the tint control (NTSC, may not be present on PAL sets).

Increase the brightness until a raster is just visible in the darkest (shadow) areas of the picture and then back off until it **just** disappears.

Increase the contrast until the desired intensity of highlights is obtained.

Since brightness and contrast are not always independent, go back and forth until you get the best picture.

Initially adjust the color control for pastel shades rather than highly saturated color. Set the tint control for best flesh tones. Then, increase the color control to obtain the desired degree of color saturation.

Internal adjustments

All of the service adjustments are accomplished either using controls inside the set (though some may be accessible by holes in the rear of the cabinet). These are usually pots on the mainboard and CRT neck boards, or in newer TVs, mostly via a service menu accessed from the remote or by using a manufacturer specific computer interface.

A Web site with some information on the general objectives of video and color setup procedures for both direct view and projection TVs is Tru-line Video Technologies.

- Where actual pots are present, they may be labeled on the circuit boards or identified by a sticker on the TV's cover. Otherwise, the service manual or Sams' for the set will be required unless their function of the relevant pot is obvious.

- For service menus accessed via the remote control, service information is almost a necessity since adjustment procedures vary widely and it is all too easy to totally mess things up - even to the point of inflicting serious and expensive damage to the set.

For information on accessing the service menus if used on your model, see the section: Setup adjustments lost - TV service codes. However, even if the access procedure is known, get the service manual or Sams'!

- If a computer interface is required, you can most probably forget about attempting to adjust anything unless you find a friendly shop to provide the adapter and walk you through the procedure. Why would they want to do this? Because they know you there is a good chance that you will have to pay them to unscramble the mess you created!

Focus adjustment

On a decent TV, you should be able to make out the individual scanning lines. If they are fuzzy, especially in bright areas, then focus may need to be adjusted.

The focus pot is usually located on the flyback transformer or on an auxiliary panel nearby. Where there are two adjustment knobs on the flyback transformer, the top one is generally for focus and the bottom one is for G2.

The focus wire usually comes from the flyback or the general area or from a terminal on a voltage the multiplier module (if used). It is usually a wire by itself going to the little board on the neck of the CRT.

Let the set warm up for at least half an hour. Display a good quality signal. Turn the user color control all the way down and the brightness and contrast controls all the way up. This will be the worst case. Adjust the focus control for best overall sharpness - you may not be able to get it perfect everywhere - center as well as corners. If best focus is at one end of the focus pot's range and still not good enough, there may be a problem in the focus divider, focus pot, or some related component.

Adjustment of the internal SCREEN and color controls

The screen should be adjusted with a white pattern (snow from the tuner should do or turn the user COLOR control all the way down to get a black and white picture). Put the set in Service mode (horizontal line) if it has such a switch in the back or inside. If not, just use the raster in a darkened room. Adjust screen for a dim white line (raster). If the line is not white at its dimmest point, you will need to adjust the drive and cutoff controls for R, G, & B.

Alternatively, you can use the following procedure:

Turn R, G, and B screen (or background) controls down. Now turn color control fully counterclockwise -- off. Now turn up red screen until the screen just shows a red hue. Now turn red gun down until red tint just goes away. Now do the same with the green and blue screen controls. Now adjust the two DRIVE controls for the best black and white picture. That`s all there is to it. I don`t like to work with just a thin "SETUP" line. Cartoons seem to be the best thing to have on while doing the above procedure. You can also use just plain snow (no program) if you prefer. If you can obtain a good b@w pic. when you`re done, the tube is good and the set if most likely functioning properly. Be patient and go slow while watching the large mirror that you are using during this procedure. (LEE)

Optimal procedure for setting brightness/background and screen adjustments

For slight tweaks, the following is not necessary. However, if someone turned all the internal controls or if you are making significant changes that affect G2 (screen), then following the procedure below is desirable to achieve best performance and maximize life of the CRT.

The typical user controls - brightness and contrast can, of course, be set arbitrarily, depending on video content and ambient lighting conditions.

Set the user brightness and contrast controls in the middle for the following adjustments and let the set warm up for 20 minutes or so.

(From: Jeroen H. Stessen (Jeroen.Stessen@philips.com).)

Now the screen control, that's another matter. It sets the voltage on the second grid of the electron guns, typically between +500 and +1000 V. You will want to use a well-isolated screwdriver for that if it is a naked potentiometer. In the old days there used to be 3 separate potentiometers for 3 G2s, now there is generally only one.

Its purpose is to set the cutoff voltage for the guns, i.e. the voltage between K and G1 at which the beam is just off. The higher you set the VG2, the higher VK - VG1 must be to cut off the beam.

If you set VG2 too low then your picture will be dark. You can compensate for that with the brightness control, which in effect will lower the VKs. A disadvantage is that you will not get optimum sharpness and peak brightness from your picture tube.

If you set VG2 too high then your picture will be bright. You can compensate for that with the brightness control, which in effect will raise the VKs. You might even get retrace lines which can usually not be made to disappear with the brightness control. Another disadvantage is that you will not get optimum LIFETIME from your picture tube. With a too high cutoff voltage the cathode (electron emitting surface) will wear out too soon.

You will need to see the picture tube specifications (or possibly the Sams' Photofact or service manual for the set --- sam) in order to find the correct setting for the cutoff voltage. This is measured as VK - VG1 (for each channel RGB) and is typically 130-160 V max. There will be spread between the 3 channels, typically the highest of the 3 measured values will be set against the upper limit.

The usual adjustment procedure is as follows:

- Use any low-level adjustments to set a black picture with all 3 cathode voltages at the specified level (e.g. 130 V) above the VG1 voltage (may be 0 V or 12 V or 20 V ?). (These are typically called RGB brightness, bias, or background level and are often on the little board on the neck of the CRT but not always --- sam).

- Adjust VG2 (screen) until one colour just starts too light up, turn it back down until the screen is just black again. (Occasionally, there are two G2 controls - one on the flyback and another on the CRT neck board or elsewhere. If so, they control are basically in series - leave the one on the flyback alone if the other one has enough range.)

- Now adjust 2 of the 3 low-level black controls until the other 2 colours just light up, and then back to black again.

- Select a white picture and use 2 low-level white (RGB drive or gain, also generally on the neck board --- sam) controls to set the proper colour temperature for white to your own taste.

- Check your black calibration again, may have to iterate a bit.

Color balance adjustment

Color balance needs adjustment if the highlights and/or shadows of a black and white picture (turn the color control all the way down) are not a perfectly neutral gray.

Note: Some TV designs (Zenith uses this in a few models) automatically balance CRT cathode drive by sensing emission from the red, green, and blue guns using a gray scale reference pulse outside the viewable picture. If this is the case with your set, there may be no user OR service adjustments :-(. A color balance problem in this case means either a failure of this circuitry or a CRT where the emission from the 3 cathodes is so unbalanced (usually due to one being much much weaker than the others) that compensation is not possible.

To adjust the color balance: Turn the color control all the way down so that you get what should be a B/W picture. Set the user brightness and contrast controls about mid-range. The tint control should not matter (if it does at this point, you have other chroma problems or an 'autocolor' switch is on limiting the range of some controls).

Adjust the sub-brightness controls (may be called color screen, background, or the like) so that the dark areas of the picture are just visible and neutral gray. Then, adjust the color gain controls until the brightest areas are neutral white but not so bright that there is 'color bleeding' in the highlights.

This should get you close. If something is still shifting after warmup and get some cold-spray or even a little blower and try to locate the component that is drifting. Most likely a transistor or capacitor.

More on 'Calibrating' TV color

If you don't know how to access the color and tint controls on your TV and are happy with green flesh tones and cartoon colors, you can skip this section. Most people can adjust their color and tint controls resulting in a reasonable hue and saturation. However, here are some ways of getting closer to perfection.

(From: Chris Johnson (wjohnson@palmnet.net).)

If you have access to a DVD player, get the 'Video Essentials' DVD and follow the directions.

If you have access to a LaserDisc player, get 'A Video Standard' and follow the directions.

But, here are a few quick pointers:

Back off the color control all the way on a program. Set the color balance for a true grey appearance without any bias toward red, green, or blue. (Or any other color.)

Max brightness should not be high enough that vertical lines (like the needle pulse on the test LD or DVD) don't bend.

On the test pattern with the multicolored bars, the large bars should have the following colors: white (actually grey, but fairly light), yellow, cyan, green, purple, red, blue.

The purpose of the narrow bars just below the large bars is to match up the tint balance. You do this with a blue filter, or killing the R and G guns. The narrow bars will be exactly the same intensity as the large bars above them, if the color and tint balance is correct.

Here's a quick trick if you're lucky enough to have a set with separate gun killer switches for R, G, and B guns: When properly set, the narrow bars will be the same intensity as the large bars above them, if you only turn one gun on at a time. First do red, then green, then blue. Go through the process once and you'll never forget what it looks like.

Last point: The pluge bar (in the lower right section of the color bar screen) should NOT be visible, being ten percent below black level. If you can see it, back off the brightness.

Remember:

- Brightness sets black level, it should ideally be as black as the screen itself, no more, no less.

- Contrast sets white level. Too bright and vertical lines start to bend.

  Using just these concepts, you can get REAL close to a proper alignment.

Most people set the color too high. News programs should NOT be as colorful as the movie 'Jingle All The Way'. (Which, by the way, is a real test of your TV's abilities.) Most people's faces should not be red.

You know you have it all set right when black clothing on people on TV has texture and depth to it, and also when purple and blue are two distinct colors. Some TV sets don't do that very well as shipped.

Horizontal position, size, and linearity adjustment

Horizontal position may be set via a switch or jumper, a pot, or (mostly in B/W TVs) a set of rings on the CRT neck.

Horizontal size should be set so that there is about 10-15 percent overscan left and right. This will allow ample margin for power line voltage fluctuations, component aging, and the reduction in raster size that may occur with some VCR special effects (fast play) modes.

Many sets no longer have any horizontal size adjustments and depend on accurate regulation of the voltage to the horizontal output stage to control horizontal size. There may be a B+ adjustment to perform first.

On those that do, the adjustment may either be done by setting the B+ voltage, by a pot, or a width coil in series with the horizontal deflection coils.

Modern sets do not generally have any linearity control but you may find this on older models. You will need to go back and forth between size and linearity as these adjustments are usually not independent.

Some of the newest sets control all these parameters via settings in non-volatile memory and use service menus accessed via the remote control for nearly all setup adjustments.

Vertical position, size, and linearity adjustment

Vertical position may be set via a switch or jumper, a pot, or (mostly in B/W TVs) a set of rings on the CRT neck.

Vertical size should be set so that there is about 10-15 percent overscan top and bottom. This will allow ample margin for power line voltage fluctuations, component aging, and the reduction in raster size that may occur with some VCR special effects (fast play) modes.

Some sets no longer have any vertical size adjustments and depend on the accurate regulation of the voltage to the vertical output stage to control vertical size.

On those that do, the adjustment is usually a pot in the vertical output circuitry. If your set has a linearity control, you will need to adjust this in conjunction with the size control as these are usually not independent.

Some of the newest sets control all these parameters via settings in non-volatile memory and use service menus accessed via the remote control for nearly all setup.

Pincushion adjustments

There may be two controls - amplitude and phase. Pincushion amplitude as its name implies, controls the size of the correction. Pincushion phase affects where on the sides it is applied. Don't expect perfection.

If the controls have no effect, there is probably a fault in the pincushion correction circuitry.

It is best to make these adjustments with a crosshatch or dot test pattern

Geometry adjustment

This refers to imperfections in the shape of the picture not handled by the pincushion and size adjustments. These types of defects include trapezoidal or keystone shaped raster and jogs or wiggles around the periphery of the raster. Unfortunately, one way these are handled at the factory is to glue little magnets to strategic locations on the CRT and/or rotate little magnets mounted on the yoke frame. Unless you really cannot live with the way it is (assuming there isn't something actually broken), leave these alone! You can end up with worse problems. In any case, carefully mark the position AND orientation of every magnet so that if this happens, you can get back to where you started. If the magnets are on little swivels, some experimenting with them one at a time may result in some improvement. Of course, it is best to obtain a service manual and follow its instructions.

Why is the convergence on my set bad near the edges

Very simple - nothing is quite perfect. Perfect convergence is not even necessarily possible in theory with the set of adjustments available on a typical TV. It is all a matter of compromises. Consider what you are trying to do: get three electron beams which originate from different electron guns to meet at a single point within a fraction of a mm everywhere on the screen. This while the beams are scanning at an effective writing rate of 20,000 mph across the face of a 27" CRT in a variable magnetic environment manufactured at a price you can afford without a second mortgage!

CRT purity and convergence problems

Purity assures that each of the beams for the 3 primary colors - red, green, and blue - strikes only the proper phosphor dots for that color. A totally red scene will appear pure red and so forth. Symptoms of poor purity are blotches of discoloration on the screen. Objects will change shades of color when the move from one part of the screen to another.

Convergence refers to the control of the instantaneous positions of the red, green, and blue spots as they scan across the face of the CRT so that they are as nearly coincident as possible. Symptoms of poor convergence are colored borders on solid objects or visible separate R, G, and B images of fine lines or images,

Note: It is probably best to face the set East-West (front-to-back) when performing any purity and convergence adjustments. Since you probably do not know what orientation will eventually be used, this is the best compromise as the earth's magnetic field will be aligned mostly across the CRT. This will minimize the possible rotation of the picture when the unit is moved to its final position but there may be a position shift. Neither of these is that significant so it probably doesn't really matter that much unless you are super fussy. Of course, if you know the final orientation of the TV in your entertainment center - and you don't expect to be redecorating, use that instead. Or, plan to do the final tilt and position adjustments after the set is in position - but this will probably require access to the inside!

First, make sure no sources of strong magnetic fields are in the vicinity of the TV - loudspeakers, refrigerator magnets, MRI scanners, etc. A nearby lightning strike or EMP from a nuclear explosion can also affect purity.

Cycle power a couple of times to degauss the CRT (1 minute on, 20 minutes off) - see the section: Degaussing (demagnetizing) a CRT. If the built in degaussing circuits have no effect, use an external manual degaussing coil.

Assuming this doesn't help, you will need to set the internal purity and/or convergence adjustments on the CRT. Modern CRTs usually use a combination of a series of magnetized moveable rings on the neck, and yoke position and orientation to set purity and convergence.

First, mark the positions of all adjustments - use white paint, 'White out', or a Magic Marker on the ring magnets on the neck of the CRT, the position and tilt of the deflection yoke, and any other controls that you may touch deliberately or by accident.

However, if your set is still of the type with a drawer or panel of knobs for these adjustments, don't even think about doing anything without a service manual and follow it to the letter unless the functions of all the knobs is clearly marked (some manufacturers actually do a pretty good job of this).

Note: some CRTs do not have any adjustable rings for purity (and static convergence). Either an internal structure in the neck of the CRT or an external 'permalloy' sleeve is permanently magnetized at the factory and there is not way of tweaking it in the field. However, it may be possible to use a normal set of magnet rings in addition to or in place of it to correct for purity or convergence problems due to loss of magnetism due to age or someone waving a 10 pound magnet near the CRT neck!

CRT purity adjustment

Purity on modern CRTs is usually set by a combination of a set of ring magnets just behind the deflection yoke on the neck of the CRT and the position of the yoke fore-aft. As always, mark the starting position of all the rings and make sure you are adjusting the correct set if rings!

Use the following purity adjustment procedure as a general guide only. Depending on the particular model TV, the following purity adjustment procedure may substitute green for red depending on the arrangement of the guns in the CRT. This description is based on the Sams' Photofact for the RCA CTC111C chassis which uses a slot-mask CRT. The procedures for dot-mask and Trinitron (aperture grille) CRTs will vary slightly. See you service manual!

Obtain a white raster (sometimes there is a test point that can be grounded to force this). Then, turn down the bias controls for blue and green so that you have a pure red raster. Let the set warm up for a minimum of 15 minutes.

Loosen the deflection yoke clamp and move the yoke as far back as it will go,

Adjust the purity magnets to center the red vertical raster on the screen.

Move the yoke forward until you have the best overall red purity.

Now, move the yoke forward until you have the best overall red purity. Tighten the clamp securely and reinstall the rubber wedges (if you set has these) to stabilize the yoke position. Reset the video adjustments you touched to get a red raster.

CRT convergence adjustment

In the good old days when TVs were TVs (and not just a picture tube with a little circuit board attached) there were literally drawers full of knobs for setting convergence. One could spend hours and still end up with a less than satisfactory picture. As the technology progressed, the number of electronic adjustments went down drastically so that today there are very few if any.

Unless you want a lot of frustration, I would recommend not messing with convergence. You could end up a lot worse. I have no idea what is used for convergence on your set but convergence adjustments are never quite independent of one another. You could find an adjustment that fixes the problem you think you have only to discover some other area of the screen is totally screwed. In addition, there are adjustments for geometry and purity and maybe others that you may accidentally move without even knowing it until you have buttoned up the set.

Warning: Accurately mark the original positions - sometimes you will change something that will not have an obvious effect but will be noticeable later on. So it is extremely important to be able to get back to where you started. If only red/green vertical lines are offset, then it is likely that only a single ring needs to be moved - and by just a hair. But, you may accidentally move something else!

If you really cannot live with it, make sure you mark everything very carefully so you can get back to your current state. A service manual is essential!

Convergence is set using a white crosshatch or dot test pattern. If you do not have a test pattern generator, any static scene (from a camcorder or previously recorded tape, for example) with a lot of fine detail will suffice. Turn the color control all the way down so you have a B/W picture.

Static convergence sets the beams to be coincident in the exact center of the screen. This is done using a set of ring magnets behind the purity magnets on the CRT neck.

From the Sams' for the RCA CTC111C: "adjust the center set of magnets to converge blue to green at the center of the screen. Adjust the rear set of magnets to converge red to green at the center of the screen." Your set may have a slightly different procedure.

Dynamic convergence adjusts for coincidence at the edges and corners.

On old tube, hybrid, and early solid state TVs, dynamic convergence was accomplished with electronic adjustments of which there may have been a dozen or more that were not independent. With modern sets, all convergence is done with magnet rings on the neck of the CRT, magnets glued to the CRT, and by tilting the deflection yoke. The clamp in conjunction with rubber wedges or set screws assures that the yoke remains in position.

From the Sams' for the RCA CTC111C: "Loosen the screws at the 6 o'clock and 10 o'clock positions to permit the yoke to be tilted vertically. Rock yoke up and down to converge the right and left sides of the screen. Tighten screw at 6 o'clock and loosen screw at 3 o'clock to permit the yoke to be tilted horizontally. Rock yoke from side to side to converge the top and bottom of the screen. Tighten screws at 3 o'clock and 10 o'clock."

Many sets simply use the main clamp which locks the yoke to the neck of the CRT in conjunction with rubber wedges between the yoke and the funnel of the CRT to stabilize the yoke position position.

Refer to your service manual. (Is this beginning to sound repetitious?)

For additional comments on convergence adjustments, see the sections: "Tony's notes on setting convergence on delta gun CRTs" and "Saga and General setup for large CRT TVs".

Tilted picture

You have just noticed that the picture on your fancy (or cheap) TV is not quite horizontal - not aligned with the front bezel. Note that often there is some keystoning as well where the top and bottom or left and right edges of the picture are not quite parallel - which you may never have noticed until now. Since this may not be correctable, adjusting tilt may represent a compromise at best between top/bottom or left/right alignment of the picture edges. You may never sleep again knowing that your TV picture is not perfect! BTW, I can sympathize with your unhappiness. Nothing is more annoying than a just noticeable imperfection such as this. However, since TVs always overscan, the only time you will really notice a minor tilt without going out of your way to look for it is if there is text or graphics near the edge of the screen.

There are several possible causes for a tilted picture:

1. Set orientation. The horizontal component of the earth's magnetic field affects this slgithly. Therefore, if you rotate the TV you may be able to correct the tilt. Of course, it will probably want to face the wall!

   Other external magnetic fields can sometimes cause a rotation without any other obvious effects - have you changed the TV's location? Did an MRI scanner move in next door?

2. Need for degaussing. Most of the time, magnetization of the CRT will result in color problems which will be far more obvious than a slight rotation. However, internal or external shields or other metal parts in the set could become magnetized resulting a tilt. More extensive treatment than provided by the built-in degaussing coil may be needed. Even, the normal manual degaussing procedure may not be enough to get close enough to all the affected parts.

3. You just became aware of it but nothing has changed. Don't dismiss this offhand. It is amazing how much we ignore unless it is brought to our attention. Are you a perfectionist?

4. There is an external tilt control which may be misadjusted. Newer Sony monitors have this (don't know about TVs) - a most wonderful addition. Too bad about the stabilizing wires on Trinitron CRTs. A digital control may have lost its memory accidentally. The circuitry could have a problem.

5. There is an internal tilt control that is misadjusted or not functioning. The existance of such a control is becoming more common.

6. The deflection yoke on the CRT has gotten rotated or was not oriented correctly at the time of the set's manufacture. Sometimes, the entire yoke is glued in place in addition to being clamped adding another complication.

   If the TV was recently bumped or handled roughly, the yoke may have been knocked out of position. But in most cases, the amount of abuse required to do this with the yoke firmly clamped and/or glued would have totally destroyed the set in the process.

   There is a risk (in addition to the risk of frying yourself on the various voltages present inside an operating TV) of messing up the convergence or purity when fiddling with the yoke or anything around it since the yoke position on the neck of the tube and its tilt may affect purity and convergence. Tape any rubber wedges under the yoke securely in place as these will maintain the proper position and tilt of the yoke while you are messing with it. (Don't assume the existing tape will hold - the adhesive is probably dry and brittle).

7. The CRT may have rotated slightly with respect to the front bezel. Irrespective of the cause of the tilt, sometimes it is possible to loosen the 4 (typical) CRT mounting screws and correct the tilt by slightly rotating the CRT. This may be easier than rotating the yoke. Just make sure to take proper safety precautions when reaching inside!

B/W TV size, position, and geometry adjustments

These tend to be a lot simpler and less critical than for color monitors or TV sets.

On a B/W TV you will probably see some of the following adjustments:

1. Position - a pair of rings with tabs on the neck of the CRT. There may be electronic position adjustements as well though this is not that common on small TVs.

2. Width and height (possibly linearity as well) controls. There may be some interaction between size and linearity - a crosshatch test pattern is best for this. Vertical adjustments are almost always pots while horizontal (if they exist) may be pots and/or coils. Size will normally be set for 5-10% overscan to account for line voltage fluctuations and

component drift. Confirm aspect ratio with test pattern which includes square boxes.

3. Geometry - some little magnets either on swivels around the yoke or glued to the CRT. If these shifted, the the edges may have gotten messed up - wiggles, dips, concave or convex shapes. There may be a doxen or more each mostly affecting a region around the edge of the raster. However, they will not be totally independent.

Check at extremes of brightness/contrast as there may be some slight changes in size and position due to imperfect HV regulation.

There may be others as well but without a service manual, there is no way of knowing for sure. Sams' often has folders for B/W TVs.

Just mark everything carefully before changing - then you will be able to get back where you started.

Low Voltage Power Supply Problems

Low voltage power supply fundamentals

TVs require a variety of voltages (at various power levels) to function. The function of the low voltage power supply is to take the AC line input of either 115 VAC 60 Hz (220 VAC 50 Hz or other AC power in Europe and elsewhere) and produce some of these DC voltages. In all cases, the power to the horizontal output transistor of the horizontal deflection system is obtained directly from the low voltage power supply. In some cases, a variety of other DC voltages are derived directly from the AC line by rectification, filtering, and regulation. In other designs, however, most of the low voltages are derived from secondary windings on the flyback (LOPT) transformer of the horizontal deflection system. In still other designs, there is a separate switchmode power supply that provides some or all of these voltages. There are also various (and sometimes convoluted) combinations of any or all of the above.

There will always be:

1. A power switch, relay, or triac to enable main power.

2. A set of rectifiers - usually in a bridge configuration - to turn the AC into DC. Small ceramic capacitors are normally placed across the diodes to reduce RF interference.

3. One or more large filter capacitors to smooth the unregulated DC. In the U.S., this is most often a voltage around 150-160 V DC. In countries with 220 VAC power, it will typically be around 300-320 V DC.

4. A discrete, hybrid, or IC regulator to provide stable DC to the horizontal deflection system. Sometimes feedback from a secondary output of the flyback or even the high voltage is used. This regulator may be either a linear or switching type. In some cases, there is no regulator.

5. Zero or more voltage dividers and/or regulators to produce additional voltages directly from the line power. This relatively rare except for startup circuits. These voltages will not be isolated from the line.

6. A degauss control circuit usually including a thermistor or Posistor (a combination of a heater disk and Positive Temperature Coefficient (PTC) thermistor in a single package). When power is turned on, a relatively high AC current is applied to the degauss coil wrapped around the periphery of the CRT. The PTC thermister heats up,

increases in resistance, and smoothly decreases the current to nearly zero over a couple of seconds.

7. A startup circuit for booting the horizontal deflection if various voltages to run the TV are derived from the flyback. This may be an IC or discrete multivibrator or something else running off a non-isolated voltage or the standby power supply.

8. A standby power supply for the microcontroller and remote sensor. Usually, this is a separate low voltage power supply using a small power transformer for line isolation. However, some sets use other (probably cheaper) approaches. See below.

Always use an isolation transformer when working on a TV but this is especially important - for your safety - when dealing with the non-isolated line operated power supply. Read and follow the information in the section: Safety guidelines.

Standby power supplies

Where the TV has a remote control (which most do nowadays), there needs to be some source of voltage(s) for the remote receiver, microcontroller, and other circuitry that watch for the 'power on' commend. These sets are never totally off.

The standby supply may consist of:

- A low voltage power transformer feeding one or more sets of rectifiers, filter capacitors, and possibly regulators.

  A power surge could cause the primary of the transformer to open up. There may also be a thermal fuse under the outer layers of insulation which blew either due to overheating or a power surge. However, if the primary is open, it is best to replace the transformer rather than attempting repair it.

- One or more voltage dividers connected directly to the AC line feeding rectifiers, filter capacitors, and possibly regulators.

  Open resistors and dried up capacitors are common failures since the resistors are often not rated adequately and run hot, in close proximity to the capacitors.

- A portion of the main (switchmode) power supply that runs all the time.

  Failures could be almost anything that would affect normal operation of the power supply as well as problems with the control circuitry.

Typical TV power supply front end

The partial schematic below is similar to those found in the majority of TVs sold in countries with 110 to 120 VAC power. Many parts are not shown including the power switch or relay, RFI bypass capacitors across the rectifier diodes, and RFI line filter.

```
                                          Bypass resistor
     Line fuse    Main bridge  Fusable    +----/\/\-----+
           _       rectifier   resistor   |   +-----+   |
     H o--_ --+------|>|---+---/\/\--+---+---| REG |---+---+---o B+
              |            |         |       +-----+       |
              |  +---|>|---+      C1 _|_ Main    |         _|_ Regulator
   115 VAC    |  |           400 uF --- filter  |         --- output
```

```
              +--|---|<|---+  200 V  |  cap     |          |  capacitor
                 |         |         |          |          |
 +-> N o---------+---|<|---+---------+----------+----------+---o Non-isolated
 |                                                                  return
 +-> G - Power line earth ground via building wiring
```

- The line fuse is typically 2 to 4 A, usually a normal fast blow type. Even so, it may not blow as a result of faults down the line - the fusable resistor or regulator may fail first.

- The main bridge rectifier is often composed of 4 discrete diodes (similar to 1N400Xs) but may also be a single unit. Failures - usually shorted diodes - are common.

- The main filter capacitor can range in size from 200 to 800 uF or more at 200 to 250 V. THIS CAN BE LETHAL! A typical TV may continue to work at normal line voltage without any noticeable degradation in performance (hum bars, hum in sound, or shutdown) even if this capacitor is reduced in value by 75%. Its uF value is therefore not critical.

- The regulator is often an IC or hybrid module. Failures resulting in no or reduced output, or no regulation are common.

- The regulator output capacitor is needed for the B+ regulator to function properly. If this capacitor is reduced in value or develops a high ESR, regulation may fail resulting in instability, oscillation, or excessive B+ and shutdown.

- The regulator bypass resistor reduces the amount of current control needed of the regulator. Caution: even if the regulator has been pulled, the B+ line will have substantial voltage as a result of this resistor.

Totally dead set

This can be as simple as a bad outlet (including blown fuse or tripped circuit breaker due to some other fault), switched outlet and the switch is off, or bad cordset.

- Plug a lamp into the outlet to make sure it is live. If the lamp works, then the problem is the TV. It not, the outlet is defective or the fuse is blown or the circuit breaker is tripped. There is another very simple explanation that is sometimes overlooked: This is a switched outlet. You always wondered what that wall switch was for that didn't seem to do anything and you flipped randomly. :-) Well, now you know!

- Try wiggling the TV's cord both at the outlet (also push the wire toward the plug) and TV (also push the cord toward the TV) with the set on and/or while pressing the power-on button. If you can get a response, even momentarily, the cord likely has broken wires internally.

Beyond these basic causes, troubleshooting will be needed inside the set to determine what is defective. Also see the section: Intermittently dead set - bad cordset.

Intermittently dead set - bad cordset

There are two problems which are common with the line cord on appliances. Don't overlook these really simple things when troubleshooting your vacuum cleaner - or fancy electronic equipment! If wiggling the cord has an effect, then the following are likely causes:

- Repeated flexing results in the internal conductors breaking either at the plug or appliance end. If flexing the cord/squeezing/pulling results in the device going on and off, it is bad. If the problem is at the plug end, cut off the old plug a couple of inches beyond the problem area and replace just he plug. If the problem is at the appliance end, an entire new cordset is best though you can probably cut out the bad section and solder what remains directly to the mainboard.

In either case, observe the polarity of the cord wires - they will be marked in some way with a ridge or stripe. It is important that the new plug be of the same type (polarized usually) and that the cord is wired the same way.

- The prongs do not fit snugly into older worn outlets. This can usually be remedied by using a pointed tool like an awl or utility knife to spread apart the pair of leaves often used to form each prong of the plug. If the prongs are made of solid metal, it may be possible to spread them apart - widen the space between them. Alternatively, get a 3 to 2 prong adapter just to use as an intermediate connector. Spread the leaves of its prongs. However, a new outlet is best.

- Bad connections on the mainboard. As you flex the cord, it is also stressing the attachment to the mainboard and affecting some marginal solder joints.

It is important to deal with these symptoms as soon as possible as erratic power cycling can lead to much more serious and expensive problems down the road.

Power button on set is flakey

If the on/off (or other button) on the set itself behaves erratically but the remote control works fine, then it could be a dirty button or cable or other connections to the switch PCB, particularly if the buttons on the set itself are rarely used. There could possibly be a bad pullup resistor or something of that sort - but is it worth the effort to locate?

Why not just continue to use the remote? There is no reason to suspect that it will develop similar symptoms. However, there is some risk that if the button is dirty, you may find the TV coming on at random times in the middle of the night (of course!).

I think I have an older Sylvania that does that sort of thing - don't really know as I never use the power button on the set!

If power is controlled by a hard switch - a pull or click knob, or mechanical push-push switch and this has become erratic due to worn contacts, replacements are available but often only directly from the original manufacturer to physically fit and (where applicable) have the volume or other controls built in. As an alternative, consider mounting a small toggle switch on the side of the cabinet to substitute for the broken switch. This will almost certainly be easier and cheaper - and quite possibly, more reliable.

TV blows fuse

A blown fuse is a very common type of fault due to poor design very often triggered by power surges due to outages or lightning storms. However, the most likely parts to short are easily tested, usually in-circuit, with an ohmmeter and then easily removed to confirm.

Note that it *may be* useful to replace a fuse the *first* time it blows (though it would be better to do some basic checks for shorted components first as there is a small chance that having a fuse blow the second time could result in additional damage which would further complicate the troubleshooting process). However, if the new one blows, there is a real problem and the only use in feeding the TV fuses will be to keep the fuse manufacturer in business!

Sometimes, a fuse will just die of old age or be zapped by a power surge that caused no damage to the rest of the TV. However, it must be an EXACT replacement (including slo-blow if that is what was there originally). Else, there could be safety issues (e.g., fire hazard or equipment damage from too large a current rating) or you could be chasing a non-existent problem (e.g., if the new fuse is not slo-blow and is blown by the degauss circuit inrush current but nothing is actually wrong).

If the fuse really blows absolutely instantly with no indication that the circuits are functioning (no high pitched horizontal deflection whine (if your dog hides under the couch whenever the TV is turned on, deflection is probably working).) then this points to a short somewhere quite near the AC power input. The most common places would be:

- Degauss Posistor - very likely.
- Horizontal output transistor.
- Power supply regulator if there is one.
- Power supply chopper (switchmode) transistor if there is one.
- Diode(s) in main bridge
- Main filter capacitor(s).

You should be able to eliminate these one by one.

Unplug the degauss coil as this will show up as a low resistance.

First, measure across the input to the main power rectifiers - it should not be that low. A reading of only a few ohms may mean a shorted rectifier or two or a shorted Posistor.

- Test the rectifiers individually or remove and retest the resistance.

- Some sets use a Posistor for degauss control. This is a little cubical (about 1/2" x 3/4" x 1") component with 3 legs. It includes a line operated heater disk (which often shorts out) and a PTC thermister to control current to the degauss coil. Remove the posistor and try power. If the monitor now works, obtain a replacement but in the meantime you just won't have the automatic degauss.

If these test good, use an ohmmeter with the set unplugged to measure the horizontal output transistor. Even better to remove it and measure it.

- C-E should be high in at least one direction.
- B-E may be high or around 50 ohms but should not be near 0.

If any readings are under 5 ohms, the transistor is bad. The parts sources listed at the end of this document will have suitable replacements.

If the HOT tests bad, try powering the set first with your light bulb and if it just flashes once when the capacitor is charging, then put a fuse in and try it. The fuse should not blow with the transistor removed.

Of course, not much else will work either.

If it tests good, power the set without the transistor and see what happens. If the fuse does not blow, then with the good transistor (assuming it is not failing under load), it would mean that there is some problem with the driving circuits possibly or with the feedback from the voltages derived from the horizontal not regulating properly.

Look inside the TV and see if you can locate any other large power transistors in metal (TO3) cans or plastic (TOP3) cases. There may be a separate transistor that does the low voltage regulation or a separate regulator IC. Some TVs have a switchmode power supply that runs off a different transistor than the HOT. There is a chance that one of these may be bad. If it is a simple transistor, the same ohmmeter check should be performed.

If none of this proves fruitful, it may be time to try to locate a schematic.

A blown fuse is a very common type of fault due to poor design very often triggered by power surges due to outages or lightning storms. However, the most likely parts to short are easily tested, usually in-circuit, with an ohmmeter and then easily removed to confirm.

If you find the problem and repair it yourself, the cost is likely to be under $25.

Fuse blows or TV blows up when sync is disrupted

This is a problem which is not going to be easy to identify. One possibility is a drive problem. The messed up sync resulting from swtiching channels, or changing input connections might be resulting in an excessively long scan time for just one scan line. However, this may be enough to cause a current spike in the horizontal output circuit or an excessive voltage spike on the collector of the horizontal output transistor. Normally, the HOT current ramps up during scan. During flyback, the current is turned off. This current is normally limited and the voltage spike on the collector of the HOT is also limited by the snubber capacitors to a safe value. If scan time is too long, current continues to increase. At some point, the flyback core saturates and current goes way up. In addition, the voltage spike will be much higher - perhaps destructively so.

Troubleshooting these sorts of problems is going to be tough. However, a likely area to investigate would be:

- Drive circuitry for the HOT including the coupling components.

- The chip that generates takes the sync input and generates the horizontal drive signal.

- A bad low voltage regulator might permit the B+ to rise to excessive levels during black scenes (i.e., video mute during channel changing).

Internal fuse blew during lightning storm (or elephant hit power pole)

Power surges or nearby lightning strikes can destroy electronic equipment. However, most of the time, damage is minimal or at least easily repaired. With a direct hit, you may not recognize what is left of it!

Ideally, electronic equipment should be unplugged (both AC line and phone line!) during electrical storms if possible. Modern TVs, VCRs, microwave ovens, and even stereo equipment is particularly susceptible to lightning and surge damage because some parts of the circuitry are always alive and therefore have a connection to the AC line. Telephones, modems, and faxes are directly connected to the phone lines. Better designs include filtering and surge suppression components built in. With a near-miss, the only thing that may happen is for the internal fuse to blow or for the microcontroller to go bonkers and just require power cycling. There is no possible protection against a direct strike. However, devices with power switches that totally break the line connection are more robust since it takes much more voltage to jump the gap in the switch than to fry electronic parts. Monitors and TVs may also have their CRTs magnetized due to the electromagnetic fields associated with a lightning strike - similar but on a smaller scale to the EMP of a nuclear detonation.

Was the TV operating or on standby at the time? If it was switched off using an actual power switch (not a logic pushbutton or the remote control), then either a component in front of the switch has blown, the surge was enough to jump the gap between the switch contacts, or it was just a coincidence (yeh, right).

If the TV was operating or on standby or has no actual power switch, then a number of parts could be fried.

TVs usually have their own internal surge protection devices like MOVs (Metal Oxide Varistors) after the fuse. So it is possible that all that is wrong is that the line fuse has blown. Remove the cover (unplug it first!) and start at the line cord. If you find a blown fuse, remove it and measure across the in-board side of fuse holder and the other (should be the neutral) side of the line. The ohmmeter reading should be fairly high - well certainly not less than 100 ohms - in at least one direction. You may need to unplug the degaussing coil to get a reasonable reading as its resistance may be 25 or 30 ohms. If the reading is really low, there are other problems. If the resistance checks out, replace the fuse and try powering the TV. There will be 3 possibilities:

1. It will work fine, problem solved.

2. It will immediately blow the fuse. This means there is at least one component shorted - possibilities include an MOV, line rectifiers, main filter cap, regulator transistor, horizontal output transistor, etc. You will need to check with your ohmmeter for shorted semiconductors. Remove any that are suspect and see of the fuse now survives (use the series light bulb to cut your losses - see the section: The series light bulb trick.

3. It will not work properly or appear dead. This could mean there are open fusable resistors other defective parts in the power supply or elsewhere. In this case further testing will be required and at some point you may need the schematic.

If the reading is very low or the fuse blows again, see the section: TV blows fuse.

Fuse replaced but TV clicks with power-on but no other action

The click probably means that the power relay is working, though there could be bad contacts.

Since the fuse doesn't blow now (you did replace it with one of the same ratings, right?), you need to check for:

- Other blown fuses - occasionally there are more than one in a TV.

  Replace with one of exactly the same ratings.

- Open fusable resistors. These sometimes blow at the same time or in place of the fuses. They are usually low values like 2 ohms and are in big rectangular ceramic power resistor cases or smaller blue or gray colored cylindrical power resistors. They are supposed to protect expensive parts like the HOT but often blow at the same time.

If any of these are bad, they will need to be replaced with flameproof resistors of the same ratings (though you can substitute an ordinary resistor for testing purposes). Before applying power, check: Rectifier diodes, horizontal output transistor, regulator pass or chopper transistor (if present), and main filter capacitor for shorts.

An initial test with an ohmmeter can be done while in-circuit. The resistance across each diode and the collector to emitter of the transistors should be relatively high - a few hundred ohms at lest - in at least one direction (in-circuit). If there is a question, unsolder one side of each diode and check - should be in the Megohms or higher in one direction. Removed from the circuit, the collector-emitter resistance should be very high in one direction at least. Depending on the type, the base-emitter resistance may be high in one direction or around 50 ohms. If any reading on a semiconductor device is under 10 ohms - then the device most likely bad. Assuming that you do not have a schematic, you should be able to locate the rectifiers near where the line cord is connected and trace the circuit. The transistors will be either in a TO3 large metal can or a TOP3 plastic package - on heat sinks. The filter capacitor should eventually measure high in one direction (it will take a while to charge from your ohmmeter). It could still be failing at full voltage, however.

If you find one bad part, still check everything else as more than one part may fail and just replacing one may cause it to fail again.

Assuming everything here checks out, clip a voltmeter set on its 500 V scale or higher across the horizontal output transistor and turn the power on. Warning - never measure this point if the horizontal deflection is operating. it is ok now since the set is dead. If the voltage here is 100-150, then there is a problem in the drive to the horizontal output circuit. If it is low or 0, then there are still problems in the power supply or with the winding on the flyback transformer.

Other possible problems: bad hybrid voltage regulator, bad startup circuit, bad standby power supply (dried up filter capacitor, etc.) bad relay contacts as mentioned above. However, these probably would not have blown the fuse in the first place so are less likely.

Power-on tick-tick-tick or click-click-click but no other action

A variety of power supply or startup problems can result in this or similar behavior. Possibilities include:

- Lack of startup horizontal drive - see the section: Startup problems - nothing happens, click, or tick-tick-tick sound. The main regulator is cycling on overvoltage due to lack of load.

- Excessive load or faulty power supply cycling on its overcurrent protection circuit.

- High voltage shutdown, or some other system detecting an out of regulation condition. However, in this case, there should be some indication that the deflection and HV is attempting to come up - momentary whine, static on the screen, etc.

- A dried up main filter capacitor or other filter capacitor in the low voltage power supply that is producing an out-of-regulation condition until it warms up. A bad filter capacitor on the output of a series regulator may result in excessive voltage and subsequent shutdown.

- A problem with the microcontroller, relay or its driver, or standby power supply.

One possible test would be to vary the line voltage and observe the set's behavior. It may work fine at one extreme (usually low) or the other. This might give clues as to what is wrong.

Also see the section: Dead TV with periodic tweet-tweet, flub-flub, or low-low voltage.

No picture or raster and no sound

The screen is blank with no raster at all. There are indications that the channel numbers are changing in the display. This indicates that some of the low voltages are present but these may be derived from the standby supply.

Assuming there is no deflection and no HV, you either have a low voltage power supply problem, bad startup circuit, or bad horizontal output transistor (HOT) or other bad parts in the horizontal deflection.

Check for bad fuses.

(If you have HV as indicated by static electricity on the front of the screen and you hear the high pitched whine of the horizontal deflection when it is turned on, then the following does not apply).

1. Use an ohmmeter to test the HOT for shorts. If it is bad, look for open fusable resistors or other fuses you did not catch.

2. Assuming it is good, measure the voltage on the collector-emitter of the HOT (this is safe if there is no deflection). You should see the B+ - probably between 100 and 150 V.

3. If there is no voltage, you have a low voltage power supply problem and/or you have not found all the bad/open

parts.

4. If there is voltage and no deflection (no high pitched whine and no HV), you probably have a startup problem - all TVs need some kind of circuit to kick start the horizontal deflection until the auxiliary power outputs of the flyback are available. Some Zeniths use a simple multivibrator for this - a couple of transistors. Others power the horizontal osc. IC from a special line-derived voltage. The multivibrator type are sometimes designed to fail if someone keeps turning the set on and off (like kids playing) since the power rating is inadequate.

   Test the transistors if it is that type with an ohmmeter. If one is shorted, you have a problem. The usual way a TV service person would test for startup problems is to inject a signal to the base of the HOT of about 15.75 kHz. If the TV then starts and runs once this signal is removed, the diagnosis is confirmed. This is risky - you can blow things up if not careful (including yourself). See the section: Bypassing the Startup Circuit for details.

If you hear the high pitched whine of the deflection and/or feel some static on the scree, confirm that the horizontal deflection and high voltage are working by adjusting the SCREEN control (probably on the flyback). If you can get a raster then your problem is probably in the video or chroma circuits, not the deflection or high voltage.

Reduced width picture and/or hum bars in picture and/or hum in sound

The most likely cause is a dried up main filter capacitor. Once the effective capacitance drops low enough, 120 Hz (or 100 Hz in countries with 50 Hz power) ripple will make its way into the regulated DC supply (assuming full wave rectification).

Another likely cause of similar symptoms is a defective low voltage regulator allowing excessive ripple. The regulator IC could be bad or filter capacitor following the IC could be dried up.

Either of these faults may cause:

1. A pair of wiggles and/or hum bars in the picture which will float up the screen. For NTSC where the power line is 60 Hz but the frame rate is 59.94 Hz, it will take about 8 seconds for each bar to pass a given point on the screen. (On some sets, a half wave recitifier is used resulting in a single wiggle or hum bar).

2. Hum in the sound. This may or may not be noticeable with the volume turned down.

3. Possible regulation problems resulting in HV or total shutdown or power cycling on and off.

The best approach to testing the capacitors is to clip a good capacitor of approximately the same uF rating and at least the same voltage rating across the suspect capacitor (with the power off). A capacitor meter can also be used but the capacitor may need to be removed from the circuit.

Once the capacitors have been confirmed to be good, voltage measurements on the regulator should be able to narrow down the problem to a bad IC or other component.

Excessive B+ from fixed regulator like STR30123/STR30130/STR30135

These are fixed regulators that do fail but the problem may be elsewhere.

If the B+ goes to high, the X-ray protection circuitry may kick in and shut down the horizontal deflection.

If there is little or no load (horizontal deflection not running at all), all bets are off as well - the resistor that is likely across input-output will dominate and boost the voltage above the proper output for the regulator chip. Use a Variac to bring up the voltage to the TV. If the deflection does not start up at any voltage even with the B+ ramping up past its normal value, the problem is probably in the horizontal deflection/startup circuitry, not the regulator.

Some of these may go out of regulation if the output electrolytics are dried up. There might a a 10 uF 200 V or so electrolytic across the output to ground. Test it or substitute a known good one of about the same uF rating and at least equal voltage rating. If you can get the TV to work at reduced voltage using a Variac (but possibly with hum bars in the picture and hum in the audio), check the output capacitor.

Otherwise, it could be the regulator or one of its biasing components (sets current to B input - the voltage at this input should be close to the output voltage value). Also check to be sure the input voltage is solid - main filter capacitor is not dried up.

TV power cycling on and off

The power light may be flashing or if you are runing with a series light bulb it may be cycling on and off continuously. There may be a chirping or clicking sound from inside the set. (Note: using too small a series light bulb load during testing for the size of the TV may also result in this condition.)

If there is a low voltage regulator or separate switching supply, it could be cycling on and off if the horizontal output, flyback, or one of its secondary loads were defective.

Does this TV have a separate low voltage regulator and/or switching power supply or is it all part of the flyback circuit? For the following, I assume it is all in one (most common).

Some simple things to try first:

Verify that the main filter capacitor is doing its job. Excessive ripple on the rectified line voltage bus can cause various forms of shutdown behavior. An easy test is to jumper across the capacitor with one of at least equal voltage rating and similar capacitance (make connections with power off!).

Use a Variac, if possible, to bring up the input voltage slowly and see if the TV works at any point without shutting down. If it does, this could be an indication of X-ray protection circuit kicking in, though this will usually latch and keep the set shut off if excessive HV were detected.

Dead TV with periodic tweet-tweet, flub-flub, or low-low voltage

A TV which appears to be dead except for a once a second or so tweet or flub usually indicates an overload fault in the power supply or a short in one of its load circuits. In some cases, the low voltage (including B+) will just be reduced to a fraction of their normal value as a result of an overload on one of the outputs - usually the main B+.

This may be caused by a shorted rectifier in the power supply, flyback, or even the yoke, but check the the loads first. Wait a few minutes for the filter caps to discharge (but stay away from the CRT HV connector as it may retain a dangerous and painful charge for a long time), use an ohmmeter across the various diodes in the power supply. Using an ohmmeter on the rectifier diodes, the resistance in at least one direction should be greater than 100 ohms. If it is much less (like 0 or 5 ohms), then the diode is probably bad. Unsolder and check again - it should test infinite (greater than 1M ohms) in one direction.

Summary of possible causes:

- Bad solder connections.
- Other shorted components like capacitors.
- Other problems in the power supply or its controller.
- Bad flyback.

- Short or excessive load on secondary supplies fed from flyback.
- Short in horizontal yoke windings.
- Problem with startup drive (cycling on overvoltage).

Bypassing the Startup Circuit

Where the TV is dead and a startup problem is suspected, a TV service person would test for startup problems by injecting a signal into the base of the HOT of about 15.75 kHz. If the TV then starts and runs once this signal is removed, the diagnosis is confirmed. This is risky - you can blow things up if not careful (including yourself). A 555 timer based circuit will work fine as a signal source for this.

WARNING: be careful if you do this. The HOT circuit may be line-connected and it is possible to destroy the HOT and related components if this is not done properly. I once managed to kill not only the HOT but the chopper transistor as well while working in this area. An expensive lesson.

You can reduce the risk somewhat (to the TV at least) by using a series light bulb load and/or running on reduced line voltage. The most important thing to avoid is putting in an excessively long drive pulse which will result in the flyback transformer saturating, huge amounts of current, and likely a dead HOT and possibly other parts if there is nothing to limit the current. For NTSC/PAL, it is fairly safe to assume that a 50 percent duty cycle 15 to 16 kHz drive signal will not result in fireworks as long as there aren't other problems (like a shorted flyback/LOPT).

If after a second or so, the TV fires up (not literally!) and stays happy until it is turned off, a startup problem is almost certain. It could be the standby supply (if used) or a dedicated startup circuit that has failed.

But, don't push your luck - if the TV starts after a second or so of your drive signal but doesn't continue to run when it is removed, don't be tempted to leave your circuit connected - it could still be stressing other parts. Find out why the normal horizontal drive is not being generated - possibly a power supply or horizontal oscillator problem.

If nothing happens, either startup is not the problem or there are other components that have failed preventing the HOT drive signal from having any effect.

Shorted Components

A failure of the horizontal output transistor or power supply switchmode transistor will blow a fuse or fusable resistor.

Look for blown fuses and test for open fusable resistors in the power circuits. If you find one, then test the HOT and/or switchmode transistor for shorts.

Other possibilities: rectifier diodes or main filter capacitor.

While you are at it, check for bad connections - prod the circuit board with an insulated stick when the problem reoccurs - as these can cause parts to fail.

Startup problems - nothing happens, click, or tick-tick-tick sound

TVs and monitors usually incorporate some kind of startup circuit to provide drive to the horizontal output transistor (HOT) until the flyback power supply is running. Yes, TVs and monitors boot just like computers.

There are two typical kinds of symptoms: power on click but nothing else happens or a tick-tick-tick sound indicating cycling of the low voltage (line regulator) but lack of startup horizontal drive.

Check the voltage on the horizontal output transistor (HOT). If no voltage is present, there may be a blown fuse or open fusable resistor - and probably a shorted HOT.

However, if the voltage is normal (or high) - usually 100-150 V, then there is likely a problem with the startup circuit not providing initial base drive to the HOT.

The startup circuits may take several forms:

1. Discrete multivibrator or other simple transistor circuit to provide base drive to the HOT.

2. IC which is part of deflection chain powered off of a voltage divider or transformer.

3. Other type of circuit which operates off of the line which provides some kind of drive to the HOT.

The startup circuit may operate off of the standby power supply or voltage derived from non-isolated input. Be careful - of course, use an isolation transformer whenever working on TVs and especially for power supply problems.

Note that one common way of verifying that this is a startup problem is to inject a 15 kHz signal directly into the HOT base or driver circuit (just for a second or two). If the TV then starts up and continues to run, you know that it is a startup problem. However, this is a risky procedure for both you and the TV. See the section: Bypassing the Startup Circuit.

I have also seen startup circuits that were designed to fail. Turning the TV on and off multiple times would exceed the power ratings of the components in the startup circuit. Some Zenith models have this 'feature'.

When this situation exists, it could be that the circuit is not providing the proper drive or that due to some other circuit condition, the drive is not always sufficient to get the secondary supplies going to the point that the normal circuits take over.

I would still check for bad connections - prod the circuit board with an insulated stick when the problem reoccurs.

TV turns off after warming up

If you can turn it back on with the s momentary key or power button:

When it shuts off, do you need to push the power button once or twice to get it back on? Also, does anything else about the picture or sound change as it warms up?

1. If once, then the controller is shutting the TV down either as a result of a (thermally induced) fault in the controller or it sensing some other problem. Monitoring the voltage on the relay coil (assuming these is one) could help determine what is happening. The controller thinks it is in charge.

2. If twice, then the power supply is shutting down as the controller still thinks it is on and you are resetting it. A couple of possibilities here would be low voltage or high voltage regulation error (excessive high voltage is sensed and causes shutdown to prevent dangerous X-ray emission). A partially dried up main filter capacitor could also cause a shutdown but there might be other symptoms like hum bars in the picture just before this happened. Clipping a good capacitor across the suspect (with power off!) would confirm or eliminate this possibility.

If it uses a pull-knob (or other hard on/off switch), then this may be like pulling the plug and would reset any abnormal condition.

TV doesn't power up immediately

The TV may do nothing, cycle on and off for a while, power up and then shutdown in an endless cycle - or at least for a while. Then it comes on and operates normally until it is turned off.

A couple of possibilities:

1. The main filter capacitor or other filter capacitors in the low voltage power supply is dried up and this can cause all kinds of regulation problems.

2. The power supply regulator is defective (or marginal) allowing excessive voltage on its output and then the X-ray protection circuitry shuts you down.

If you can get access to a Variac, it would be worth bringing up the input voltage slowly and seeing if there is some point at which it would stay on.

If there is, then if the picture has serious hum bars in it the main filter cap could be bad. If more or less a decent picture with minor hum bars then it could be the regulator.

Old TV requires warmup period

So, what else is new? In the old days, a TV was expected to take a few minutes (at least) to warm up. We are all spoiled today. Of course, you usually maintained a full time technician or engineer to fiddle with the convergence adjustments!

A TV (from around 1983) needs at least 5 min. to warm up (lighting up the screen and making sound if I give it a cold start. Once warmed up, you can it off and on again from the front panel and it will work immediately. Another thing this TV has a sub-power switch in the rear.

1983 sounds a bit late, but sets in the late '70 during the transition from tubes to all solid state chassis often had the 'sub-power' switch providing some power to the filaments of the CRT and other tubes - usually in the deflection and high voltage circuits since these would take a while to heat up and stabilize. The idea was to leave this switch on all the time (except when going on vacation - it was sometimes labeled 'vacation') so that you would have nearly instant warm up. Supposedly, this led to an increased risk of fire as well (see the section: About instant-on TVs).

If it is a totally solid state chassis, then there is some component - probably a capacitor in the power supply since it affects both picture and sound - that is drifting with temperature and needs to be located with cold spray or a heat gun.

TV shuts down with bright picture or when brightness is turned up

This is probably a protection circuit kicking in especially if turning power off or pulling the plug is required to restore operation.

The detection circuit could be in the power supply or horizontal deflection output circuit. It may be defective or the current may be too high for some other reason. A couple of tests can be performed to confirm that it is due to beam current:

- Determine if behavior is similar when adjusting the user brightness control and the screen (G2) pot (on the flyback) or master brightness control. If the TV quits at about the same brightness level, overcurrent protection is likely.

- Disconnect the filaments to the CRT (unsolder a pin on the CRT socket) and see if it still shuts down under the same conditions. If it is overcurrent protection, shut down should now *not* take place since there is no beam current.

Relays in the Power Circuitry of TVs

Where power on or power off is erratic or only seems to work part way (e.g., the picture goes off but not the sound), it may just be a sticking or dirty relay. Of course, general on/off problems could also be relay related but could also be a lot of other things.

For erratic on/off problems, gently tapping on the relay when the problem occurs will confirm that the relay is at fault - if the set then switches on or off properly, it's almost certainly the relay and replacing it will fix the problem. But double check its solder connections to make sure it isn't a simple bad connection to the relay or in its vicinity.

So what exactly is the purpose of such a power relay in a TV set? Why doesn't the power switch on the TV just apply power directly instead of through a relay?

The usual reason for a relay instead of a knob switch is to permit a remote control to turn power on and off. If your TV does not have a remote, then it is simply the same chassis minus 24 cents worth of circuitry to do the remote function. Isn't marketing wonderful?

The only unknown is the coil voltage. It is probably somewhere in the 6 to 12 volt range. You should be able to measure this on the coil terminals in operation. It will be a DC coil.

However, the relay controls the 125 VAC (or 220 VAC) which you should treat with respect - it is a lot more dangerous than the 25kV+ on the CRT!

Almost certainly, the relay will have 4 connections - 2 for power and 2 for the coil. If it is not marked then, it should be pretty easy to locate the power connection. One end will go to stuff near the AC line and the other end will go to the rectifier or maybe a fusable resistor or something like that. These will likely be beefier than the coil connections which will go between a transistor and GND or some low voltage, or maybe directly into a big microcontroller chip.

However, a few sets use a latching relay - separate coils (sharing a common connection) to 'set' and 'reset' the relay - like a flip flop. In such a case, the controller knows which state the TV is in (on or off) and sens the appropriate pulse to the relay to change state. And, there will be NO voltage on the coils of a latching relay except when turning the set on or off.

Of course, the best thing would be to get the schematic. Some big public libraries carry the Sams' photofact series for TVs and VCRs. If not, take 10 minutes and trace it. You should be able to get far enough to determine the relay connections.

Once you are sure of the AC connections - measure across them while it is off and also while it is on. While off, you should get 110 to 125 VAC. While on and working - 0. While on and not working either 110 to 125 VAC if the relay is not pulling in or 0 if it is and the problem is elsewhere. We can deal with the latter case if needed later on. Note the even if the relay contacts are not working, the problem could still be in the control circuitry not providing the correct coil voltage/current, though not likely.

It may be expensive and/or difficult to obtain an exact replacement, but these are pretty vanilla flavored as relays go. Any good electronics distributor should be able to supply a suitable electrical replacement though you may need to be creative in mounting it.

What is a posistor?

A posistor is a combination of a PTC (positive temperature coefficient) resistor and another resistor-element to heat it up and keep it hot. Sometimes, these will go by the name posister or thermistor. The heater is a disk shaped resistor across the power line and the themister is a disk shaped device in series with the degauss coil. They are in clamped together to be in close contact thermally. You can pry off the lid and see for yourself.

The most common failure mode is for the part to short across the line.

Its function is to control degauss, so the only thing you lose when you remove one of these is the degauss function on power-on. When you turn the TV or monitor on, the PTC resistor is cold and low resistance. When heated, it becomes very high resistance and turns off the degauss coil but gradually - the current ramps down to zero rather than being abruptly cut off..

Computer Component Source stocks a wide variety, I believe but it may be cheaper to go direct to the manufacturer if they will sell you one.

Flameproof Resistors

Flameproof Resistor or Fusable Resistor are often designated by the symbol 'FR'. They are basically the same. The designation "Flameproof" means that if they fail due to excessive current, there will be no chance of, well, them going up in flames. :) They will also have a power rating and thus can act as a protective device, though a specific circuit may not depend on a precise fuse rating, rather that the resistor will open with massively excessive current.

You may see these in the switchmode power supplies used in TVs and monitors. They will look like power resistors but will be colored blue or gray, or may be rectangular ceramic blocks. They should only be replaced with flameproof resistors with identical ratings. They serve a very important safety function.

These usually serve as fuses in addition to any other fuses that may be present (and in addition to their function as a resistor, though this isn't always needed). Since your FR has blown, you probably have shorted semiconductors that will need to be replaced as well. I would check all the transistors and diodes in the power supply with an ohmmeter. You may find that the main switch mode transistor has decided to turn into a blob of solder - dead short. Check everything out even if you find one bad part - many components can fail or cause other components to fail if you don't locate them all. Check resistors as well, even if they look ok.

Since they function as fuses, flameproof resistors should not be replaced with higher wattage types unless specifically allowed by the manufacturer. These would not blow at the same level of overload possibly resulting in damage to other parts of the circuitry and increasing the risk of fire.

Then, with a load on the output of the power supply use a Variac to bring up the voltage slowly and observe what happens. At 50 VAC or less, the switcher should kick in and produce some output though correct regulation may not occur until 80 VAC or more. The outputs voltages may even be greater than spec'd with a small load before regulation is correct.

Width and height change with warmup

Since both width and height are affected, this points to something common like the low voltage power supply. If there are any indications of hum bars, first check the main filter capacitor(s) or substitute a known good one. There might even be other symptoms like faint retrace lines on at least part of the screen.

Start by monitoring the B+ to the flyback (feeding the HOT) to see if this drifts at all. If it does, then there is probably a low voltage regulator problem - bad capacitor, resistor, or chip. Use freeze spray to narrow it down. If this is solid, then there could be a high voltage drift but this would be somewhat unusual without other symptoms (like arcing) since the HV is nearly always tracks the low voltage supply.

Problems with SCR based regulators

Here are typical symptoms:

> "Sharp TV has a short blast of high voltage and sound then shuts down. All components in regulator area test good. I have two of these sets." Is there a good sharp tech out there thats seen this problem?"

(From: Mr. Caldwell (jcaldwel@iquest.net).)

There is a bulletin from Sharp on troubleshooting *any* SCR regulated TV, this can easily be adapted to RCA, GE, Emerson and Panasonic sets that have similar circuits given a little thought but the technician.

You are going to need to figure part of this out as I no longer have the schematics available. All this will do is allow you to rule out either the regulator or the horizontal section.

Don't plug this in until you've read the whole list.

Figure out how to bypass the turn on circuit from the microprocessor (unless it's a manual one). This is usually just jumpering the relay but sometimes Sharp puts a horizontal Vcc turn on transistor that also must be jumpered.

Next jumper across the SCR anode to cathode.

Now using an *variable isolation transformer* turn the voltage on it down and plug the set in. Bring the voltage up slowly, if you can bring the AC up so that the DC on the jumper across the SCR is within the regulated voltage you should have a picture and this rules out the horizontal section as the culprit.

If the set shuts down prior to getting the DC up enough then you've got problems in the horizontal section. Either you have something wrong with the high voltage transformer or the tuning caps or there is a problem with the x-ray protect pick off voltage to the deflection IC.

If it's the horizontal section you can set the AC at approx. 25v and look at the waveforms in the horizontal output section for defects like ringing.

I've never gotten a good troubleshooting technique down for the regulator since it's an active circuit the waveforms and voltages are not stable when it's failed. A good diode, transistor and capacitor checker will help.

It would help to get the service manual for that set, the training manual for that chassis and the bulletin dealing with troubleshooting SCR regulators.

Also the training manual should have a good explanation of how this regulator works. In a nutshell the regulator is a switched mode circuit that uses a winding from the high voltage transformer to turn off the SCR. The regulator is always turned off at the same time by a pulse from the high voltage transformer. Regulation is achieved by controlling when the SCR is allowed to turn on.

TV shuts down with dark picture or when changing channels

This may happen at any time or possibly after being on for awhile in which something heats up and drifts out of spec.

The low voltage regulator may be letting the voltage rise excessively. Then, a dark picture or video muting during a channel change triggers the X-ray or power supply overvoltage protection.

Monitor the output of the low voltage power supply B+ to see if it is stable as the brightness/scene changes.

Deflection Problems

Deflection fundamentals

Note: the following is just a brief introduction. For more detailed deflection system theory of operation and sample circuits, see the document: TV and Monitor Deflection Systems.

The electron beams in the CRT need to be scanned horizontally and vertically in a very precise manner to produce a raster - and a picture.

For NTSC and PAL, the horizontal scan rates are 15,734 and 15,625 Hz respectively.

For NTSC and PAL, the vertical scan rates are 60 and 50 Hz (approximately) respectively.

The deflection yoke includes sets of coils for horizontal and vertical scanning oriented at 90 degrees with respect to each other. Additional coils are needed to correct for pincushion and other geometric defects.

The deflection circuits must be synchronized and phase locked to the incoming video signal.

Therefore, we have the following functions:

1. Sync separator to obtain horizontal and vertical synchronization pulses.

2. Horizontal oscillator which locks to horizontal sync pulses.

3. Horizontal drive followed by horizontal output which feeds deflection yoke (and flyback for HV and other voltages), Yoke requires a sawtooth current waveform for linear horizontal deflection. Horizontal output in all but the smaller TVs is a large discrete power transistor, most often an NPN bipolar type.

4. Vertical oscillator which locks to vertical sync pulses. Yoke requires sawtooth waveform for linear vertical deflection.

5. Vertical drive/output which feeds vertical deflection yoke. Newer TVs use ICs for vertical drive and output.

6. Various additional deflection signals to correct for the imperfections in the geometry of large angle deflection CRTs. These may be fed into the normal deflection coils and/or there may be separate coils mounted on the neck of the CRT.

About the vertical scan rate

Some people believe that the TV scan rate is locked to the local power line. TVs never ever used the line frequency for vertical rate. The vertical rate is not even equal to line frequency, actually 59.94 Hz (NTSC). It was set originally to 60 Hz to minimize the visibility of interference between the deflection and power transformer. When NTSC added color, it changed to 59.94 Hz for highly technical reasons. And, TVs no longer have power transformers.

See Symptoms of Some Common Deflection Problems when referring to the specific descriptions below.

Picture squeezed in then died

You were watching 'Knight Rider' reruns and all of a sudden, the picture "squeezed in" slowly from the right hand side. It "squeezed in" about 2 inches or so when the entire picture went dead - has remained like this since. Sound is fine, but no activity at all from the tube. Has it died? How much time, effort, and expense to fix?

No, it's not dead, at least it certainly is not the picture tube.

Your set probably didn't like Knight Rider - at least that episode!

Seriously, how old is the set? Is it a totally solid state chassis or are there tubes in the deflection circuits?

Is there any indication of light on the screen? Any indication of the 15735 Hz horizontal running at all? (You would normally hear the high pitch sound).

Newer TVs almost always derive voltages for the sound circuits from the horizontal deflection but older hybrids may run the sound off of its own power.

In any case, there is a problem in the horizontal deflection and you probably have no high voltage as well assuming no light on the screen.

The fact that it squeezed in first indicates that a partial short or other fault may have developed in the horizontal deflection circuits - possibly the deflection yoke or flyback transformer. It could also have been a bad connection letting loose. Once it failed completely, the horizontal output transistor may have bought the farm or blown a fuse.

TV non-linearity

Most modern TVs are nearly perfect with respect to linearity. There are never any user adjustments and there may not even be any internal adjustments. See the sections: Horizontal position, size, and linearity adjustment and/or Vertical position, size, and linearity adjustment.

A sudden change in linearity or a TV that requires a warmup period before linearity becomes acceptable may have a bad component - probably a capacitor in the horizontal deflection circuits. For the latter, try some cold spray or a heatgun to see if you can locate the bad part.

Horizontal deflection shutting down

Confirm that the horizontal deflection is shutting down (along with the high voltage since it is derived from horizontal deflection: listen for the high pitched deflection whine, test for static on the screen, see if the CRT filaments are lit, turn up the brightness and/or screen control to see if you can get a raster) and then why:

1. Power is failing to the horizontal output transistor - this could be due to a low voltage power supply problem, bad connection, etc.
2. Base drive to the horizontal output transistor is failing - could be a fault in the horizontal oscillator or bad connection.
3. Problem with the flyback transformer or its secondary loads (flyback may provide other power voltages).
4. X-ray protection is activating - either due to excess HV or due to a fault in the X-ray protection circuitry.

If the problem comes and goes erratically it sounds like a bad connection, especially if whacking has an effect. If it comes and goes periodically, then a component could be heating up and failing, then cooling, etc.

TV will not sync

There are a wide variety of causes for a TV that will not display a stable or properly configured picture. Among the symptoms are:

- Lack of sync horizontal - drifts smoothly horizontally. Depending on the difference between the video horizontal rate and the free-run frequency of the horizontal oscillator, the picture may be torn left or right (as shown in Symptoms of Some Common Deflection Problems or have multiple images superimposed horizontally. The situation where the picture is neatly split horizontally (which is what you might expect) is a special case where the frequencies are virtually the same. The key symptom common to all these is that there IS vertical lock (no blanking bar visible) AND there is no evidence that the deflection is even attempting to lock horizontally.

  This may mean that the horizontal sync signal is missing due to a sync separator problem or that there is some other fault in the sync processing circuitry.

- Incorrect lock horizontal - a more-or-less stable torn picture. This means that the sync signal is reaching the deflection system but that it is having problem locking to it. The horizontal oscillator free-run frequency may be too far from what it is supposed to be (15,734 or 15,625 for NTSC and PAL, respectively).

- Lack of sync vertical - rolls smoothly vertically. This may mean that the vertical sync signal is missing or the deflection system is ignoring it.

- Lock not stable vertical - jumps or vibrates vertically. This may be a fault in the vertical sync circuitry.

- Multiple or repeated images horizontally or vertically. Problems in sync processing circuitry.

  Additional comments on some of these problems follow in the next few sections.

Horizontal lock lost

A TV which loses horizontal lock when changing channels, momentarily losing the signal, or switching inputs may have a horizontal oscillator that is way out of adjustment or has drifted in frequency due to aging components.

Note that the characteristics of this are distinctly different than for total loss of sync. In the latter case, the picture will drift sideways and/or up and down while with an off frequency oscillator, the torn up picture will try at least to remain stationary.

This could be a capacitor or other similar part. Or, the oscillator frequency may just need to be tweaked (particularly with older sets). There may be an internal horizontal frequency adjustment - either a pot or a coil - which may need a slight tweak. If a coil, use a plastic alignment tool, not metal to avoid cracking the fragile core.

A schematic will be useful to locate the adjustment if any or to identify possible defective parts. Try a large public library for the Sams' Photofact for this set.

Insufficient width (without hum bars)

If there are hum bars or wiggles in the picture and/or hum in the sound, see the section: Reduced width picture and/or hum

bars in picture and/or hum in sound.

If both width and height are affected, the cause is likely something common: low, low voltage power supply voltages or excessive high voltage (resulting in a 'stiffer' beam).

(From: Jerry G. (jerryg@total.net).)

Lack of width is usually caused by defective power supply, low horizontal drive to the yoke and flyback, defective circuits in the pincushioning amplifier section, excessive high-voltage caused by defective voltage regulation, and or excessive loading on the secondary side of the flyback.

Vertical lock lost

This indicates a picture that is correct but rolling vertically.

If the picture is rolling down the screen the frequency of the vertical oscillator is incorrect - too high - and this may be the problem. Generally, the free run frequency of the vertical oscillator should be a little below the video rate (of around 50 or 60 Hz depending on where you live).

If it is rolling continuously without jumping, then there is a loss of sync from the sync separator or faulty components in the vertical oscillator causing it to totally ignore the sync pulses.

If it is rolling up rapidly and not quite able to remain locked, the free run frequency may be too low or there could be a fault in the sync circuits resulting in an inadequate vertical pull-in range.

On older sets, there was actually a vertical hold (and possibly even a separate vertical frequency) control. On anything made in the last decade, this is unlikely. There may be Vertical Frequency and Vertical Pull-in Range adjustments (and others) accessible via the service menu. However, if any of these ever change, it indicates a possible problem with the EEPROM losing its memory as component drift is unlikely.

As with everything else, bad connections are possible as well. You will need a schematic and possibly setup info to go beyond this.

Vertical squashed

This is a vertical deflection problem - possibly a bad capacitor, bad connection, flyback/pumpup diode, or other component. None of these should be very expensive (in a relative sort of way).

If the symptoms change - particularly if they become less severe - as the set warms up, a dried up electrolytic capacitor is most likely. If they get worse, it could be a bad semiconductor. Freeze spray or a heat gun may be useful in identifying the defective component.

It is often easiest to substitute a good capacitor for each electrolytic in the vertical output circuit. Look for bad connections (particularly to the deflection yoke), then consider replacing the vertical output IC or transistor(s).

A defective deflection yoke is also possible or in rare cases, a bad yoke damping resistor (e.g., 500 ohms, may be mounted on the yoke assembly itself).

Where the entire top half or botton half of the picture is squashed into into the center (i.e., only half the picture shows), a missing power supply voltage, defective vertical output IC, or a component associated with it is likely bad. A bad connection or blown fusable resistor may be the cause of a missing power supply voltage.

The following are NOT possible: CRT, flyback (except possibly where it's the source for a missing voltage but this is more likely just a bad solder connection at a flyback pin), tuner (except for the famous RCA/GE/Proscan or Sony models where the controller is at fault - see the sections on these specific brands). I am just trying to think of really expensive parts that cannot possibly be at fault :-).

Note that some movies or laser karaoke discs are recorded in 'letterbox' format which at first glance looks like a squashed vertical problem. However, the picture aspect ratio will be correct and turning up the brightness will reveal a perfectly normal raster above and below the picture.

Part of picture cut off

The following applies if the part of the picture is missing but not otherwise squashed or distorted. For example, 85% is missing but the portion still visible is normal size.

Wow! That's an interesting one, more so than the typical run-of-the-mill "my TV just up and died on me". Or, "my pet orangutan just put a hole in the CRT, what should I do"?

Since the size of the picture fragment is correct but 85% is missing, my first thought would be to check waveforms going into the vertical output stage. The supply voltage is probably correct since that often determines the size. It almost sounds like the waveform rather than being mostly on (active video) and off for the short blanking period is somehow only on during the last part of the active video thus giving you just the bottom of the picture. If there is a vertical output IC, it may be defective or the blanking input to it may be corrupted. The problem may be as far back as the sync separator. Then again who knows, maybe wait for the schematics.

CAUTION: To prevent damage to the CRT phosphors, immediately turn down the brightness so the line is just barely visible. If the user controls do not have enough range, you will have to locate and adjust the master brightness or screen/G2 pots.

Since you have high voltage, the horizontal deflection circuits are almost certainly working (unless there is a separate high voltage power supply - almost unheard of in modern TVs and very uncommon in all but the most expensive monitors).

Check for bad solder connections between the main board and the deflection yoke. Could also be a bad horizontal coil in the yoke, linearity coil, etc. There is not that much to go bad based on these symptoms assuming the high voltage and the horizontal deflection use the same flyback. It is almost certainly not an IC or transistor that is bad.

Single Horizontal Line

CAUTION: To prevent damage to the CRT phosphors, immediately turn down the brightness so the line is just barely visible. If the user controls do not have enough range, you will have to locate and adjust the master brightness or screen/G2 pots.

A single horizontal line means that you have lost vertical deflection. High voltage is most likely fine since there is something on the screen.

This could be due to:

1. Dirty service switch contacts. There is often a small switch located inside on the main board or perhaps accessible from the back. This is used during setup to set the color background levels. (On some sets, this is located on the CRT neck board and may be a jumper plug or other means of selecting service mode - not an actual switch.)

When moved to the 'service' position, it kills vertical deflection and video to the CRT. If the switch somehow changed position or got dirty or corroded contacts, you will have this symptom. Flip the switch back and forth a couple of times. If there is some change, then replace, clean, resolder, or even bypass it as appropriate.

2. Bad connection to deflection yoke or other parts in vertical output circuit. Bad connections are common in TVs and monitors. Check around the pins of large components like transformers, power transistors and resistors, or connectors for hairline cracks in the solder. Reseat internal connectors. Check particularly around the connector to the deflection yoke on the CRT.

3. Bad vertical deflection IC or transistor. You will probably need the service manual for this and the following. However, if the vertical deflection is done with an IC, the ECG Semiconductor Master Substitution guide may have its pinout which may be enough to test it with a scope.

4. Other bad parts in vertical deflection circuit though there are not that many parts that would kill the deflection entirely.

5. Loss of power to vertical deflection circuits. Check for blown fusable resistors/fuses and bad connections.

6. Loss of vertical oscillator or vertical drive signals.

The most likely possibilities are in the deflection output stage or bad connections to the yoke.

Keystone shaped picture

This means that the size of the picture is not constant from top to bottom (width changes) or left to right (height changes). Note that some slight amount of keystoning is probably just within the manufacturing tolerance of the deflection yoke and factory setup (geometry magnet placement, if any). On a TV, this is only noticeable with scenes having straight edges (e.g., video games) in relationship to the CRT bezel.

However, a sudden increase (and it will usually be rather substantial in a TV) may indicate a problem with the deflection yoke.

An open or short in a winding (or any associated components mounted on the yoke assembly) will result in the beam being deflected less strongly on the side where that winding is located. Typical TV yokes have fewer individual windings in parallel than high scan rate monitors so the effects of one such fault are more dramatic. See the section: Deflection yoke testing.

If the set has been dropped off a 20 story building, the yoke may have shifted its position on the neck, of the CRT resulting in all sorts of geometry and convergence problems (at the very least).

Loss of Horizontal Sync (also applies to vertical) after Warmup

The problem lies either in the horizontal oscillator or in the sync system. If it really is a problem with sync pulses not reaching the oscillator, the picture will move around horizontally and can be brought to hold momentarily with the hold control. If the picture breaks up into strips, there is a problem in the horizontal oscillator. Rotate the hold control: if the frequency is too far off, the picture will not settle into place at any adjustment of the hold control. Look around the horizontal oscillator circuit: all of the oscillator parts will be right there, or check on the horizontal oscillator module. Another horizontal problem can occur if the set is an RCA made from around 1972-1980: these sets are designed to slip very far off sync if the high voltage is too high, to protect against radiation. Turning up the brightness will decrease the number of bars if this system is in question, as the high voltage is decreasing. In this case, check around the high-voltage regulation system on the deflection systems board. I've had 2 1970's RCA's with this problem.

Intermittent jumping or jittering of picture or other random behavior

This has all the classic symptoms of a loose connection internal to the TV or monitor - probably where the deflection yoke plugs into the main PCB or at the base of the flyback transformer. TVs and monitors are notorious for both poor quality soldering and bad connections near high wattage components which just develop over time from temperature cycling. The problem may happen any time or more when cold or hot.

The following is not very scientific, but it works: Have you tried whacking the TV when this happened and did it have any effect? If yes, this would be further confirmation of loose connections.

What you need to do is examine the solder connections on the PCBs in the monitor, particularly in the area of the deflection circuits and power supply. Look for hairline cracks between the solder and the component pins - mostly the fat pins of transformers, connectors, and high wattage resistors. Any that are found will need to be reflowed with a medium wattage (like 40W) or temperature controlled soldering iron.

It could also be a component momentarily breaking down in the power supply or deflection circuits.

One other possibility is that there is arcing or corona as a result of humid weather. This could trigger the power supply to shut down perhaps with a squeak, but there would probably be additional symptoms including possibly partial loss of brightness or focus before it shut down. You may also hear a sizzling sound accompanied by noise or snow in the picture, static in the sounds, and/or a smell of ozone.

Horizontal output transistors keep blowing (or excessively hot)

Unfortunately, these sorts of problems are often difficult to definitively diagnose and repair and will often involve expensive component swapping.

You have just replaced an obviously blown (shorted) horizontal output transistor (HOT) and an hour (or a minute) later the same symptoms appear. Or, you notice that the new HOT is hotter than expected:

Would the next logical step be a new flyback (LOPT)? Not necessarily.

If the set performed normally until it died, there are other possible causes. However, it could be the flyback failing under load or when it warms up. I would expect some warning though - like the picture shrinks for a few seconds before the poof.

Other possible causes:

1. Improper drive to horizontal output transistor (HOT). A weak drive might cause the HOT to turn on or (more likely) shut off too slowly (greatly increasing heat dissipation. Check driver and HOT base circuit components. Dried up capacitors, open resistors or chokes, bad connections, or a driver transformer with shorted windings or broken or loose core can all affect drive waveforms.

2. Excessive voltage on HOT collector - check LV regulator (and line voltage if this is a field repair), if any.

3. Defective safety capacitors or damper diode around HOT. (Though this usually results in instant destruction with little heating).

4. New transistor not mounted properly to heat sink - probably needs mica washer and heat sink compound.

5. Replacement transistor not correct or inferior cross reference. Sometimes, the horizontal deflection is designed

based on the quirks of a particular transistor. Substitutes may not work reliably.

6. CRT shorting internally. If this happens only once in two weeks, it may be diffuclt to track down :-(.

The HOT should not run hot if properly mounted to the heat sink (using heatsink compound). It should not be too hot to touch (CAREFUL - don't touch with power on - it is at over a hundred volts with nasty multihundred volt spikes and line connected - discharge power supply filter caps first after unplugging). If it is scorching hot after a few minutes, then you need to check the other possibilities.

It is also possible that a defective flyback - perhaps one shorted turn - would not cause an immediate failure and only affect the picture slightly. This would be unusual, however. See the section: Testing of flyback (LOPT) transformers.

Note that running the set with a series light bulb may allow the HOT to survive long enough for you to gather some of the information needed to identify the bad component.

Horizontal output transistors blowing at random intervals

The HOT may last a few months or years but then blow again.

These are among the hardest problems to locate. It could even be some peculiar combination of user cockpit error - customer abuse - that you will never identify. Yes, this should not happen with a properly designed TV though newer horizontal processor chips are quite smart about preventing HOT killing signals from reaching the horizontal driver.

However, a combination of channel changing, loss of sync when switching video sources, and frequent power cycles, could test the TV in ways never dreamed of by the designers. It may take only one scan line that is too long to blow the HOT.

On the other hand, the cause may be along the lines of those listed in the section: Horizontal output transistors keep blowing (or excessively hot) and just not as obvious - blowing in a few days or weeks instead of a few seconds but in this case, the HOT will likely be running very hot even after only a few minutes.

Another possible cause for random failures of the HOT are bad solder connections in the vicinity of the flyback and HOT (very common due to the large hot high power components) as well as the horizontal driver and even possibly the sync and horizontal oscillator circuits, power supply, or elsewhere.

Vertical foldover

The picture is squashed vertically and a part of it may be flipped over and distorted.

This usually indicates a fault in the vertical output circuit. If it uses an IC for this, then the chip could be bad. It could also be a bad capacitor or other component in this circuit. It is probably caused by a fault in the flyback portion of the vertical deflection circuit - a charge pump that generates a high voltage spike to return the beam to the top of the screen.

Test components in the vertical output stage or substitute for good ones.

Comments on vertical problems

(From: Bert Christensen (bert.christensen@rose.com).)

As a general rule, vertical faults can be divided into two types: ones that cause geometric distortion (a circle will not be round) and those that simply black out a portion of the screen. The former are faults in the vertical oscillator, drive, or output stages. The latter are blanking faults. Blanking faults are almost always caused by electrolytic capacitors changing value and thereby changing the timing of the pulses which blank the screen during vertical retrace. In other words, the pulses are turning off the video signals at the wrong time.

The most common true vertical fault is geometric distortion and a foldover of white lines at the top of the screen. This is almost always caused by the electrolytic capacitor on or near the collector of the vertical output transistor or part of the IC which has the supply voltage (B+) on it. In the old tube days, the general rule was that bottom distortion was in the cathode of the output tube and distortion at the top was caused by a fault in the drive circuit.

Jagged or uneven vertical sweep

(From: Matthias Meerwein (Matthias.Meerwein@rt.bosch.de).)

I recently fixed two CRT display devices that both developed a very similar problem: The vertical deflection was severely "jagged" with uneven line spacing and partial vertical foldover. One patient was a nameless el-cheapo 28-inch TV (1988 made), the other one a 14 inch ADI SVGA monitor (1991 vintage).

My first suspicions were bad contacts on the PCB or yoke connectors or isolation / connectivity problems inside the yoke. However, as the picture didn't change with warmup or tapping, those causes could be ruled out. Examining the vertical deflection waveform with the scope showed the problem being a parasitic high frequency oscillation around the vertical output IC. On the TV, the oscillation extended over the entire scan period, while the monitor exhibited the problem only near the vertical current zero cross.

In both cases I found the capacitor of the RC damping network on the amp output to be at fault. Replacing it fixed the problem in both sets. This is not the well-known dried-up-electrolytic problem described in the FAQ. The culprits were mylar caps (.1 and .47 uF) looking completely unsuspicious. They were probably a bit underrated voltage-wise (40 volts) so I replaced them with 100 volts rated ones. The 2.2 ohms resistor in series with the cap was fine in both cases.

Excessive width/pincushioning problems

This would mean that the left and right sides of the picture are 'bowed' and the screen looks something like the diagram below (or the opposite - barrel distortion).

However, the obvious symptoms may just be excess width as the curved sides may be cut off by the CRT bezel.

```

 /                                          \
==============================================
```

In particular, this sounds like a pincushion problem - to correct for pincushion, a signal from the vertical deflection that looks something like a rectified sinewave is used to modify width based on vertical position. There is usually a control to adjust the magnitude of this signal and also often, its phase. It would seem that this circuit has ceased to function.

If you have the schematics, check them for 'pincushion' adjustments and check signals and voltages. If not, try to find the 'pincushion' magnitude and phase adjustments and look for bad parts or bad connections in in the general area. Even if there are no adjustment pots, there may still be pincushion correction circuitry.

If the internal controls have absolutely no effect, then the circuit is faulty. With modern digital setup adjustments, then it is even tougher to diagnose since these control a D/A somewhere linked via a microprocessor.

Pincushion adjustment adds a signal to the horizontal deflection to compensate for the geometry of the CRT/deflection yoke. If you have knobs, then tracing the circuitry may be possible. With luck, you have a bad part that can be identified with an ohmmeter - shorted or open. For example, if the pincushion correction driver transistor is shorted, it will have no effect and the picture will be too wide and distorted as shown above.

However, without a schematic even this will be difficult. If the adjustments are digital this is especially difficult to diagnose since you don't even have any idea of where the circuitry would be located.

Faulty capacitors in the horizontal deflection power supplies often cause a similar set of symptoms.

Deflection yoke testing

A faulty deflection yoke can affect the geometry (size and shape) of the raster, result in insufficient high voltage and/or other auxiliary power problems, and blow various components in the low voltage power supply or elsewhere.

- A simple test to determine if the yoke is at fault for a major geometry problem (e.g., a keystone shaped picture) is to interchange the connections to the yoke for the axis that is not affected (i.e., the vertical coils if the width is varying from top to bottom). If the raster/picture flips (indicating that you swapped the proper connections) but the shape of the raster remains the same - the geometry is unchanged, the problem is almost certainly in the deflection yoke.

- Where high voltage (and other flyback derived voltages) are reduced and other problems have been ruled out, unplugging the deflection yoke (assuming no interlock) may reveal whether it is likely at fault. If this results in high voltage and a relatively clean deflection waveform or returns the power supply or deflection chip load to something reasonable, a defective yoke is quite possible.

  CAUTION: powering a TV or monitor with a disconnected yoke must be done with care for several reasons:

  - The CRT electron beam(s) will not be deflected. If it turns out that the yoke is the problem, this may result in a very bright spot in the center of the screen (which will turn into a very dark permanent spot quite quickly) :-(. Disconnecting only the winding that is suspect is better. Then, the other direction will still scan resulting in a very bright line instead of a super bright spot. In any case, make sure the brightness is turned all the way down (using the screen/G2 control on the flyback if necessary). Keep an eye on the front of the screen ready to kill power at the first sign of a spot or line. Disconnecting the CRT heater as an added precaution would be even better unless you need to determine if there is a beam.

  - Removing the yoke (which is effectively in parallel with the flyback) increases the inductance and the peak flyback voltage on the HOT. In the extreme, this may blow the HOT if run at full line voltage/normal B+. It is better to perform these tests using a Variac at reduced line voltage if possible.

- The deflection system will be detuned since the yoke inductance plays a very significant role in setting the resonance point in most designs. Don't expect to see totally normal behavior with respect to high voltage. However, it should be much better than with the faulty yoke.

- If possible, compare all measurements with a known good identical deflection yoke. Of course, if you have one, swapping is the fastest surest test of all! In many cases, even a not quite identical yoke will be close enough to provide useful information for testing. However, it must be from a similar piece of equipment with similar specifications - size and scan range. Don't expect a color TV yoke to work in a high performance SVGA monitor!

  Note: the substitute yoke doesn't have to be mounted on the CRT which would disturb purity and convergence adjustments but see the caution above about drilling holes in the CRT face plate!

The deflection yoke consists of the horizontal coils and vertical coils (wound on a ferrite core), and mounting structure. Little magnets or rubber/ferrite strips may be glued in strategic locations. DO NOT disturb them! In rare instances, there may be additional coils or other components mounted on the same assembly. The following deals only with the actual deflection coils themselves - the other components (if any) can be tested in a similar manner.

Where the test procedure below requires removal of the yoke, see the section: Removing and replacing the deflection yoke first.

- Horizontal - the horizontal section consists of an even number of windings hooked up in parallel/interleaved with half of the windings on each of the two ferrite core pieces.

  The horizontal windings will be oriented with the coil's axis vertical and mounted on the inside of the yoke (against the CRT neck/funnel). It may be wound with thicker wire than that used for the vertical windings.

  - Resistance check - This may be possible without removing the yoke from the CRT if the terminal block is accessible. Disconnect the individual windings from each other and determine if the resistances are nearly equal. Check for shorts between windings and between the horizontal and vertical windings as well.

    Typical resistance of the intact windings (at the yoke connector assuming no other components): TV or NTSC/PAL monitor - a few ohms (3 ohms typical), SVGA monitor - less than an ohm (.5 ohms typical).

  - Inspection - Look for charring or other evidence of insulation breakdown due to arcing or overheating. For the horizontal windings, this will require removing the yoke from the CRT since little if any of the windings are visible from the outside. However, even then, most of the windings are hidden under layers of wire or behind the ferrite core.

  - Ring test. See the document "Testing of Flyback (LOPT) Transformers". This deals with flyback transformers but the principles are the same. Disconnecting the windings may help isolate the location of a fault. However, for windings wound on the same core, the inductive coupling will result in a short anywhere on that core reducing the Q.

- Vertical - The vertical section is usually manufactured as a pair of windings wired in parallel (or maybe in series) though for high vertical scan rate monitors, multiple parallel/interleaved windings are also possible.

  The vertical windings will be oriented with the coil's axis horizontal and wound on the outside of the yoke. The wire used for the vertical winding may be thinner than that used for the horizontal windings.

  - Resistance check - This may be possible without removing the yoke from the CRT if the terminal block is accessible. Disconnect the individual windings from each other and determine if the resistances are nearly equal. Check for shorts between windings and between the horizontal and vertical windings as well.

Typical resistance of the intact windings (at the yoke connector assuming no other components): TV or NTSC/PAL monitor - more than 10 ohms (15 ohms typical), SVGA monitor - at least a few ohms (5 ohms typical).

- Inspection - Look for charring or other evidence of insulation breakdown due to arcing or overheating. The accessible portions of the vertical windings are mostly visible without removing the yoke from the CRT. However, most of the windings are hidden under layers of wire or behind the ferrite core.

- Ring test - Since the vertical windings have significant resistance and very low Q, a ring test may be of limited value.

Deflection yoke repair

So you found a big black charred area in/on one of the yoke windings. What can be done? Is it possible to repair it? What about using it for testing to confirm that there are no other problems before ordering a new yoke?

If the damage is minor - only a few wires are involved, it may be possible to separate them from each other and the rest of the winding, thoroughly clean the area, and then insulate the wires with high temperature varnish. Then, check the resistances of each of the parallel/interleaved windings to make sure that you caught all the damage.

Simple plastic electrical tape can probably be used for as insulation for testing purposes - it has worked for me - but would not likely survive very long as a permanent repair due to the possible high temperatures involved. A new yoke will almost certainly be needed.

Testing of flyback (LOPT) transformers

How and why do flyback transformers fail?

Flybacks fail in several ways:

1. Overheating leading to cracks in the plastic and external arcing. These can often be fixed by cleaning and coating with multiple layers of high voltage sealer, corona dope, or even plastic electrical tape (as a temporary repair in a pinch).

2. Cracked or otherwise damaged core will effect the flyback characteristics to the point where it may not work correctly or even blow the horizontal output transistor.

3. Internal shorts in the FOCUS/SCREEN divider network, if present. One sign of this may be arcover of the FOCUS or SCREEN sparkgaps on the PCB on the neck of the CRT.

4. Internal short circuits in the windings.

5. Open windings.

More than one of these may apply in any given case.

First, perform a careful visual inspection with power off. Look for cracks, bulging or melted plastic, and discoloration, Look for bad solder connections at the pins of the flyback as well. If the TV or monitor can be powered safely, check for arcing or corona around the flyback and in its vicinity, Next, perform ohmmeter tests for obvious short circuits between windings, much reduced winding resistances, and open windings.

For the low voltage windings, service manuals may provide the expected DC resistance (Sams' PhotoFact, for example). Sometimes, this will change enough to be detected - if you have an ohmmeter with a low enough scale. These are usually a fraction of an ohm. It is difficult or impossible to measure the DC resistance of the HV winding since the rectifiers are usually built in. The value is not published either.

Caution: make sure you have the TV or monitor unplugged and confirm that the main filter capacitor is discharged before touching anything! If you are going to remove or touch the CRT HV, focus, or screen wires, discharge the HV first using a well insulated high value resistor (e.g., several M ohms, 5 W) to the CRT ground strap (NOT signal ground. See the section: Safe discharging of capacitors in TVs and video monitors.

Partially short circuited windings (perhaps, just a couple of turns) and sometimes shorts in the focus/screen divider will drastically lower the Q and increase the load the flyback puts on its driving source with no outputs connected. Commercial flyback testers measure the Q by monitoring the decay time of a resonant circuit formed by a capacitor and a winding on the flyback under test after it is excited by a pulse waveform. It is possible to easily construct testers that perform a well. See the companion document Testing of Flyback (LOPT) Transformers for further information.

High Voltage Power Supply Problems

HV power supply fundamentals

Most, if not all, TVs derive the high voltage for the CRT second anode, focus, and (sometimes) screen (G2) from the horizontal deflection system. This technique was developed quite early in the history of commercial TV and has stuck for a very simple reason - it is very cost effective. A side effect is that if the horizontal deflection fails and threatens to burn a (vertical) line into the CRT phosphors, the high voltage dies as well.

Most TV high voltage supplies operate as follows:

1. Horizontal output transistor (HOT) turns on during scan. Current increases linearly in primary of flyback transformer since it appears as an inductor. Magnetic field also increases linearly. Note: flyback is constructed with air gap in core. This makes it behave more like an inductor as far as the primary drive is concerned.

2. HOT shuts off at end of scan. Current decreases rapidly. Magnetic field collapses inductively coupling to secondary and generates HV pulse. Inductance and capacitance of flyback, snubber capacitors, and parasitic capacitance of circuitry and yoke form a resonant circuit. Ideally, voltage waveform across HOT during flyback (retrace) period will be a single half cycle and is clamped by damper diode across HOT to prevent undershoot.

3. Secondary of flyback is either a single large HV winding with HV rectifiers built in (most often) or an intermediate voltage winding and a voltage multiplier built in or a separate unit (see the section: What is a tripler?. The output will be DC HV pulses.

4. The capacitance of the CRT envelope provides the needed filtering to adequately smooth the HV pulses into a DC voltage.

5. A high resistance voltage divider provides the several kV focus voltage and sometimes the several hundred volt

screen (G2) voltage as well. Often, the adjustments for these voltages are built into the flyback. Sometimes they are mounted separately. The focus and screen are generally the top and bottom knobs, respectively.

What is a tripler?

In some TVs, the flyback transformer only generates about 6-10 kV AC which is then boosted by a diode-capacitor ladder to the 18-30 kV needed for modern color CRTs. The unit that does this is commonly called a tripler since it multiplies the flyback output by about 3 times. Some TVs use a quadrupler instead. However, many TVs generate the required HV directly with a winding with the required number of turns inside the flyback transformer.

Triplers use a diode-capacitor ladder to multiply the 6-10 kV AC to 18-30 kV DC. Many triplers are separate units, roughly cubical, and are not repairable. Some triplers are built in to the flyback - it is probably cheaper to manufacture the HV diodes and capacitors than to wind a direct high voltage secondary on the flyback core. In either case, failure requires replacement of the entire unit.

For external multipliers, the terminals are typically marked:

- IN - from flyback (6-10 kV AC).
- OUT - HV to CRT (20-30 kV DC).
- F - focus to CRT (2-8 kV).
- CTL - focus pot (many megohm to ground).
- G, GND, or COM - ground.

Symptoms of tripler failure are: lack of high voltage or insufficient high voltage, arcing at focus protection spark gap, incorrect focus voltage, other arcing, overload of HOT and/or flyback, or focus adjustment affecting brightness (screen) setting or vice-versa. Where there is overloading, if you disconnect the tripler and everything else comes back to life (obviously, there will be no HV or picture), then it is very likely bad.

High voltage shutdown due to X-ray protection circuits

A TV that runs for a while or starts to come on but then shuts down may have a problem with the X-ray protection circuitry correctly or incorrectly determining that the high voltage (HV) is too great (risking excessive X-ray emission) and shutting everything down.

A side effect of activation of this circuitry is that resetting may require pulling the plug or turning off the real (hard) power switch.

Was there anything else unusual about the picture lately that would indicate an actual problem with the HV? If this is the case, then there may be some problem with the HV regulation. If not, the shutdown circuit may be overly sensitive or one of its components may be defective - a bad connection of leaky cap (or zener).

If the horizontal frequency is not correct (probably low) due to a faulty horizontal oscillator or sync circuit or bad horizontal hold control (should one exist!), HV may increase and trigger shutdown. Of course, the picture won't be worth much either!

One symptom of excessive HV (but not required) is an overly bright picture of reduced size.

The HV shutdown circuit usually monitors a winding off of the flyback for voltage exceeding some reference and then sets a flip flop shutting the horizontal drive off.

On some Sony models, a HV resistive divider performs this function and these do fail - quite often. The big red Hstat block is a common cause of immediate or delayed shutdown on certain Sony monitors and TVs. See the section: Sony TVs/monitors and Hstat.

Low or no high voltage

Most of these problems are due to faults in the horizontal deflection system - shorted HOT, shorted windings or HV rectifiers in the flyback, defective tripler, or other bad parts on the primary side of the flyback.

However, if you discover an inch layer of filth inside the TV, the HV could simply be shorting out - clean it first.

In most cases, these sorts of faults will put an excessive load on the horizontal output circuits so there may be excessive heating of the HOT or other components. You may hear an audible arcing or sizzling sound from internal shorts in the flyback or tripler. Either of these may bet hot, crack, bulge, or exhibit visible damage if left on with the fault present.

Most modern TVs do not regulate HV directly but rather set it via control of the low voltage power supply to the HOT (B+), by snubber capacitors across the HOT, and the turns ratio of the flyback. The HV is directly related to the B+ so if this is low, the HV will be low as well. Faulty snubber capacitors will generally do the opposite - increase the HV and the X-ray protection circuits may kick in. However, low HV is also a possibility. The only way the turns ratio of the flyback can change is from a short which will manifest its presence in other ways as well - excessive heating and load on the horizontal output circuits.

While a shorted second anode connection to the CRT is theoretically possible, this is quite unlikely (except, as noted, due to dirt).

Excessive high voltage

Any significant increase in HV should cause the X-ray protection circuits to kick in and either shut down the set or modify the deflection in such a way as to render it harmless.

Symptoms include arcing/sparking of HV, smaller than normal picture, and under certain scenarios, possible excessive brightness.

Causes of the HV being too high are:

1. Excess B+ voltage to the HOT. The likely cause is to a low voltage regulator failure.

2. Open snubber capacitors across the HOT. These are under a lot of stress and are located near hot components so failure is possible.

3. Incorrect excessively long scan drive to HOT caused by failure of horizontal oscillator/sync circuits. However, other things like the HOT will probably blow up first. The picture will definitely be messed up.

4. Failure of HV regulator (tube sets and a few solid state sets - actual HV regulators are relatively uncommon today.) This may result in an underscanned (smaller than normal) picture.

Snaps, crackles, and other HV breakdown

Various problems can result in occasional or sustained sparking or arcing sounds from inside the monitor. Note that a static electricity buildup is common on the front of the screen. It is harmless and there iss nothing you can do about it anyhow.

The following may result in occasional or sustained sounds not commonly associated with a properly working TV or monitor. There may or may not be flashes or blanking of the screen at the same time as the audible noise. See the same-named sections that follow for details.

- Arcing, sparking, or corona from CRT HV anode (red wire/suction cup).
- Arcing at CRT sparkgaps.
- Arcing from flyback or vicinity.
- Arcing due to bad connections to or disconnected CRT return.
- Flashovers inside the CRT.

Arcing, sparking, or corona from CRT HV anode (red wire/suction cup)

Symptoms could include a sizzling corona or more likely, an occasional or rapid series of sharp snaps - possibly quite loud and quite visible - from the anode connection (at the suction cup) on the CRT to the grounded coating on the outside of the CRT or a chassis ground point (or any other conductor nearby). Corona is a high resistance leakage through the air without total breakdown. The snapping is caused by the sudden and nearly complete discharge of the CRT anode capacitance through a low resistance ionized path similar to lightning.

There are two likely causes:

1. Dirt, dust, grime, around and under the suction cup on the CRT are providing a discharge path. This may be more severe in humid weather. Safely discharge the HV and then remove and thoroughly clean the HV suction cup and the area under it and on the CRT for several inches around the HV connection. Make sure there are no loose wires or other possible places for the HV to discharge to in the vicinity.

2. The high voltage has gone through the roof. Usually, the X-ray protection circuitry should kick in but it can fail. If cleaning does not help, this is a likely possibility. See the sections: "High voltage shutdown due to X-ray protection circuits" and "Excessive high voltage".

Arcing from flyback or vicinity

Arcing may be visible or audible and result in readily detectable levels of ozone. Note that very slight traces of ozone may not indicate anything significant but if the TV smells like an office copier, there is probably some discharge taking place.

WARNING: It is possible for arcing to develop as a result of excessive high voltage. Symptoms might be a smaller than normal excessively bright picture but this may not be able to be confirmed until the flyback is repaired or replaced. See the section: Excessive high voltage.

- On the HV output, it will probably be a loud snapping sound (due to the capacitance of the CRT) with associated blue/white sparks up to an inch or more in length. If the arc length is short enough, this may turn into a nearly continuous sizzling sound with yellow/orange arc and melting/burning plastic.

- Prior to the HV rectifier, it will likely be a continuous sizzle with orange/yellow/white arc and melting/burning plastic or circuit board material.

- Internal arcing in the flyback may be audible and eventually result in a bulging and/or cracked case (if some other component doesn't fail first as this would take some time to develop).

- A corona discharge without actual sparks or a visible well defined arc is also possible. This may be visible in a totally dark room, possibly more likely when the humidity is high. A thorough cleaning to remove all dust and grime may be all that is needed in this case.

- If the arc is coming from a specific point on the flyback - a crack or pinhole - this may be patched well enough to confirm that the rest of the TV is operational and a new flyback is worth the money. Otherwise, there is no way of knowing if the arcing may have damaged other circuitry until a replacement flyback - possibly money wasted - arrives.

  To attempt a repair, scrape off any dirt or carbon that is present along the path of the arcing and its vicinity. Then, clean the area thoroughly with alcohol and dry completely. Otherwise, the dirt and carbon will just act as a good conductor and the arcing will continue under your repair! Several layers of plastic electrical tape may be adequate for testing. Multiple coats of high voltage sealer or non-corroding RTV silicone (if it smells like vinegar - acetic acid - as it cures, this may get in and affect the windings) would be better if the objective is an actual repair. A thick layer of Epoxy may be even better and affected less by possible HV corona. Either of these may prove to be a permanent fix although starting the search for a source for a new flyback would not hurt just in case. The arc most likely did damage the insulation internally which may or may not be a problem in the future.

  Also see the section: Dave's complete procedure for repair of an arcing flyback.

- In some cases, the pinhole or crack is an indication of a more serious problem - overheating due to shorted windings in the flyback or excessive secondary load.

- If the arc is from one of the sparkgaps around the CRT, the CRT socket, or the plastic 'alignment base' on the CRT itself, this could also be a flyback problem indicating internal shorts in the focus/screen network.

- If the arcing is inside the CRT, this could indicate a bad CRT or a problem with the flyback focus/screen network and no or inadequate sparkgap protection.

Where repair seems possible, first, clean the areas around the arc thoroughly and then try several layers of plastic electrical tape. If the TV works normally for say, an hour, then there is probably nothing else wrong and you can try for a proper sealing job or hope that tape holds out (put a few more layers on - each is good for about 8-10 kV theoretically).

However, replacement of the flyback really is the best alternative to minimize risk of future problems. This is the only option where there could be a potential issue of liability should subsequent failure result in a fire.

Once I had a TV where the main problem was a cracked flyback arcing but this took out one of the fusable resistors for the power supply to the *vertical* output so the symptoms included a single horizontal line. Don't ask me to explain - replacing that resistor and the flyback (the flyback tested good, but this was for someone else) fixed the TV.

In another case, a pinhole developed in the flyback casing probably due to poor plastic molding at the time of manufacture. This resulted in a most spectacular case of sparking to a nearby bracket. A few layers of electrical tape was all that was needed to affect a permanent repair.

Dave's complete procedure for repair of an arcing flyback

(From: Dave Moore (penguin@datastar.net).

First I clean the afflicted area with Electromotive spray from Autozone. It's for cleaning alternators. On Z-line I remove the focus control and wash with the alternator cleaner and a tooth brush until all dirt and carbon deposits are removed. Then I take an xacto knife and carve out the carbonized hole where the arcing broke through. Then take your soldering iron and close the hole by melting adjacent plastic into it. (clean any solder off your iron with solder-wick first). Then cut some plastic off of some other part off the flyback where it wont be needed and use this to plastic weld (with your iron) a hump of a patch into and over the arc hole. Smooth and seal with iron. Next apply as thick a layer of silicone rubber as you can and let dry overnight.

Arcing at spark gaps and gas discharge tubes on CRT neck board or elsewhere

These are protective devices intended to breakdown and divert excessive voltage away from the CRT (usually).

This is rarely due to a defective sparkgap or gas discharge tube but rather is a safety mechanism like a fuse designed to protect the internal electrodes of the CRT if the focus or screen voltage should become excessive. The sparkgap breaks down first and prevents internal arcing in the CRT. These sparkgaps may be built into the CRT socket as well.

Arcing at a sparkgap or a glowing or flashing discharge tube may be accompanied by total loss of picture or bad focus, brightness or focus fluctuations, or any of a number of similar symptoms. A common cause is a breakdown inside the focus divider (usually part of the flyback or tripler) but could also be due to excessive uncontrolled high voltage due to a failure of the B+ regulator or HOT snubber capacitor, or (ironically) even a short inside the CRT.

- Spark gaps may be actual two or three pin devices with seemingly no insides, part of the CRT socket, or printed on the circuit board itself.

- Gas discharge tubes look like small neon lamps (e.g., NE2) but could be filled with some other gas mixture to provide a controlled higher breakdown voltage.

Therefore, like a fuse, don't just replace or disable these devices, locate and correct underlying problem. The CRT makes an expensive fuse!

Arcing due to bad connections to or disconnected CRT return

The Aquadag coating on the outside of the CRT is the negative plate of the HV filter capacitor. If this is not solidly connected to the HV return, you will have your 25 kV+ trying to go where it should not be. There should be a wire solidly attached to the CRT neck board or chassis. Without this, voltage will build up until it is able to take some other path - possibly resulting in damage to sensitive solid state components in the process. Therefore, is is important to rectify the situation.

Warning: If you find this disconnected, don't just attach it anywhere. You may instantly kill ICs or other solid state components. It must be connected to the proper return point on the CRT neck board or chassis.

Flashovers inside the CRT

Due to sharp edges on the electron gun electrodes, impurities, and other manufacturing defects, there can be occasional arcing internal to the CRT. Properly designed HV, deflection, and power supply circuits can deal with these without failing but not all monitors are designed well.

There is nothing you can do about flashovers assuming your HV is not excessive (see the section: Excessive high voltage. If these persist and/or become more frequent, a new CRT or new TV will be needed.

Ozone smell and/or smoke from TV

Smoking is just as bad for TVs as for people and usually more quickly terminal.

White acrid smoke may indicate a failed electrolytic capacitor in the power supply probably in conjunction with a shorted rectifier. Needless to say, pull the plug at once.

A visual inspection should be able to easily confirm the bad capacitor as it will probably be bulging and have condensed residue nearby. Check the rectifier diodes or bridge rectifier with an ohmmeter. Resistance across any pair of leads should be more than a few ohms in at least one direction. Remove from the circuit to confirm. Both the faulty diode(s) and capacitor should be replaced (though the capacitor may work well enough to test with new diode(s).

If a visual inspection fails to identify the smoking part, you can probably plug the set in for a few seconds until the source of the smoke is obvious but be prepared to pull the plug in a real hurry.

If the smell/smoke is coming from the flyback, then it has probably gone belly up. You may be able to see a crack or bulge in the case. While the flyback will definitely need to be replaced, it is likely that nothing else is wrong. However, it might be prudent to use a Variac when performing initial testing with the replacement just in case there is a secondary short circuit or excess HV problem.

X-ray and other EM emission from my TV or monitor?

X-ray radiation is produced when a high velocity electron beam strikes a target containing heavy metals. In a modern TVs and monitors, this can only take place at the shadow mask/aperture grille and phosphor screen of the CRT.

For X-rays, the amount of radiation (if any) will be proportional to brightness. The energy (determined by the CRT high voltage, called kVP in the medical imaging field) is not affected. This is one reason many monitors and TVs are designed with brightness limiting circuits.

In any case, there will be virtually no X-ray emissions from the front of the CRT as the glass is greater than an inch thick and probably contains some lead for added shielding. Also see the section: Should I be worried about X-ray exposure while servicing a TV or monitor?.

Electromagnetic radiation (EM) is produced mostly from the deflection yoke and to a lesser extent from some of the other magnetic components like transformers and inductors. Depending on monitor design (some are specifically designed to reduce this), EM emissions can vary quite a bit. Frequencies range from the 50/60 Hz of the power line or vertical scan rate to several hundred kHz in the AM broadcast band. The intensity and spectral distribution will vary depending on horizontal and vertical scan rate.

A totally black screen will reduce X-ray emission to zero. It will not affect EM emissions significantly as most of this comes from the magnetic parts, particularly the deflection yoke.

There is no measurable microwave, IR, or UV radiation.

I refuse to get into the discussion of what, if any, health problems result from low level EM emissions. There is simply not enough data.

Should I be worried about X-ray exposure while servicing a TV or monitor?

The only source of X-rays in a modern TV or monitor is from the CRT. X-rays are generated when a high velocity electron beam strikes a heavy metal target. For anything you are likely to encounter, this can only happen in a vacuum - thus inside the CRT. The higher the voltage, the greater the velocity and potential danger. Really old TVs (prior to around 1975) may still have HV rectifier and regulator tubes - other sources of X-rays. However, modern TVs and monitors implement these functions with solid state components.

The thick front CRT faceplate protects users adequately but there may be some emission from the thinner sides. At 25-30 kV (quite low as X-ray energies go) X-rays will be stopped by almost any metal so what you have to worry about is where there are no shields.

Other than lowering the brightness (or high voltage!), there isn't anything you can do to reduce X-ray emission from the front of the monitor. Any sort of add-on screen (grounded or otherwise) unless it is made of thick leaded glass, will have no significant effect on X-rays. If you are still concerned, sit farther away.

However, realistically, there is very little danger. I would not worry about exposure unless you plan to be sitting for hours on the sides, behind, or under the TV or monitor - with a picture (there will be none if the screen is black).

It is interesting that even those 1.5" Watchman and .5" camcorder viewfinder CRTs have X-ray warning labels even though the high voltage used with these isn't anywhere near high enough to be of any concern!

More on radiation from TVs and monitors

(From: Jerry Greenberg (jerryg50@hotmail.com).)

Your standard TV set or monitor should not exceed about 0.2 mR/Hr of radiation from a distance of 5 cm from any part of the cabinet. Most TV monitor equipment is less than half of this amount.

The CRT has a coating on the inner wall of its glass envelope, and also there is a metal shadow mask or aperture grill in the front. There is also a metal shroud around its parameter.

The type of emission from the CRT is known as soft X-Ray emission. This is because it is low power, and is in the lower X-Ray region.

The X-Ray emission is strongest at the rear of the TV set because there is some opened area where the electron gun is located. But, this is very weak as well. The radiation from a TV or monitor is not being focused to one point, and is also below the threshold level of being dangerous.

The long term effect of the total radiation from normal operating TV equipment is not fully known. However, the effect of X-Ray radiation is accumulative over time if there are no breaks in between the exposures. As for standard focused X-Rays like the ones used in a medical or security facility, these and most of their effects are well known.

As for normal working TV equipment, when used normally, the total radiation is less that what you would get when walking on the street. There are many satellites beaming down signals, radio and TV broadcast stations, communications systems, and then cell phones.

The X-Ray radiation in a TV set is emitted from the effect of the High Voltage drive generating the electron beam. If the High Voltage exceeds the designed safety limit for the CRT, then there is concern that the X-Ray radiation may have some effect on anyone that is in close proximity to the CRT. The amount of by which the high voltage exceeds the design specfifications will determine the total X-Ray emission. Since this emission is not focused into a fine area, its immediate danger is also greatly reduced.

All TV sets by law must have in their design some type of protection to shut the TV down if there is excessive High Voltage, excessive High Voltage current drive, and a number of other safety criterias.

There is also the concern about electromagnetic radiation. In fact all radio frequencies are based on electromagnetic radiation (EMR).

There was a great concern about the low frequency EMR. This would come from the power supply, deflection amplifier stages, and then from the deflection yoke and flyback transformer. There different types of EMR from TV sets.

Concerning TV's and monitors, this radiation worry comes up from time to time. If a woman is pregnant it would be wiser for her to not expose the unborn baby by working close to a terminal or monitor. This nonexposure is a good policy to make sure that everyone is safe rather than suffer any type of damage or health risks.

As for a safety concern for a mother to be, or a small baby, they can be in front of a TV set but at least 5 to 7 feet away. From this distance there should not be any danger at all.

The above is from my personal observations and is very general. I have also read various publications over the years that pertain to this subject.

I have a personal concern about the radiation from TV sets and monitors because I do an extensive amount of service on these. I am also doing a lot of picture tube changes in monitor equipment. I am then exposed for a few hours because I must do the purity and convergence setups of these sets. I have some days where I work 10 to 12 hours doing TV and monitor service work.

If you want a TV monitor that will put out near zero X-Ray radiation, and very low electromagnetic radiation, then go for one of the new LCD flatscreen monitors.

Flyback shot by 4 year old with water pistol

Your 4 year old son shot the Sony in the flyback transformer. Smoke and sparks everywhere. Great aim!

Who says these FAQs cannot be funny?

Needless to say, unplug the set immediately. Inspect around the target area for obviously blown or damaged components. Test fuses and fusable resistors. Repair burnt solder connections and circuit board traces. Once the set is entirely dried out, power it up - preferably through a series light bulb and/or Variac until you are sure nothing else will let loose. Look, listen, and smell for any unusual behavior. If it now works, then consider yourself lucky. If not, there may be damage to transistors, ICs, or other components.

(From: Richard Symonds (edison@nelson.planet.org.nz).)

We're seeing another 'hazard' these days, people cleaning their television screens with window cleaner - no problem in the days of separate chassis but with the entire circuit board jammed under the tube on most TVs these days just a few drips and its all over. Some have just corroded the switch banks (had one recently just got into the A/V switch - when you walked around the room the set changed to A/V and back by itself!) but a few have got around the microprocessors and surface mount components and resulted in complete write-offs. I suppose the damage is the opposite of electroplating as the microprocessors have constant voltage to them. Never mind, they'll be a good source of parts for future use.

Blooming or breathing problems

There are several symptoms that are basically similar:

- Blooming is defined as an expansion of the raster or horizontal sections of the raster with bright material. For example, switching between dark and light picture causes the size of the picture to expand by 10%. A slight change in size is unavoidable but if it is greater than 1 or 2 percent from a totally black image to a full white one, this is either an indication of a defective TV or one that is badly designed. The cause is poor low or high voltage regulation.

  Check the B+ to the horizontal deflection. This is usually well regulated. If it is varying in sympathy to the size changes, trace back to determine why the low voltage regulator is not doing its job. The reason for the size change is that the high voltage is dropping and reducing the stiffness of the electron beam.

- Expansion of the raster width in areas of bright imagery is an indication of short term regulation problems. The video drive may be interacting with the other power supplies. Check for ripple - this would be at the vertical scan rate - in the various regulated power supplies. The cause may be a dried up electrolytic capacitor - once you locate the offending voltage, test or substitute capacitors in that supply.

In both these cases, if this just started after some work was done to the TV, the brightness limiter and/or video drive may simply be set so high that the TV cannot supply enough current to the high voltage. If the brightness is acceptable with these turned down slightly and still have acceptable brightness, then there may be nothing wrong.

- Breathing is defined as a periodic change in the size of the raster which may be independent of what is displayed or its severity or frequency may be related to the brightness or darkness of the image. This is another type of regulation problem and may be caused by bad electrolytic capacitors or other components in the low voltage power supplies.

  If the TV uses a switchmode power supply or low voltage regulator separate from the horizontal deflection, first check its output(s) for a variation in voltage at the breathing rate. Test with a light bulb or resistor load to confirm that the problem is here and not the deflection or other subsystem of the TV.

- A condition with somewhat similar symptoms is bad focus - fuzzy picture - but only with bright (high beam current) scenes. This could be just a matter of adjusting the focus control but may also indicate sub-optimal filament voltage due to bad connections or components in the filament circuit, or a tired worn CRT. You won't get high beam current without some serious spot blooming (a fat beam because too much cathode area is used) and you will get cathode 'poisoning' after prolonged use.

  Visually inspect the neck of the CRT for the normal orange glow of the filaments and check for bad connections and bad parts.

Erratic focus or screen (G2) voltage and/or controls on flyback

Symptoms may include fluctuating focus or brightness. In extreme cases, the result may be a too bright or dark picture or other behavior caused by breakdown in the Focus/Screen(G2) divider network.

Usually, this will require flyback replacement to repair reliably. Sometimes, the section with the controls can be snapped apart and cleaned but this is not common.

First, just try rotating the screen (G2) control back and forth a few times. This may clean up the contacts and eliminate the erratic behavior. Possibly, positioning it a bit to one side of the original location will help. Then, use the individual or other master background/bias adjustments to compensate for the improper brightness.

If pressing in on the erratic control helps to stabilize the setting, you might try adjusting it to the optimal position and then put a dab of hot-melt glue (or Superglue if you can manage not to stick your fingers together) on the shaft to hold it with a little more contact force.

If none of this helps, here is a 'well it's going in the dumpster anyhow' procedure to try:

After discharging the CRT (so you don't get zapped) drill a tiny hole in the plastic cover near the bad control. Be careful you don't damage anything inside - you just want access to the contacts of the controls. Use a hand drill with, say, a 1/16" bit. Don't drill more than about 1/8" deep which should enter the airspace. Then spray some contact cleaner through the hole and work the controls. Wait sufficient time (say, 24 hours) for everything to dry COMPLETELY and see if behavior changes (or it works at all).

This is a 'you have got to be kidding' type of repair so no guarantees :-).

If by some miracle it does work, fill the hole with a drop of RTV or just put a couple of layers of electrical tape over it.

Focus/Screen divider bypass surgery

This is kludge number 41256 but may be the difference between a bit more life and the dumpster.

If the previous extreme measures don't help, then it may be possible to simply substitute a good divider network externally.

Note that if there is evidence of internal breakdown in the divider of the original flyback (hissing, cracks, overheating, bulging case, etc.), this will not work unless you can disconnect it from its HV connection.

There are two issues:

1. Is this a stable situation? Even if you provide an external substitute, the parts inside the flyback may continue to deteriorate eventually resulting in other more total failure of the flyback or worse.

2. If you provide an external focus/screen divider, it must be done is such a manner (including proper mounting and super insulation) such that it cannot be called into question should there be a fire where the monitor is even the slightest bit suspect.

Various size external focus/screen divider networks can be purchased but whether this is truly a cost effective solution is not obvious.

(From: Larry Sabo (sabo@storm.ca).)

I just ordered a 'bleeder resistor' from Data Display Ltd (Canadian sub of CCS) to use as a cure for flybacks with flaky focus/screen pots. It contains focus and screen pots, and costs Cdn$ 16.99, which is a lot less than a complete flyback, that's for sure. I expect it will be compatible with quite a wide range of flybacks.

I have used bleeder resistor assemblies from duff flybacks a couple of times with good success. You connect the HV lead into the HV cap of the original flyback, ground all pins of the sub flyback, and use the focus and screen leads from the sub bleeder assembly in place of the originals.

Looks like hell but works fine. Mounting (and securing) the substitute is a challenge given the limited space available. I only use this approach on what would otherwise be uneconomical to repair, and always advise the owner or customer of the cobbling job. It also enables you to verify whether it is the flyback that needs replacement, versus the CRT.

Decaying or erratic focus or screen (G2) voltages

The following applies to both CRT focus voltage (which should be a few kV) and screen or G2 voltage (which should be several hundred V).

> "The screen voltage will come up to normal after sitting over night, 400 V or so. After approximately 5 minutes or slightly longer, I hear a slight arcing. From that point on, the screen voltage will wander anywhere from 75 V up to maybe 150 V. Adjustment of the screen control on the flyback has only a small effect and is not permanent. Removing the CRT pcb results in the screen voltage returning to normal."

This is very likely a short between electrodes inside the CRT unless there is something on the neck board that is breaking down as a result of some connection to the CRT. The flyback should largely not know the difference with the socket plugged into the CRT. However, on rare occasions, there is contamination within the 'plastic alignment base' on the end of the CRT neck. (It is possible to *carefully* remove the plastic piece and clean the CRT glass/pins. Reinstall the plastic piece if it is still intact or leave it off - just take care in replacing the CRT neck board.)

One possibility is that glue used to hold components down on some circuit boards has deteriorated and turned conductive. Check for tan to brown stuff shorting traces on the CRT neck board. If this is present on the focus or screen traces or wires, it may just be your problem. Scrape off all of the old glue and then clean thoroughly. Repair any damaged traces.

What happens to the HV? A HV breakdown possibly inside the CRT would result in all the voltages being dragged down.

What happens to the picture?

If you connect a charged HV capacitor (guessing a couple hundred volts, a couple microfarads) between G2 and G1 or focus, you **will** know if tapping the neck results in a momentary short! I cannot predict whether this will be a temporary cure or permanent killer. See the section: Rescuing a shorted CRT.

Here is another thing to try: put a 100 M ohm or so resistor between SCREEN and the CRT socket. This should not affect the behavior much until the failure occurs. Then, check the voltage on both sides with a high impedance voltmeter (1000 M). If the CRT is arcing, it will be much lower on the CRT side and will probably fluctuate. You can play similar games with focus voltage.

Disconnecting flyback wire(s) from CRT driver board

In some cases, there may be one or more separate wires running to directly to the CRT socket. These are typically for focus which has a relatively high voltage so better insulation is needed but there may be no obvious means of removal should flyback replacement be needed.

One alternative is simply to cut the wire(s) in a location that is well away from any place to short out, solder, and then do a most excellent job of insulating the splice. If there is more than one wire, make sure to label them first if they aren't color coded.

However, you may find that the cap on the CRT socket snaps off using a thin knife blade or screwdriver. The wire may be soldered or just pressed in place in such a way that pulling it out is difficult or impossible without removing the cover. If there is more than one wire, label them before removal unless the locations are clearly marked. Sometimes the color is stamped on the plastic but there may just be a designation like "A" and "B".

(From: Raymond Carlsen (rrcc@u.washington.edu).)

The last one I worked on puzzled me for a few moments. See if you can see a space between the little cup (where the wire enters the socket) and the socket itself. Pry up on the cap with a knife and it should pop right off. The wire is soldered to a pin under it. Don't apply heat for very long... you may melt the socket.

Focus or screen voltage drifts after warmup only when CRT is connected

> "I have a 3-5 yr old TV that loses screen voltage. I believe that the problem is specific to the CRT or the flyback, either one is a guess I'd rather be sure of prior to ordering a part.
>
> The screen voltage will come up to normal after sitting over night, 400 V or so. After approximately 5 minutes or slightly longer, I hear a slight arcing. From that point on, the screen voltage will wander anywhere from 75 V up to maybe 150 V. Adjustment of the screen control on the flyback has only a small effect and is not permanent. Removing the CRT pcb results in the screen voltage returning to normal.

> I cannot find the source of the arcing, as it happens quickly and I have always been on the other side of the set when it happens. I have replaced the CRT socket, thinking the spark gap was arcing. I have checked the CRT for G1 and HK shorts on a sencore CRT checker, it checks good, but I am aware that since it is an intermittent problem, that the checker probably will not catch it."

This is very likely a short between electrodes inside the CRT unless there is something on the neck board that is breaking down as a result of some connection to the CRT. The flyback should largely not know the difference with the socket plugged into the CRT. However, on rare occasions, there is contamination within the 'plastic alignment base' on the end of the CRT neck. (It is possible to *carefully* remove the plastic piece and clean the CRT glass/pins. Resinstall the plastic piece if it is still intact or leave it off - just take care in replacing the CRT neck board.)

One possibility is that glue used to hold components down on some circuit boards has deteriorated and turned conductive. Check for tan to brown stuff shorting traces on the CRT neck board. If this is present on the focus or screen traces or wires, it may just be your problem. Scrape off all of the old glue and then clean thoroughly. Repair any damaged traces.

What happens to the HV? A HV breakdown possibly inside the CRT would result in all the voltages being dragged down.

What happens to the picture?

If you connect a charged HV capacitor (guessing a couple hundred volts, a couple microfarads) between G2 and G1 or focus, you **will** know if tapping the neck results in a momentary short! I cannot predict whether this will be a temporary cure or permanent killer.

Here is another thing to try: put a 100 M ohm or so resistor between SCREEN (or FOCUS) and the CRT socket. This should not affect the behavior much until the failure occurs. Then, check the voltage on both sides with a high impedance voltmeter (>1000 M). If the CRT is arcing, it will be much lower on the CRT side.

Raster, Color, and Video Problems

No color - black and white picture

This means absolutely no color - equivalent to a black and white picture. Not even a hint of color.

First, confirm that the source is actually in color - try another channel or input device.

Next, check the settings of the color control - it may have accidentally been turned down. If your TV has some kind of automatic picture mode, try turning if off and adjusting the color control. Try adjusting fine tuning if you have such a control and the problem is with a broadcast or cable transmission.

At this point with a confirmed color signal source, there is a problem with the chroma circuitry.

Note that to the average person, the obvious question becomes: is my color picture tube bad? The answer is a definitive NO. It is virtually impossible for a defective CRT to cause a total loss of color. A defective CRT can cause a lack of a primary color - R, G, or, B or a short between two colors which will mess up the color but is not likely to result in a black and white picture.

Some possibilities in no particular order:

1. Weak signal or defect in tuner/IF causing loss of signal strength.

2. Coler killer set too high (internal control) if it has one.

3. Defective part around the chroma chip/circuit. Faulty color oscillator.

4. Bad connections in area of chroma chip/circuit.

5. Defective chroma chip (don't suspect this first just because it is probably very expensive).

A service manual or Sams', DMM, and scope will help greatly in attempting to troubleshoot this unless it is an obvious bad connection. Try prodding the main board around the chroma chip with an insulated tool to see if you can make the color come and go.

I had one set where a $.02 resistor decided to open up causing just this problem - perfect BW picture, no color. Another had a coil with a broken wire.

Saturated color but almost no brightness

This means you have lost the luminance input to the chroma decoder or final video chip. A failure of the brightness limiter may result in similar symptoms.

A few common causes are:

- Check the service switch (if any). Its contacts may be dirty and moving it back and forth a few times or using contact cleaner may be all that is needed.

- Check for open high value resistors around the chroma decoder IC.

- Check for open high value resistors in the brightness limiter circuit.

With a scope and schematic (or even just a pinout for the chip), you should be able to trace the luminance signal to see where it is getting lost.

This is also *not* a picture tube problem. :-)

(From: John Mehrtens (sarge@drag-net.com).)

I have had several TVs and monitors where the delay line in the luminance circuitry has failed. Usually it's made out of glass, and inherently is fragile. Sometimes whacking the monitor would make it come back, leading to the thought of connectoritis or a cold solder joint -- where in fact it was the delay line (long rectangular unit with two to four leads). Replacing the delay line was the solution, but to check it first it'd be a good idea to look for 'in' and 'out' on the line and short the pins. The picture may be shifted, colours may not line up, but it'll tell you that it's the delay line if the picture comes back at all. It's better than looking at a saturated picture with no luminance! :)

Brightness control has no effect

The following assumes that the picture is fine but the brightness is fixed - probably at too high a level. However, there could be several interrelated problems if a common supply voltage were missing, for example.

If it is a knob, then it should be varying the control grid (G1) voltages relative to the cathodes (K) of the CRT. This is not likely to be a very complex circuit. If you do not have a schematic, I would start by tracing from the control, check continuity and solder connections. Check the control itself for proper operation with an ohmmeter. A power supply going to one side of the control (negative probably) may be missing. Tbe control grid voltage will end up on the little board on the neck of the CRT - check there as well for bad solder connections or open resistors.

If brightness is a digital control, then you will need a schematic unless there is an obvious bad connection.

One color is too weak or too strong

If the problem is slight and/or has gradually gotten worse, this may just require an adjustment of the color brightness/background/bias and/or color gain/drive controls inside the TV. See the section: Color balance adjustment.

Note that if it is possible to obtain a good black and white picture with the user color control set to its minimum, then this is not likely a problem with one of the primary color channels (red, green, or blue) but with the chroma decoding circuitry. Or, perhaps, you are just watching MTV!

Even if it appears as though there is an excess, this may actually be a reduction in one of the primary colors. For example, a magenta tinge is represents a reduction in the strength of the green signal.

- Too high an intensity for one of the color channels will result in a tint of one of the primaries: red, green or blue.
- Too low an intensity for one of the color channels will result in a tint of the complement of one of the primaries: yellow, cyan, or magenta.
- Problems mainly in the shadows or dark areas of the picture usually represent a fault with brightness/bias/background.
- Problems mainly in the highlights or bright areas of the picture usually represent a fault with the gain/drive.

A color that that is now suddenly brighter or darker than normal resulting in incorrect color balance or a tint in the background could be due to a number of causes:

- Bad connections or bad component in video amplifier or on CRT neck board for that color.
- Fault in chroma decoder.
- Weak gun in CRT (reduced color).

Psychodelic color

The means colors that are not normal and that adjustment of the user controls is not able to correct it so that all colors of the picture are properly displayed at the same time. For example, you are unable to get any yellows or blues in scenes that should have these colors..

Make sure the user color and tint controls have not been accidentally turned while cleaning or purposedly misadjusted by small (or large) kids.

Perform the user setup described in the section: User picture adjustment.

Confirm that the source is not a weird color video - try another channel or a tape.

Verify that this is not a missing color problem - one of the primary R, G, or B, has disappeared. If so, refer to the section: Intermittent or missing colors.

Once these have been eliminated, you are left with the following possibilities:

1. Defective part around the chroma chip/circuit. Misadjusted color oscillator.

2. Bad connections or short circuit in area of chroma chip/circuit.

3. Defective chroma chip (don't suspect this first just because it is probably very expensive).

4. Bad degauss circuit resulting in lack of degauss or abrupt termination of degauss current rather than smooth tail off. The CRT is not being properly demagnetized and color purity is totally messed up.

5. Bad CRT - the shadow mask has been damaged and it is impossible to properly adjust purity across the screen.

A service manual or Sams', DMM, and scope will help greatly in attempting to troubleshoot this unless it is an obvious bad connection. For (1)-(3), try prodding the main board around the chroma chip with an insulated tool to see if you can restore normal color. For (4) try manually degaussing (see the section: Degaussing (demagnetizing) a CRT. If this clears up the colors until at least when it is power cycled, then a degauss problem is likely.

Something as simple as a bad resistor or inductor can be the cause - don't immediately suspect the most expensive and difficult to replace part.

No picture/dark picture/erratic picture

With power off, remove the picture tube socket (carefully!) and clean the pins with fine sandpaper and use contact cleaner on the socket. This source of bad connections can result in a variety of erratic symptoms.

TV and monitor manufacturing quality and cold solder joints

Any intermittent problems with monitors that cause random sudden changes in the picture brightness, color, size, or position are often a result of bad connections. Strategically placed bad connections can also cause parts to blow. For example, a bad connection to the SCR anode in a phase controlled power supply can result in all the current passing through the startup resistor, blowing it as well as other components. I had a TV like this - the real problem was a bad solder joint at a pin on the flyback. Thus, erratic problems, especially where they are power or deflection related, should not be ignored!

Bad solder joints are very common in TVs and monitors due both to poor quality manufacturing as well as to deterioration of the solder bond after numerous thermal cycles and components running at high temperature. Without knowing anything about the circuitry, it is usually possible to cure these problems by locating all bad solder connections and cleaning and reseating internal connectors. The term 'cold solder joint' strictly refers to a solder connection that was either not heated enough during manufacturing, was cooled too quickly, or where part pins were moved before the solder had a chance to solidify. A similar situation can develop over time with thermal cycling where parts are not properly fastened and are essentially being held in by the solder alone. Both situations are most common with the pins of large components like transformers, power transistors and power resistors, and large connectors. The pins of the components have a large thermal mass and may not get hot enough during manufacturing. Also, they are relatively massive and may flex the connection due to vibration or thermal expansion and contraction.

To locate cold solder joints, use a strong light and magnifier and examine the pins of large components for hairline cracks in the solder around the pin. Gently wiggle the component if possible (with the power off). Any detectable movement at the joint indicates a problem. With the power on, gently prod the circuit board and suspect components with an insulated tool to see if the problem can be effected.

When in doubt, resolder any suspicious connections. Some monitors may use double sided circuit boards which do not have plated through holes. In these cases, solder both top and bottom to be sure that the connections are solid. Use a large enough soldering iron to assure that your solder connection is solid. Put a bit of new solder with flux on every connection you touch up even if there was plenty of solder there before.

Why can't TV manufacturers learn to solder properly?

I can think of several potential reasons - all solvable but at higher manufacturing cost.

1. Mass of large component leads (like shields) does not get adequately heated during manufacture leading to latent cold solder joints. While they may look ok, the solder never actually 'wetted' the heavy pins and therefore did not form a good mechanical or electrical bond.

2. Thermal cycles and differential thermal coefficients of circuit boards, traces, and solder. While it is not easy to do anything about the material properties, using plated through-holes or a similar mechanical via would greatly increase the surface area of the joint and prevent the formation of cracks.

3. Vibration. This is also directly related to the single sided circuit boards without plated through-holes to strengthen the joints.

4. Lack of adquate mechanical support (single sided circuit boards without plated through-holes (vias).

I believe that the single most significantimprovement would come about by using plated trhough-holes but this would add to the cost and apparently the consumer is not willing to pay more for better quality and reliability! Some designs have used rivlets - mechanical vias instead of plated ones. While this is good in principle, the execution has often been flawed where cold solder joints resulted between the rivlets and the circuit board traces due to lack of adequate process control.

The Sony and RCA/GE tuner shield problem is interesting because this could have been solved years ago at essentially no additional cost as other manufacturers - and their own repair procedures - have proven.

Intermittent or missing colors

This is a catch-all for some of the most common TV and monitor problems.

Note that due to the additive color scheme used in all emissive color displays like CRT or flat panel TV sets and video monitors, a single missing primary color (red, green, or blue) will result in the following appearance (for a white screen):

```
   Missing Color       Appearance
 ------------------------------------------------
      Red              Cyan (blue-green)
      Green            Magenta (reddish-purple)
      Blue             Yellow
```

Which color is affected may be even more obvious if the set has a color on-screen display for which you recall the proper colors.

- If gently whacking the set can make the color(s) come and go suddenly, then bad connections are probable. The most likely place for these are solder pads on the little circuit board on the neck of the CRT or even dirty CRT socket pins that are not making solid contact. Try prodding the CRT neck board with an insulated stick to see if you can affect the colors.

  Although not impossible, this is not likely to be a CRT problem.

- If the color fades in and out with a delay of about 10-15 seconds, it is probably intermittent power to the CRT filament for that color and probably means a bad CRT since the three filaments are wired in parallel inside the CRT. One of the internal connections has come loose.

  Look in the neck of the CRT to make sure all three filaments are glowing orange. If one is out or goes on and off, toss the set. Replacing the CRT is probably not worth it. However, if they all go on and off together (all colors would be fading in and out though perhaps not quite in unison), then bad connections for the CRT filaments on the CRT neck board are indicated.

To narrow down the problem:

- Locate the output for the bad color on the video driver board on the neck of the CRT. This will probably read a significantly higher voltage than the corresponding pins for the good colors. A circuit problem is likely - probably on this board.

- Test components on this board for the good and bad color channels. A shorted transistor or open resistor can kill one channel. Swap parts between good and bad colors to confirm.

- Gently pull the CRT neck board off of the CRT and replace it. This will tend to clean the contacts.

- Connect an output of the video/chroma circuit/chip that is working (i.e., a color that appears on the screen) to *all* three color drivers on the CRT neck board.

  - If you now get a more-or-less black and white picture (there may be a moderate color tint as the relative intensities of R,G,B may not be balanced), the problem is likely with the chroma decoder or its support circuitry.

    Note: the picture will be the intensity of only one color channel so it will not be quite *normal* in any case.

  - If you still have missing or messed up colors, the problem is on the CRT neck board or with the CRT.

Most of the causes of intermittent colors boil down to bad connections of one form or another. For totally dead colors - not intermittent - bad components are also a possibility.

- Printed circuit board on the CRT neck. This is a common location for cold solder joints. Check with a bright light and magnifying glass for hairline cracks around the pins of larger parts. Prod and tap with an insulated tool to see if the problem is effected. Resolder if necessary.

- Cold solder joints elsewhere in TV or monitor usually around the pins of large parts such as transformers, power transistors and resistors, and internal connectors.

- Internal connectors (including CRT socket) that need to be cleaned and reseated. Remove, clean with contact cleaner, burnish, and replace.

Some commentary on monitor and TV whacking

Anytime that intermittent symptoms are experienced, I recommend gently whacking the patient to determine if mechanical shock or vibration affects the behavior. Here are a couple of responses to this suggestion.

(The following is from Marc Gelfond (71363.1700@CompuServe.COM).)

I just love the bit about "whacking it". It brings to mind an episode from the old Andy Griffith show, where a new fangled piece of electronics gear, was broght into Emmets repair shop. After many long hours of fruitless troubleshooting, out of frustration Emmet gave the thing a whack, and sure enough it fixed the problem.

As we say in the Telephony business, it "CCWT" or Came Clear While Testing. Another saying is that it "CCBFM" Came Clear By F------ Magic!!

(To which Gavin Adams (gaa@hopi.com) comments):

In the video industry we had a saying concerning malfunctioning gear:

"If it's broke, hit it with a hammer"
"If that doesn't fix it, paint it and sell it"

My DEC 16" monitor is case in point. Evey once in a while it would lose sync, and smacking it would bring it back (sometimes a few smacks). Recently it gave up the ghost completely, and after the local DEC office gave me a quote of $900 to fix it (Bermuda), I ordered a new Viewsonic 17" for the same price.

I ripped the guts out of the DEC beast, painted it with a marble finish, put plants in it, and sold it! :>

Retrace lines in picture

During the time the electron beam is returning from right to left at the end of a line and bottom to top (over the course of multiple lines), it is supposed to be result in no visible light on the screen. However, a number of faults can result in visible retrace lines.

The appearance will likely be a general reduction in contrast from the visible horizontal retrace on every scan line and two dozen or so diagonal lines lines (lower left to upper right) resulting from the vertical retrace.

The retrace lines may be either white or gray (possibly with a slight color tint due to unequal settings of the color adjustments) or a primary color - red, green, or blue. Anything in between is also possible but less likely.

White/gray retrace lines

Where all colors are involved - the lines are essentially white or gray (or with a slight tint due to slight unequal settings of the color adjustments), look for something common like an incorrectly adjusted screen (G2) or master brightness/background/bias control or a problem in one of these circuits, a defective power supply or a problem in the blanking circuitry:

- Screen (G2) or master brightness/background/bias control - mark setting and then see if a slight adjustment removes the retrace lines. See the chapter: "TV Adjustments". Of course, if this happened suddenly, the problem is not due to a misadjusted control though a dirty pot is possible - turn it back and forth - this might clean it and restore normal operation.

- Power supply or connection to CRT neck board - insufficient voltage will result in the CRT never totally blanking. Check (usually scan derived) power supply components (from flyback).
- General power supply - check B+ for correct value and ripple. A main power supply fault might result in these symptoms (and usually many others).
- Blanking circuit - this may be a part of the video/chroma chip or separate. Check waveforms to determine if the blanking pulses are making it to the video output.

Red, green, or blue retrace lines

Where only one color is showing, suspect an incorrectly adjusted individual background/bias control or bad part on the CRT neck board for that color.

- Individual brightness/background/bias control(s) - mark setting of pot for the problem color and then see if a slight adjustment removes the retrace lines. See the chapter: "TV Adjustments". Of course, if this happened suddenly, the problem is not due to a misadjusted control though a dirty pot is possible - turn it back and forth - this might clean it and restore normal operation.
- Component or connection on CRT neck board - insufficient voltage to or incorrect biasing of the video driver for this color can result in the CRT never totally blanking. Compare voltages and signals, and swap components between good and bad channels to confirm.
- Blanking circuit - this may be a part of the video/chroma chip or separate. Check and compare waveforms of good and bad colors to determine if the blanking pulses are making it to the video output.

There is a slight possibility that a bad CRT may result in visible retrace lines. To eliminate this possibility:

- Disconnect the filament - all evidence of a picture, raster, and retrace lines should disappear once the filaments/cathodes have cooled (15 seconds or so. If there are still visible retrace lines, the CRT is suffering from cold or field emission from someplace (may not even be the cathode).
- Turn down the screen (G2) control on the flyback (usually). If one color remains no matter how you set the control, again there is some kind of weird emission from the CRT. However, if white/gray retrace lines remain, the problem may be in the screen supply.

See the section: Bad CRT causing retrace lines.

Bad CRT causing retrace lines

(From: Jeroen H. Stessen (Jeroen.Stessen@philips.com).)

The TV which I bought last started developing retrace lines after a month or so of use. I took it back to the lab for warranty (special deal) and had it examined by the real experts. They found that even with the filament supply disconnected and VG2 at 0V the screen would still light up. They could even see that the electrons weren't even coming from the cathode. That was with only the picture tube in a test rig. So in this case the obvious conclusion had to be that the tube was bad, and it was replaced (32" 16:9 SF, very $$). It had something to do with processing problems during manufacturing of the electron guns.

So even if this was a rare case, it *can* happen that retrace lines are due to a bad picture tube. It's more usual to suspect the VG2 (screen voltage) or a defect somewhere in the RGB video path.

Red, green, or blue full on - fog over picture

This could be a heater-cathode (H-K) short in the CRT, a failure of a component in the chroma circuits or video output (driver board), or bad connections there or elsewhere.

Don't panic - heater-cathode shorts in CRTs can often be worked around.

Note: before proceeding, it is a good idea to make sure that the screen is degaussed - else you could be attempting to track down problems with the wrong color!

Some simple tests can confirm or rule out other possibilities.

- Compare the voltages for the video drive signals to the CRT on the little board on the neck of the CRT with the CRT both connected and unplugged. A schematic will help greatly in locating these signals.
  - If there is a significant difference especially on the bad color, then the CRT is a likely candidate. Try tapping the neck of the CRT GENTLY (with it plugged in and while viewing a picture) to see if it is an intermittent problem.
  - If there is no significant difference, you may have a bad driver or a problem in the chroma circuits.
- Look for bad connection/cold solder joints, probably on the little board on the neck of the CRT. Use an insulated stick to gently prod the board and its components in an effort to induce/cure the problem. Look carefully for hairline cracks around the component leads.
- You can swap components between two colors and/or test with an ohmmeter on that driver board to determine what is bad. The nice thing about color monitors and TVs is that there three copies of each of these components. Swapping and/or comparisons between these is an excellent diagnostic technique.
- Another simple test: Disconnect the cathode for the full-on color from its drive. If it is still full-on, there is probably an H-K short in the CRT since the only way to get each color on the screen is via the cathode connection to the CRT neck board. If it is removed and there is still that color, the current must be taking another path inside the CRT.
- Alternatively, interchange the outputs of the bad color with a good one by jumpering on the video driver board (on the CRT neck). If the bad color changes, then the problem is in the circuitry and not the CRT.

Here is the procedure in more detail (example for red full on):

(From: J. K. Emerine (jkemerine@aol.com).)

To identify if the fault is in the CRT or a control problem try this (WITH SET OFF):

On the CRT board, lift the output end of the green cathode final resistor. Do the same with the offending red cathode's resistor. Use short insulated jumpers to 'swap' drive signals - drive the red cathode with the green drive and the green cathode with red drive. (Note that if this problem only occurs after a warmup period, color at turn on will be - well - wierd, but it is just a test.)

- If the symptom returns = 'goes red' the CRT is shorting. (See the section: Providing isolation for a CRT H-K short. --- sam)

- If instead the symptom becomes 'goes green' then the red drive leg has the fault and the CRT is probably good. (In this case, there may be bad connections or a bad component on the CRT drive board or further back in the chroma circuitry. --- sam)

Shorts in a CRT

Occasionally, small conductive flakes or whiskers present since the day of manufacture manage to make their way into a location where they short out adjacent elements in the CRT electron guns. Symptoms may be intermittent or only show up when the TV or monitor is cold or warm or in-between. Some possible locations are listed below:

- Heater to cathode (H-K). The cathode for the affected gun will be pulled to the heater (filament) bias voltage - most often 0 V (signal ground). In this case, one color will be full on with retrace lines. Where the heater is biased at some other voltage, other symptoms are possible like reduced brightness and/or contrast for that color. This is probably the most common location for a short to occur.

- Cathode to control grid (K-G1). Since the G1 electrodes for all the guns are connected together, this will affect not only the color of the guilty cathode but the others as well. The result may be a very bright overloaded *negative* picture with little, none, or messed up colors.

- Control grid to screen (G1-G2). Depending on circuitry can result in any degree of washed out or dark picture.

- Screen to focus (G2-F). Screen (G2) and focus voltage will be the same and the controls on the flyback will interact. Result will be a fuzzy white raster with retrace lines and little or very low contrast picture. Symptoms will be similar to those of a flyback with breakdown in the focus/screen divider network.

- Focus to high voltage (F-HV). High voltage will be pulled down - probably arcing at the focus spark gaps/other protective devices. Line fuse and/or HOT may blow. A high impedance short may only result in increased focus voltage but this is probably unusual.

- Other locations between electron gun elements as feed wires.

Except for the high voltage to other places, the short may actually be located in the CRT *socket* or even on the CRT neck board, probably in the spark gap(s) for the problem pins. Remove the socket and test between the suspect pins on the CRT itself. If the CRT itself is fine, the spark gaps should be inspected and cleaned/repaired and/or components replaced. At this point, the cause may still be present - a short inside the flyback for example resulting in excessive voltage on one or more pins.

Assuming this is not the case, replacing the CRT may be the best solution but there are a variety of 'techniques' that can often be used to salvage a TV that would otherwise end up in the dump since replacing a CRT is rarely cost effective:

1. Isolation - this will usually work for H-K shorts as long as only one gun is involved.

2. Blowing out the short with a capacitor - depending on what is causing the short, this may be successful but will require some experimentation.

3. Placing the CRT (TV or monitor) face down on a soft blanket and *gently* tapping the neck to dislodge the contamination. Depending on the location of the short, one side or the other might be better as well. Sometimes, this can be done in-place while watching the picture.

A combination of (2) and (3) may be required for intermittent shorts which don't appear until under power. See the sections below for additional details. However, for shorts involving the focus and high voltage elements, even a sharp edge can result in arcing even if there is no actual short. There is no remedy for these types of faults.

Providing isolation for a CRT H-K short

This procedure will substitute a winding of your own for the one that is built in to the flyback to isolate the shorted filament from the ground or voltage reference. Note that if you have a schematic and can determine where to disconnect the ground or voltage reference connection to the filament winding, try this instead.

The flyback is the thing with the fat red wire coming out of it (and perhaps a couple of others going to the CRT board or it is near this component if your set has a separate tripler) and may have a couple of controls for focus and screen. It should have some exposed parts with a ferrite core about 1/2-3/4" diameter.

The filament of the CRT is the internal heater for each gun - it is what glows orange when the set is on. What has happened is that a part of the fine wire of the bad color's filament (assuming this is indeed your problem) has shorted to the cathode - the part that actually emits the electrons. Normally, the heater circuit is grounded or tied to a reference voltage so when it shorts to the cathode, the cathode voltage level is pulled to ground or this reference.

You will need some well insulated wire, fairly thick (say #18-22). Find a spot on the flyback where you can stick this around the core. Wrap two turns around the core and solder to the CRT filament pins after cutting the connections to the original filament source (scribe the traces on the board to break them). Make sure you do not accidentally disconnect anything else.

This winding should cause the filaments to glow about the same brightness as before but now isolated from ground. If they are too dim, put another turn on the flyback to boost the voltage as this will result in low emission, blooming, and possible damage to the cathodes after awhile. (Don't go overboard as you may blow the filament totally if you put too many turns on the core - you then toss the TV.)

Route the wires so that there is no chance of them getting near the high voltage or any sharp metal edges etc. Your picture quality may be a tad lower than it was before because of the added stray capacitance of the filament wiring being attached to the the (formerly bad) video signal, but hey, something is better than nothing.

If you are not inclined to build your own isolation transformers, kits are available.

Rescuing a shorted CRT

If the short is filament-cathode (H-K), you don't want to use the following approach since you may blow out the filament in the process. If this is the case, you may be able to float the filament and live with the short (see the section on: "Red, green, or blue full on - fog over picture".

Shorts in the CRT that are between directly accessible electrodes can be dealt with in a more direct way than for H-K shorts. At this point you have nothing to loose. A shorted CRT is not real useful.

If the short is between two directly accessible electrodes like cathode-grid, then as a last resort, you might try zapping it with a charged capacitor. Start with a relatively small capacitor - say a few uF at a couple hundred volts. Check to see if the short is blown after each zap - few may be needed. Increase the capacitance if you fell lucky but have had little success with the small capacitor.

If the fault is intermittent, you will, of course, need to catch the CRT with the socket disconnected and the short still present. Try some gentle tapping if necessary. If you do this with the charged capacitor across the suspect electrode, you **will** know when the short occurs!

Also see the section: High voltage to focus short.

Picture tube replacement

It is possible to replace the picture tube. However, this is likely to be both expensive and possibly time consuming with respect to adjustments like purity and convergence. When replacing:

- Discharge both the old and new tubes before you start to be sure you won't have any unpleasant surprises.
- Take extreme care when handling - at the very least, a slip can result in a broken neck and a bad and expensive day.

  "The 25VCXP22 picture tube of my RCA Accutouch XL-100 CCU-942 TV start fading. Its 100% transistorized, everything still works perfectly after about 20 years service. But:

  - Can I still buy new RCA 25VCXP22 picture tube? What is the approximate cost?
  - Any equivalent tube for direct replacement? Cost?
  - If no replacement picture tube is available, what is other option?"

(From: Chris Jardine (cjardine@wctc.net).)

What you have here is genericly referred to as the 25V as opposed to the 25A picture tube. While there are minor differences with respect to the letters after the V for the most part they are interchangeable. When I worked my way through engineering college I worked at a TV repair shop and my job was mostly changing picture tubes. Yeah, we did enough of them to keep a tech busy 4 to 5 hours a day changing them and I got pretty good and could change, color balance, convergence, etc. the tube in about 45 minutes. We for the most part used 3 major tubes, 1) 25A, 2) 25V, and 3) 21FJ (a little nostalgic for those who remember this one). This was back when your TV would have been fairly new (1981 to 82). These are available from many different sources - RCA, Channel Master, Wisconsin Tube, etc. The price would vary depending on the quality of the tube. I remember that we could get a 25A for about $35 at the time due to our volume - one truck per month. The most expensive I've seen them has been just over $200. This is quite a range and there are now many other types of tubes including in-line, trinitron, etc.

I hope this helps and thanks for the trip down memory lane!

(From: Chris Jardine (cjardine@wctc.net).)

The important thing here is that the tube begins with 25V. If it does it should work in your set. The only thing you have to know is whether the tube has 'ears' attached permanently. The 25V comes both with and without these mounting ears permanently attached. I know that you can still get one of these from any of a number of suppliers. I know that Channel Master and RCA (Thomson, whatever!) still make them available as well as any of a number of local CRT rebuilders.

High voltage to focus short

Symptoms would be (with the unit powered and high voltage present):

- With the CRT neck board plugged into the CRT, the focus spark gap is likely arcing.
- With the socket unplugged, putting anything connected to ground (or any other circuitry) near the focus pin would result in a juicy spark or arc. WARNING: Removing the CRT socket and powering the set may destroy the CRT on some models. See the section: Warning about disconnecting CRT neck board.

If the CRT is gassy or up to air, forget it - it might make a decent fish tank :-). In this case, there would be visible arcing INSIDE the CRT probably not confined to a single location.

However, if there is just a metal whisker between the F and HV, that might be able to be cleared by careful tapping or a charged capacitor. You may even be able to see it if you were to remove the yoke - the gap is pretty large, about 1-2 mm - the last gap between electrodes before the start of the internal (Dag) coating.

See the section: Rescuing a shorted CRT.

Note that other damage may have been done as

Other components including the flyback, HOT, and parts on the CRT neck board and beyond, may have been damaged as a result of the short. Zapping the CRT may be just the beginning of what is required to repair it all.

Dark picture

A TV or monitor with a picture that is too dark may have a fault or the CRT may just be near the end of its useful life.

First, confirm that your video source - computer, camera, etc. - is producing a proper signal.

Is the brightness at all erratic? Does whacking the monitor have any effect? If so, then you may have bad connections on the CRT driver card or elsewhere. If the brightness tends to fade in and out over a 10 to 20 second period, a bad filament connection is likely. Check for the normal orange glow of the filaments in the neck of the CRT. There should be 3 orange glows. If they are excessively reddish, very dim, or fade in and out, you have located a problem. See the section: Picture fades in and out.

Common causes of brightness problems:

0. Dirty CRT faceplate or safety glass. Don't laugh. It sounds obvious, but have you tried cleaning the screen with suitable screen cleaner? It is amazing how dirty screens can get after a few years - especially around smokers!

   Wipe gently with a slightly dampened cloth - not soaking or you may end up with real problems when the water drips down inside and hits the electronics! On TVs with a separate protective faceplate, clean both the front and rear surfaces of this plate as well as the CRT itself.

1. Old CRT. The brightness of the CRT deteriorates with on-time. It does not matter much how bright your run your TV. An indication of a weak CRT would be that turning up the SCREEN (G2) or master brightness control only results in a not terribly bright gray raster before the retrace lines show up. There may be indications of poor focus and silvery highlights as well. A CRT brightener may help. See the section: Brightening an old CRT.

2. Bad component in filament circuit or bad connection reducing filament voltage. This should be easy to check - there are only a few parts involved. If it is erratic, bad connections are likely.

3. Brightness control faulty - bad pot, bad connections, or problem with its power supply. Depending on specific problem, control may or may not have any effect. If digitally adjusted, there could be a problem with the logic or control chip. If the button or menu item has no effect at all, then a logic or control problem is likely.

4. Improperly set SCREEN (G2) voltage (usually on flyback) or faulty divider network. See the section: Adjustment of the internal SCREEN and color controls.

5. Improperly set video bias (background) levels or fault in video drive circuitry. See the sections starting with: "Optimal procedure for setting brightness/background and screen adjustments".

6. Fault in video amplifiers. With all three color affected equally, this would most likely be a power supply problem. A video amplifier problem is likely if turning up the SCREEN (G2) or master brightenss control results in a very bright raster before the retrace lines appear. Cheack signals out of the video/chroma(IC.

7. Fault in beam or brightness limiter. Many TVs and monitors measure the beam current (possibly indirectly) and limit the maximum to a safe value. The purpose of this may be to protect the CRT phosphors, and/or to assure that the power supply does not go out of regulation, and/or to limit X-ray emission. If this circuit screws up, a dark picture may result. Checking the signals and voltages at the CRT socket should determine if this is the problem.

8. High voltage is low. However, this would likely result in other symptoms as well with focus, size, and geometry.

Brightening an old CRT

If performing adjustments of the internal background and/or screen controls still results in a dark picture even after a long warmup period, the CRT may simply be near the end of its useful life. In the old days of TVs with short lived CRTs, the CRT brightener was a common item (sold in every corner drugstore, it seemed!).

You can try a similar approach. Caution: this may shorten the life of the CRT - possibly quite dramatically (like it will blow in a couple of seconds or minutes). However, if the monitor or TV is otherwise destined for the scrap heap, it is worth a try.

The approach is simple: you are going to increase the voltage to the filaments of the electron guns making them run hotter. Hopefully, just hotter enough to increase the brightness without blowing them out.

Voltage for the CRT filament is usually obtained from a couple of turns on the flyback transformer. It is usually easy to add an extra turn or two which will increase the voltage and thus the current making the filaments run hotter. This will also shorten the CRT life - perhaps rather drastically. However, if the TV or monitor was headed for the dumpster anyhow, you have nothing to lose.

Picture tube brightener

(From: Kevin Carney (carneyke@mhv.net).)

Try a CRT brightener from MCM Electronics about $20. It boosts the filament voltage a volt or two. I have used them before and they help. You can also try running a power supply on the filament with the monitor OFF. Set the supply at the filament voltage and slowly bring the voltage up. If the filament is 6.3 volt bring it up gradually to 10 -12 volts for about a half hour. This will brighten it up some. Be careful because too much voltage can open the filament !

Before doing this did you check the screen voltage setting and the RGB settings for drive and background ?

There are also commercial CRT rejuvenators that supposedly zap the cathodes of the electron guns. A TV repair shop may be able to provide this service, though it is, at best, a short term fix.

More drastic measures to brighten CRT

(From: LEE (leep@mailhub.scf.lmsc.lockheed.com).)

As a start, I crank the brightness control all of the way up. I then turn the color control all of the way up. I let the set run with a bright screen for around 15 min. This procedure cleans up the cathode surfaces so that they can emit more electrons. Now turn the controls back to normal and see if any improvement took place. If not, Wrap 2 or 3 turns of around 18 gauge insulated wire around the flyback and add this extra power in series with existing filament leads from flyback. You can experiment with the number of turns etc. to get brighter filaments. do not run the filaments white - just a brightened yellow. This will probably turn out to be around 8-9v in most cases. I had to do this on two different Sanyo replacement flybacks as they had low filament voltage from the factory. (flakey replacement parts). I`ve been running one of these Sanyos for around 4 years now with a nice bright picture (13")

Left portion of screen is dark or faded

> "I've got an old TV where the left 1/3 of the screen is 'faded'. It is especially noticable when a dark picture is showing (like a night time scene)."

This is normally caused by a bad filter capacitor on the power supply line (typically 200 V) that feeds the RGB output transistors. It is usually a scan derived voltage off of the flyback. Look for an electrolytic capacitor of around 4.7 to 10 uF, 160 to 250 V fed from a rectifier diode on this supply.

Color balance changes across screen from left to right

The characteristics are that a solid white screen will tend to be blue tinted on one side and red tinted on the other. This is usually a subtle effect and may be unavoidable with some designs.

There are several possibilities:

1. Purity - this means the beams are landing on the wrong phosphor dots. This is what would be affected by moving from one location to another or even rotating the TV on its base without degaussing. If the problem just appeared, degaussing may be needed.

   What do you have near the TV or monitor? Loudspeakers or other devices which generate magnetic fields can easily cause all sorts of color purity problems. Relocate the offending device(s) or the TV or monitor and then degauss it.

   See the section: Degaussing (demagnetizing) a CRT.

   If the problem still persists, purity adjustment may be needed. However, this isn't likely to have changed so look for other causes before tackling these adjustments.

2. Unequal electron gun to shadowmask/screen distance - the electron beams for the red and blue video travel slightly different distances on the left and right sides of the screen so their intensity (due to focus not being optimal and other factors) in each case may differ slightly affecting color balance.

3. Doming - This would only happen in very bright areas and causes the shadow mask to expand and distort. (Doming should not be a problem with Trinitron CRTs which use tensioned wires in their aperture grill.) This would also not really affect left-right color balance in particular.

I don't really know how much of a problem (2) is in practice or whether some manufacturers compensate for it.

Bleeding highlights

On very bright areas of the picture, one or more colors may bleed to the right resulting in a trail of those colors. The difference between this problem and the section: Trailing lines in one or more colors is that in this case, only highlights are affected.

One cause of this is that the color gain, contrast, or intensity controls (whatever they are called on your set) are set too high. See the section on: "Color balance adjustment". Check the settings of any brightness limiter controls as well.

Trailing lines in one or more colors

Assuming this is not a form of ghosting resulting from poor reception conditions, then it could be any of the following:

- Poor decoupling in the power supplies for the video drive circuits - probably on the CRT neck board. Check for bad (low uF or high ESR) filter capacitors (electrolytic mostly) on this board or the power supplies feeding it.

- Insufficient CRT filament voltage. This could be a result of bad connections or a bad component in the filament power supply (probably from the flyback). Check to see if the filaments are glowing bright orange and check the voltage if possible (though this can be tricky since it is often fed from a winding on the flyback and is a pulse waveform, not DC or a sinusoid. The service manual (or Sams' Photofact) will probably have info and waveforms.

- Bad CRT (more likely if only one color is affected). A weak electron gun can result in this behavior. Swap it with one that work properly. If the same color is still bad, that CRT gun is weak. The CRT will need rejuvenation or need to be replaced (more likely, the entire TV will be tossed into the dumpster).

One simple test would be to swap two of the color outputs to the CRT pins. If the behavior moves with the swap (i.e., from red to blue), then it is likely an electronic problem. If it is still the same colors, it is probably the CRT.

Brightness changes from left-to-right across screen

Slight variations in brightness across the face of the CRT are not unusual. In fact, if you used a photometer to actually measure the brightness, you might be amazed at the actual variance even with the best monitor or TV - you just don't notice it. However, a major variation - usually a decay from left to right but could be the other way indicate a component failure. Of course, make sure the face of the screen is clean!

- A fault in the power supplies to the video amplifier and/or video output circuits. Most likely, an electrolytic capacitor has dried up and is not adequately filtering the power derived from the flyback which then has ripple at the horizontal scan rate and thus locked to the screen. The voltage decays from left-to-right between horizontal flyback pulses.

  The most likely location for these capacitors is in the vicinity of the flyback transformer on the mainboard or on the CRT neck board. Check the capacitors with capacitor tester or ESR meter and/or take a look at the power right at the video amplifier and video output drivers.

- Horizontal linearity is bad - this may actually be a horizontal geometry problem and not a brightness problem.

  See if objects on left side of the screen are stretched compared to those on the right (or vice-versa). If they are, the problem is in the horizontal deflection circuits - possibly a bad S correction capacitor or linearity coil.

- Inoperative degauss circuit, TV moved or rotated without degaussing, or magnetic field from some other device (like a permanent magnet) is affecting CRT - slight amounts of magnetization may reduce brightness (by moving the beams into the black space between phosphor dots) before affecting color purity (where the beams land on the wrong phosphor dots).

  Try deguassing manually. See the section: Degaussing (demagnetizing) a CRT.

Picture fades in and out

If the picture faded away on the order of 10-20 seconds (and if it comes back, also comes up to full brightness in same time frame - possibly with the persuasion of some careful whacking) AND with NO other significant changes such as size, focus, etc., then take a look in the back of the tube for the filament to be lit - the orange glow near the CRT socket. If there is none, then you probably have a bad solder connection on the circuit board on the neck of the CRT. Look for fine cracks around pins on that board. Try prodding it with an insulating stick to see if the picture comes back. Resolder if necessary. Dirty or corroded CRT pins/socket contacts can also do this - remove, inspect, clean, and replace the neck board. It is probably not a bad CRT as the filaments are usually wired in parallel and all would not likely go bad at the same time.

However, if only a single color fades in and out, then a bad connection inside the CRT is a distinct possibility - look for only one of the filament's glow to be coming and going. This is probably not worth fixing.

If the picture faded away with other symptoms, then there is probably a fault in the video amplifier/output one of its power supplies - still probably a loose connection if you are able to get it back by whacking.

Occasional brightness flashes

These may last only a fraction of a scan line or much much longer.

This could mean an intermittent fault in a variety of places including the video circuitry and SCREEN power supply:

- Brightness circuitry - SCREEN, master background or its power supply. Could be in or around flyback or focus/screen divider. Could perhaps be in the CRT, but probably less likely.

- Video amp before or at chroma demodulator - since after this point, you would most likely get colored flashes since only one of the RGB signals would likely be effected.

If you get it from all sources, then tuner/IF is ruled out.

Suppose you just have no signal to a direct video input. What do you get? If you still get flashes, it should be real easy to monitor either the video outputs or SCREEN supply (with a HV divider on your scope) for noise. Then trace back to power or noise source.

Excessive brightness and/or washed out picture

There are a number of possibilities including incorrect screen (G2) or bias (G1) voltages, or a problem in the video or blanking circuitry. Any of these could be the result of bad connections as well. A short in the CRT can also result in these symptoms.

- Excessive brightness/washed out picture is often an indication of a problem with the screen (G2) supply to the CRT. May be a bad capacitor or resistor divider often in the flyback transformer assembly or on the board on the neck of the CRT.

- If the excessive brightness just developed over time, then a simple adjustment of the screen or background brightness controls may keep it (and you) happy for a long time.

  When good, a typical value would be in the 200 to 600 VDC at the CRT. The screen (it may also be called master brightness, bias, or background) control should vary this voltage. However, it may be difficult to measure as the resistors in the voltage divider network may be quite large - hundreds of M ohms. If your unit has an external screen control (less likely these days) and it has no effect, trace out the circuitry in the immediate vicinity and check the resistors and potentiometer for opens, look for bad connections, etc. If it is built into the flyback transformer and is sealed, the entire flyback will need to be replaced unless the actual problem turns out to be a bad connection or bad component external to the flyback.

- Where the brightness control has no effect, suspect a missing bias supply to the G1 (control grid) electrodes of the CRT. This is usually derived from the flyback with a simple rectifier/filter capacitor power supply. Parts may have failed (though not likely the flyback itself). Adjusting the user brightness control should vary this voltage over a typical range of 0 to -50 V with respect to signal ground.

- It could also be a problem with biasing of the video output transistors. There may individual controls for background brightness on the little board on the neck of the CRT. However, we are looking for a common problem since all colors are wrong in the same way. This is likely to be a missing voltage from a secondary supply from the flyback.

- A short between electrodes inside the CRT can result in brightness problems. It may be possible to check this with an ohmmeter with the power off and the CRT socket removed. Test between G1, G2, and F where all colors are affected though a short between F and G2 will result in the focus control changing brightness and vice-versa - a classic symptom.

  However, in some cases, it only shows up when operating and one must deduce the presense and location of the short from its affect on voltages and bias levels.

  See the section: Rescuing a shorted CRT and other related topics.

First, check for bad connections/cold solder joints by gently prodding with an insulating stick. Check voltages and bias levels.

Bad focus (fuzzy picture)

Focus voltage on the CRT is usually in the range of 2-8 kV DC and should be controllable over a fairly wide range by the focus pot - usually located on the flyback or a little panel in its vicinity:

- If adjusting the pot results in a position of acceptable focus, you may be done. It is not unusual for the focus setting to drift a over time.

- If the setting is already as good as possible but not really good enough, the CRT may be tired. Alternatively, the filament voltage may be too low. Check for bad connections in the filament circuit.

- If the optimal setting is out of range of the focus pot, the problem is likely leakage in the focus divider in the flyback or one of the components on the CRT neck board.

Also see the sections: "Focus adjustment" and "Focus drifts with warmup".

The focus wire usually comes from the flyback or if the general area or from a terminal on a voltage multiplier module in some cases. It is usually a wire by itself going to the little board on the neck of the CRT.

If a sparkgap (a little 2 terminal device with a 1/8" gap in the middle) is arcing with power on, then the resistive divider has shorted inside the flyback, focus board, or HV multiplier - whatever you TV has - and the this unit will need to be replaced. Ditto if the SCREEN control affects focus and/or vice-versa.

Using a suitable high voltage meter (range at least 10 kVDC, 1000 M ohm or greater input impedance), you should be able to measure it connected and disconnected. The ground return will be the outside coating of the CRT which may or may not be the same as the metal chassis parts. If the voltage is very low (less than 2 kV) or too high and the pot has little effect:

- When measured right off of the source disconnected from the CRT neck board, then the problem is probably in the focus network in the flyback (or wherever it originates). Sometimes these can be disassembled and cleaned or repaired but usually requires replacement of the entire flyback or voltage multiplier. Note: you may need to add a HV (10 kV) capacitor between the focus wire and DAG ground to provide filtering so you get a DC level for your meter.

- When measured with the focus wire attached to the CRT neck board with the CRT connected but reasonable with the CRT unplugged, there is probably a short between the focus and another electrode inside the CRT. See the section: Rescuing a shorted CRT.

- When measured with the focus wire attached to the CRT neck board with the CRT unplugged, there is likely a component on the CRT neck board that is leaky or breaking down. Also, check for decayed (tan or brown) glue which may turn leaky with age.

Focus drift with warmup

This could be due to a problem with the focus voltage power supply, components on the CRT neck board, or a tired worn CRT.

Focus is controlled by a voltage of 2-8 kV DC usually derived from the flyback transformer and includes some resistors and capacitors. One of these could be changing value as it warms up. (assuming nothing else changes significantly as the unit warms up - e.g., the brightness does not decrease.)

Focus voltage is derived from a subset of the high voltage winding on the flyback using a resistive voltage divider which includes the focus pot. These are extremely high value resistors - 200 M ohm is common - and so leakage of any kind can reduce or increase the focus voltage. All other things being ok - i.e., the picture is otherwise fine - I would suspect this type of failure rather than the CRT.

The connection to the CRT is usually a separate wire running from the flyback or its neighborhood to the CRT neck board. Look for components in this general area. Use cold spray or a heat gun to isolate the one that is drifting. If you have access to a high voltage meter, you should be able to see the voltage change as the TV or monitor warms up - and when you cool the faulty part. If it is in the flyback, then sometimes the part with the adjustments clips off and can be repaired or cleaned. Most often, you will need to replace the flyback as a unit.

- If the optimal adjustment point of the focus control doesn't change that much but the best focus is simply not as good as it should be, the CRT is probably the problem. However, if the optimal point produces acceptable focus but it changes (and possibly moves off of one end of the adjustment knob range) as the unit warms up, the flyback or one of the components on the CRT neck board are likely drifting.

- If you have a high voltage meter, you can measure the focus voltage to determine if it is being changed by the focus pot and if it is in the ball park (2-8 kV typical). Sometimes, the part of the flyback with the focus pot can be snapped off and cleaned or parts replaced but usually you need to replace the whole unit. There may a capacitor or two on the PCB on the neck of the CRT that could have increased leakage as well thus reducing the focus voltage.

- To determine if the CRT is the problem, for sharp focus after the unit has warmed up. Power-off for an hour or so and carefully pull the CRT neck board off of the CRT. Then, power up the unit. Let it run long enough such that there would have been a detectable focus drift. Now, power-down, plug the CRT neck board back in, and power-up. Watch the image as it appears on the screen:

    - If the focus starts out fuzzy and sharpens up as the image appears and gradually becomes sharper as the CRT warms up the CRT is likely tired.

The only catch here is that plugging the CRT neck board into the CRT results in an additional load on the flyback due to the picture beam current which heats it more as well. Thus, if the problem takes a few minutes to appear, keep the brightness turned down except to check the appearance of the picture from time to time.

You can set the focus control for optimum when warmed up and just turn the TV on in well in advance of your favorite shows or add a user focus adjustment by drilling a hole in the plastic case for an *insulated* screwdriver or flyback focus knob extender :-). The CRT may continue to function for quite a while so this is not impending doom.

- If the focus is relatively stable as the image appears and increases in brightness *and* is about as sharp as it would be with the TV warmed up, the problem is most likely in the flyback. However, also check for bad components or decayed (tan or brown) glue on the CRT neck board. A drifting flyback will need to be replaced as it will probably get worse and fail completely. Clean the surface of the circuit board and CRT socket in the vicinity of the focus and screen terminals and traces. Contamination or just dirt and grime can easily cause problems especially on humid days since the resistance of these circuits is extremely high (100s of M ohms).

- If the focus is relatively stable as the image appears and increases in brightness *and* is similar to what it would be with the monitor cold, you have a very strange situation where some load on the high voltage power supply, perhaps, is causing a thermal problem. This would be rare.

Bad focus and adjustment changes brightness

This is the classic symptom of a short between the focus and screen supplies - probably in focus/screen divider which is part of the flyback or tripler. If you have a high voltage meter, measuring the focus voltage will show that (1) it is low and (2) it is affected by the SCREEN control Similarly, the SCREEN voltage will be affected by the FOCUS control (which is what is changing the brightness.

There is a slight possibility that this may be in the CRT as well. Measure the FOCUS and SCREEN voltage with a high voltage meter. If they are identical pull the plug on the CRT. If they are now their normal values, then a shorted CRT is a distinct possibility - see the section: Rescuing a shorted CRT.

Charlie's comments on focus problems

(From: Charles Godard (cgodard@iamerica.net).)

Most true focus problems that I have encountered (when the IHVT is ok) are related to leaks or resistance on the focus output. The diming of the screen when the focus pot is adjusted leads me to think in terms of a leaky socket. I'd remove the ground from the CRT socket to the tube dag and see if it sparks. If so there may be a leak in the socket to ground. It could also be leaking to another pin, such as the screen grid. A rhetorical question: What happens to the screen voltage when the focus pot is adjusted?

I have seen sockets that had no arching or other telltale signs, leak through the plastic housing to ground out the focus voltage.

Look closely at the screen. If the blurring is in the form of small circles, then you have an open or hi-resistance focus electrode inside the tube. The circles may vary in visibility with brightness.

If you still haven't found the problem, try to confirm that this is truly a focus problem. Remove the CRT socket and observe the hi-voltage. If it climbs more than about 1k, say all the way up to 25 kV, then you may have a beam current problem rather than a focus problem. In that case re-check all CRT board voltages. WARNING: Removing the CRT socket and powering the set may destroy the CRT on some models. See the section: Warning about disconnecting CRT neck board.

If you have done all of the above and removing the socket makes no change in the high voltage, then try to determine why the high voltage is low.

Watch the screen as the brightness, contrast, or screen control are adjusted. See if you can observe any signs of blooming. When the IHVT doesn't provide enough current to satisfy the demands of the tube for current, the the picture tends to appear to expand like a balloon. i.e., bloom. This can be caused by not enough drive to the IHVT. Carefully monitor the b+ to the horizontal drive stages to see that is is stable and correct.

Blank picture, good channel tuning and sound

Since the tuner and sound are ok, horizontal deflection which usually generates power for most of the set is also working.

Does 'blank picture' means a totally black screen with the brightness and contrast controls having no effect whatsoever? Or, is there is no picture but there is a raster - scan lines on the screen? The direction in which troubleshooting should proceed differ significantly depending the answer.

Here are some questions:

1. As above, is there any light on the screen at any settings of the brightness and contrast controls, and/or when switching channels? Can you see any raster scanning lines?

2. Can you hear the high pitched (15735 Hz) of the horizontal deflection?

3. Looking in the back of the set, can you see the glow of the CRT filament?

4. Do you get that static on the front of the tube that would indicate that there is high voltage? Any cracking or other normal or abnormal sounds or smells?

Possible causes of no raster:

- No or low high voltage (low voltage, deflection, or high voltage power supply failure).

- Fault with other voltages like G1 or screen (G2) to CRT.

- Filament to CRT not getting powered.

- Drive to CRT bad/shut off as a result of fault elsewhere. For example, failure of the vertical deflection may disable HV or blank the screem to protect the CRT from burn-in due to the very bright horizontal line that would result. With some sets, it is possible that the X-ray protection circuitry will blank the screen without affecting tuning or audio.

Possible causes of no video (but a good raster): Problem in video IF, video amplifiers, video output, cutoff due to other fault.

It could be as simple as a bad connection - try gently prodding the boards with an insulated stick while watching the screen. Check for loose connectors and reseat all internal connectors.

Purple blob - or worse

Have you tried demagnetizing it? Try powering it off for a half hour, then on. Repeat a couple of times. This should activate the internal degausser. See the section: Degaussing (demagnetizing) a CRT.

Is there any chance that someone waved a magnet hear the tube? Remove it and/or move any items like monster speakers away from the set.

Was your kid experimenting with nuclear explosives - an EMP would magnetize the CRT. Nearby lightning strikes may have a similar effect.

If demagnetizing does not help, then it is possible that something shifted on the CRT - there are a variety of little magnets that are stuck on at the time of manufacture to adjust purity. There are also service adjustments but it is unlikely (though not impossible) that these would have shifted suddenly. This may be a task for a service shop but you can try your hand at it if you get the Sams' Photofact or service manual - don't attempt purity adjustments without one.

If the set was dropped, then the internal shadow mask of the CRT may have become distorted or popped loose and you now have a hundred pound paper weight. See the "Sony1" and "Sony2" photos in James Sweet's Sony/Trinitron Directory for some screen shots showing the symptoms resulting from a monitor falling on its face. :(If the discoloration is slight, some carefully placed 'refrigerator' magnets around the periphery of the tube might help. See the section: Magnet fix for purity problems - if duct tape works, use it!.

It is even possible that this is a 'feature' complements of the manufacturer. If certain components like transformers and loudspeakers are of inferior design and/or are located too close to the CRT, they could have an effect on purity. Even if you did not notice the problem when the set was new, it might always have been marginal and now a discoloration is visible due to slight changes or movement of components over time.

Color rings - bullseye pattern

This probably means the degaussing circuitry is terminating suddenly instead of gradually as it should. The most likely cause is a bad solder connection to the degauss thermistor or posistor or something feeding it.

You can confirm this by manually degaussing the screen with the TV or monitor turned on. If the problem disappears, the above diagnosis is probably valid. Check for bad solder connections in the vicinity of the degauss components and AC line input.

Magnet fix for purity problems - if duct tape works, use it!

The approach below will work for slight discoloration that cannot be eliminated through degaussing. However, following the procedures in the section: CRT purity adjustment would be the preferred solution. On the other hand, the magnets may be quick and easy. And, where CRT has suffered internal distortion or dislocation of the shadowmask, adjustments may not be enough.

In any case, first, relocate those megablaster loudspeakers and that MRI scanner with the superconducting magnets.

The addition of some moderate strength magnets carefully placed to reduce or eliminate purity problems due to a distorted or dislocated shadowmask may be enough to make the TV usable - if not perfect. The type of magnets you want are sold as 'refrigerator magnets' and the like for sticking up notes on steel surfaces. These will be made of ferrite material (without any steel) and will be disks, rectangles, flexible strips. Experiment with placement using masking tape to hold them in place temporarily. Degauss periodically to evaluate the status of your efforts. Then, make the 'repair' permanent using duct tape or silicone sealer or other household adhesive.

Depending on the severity of the purity problem, you may need quite a few magnets! However, don't get carried away and use BIG speaker or magnetron magnets - you will make the problems worse.

Also note that unless the magnets are placed near the front of the CRT, very significant geometric distortion of the picture will occur - which may be a cure worse than the disease.

WARNING: Don't get carried away while positioning the magnets - you will be near some pretty nasty voltages!

(From: Mr. Caldwell (jcaldwel@iquest.net).)

I ended up with the old 'stuck on a desert island trick':

I duck taped 2 Radio Shack magnets on the case, in such a way as to pull the beam back.!!!!

A $2 solution to a $200 problem. My friend is happy as heck.

RCA sells magnets to correct corner convergence, they are shaped like chevrons and you stick them in the 'right' spot on the rear of the CRT.

(From: Tom Sedlemyer (wesvid@gte.net).)

First set purity as best you can.

Obtain some pieces of refrigerator door magnet strips from an appliance repair shop (they usually have some lying around).

Cut the strips into 1 inch pieces. Place a strip as on the bell of the picture tube as close to the yoke as possible and in line with the corner that has the purity error. Rotate the magnet until you correct the purity error and tape it in place. Multiple magnet strips can be used and you may experiment with the size of the strips for best effect. It is very important that the strips are positioned close to the yoke or the effect will not hold. The only drawback to this method is some very slight distortion of the geometry of the raster, but it beats hell out of paying for a new CRT.

Color TV only displays one color

I assume that now you have no other colors at all - no picture and no raster. Let us say it is red - R.

It is probably not the CRT. Do you have a scope? Check for the R, G, and B video signals at the CRT. You will probably find no signals for the defective colors.

This is almost certainly a chroma circuit problem as any failure of the CRT or a video driver would cause it to lose a single color - the other two would be ok. Therefore, it is probably NOT the CRT or a driver on the little board on the neck of the CRT.

Try turning up the SCREEN control to see if you can get a G and B raster just to confirm that the CRT is ok.

Locate the video drive from the mainboard for the good and a bad color. Interchange them and see if the problem moves. If so, then there is a video signal problem. If not, it is on the little CRT board.

It could be a defective chroma IC or something else in the chroma decoder.

Disappearing Red (or other color)

Problem: I have been given an old colour TV. The reception is good, but very often, when the contrast and brightness of the TV image is low (e.g. when a night scene is shown), the red colour slowly disappears, leaving behind the green and blue image and many red lines.

The remaining red retrace are the giveaway that this is most likely not a CRT problem.

(If there were no red lines, it could be the filament for the red gun of the CRT going on and off due to a bad connection inside the CRT - bad news.)

How is a black and white picture? (Turn down the color control).

If B/W picture is good, then the problem is somewhere back in the chroma decoder circuitry.

Check the video input to the CRT video driver board and signals on that board. If B/W picture is also bad, then you can compare red and green signals to determine where they are becoming different. The red lines in your description sounds like the red video output circuit is drifting and messing up the background level, blanking, screen, or other setting. Could be a capacitor or other component.

The wandering black blob on old Sony

> "I had a Sony KV-1920 TV (very old) that suddenly started to displayed a black blob on the screen. The blob was anywhere from 1" around to almost the size of the entire screen. It had a sharp, not fuzzy, outline, and it would shrink in size as the TV warmed up, usually disappearing completely in 30 minutes. It shrank in sudden jumps, not gradually. Sometimes the blob would be stationary, other times it would tumble around rapidly all over the screen."

(From: Raymond Carlsen (rrcc@u.washington.edu).)

Measure the regulated +130 volt line... I think you'll find it has drifted upwards just enough to trigger the "protective" blanking circuit. In those sets, if the B+ (and consequently the HV) went up, the screen was automatically blanked so you couldn't use the set. It was before HV shutdown. Older RCA TV sets used to throw the horizontal out of sync. The low voltage regulator is an analog type with a pass transistor that is probably leaky, causing the high B+. Changes in line voltage and loading (with brightness changes) cause the partially blanked picture to change (the black blob moves around, sometimes blanking the entire screen). When you replace the defective component, reset the 130 volts with the pot, and you're back in business. The pot itself may have a bad spot... just move it one way or the other to get off that spot.

Vertical brightness or color bars

These are typically more or less equally spaced possibly more evident at the left side of the screen. They result only in brightness or color variations, not deflection speed. Diagonal lines are straight and not squiggly.

Note that the appearance of these bars differs from those caused by ringing in the deflection circuits where diagonal lines will show a squiggling stair-step appearance.

The most likely cause is a dried up electrolytic capacitor in the scan derived power supply for the video or chroma circuits or video output. Check for this ripple with a scope or test/replace any suspect capacitors.

Tuner, AGC, and Sync Problems

No reception from antenna or cable

Make sure your source is providing a signal and that the cable connectors are good (center pin not broken or bent). Try another TV if possible.

Make sure you source select switch or mode is set correctly. Someone may have accidentally set it to direct video or AUX input.

Are all bands affected? If so, the tuner or IF is faulty. If there is a lot of snow, then it is probably toward the front (circuitry wise) of the tuner. If it is just a black screen, then it could be in the IF or video amplifier.

If only certain bands are bad - channels 2-6 for example, then certain parts of the tuner circuitry are faulty. However, make sure the CATV mode is set correctly as this affects reception on a band-by-band basis.

The problems may be due to bad solder connections of the tuner shields, connectors, coils, and other components. Try prodding the tuner to see if you can make the problem come and go or at least change.

Picture is overloaded, washed out, or noisy

This indicates an Automatic Gain Control (AGC) problem often caused by a dried up capacitor. You will probably need a schematic to go much further. This could be a problem in the tuner, IF, or video amplifiers.

The following assumes you are sure the signal source is strong - try a VCR or other local one (channel 3/4, not the RCA jacks).

(From: Glenn Watkins (blueribb@mail.comcat.com).) Substitute a variable voltage source for the tuner's AGC voltage. Most of the time the range of AGC is from 1 to 7 volts. If you can get a decent snow free picture with an external AGC source, then the tuner is probably OK.

Jumping picture on white scenes

This could be an AGC problem if the picture appears overloaded. However, if the picture is normal except unstable, the sync separate is the place to look:

(From: Jack Schidt (jack@wintel.net).)

White screens are a worst case video pattern for sync separators, and will cause an erratic shift in the vertical multivibrator trigger level unless the horizontal and video information is filtered out [integrated] prior to driving the vertical sync input of the processor IC.

This will show up with a scope as high frequency noise going into the vertical sync input.

Look for a small electrolytic [in fact, all of them], around 1-10 uF or so near the deflection/sync processor IC. Often simply increasing the value of this cap will help.

Interference when using VCR RF connection

(Some of these comments also apply to use of LaserDisc players, satellite receivers, video games, or other sources with RF modulator (Channel 3/4) outputs).

This may consist of patterns or lines in the picture.

If this only happens on the antenna or cable, it may be a problem with these sources or the tuner in the VCR rather than the TV. As a test, try the connecting the TV directly to the antenna or cable.

If it only happens on cable, there may be a (temporary) problem with cable transmission - contact your cable company.

If it happens on playback of good quality (commercial) recordings, then it could be a compatibility problem between the VCR and TV.

Make sure your patch cable connections are secure and that the cables are not damaged - in particular that the center pin is intact.

Try fine tuning if your TV has this capability. If this does not help, try switching the channel 3/4 selector on the VCR to the opposite position and try that channel, sometimes one will be better than the other particularly if one of these or an adjacent channel is active in your area.

If you have RCA baseband video inputs on your TV, try this connection to the VCR. These should work better in any case.

Confirm that it is not actually a problem with the VCR - try another TV if possible.

If you just changed your component placement, the VCR or TV may be picking up interference from another component. Turn off everything but the VCR and TV and see if that identifies the culprit. Move the TV away from the VCR so see if they are interfering with each other - the TV may be introducing interference into the VCR.

Occasionally, the particular patch cable or its length may affect reception quality - try another one.

If none of this helps, you VCR's RF modulator may be bad or slightly weak. Alternatively, the tuner in the TV may be faulty. If reception is generally noisy on all sources, AGC or RF/IF alignment may need adjusting. However, not all tuners are created equal. Your TV may simply be making the best of a marginal situation.

A light dimmer on the same circuit as the TV may result in similar symptoms. If you are tuning up your motorcycle (or automobile) in the same room, this may be spark ignition interference.

RF Interference on TV

> "I have interference lines on my TV - they are particularly heavy on 2, not so prominent on 9 - one TV is on Radio Shack Color Supreme 100 (souped up rabbit ears), other is on a roof top antenna, both have coax from antenna to TV. I have HAM operator two doors away. Is there an FAQ on interference - if so where. How do I need to describe the interference pattern in order to seek help. Thanks."

The FCC had an online interference handbook, with color photos showing how different types of interference affect a TV's picture. This has vanished from the FCC Web site but is now on the Kyes TV Web site:

- FCC TV Interference Handbook

Another Web page on interference which includes portions that have obviously been copied from the FCC document is at:

- Colin's Interference Handbook

(From: Andrew Mitchell (amitchell@sympatico.ca).)

Probably the easiest solution is to visit your ham neighbor and describe your difficulty. Amateur radio operators are licensed by federal governments (FCC) and are required as part of their examination to demonstrate a knowledge of this type of interference. It may well be that the ham is not the source of the problem and even if this is the case I'm sure he or she will be of assistance.

(From: Alan N. Alan, WDBJ-TV, KM4IG (alann@intrlink.com).)

OK, as a HAM myself, I can understand this. Channel 2 is the lowest TV channel, right above the six meter band, 50-54 Mhz. Channel 9 is well into VHF above 175 Mhz. It is possible that your neighbor operates 6 meters.

I would talk to him. First, the chances are it is YOUR equipment, and his is legal and meets FCC specs. But I would be willing to bet he will be very cooperative to help you solve your interference.

The thing to do is talk to him, calmly, and tell him about your problem. Then, schedule a time where he can transmit his gear and see if your problem exists along with his transmissions.. If it does, you can go from there. Many ham clubs have many engineers and radio and TV people in their memberships that will jump in and help you solve your problem. Again, he is probably legal, and consumer equipment is not known for it's RF resistance. Consumer manufacturers cut corners wherever they can. This includes filtering and design.

Problems with ground loops and video hum bars

> "I am having a problem isolating where my ground loop problem is coming from. The symptoms I see are Bars on my TV which scroll up the screen. The problem is these bars come and go, and when they are present they vary in intensity. I have verified that the cable ground is connected to the earth ground on the outside of the house, but the problem still remains. This problem is also screwing up any attempts to do video electronics experimentation. I am really tired of seeing these bars and any help you could give would be appreciated."

(From: Paul Grohe (grohe@galaxy.nsc.com).)

1. Do these bars show up on other TV's connected to the same cable?

2. Is your TV connected to anything else? A/V receiver? VCR?

   If so, unplug *all* the equipment and plug it in one-at-a-time until the hum appears. If you have an AV receiver in the system, try running a jumper wire from the incoming CATV ground at the TV to the receivers chassis ground (usually the "phono ground screw").

   If you have any devices with un-polarized plugs, unplug them and rotate them 180 degrees, and plug them back in.

3. If you connect a temporary antenna and view "off-the-air" signals, are the bars still there?

If you still cannot eliminate the hum, try building a simple "ground isolator" out of two 75-300 ohm baluns, as described in the link below:

- ePanorama's Groundloop Information Pages

Place it as close to the TV as possible.

(From: Charles Godard (cgodard@iamerica.net).)

This seems like a cable company problem, but you need to prove it to the cable guy before he will start climbing pole's and changing amps and couplers looking for an intermittent amp. (And I don't blame him.)

At the main cable line to the house and remove all couplers and put a single line from the cable direct to the rf input on a single TV, then watch it for a few of days. If the problem re-occurs call the cable guy and show him what you have done and explain the problem again.

Put yourself in the shoes of the cable guy. He comes into a house with VCR's and all the gadgets we all have hooked up to our TV's with lines running all over the house, and can't get to the back of the TV to see what's there, and he's not a TV repair guy anyway and nobody else in the neighborhood is complaining and this problem may happen when it rains but it may not. mmmhhh

If it does not show up on the single TV, then the problem is probably yours. Add one device at a time until you find the trouble maker. Start with the your Cable AMPLIFIER.

(From: 4real (alan69@iname.com).)

You eliminate all of the other junk attached between your main cable input to your house and your TV to be sure it isn't the cause.

You will definitely want to suspect a problem with the amplifier you have installed. Especially if it is one of those cheap ones. Usually when the filter capacitor in an amplifier goes bad it will cause the hum bars you are describing, and they can be intermittent. Another problem may be that you have too much signal going into the amplifier. Amps are rated to handle a certain amount of input signal (measured in db) depending on the number of channels you wish to amplify, and the gain provided by the amp. If you try to feed an amplifier with too much signal it will overdrive it and cause a venetian blind, or herringbone effect. It could also be possible that the cable company is supplying a signal with reverse tilt. That means more signal on the lower channels and less on the higher ones. The lower channels might be the ones overdriving the amplifier. The only way to tell for sure is to measure it with a signal level meter. (very expensive unless you happen to be in the business and have one handy) If this is the case (too much signal going in) you probably don't need the amplifier to feed only 2 TVs.

The last thing I can think of and the cable guy should have checked this: They use 60 VAC on their main trunk lines to power their line amplifiers. The taps which feed the individual houses are supposed to prevent this ac from going to the individual lines. Occasionally one of these devices fails or a line guy forgets to pull a fuse and hence the ac gets sent to your TV. It won't necessarily fry your TV but can cause problems. It may even damage the TV tuners that are connected to that feed. In most cases if you touch the center conductor of the cable and a good ground you can feel the ac. It isn't enough to hurt you but you will definitely know it's there. To be on the safe side you should test it with a volt meter.

(From: Cliff R. (craeihl1@nycap.rr.com).)

My guess would be your cable amplifier. The fact that you see TWO bars on your screen tells me that it's 120 Hz interference - the frequency caused by ailing full wave power supplies used in these amps. Take the amp out of the line for a few days. If you don't have "snow" in the picture with it out, s...can it! If you find it was bad and can't live without it, you might try making sure all your internal cable, splitters, and connections are good quality & in good shape. Radio Shack stuff......well, it stinks! You can purchase primo splitters & cable from your cable company and its not that expensive. Certainly cheaper than an amp (which you might not need if the cabling were up to snuff).

You could also cry to the cable company for more signal into your house. This may or may not work but it's worth a shot.

I would put an amp in line only as a LAST resort. Most of the inexpensive amps sold are......cheap. They can easily cause more trouble than they cure. If you must, go with a primo unit from Blonder-Tongue or Jerrold.

(From: Charles Hope (charles.hope@argonet.co.uk).)

It sounds very like a problem that I had and solved.

Cause: Modern TV sets antenna connector does not have true earth on the screen but is at a potential of half mains supply. It is possible to draw about 30 micro-amps from this.

Hum bars are induced in the amplifier because there is a small resistance in the earth path between output and input giving about 1 volt drop of this stray mains signal. Worse when raining because the cable ground is better then.

Solution: Either ground the antenna screen or fit a "braid breaker" in the screen.

Missing or noisy channel or block of channels

If you are unable to receive certain channels or blocks of channels, this is a tuner problem - could be as simple as bad connections - or even simpler:.

First, check to see that the tuning mode is correct - TV, CATV, as this is the most common cause of channels 'disappearing'.

TV channels are assigned frequencies ranging from 72 to almost 800 MHz depending on broadcast or cable channel assignment. To tune over such a wide range requires splitting it up into various bands even if these are not actually defined. If you have a varactor tuned set, then you already know about the Vl, Vh, and U bands which may use separate front-end components. Even modern quartz PLL synthesized tuners need to allocate circuitry depending on frequency range. Therefore, if a block channels is not working, it could be due to a failure of some component related to that frequency range. Aside from looking for bad connections, resoldering the shields and connector pins, prodding, pressing, praying, etc. you will need a schematic to have any chance of finding such a fault.

There is another slight possibility. Some TVs have a parental lockout capability (pre V-chip) to prevent kids or other unauthorized access to selected channels. The channel selections may have been accidentally altered. Check your user manual for instructions on programming this feature. Even on models without this option, the same internal circuitry could be present but not normally accessible. A power surge or stray cosmic ray could have put the set in a screwy mode. Unplugging power for a minute or probably a much longer time might possibly reset such an anomaly.

Loss of Channel after Warmup

If there is a general loss of picture and sound but there is light on the screen, then most likely the tuner or IF stage is pooping out.

With both no sound and no picture but a raster and static, it is most likely a problem in the tuner, power to the tuner, or its controller (if non-knob type).

If it recovers after being off for a while, then you need to try a cold spray in the tuner/controller to identify the component that is failing. Take appropriate safety precautions while working in there!

If it stays broken, then most likely some component in the tuner, its controller, or its power supply as failed. There is a slight chance that it could be a bad solder connection - I have seen these in the tuner modules of RCAs on several occasions (and many other manufacturers - apparently not a solved manufacturing problem even after 40+ years!

Channel tuning drifts as set warms up

This may be a slight drift - like someone is messing with the fine tuning or such a substantial change in tuning frequency that the channels go by as though you are surfing.

Possible causes depend on tuner type:

1. Quartz tuner (10 button direct access digital synthesizer) - For a slight drift, a component is probably changing value, possibly the crystal in the reference oscillator. For gross changes - flipping through channels - it is more likely to be a digital control problem - the microcontroller is misdirecting the synthesizer to change frequency.

2. Varactor tuner (buttons but not direct channel access) - If only a single pushbutton selection is the problem, the the varactor tuning diode for that button is probably changing capacitance. If all channels in a band (Vl, Vh, U) are having a problem, it is more likely to be a drifting D/A or faulty AFT (Automatic Fine Tuning) circuit or power supply.

3. Turret or switch tuner (Knobs) - A component like a capacitor is changing value.

You will have to get in there with a heat gun or cold spray and track it down the old fashioned way. At least, the problem is almost certainly localized to the tuner box (and possibly the controller if applicable).

As noted, gradual slight changes in tuning are likely due to frequency determining components drifting.

Uncontrolled channel surfing is probably a logic problem. For the quartz tuner, this could still be marginal connections causing the microprocessor to misdirect the synthesizer to change channels.

For the latter case, particularly, the cause may still be bad connections resulting in loss of channel memory and/or erratic behavior.

Noise in picture and sound due to bright scene

When a bright scene comes, the screen flashes and there is a lot of noise in the sound. When a dark scene comes, there is no flash or noise. Changing channel does not help. The noise persists even when the sound is muted.

(The following is from: Lattuca@Midwest.net (Sam Lattuca))

When the video detector level is adjusted too high, you will get noise in the sound while screen contains a lot of white information (i.e. letters) but won't when only dark scenes are present. The video level adjust is usually a small coil normally located near the IF section. Since your set is several years old, this wouldn't be uncommon. It can be adjusted while watching the picture and listening to the sound.

Internal interference - switchmode power supplies and digital circuitry

(From: Mr. Caldwell (jcaldwel@iquest.net).)

On virtually all newer televisions and in particular Mitsubishi televisions there is a problem with interference being emitted by the switched mode power supply.

The common symptom of this 'fault' is snake like dotted 'S' lines on channels 2-6. It doesn't matter if it's cable, antenna or satellite(channel 3/4), this symptom can occur.

The common cause of this interference being allowed into the tuner is cabling. The super cheap 'suitable for garbage tie' cable that comes with even the most expensive VCR's is the culprit in most cases. The second is a set of rabbit ears the least common is an open or high resistance to ground connection (usually at a connector) on the incoming cable line.

To fix this there is only one reliable solution. All cabling must be hand made RG-6 cable. Make as follows:

1. Strip the outer sheath of the cable to expose the braid and *fold the braid* away from the end so that it covers the unstripped outer braid.

2. Strip the inner conductor to it's proper length.

3. Install a good quality RG-6 connector *over the folded* braid.

4. Crimp with the proper RG-6 attachment to the cable crimpers, don't use a set of pliers or other -crushing- device.

If the cable company doesn't waterproof the outside connectors, Radio Shack sells a 'sealing tape' just for this purpose. Most cable companies use self sealing 'o-ring' connectors.

(From: Jeroen H. Stessen (Jeroen.Stessen@philips.com).)

There is also interference from internal microprocessors and digital text generators (on-screen display, close captioning, teletext). And with 100 Hz digital television there is a wealth of sources ...

Using only high quality shielded cable as described above seems like really good advise, FWIW I'd like to second that. I wish that everyone would take antenna cables as seriously as you.

Generally, double-braided cable (using copper foil for second shield) and coaxially constructed connectors are recommended. But I think that the hand-mountable F-type connectors (Radio Shack) would be equally good, though less robust, if mounted properly.

As far as antennas go, a decent rooftop antenna should always be better than whatever rabbit ear construction you might think of. In this case, distance counts too, the antenna WILL pick up interference.

Those darn rabbit ears

So you bought a high performance TV and a set of $20.00 rabbit ears and there are lines on channels 2 to 6. Go buy a set of rabbit ears that has *only* a coax connector on the back, throw the cable supplied with it in the bin for 'twist ties'. Also buy an inexpensive surge suppressor that has a cable protector, enough RG-6 cable and connectors for two cables.

- Make one cable long enough to get the antenna away from the set (12ft) and the other to connect the antenna to the surge suppressor.

- Connect the long cable to the set and the other end to the surge suppressor.

- Find an outlet away from the set and plug the surge suppressor in (pick the most sane order for all of this.)

- Connect the shorter cable to the surge suppressor and connect the other end to the antenna.

You're done and if you thought carefully you would have put the antenna near your easy chair so you can adjust the picture or put the antenna where you'll get the best reception and prevent interference. The surge suppressor was needed to ground the other end of the coax so as not to make the outer shield an antenna for the interference from the TV's power supply. This method can also help allevate 'dead spots' when using rabbit ears.

Herringbone lines in picture

(From: Isaac Bergen (isaac.bergen@sympatico.ca).)

Could be interference. If the pattern slowly moves up the screen, the problem is from the 60 Hz power. A line of dots or thin lines usually means corona discharge (arcing) from a nearby power line (especially on humid days). Could also be from a bad filter capacitor in the TV's power supply. A "checkered" pattern could be from a digital type noise source like a computer, etc. If you move the TV to another room and the interference changes, that's probably it.

EM or RFI hell?

> "About a mile from my home there are four TV (channels 2, 4, 9 and 14) and several broadcast FM transmitters, all working with powers in the 100+ Kw ERP class.
>
> Radio reception is a nightmare, mostly (I think) because of IM products in overloaded front end stages. In most bands there are several regions at a spacing of about 100 Khz, each 30 to 40 Khz wide with a harsh buzz stronger than anything else."

(From: Don Klipstein (don@Misty.com).)

If the buzz is of a frequency like the power line frequency or a harmonic thereof, then the nearby transmitters may not be the culprit. Instead, nearby corona on a high voltage power line, a nearby neon sign, or a nearby light dimmer may be the offender. Although the noise from these is usually broad-band, the noise could get concentrated into bands spaced 100 kHz apart if something resonant around 100 kHz is involved in the noise production.

I would try temporarily turning off all fluorescent lights, neon signs, lights with dimmers, etc. and asking your neighbors to do the same to see if any of these is the offender. I have often found light dimmers to be major RF noise sources.

Possibly, an RF noise filter for the AC power for your receiver may help things. If you isolate a single offending appliance, it may help to plug it into an RF noise filter. If you use any filters with either the offending appliance or the receiver, try all combinations of plug reversal to see what works best. Both leads of any offending appliance may not equally spew noise, and both lines in the filter may not equally block noise. Both lines of the receiver's power cord may not equally bring noise into the receiver, if this is the route the noise takes.

- Back to TV Repair FAQ Table of Contents.

Audio Problems

Picture fine, no audio

First check that any muting control is not activated. This might be a button on the remote or set itself. If you have a headphone jack, it may have dirty contacts as plugging in a headphone usually mutes the speaker.

If the set is mono or only one channel of a stereo set is out, then check for bad connections to the loudspeaker. Test the loudspeaker by disconnecting one of the wires (with the power off!) and measuring its resistance with an ohmmeter (it should be less than 100 ohms - probably less than 8 ohms). Or momentarily touch a 1.5 volt battery to the speaker terminals - you should get a click or pop from the speaker.

Next, trace back from the speaker output terminals to the circuit board and look for bad solder connections or a loose or dirty connector.

If these tests do not reveal anything, you probably need a scope (or audio signal tracer) and schematic. Or at least the part number off of the chip. Is the final amp a chip also or just a transistor? Have you tested the transistor? If there is little or no buzz from the speaker, that would indicate a problem fairly near the output. If the tuner/if were bad, I would expect some noise/humm pickup from the low level audio stages. Get the part number off of the chip. If it is in a socket, check the contacts for corrosion or looseness.

Weak or distorted audio

Assuming you are not attempting to play it at ear shattering levels, this may be due to an alignment problem in the IF/audio demodulator, a bad audio IC or other circuitry, bad connection, or a defective speaker.

If your TV has an earphone or audio line out jack, try this to see if it is clear. If so, then your problem is in the final audio amp or speaker(s).

If only one channel of a stereo TV is affected, it is almost certainly the audio amp or speaker for that channel. Interchange connection to the two speakers temporarily and see if the problem moves.

If the problem is at all intermittent - try gently whacking the TV - then it is likely a bad connection - either a cold solder joint or a dirty or tired IC socket.

The audio amplifiers in newer TVs are almost always ICs and replacements are usually readily available. If the IC is in a socket, remove the IC, clean the pins and socket contacts and reinstall it. Sometimes, the contacts on old socket lose their springiness and do not provide solid connections. Such a socket will need to be replaced.

If the set uses discrete transistors, it s also possible for one of these to become noisy.

If your TV is fairly old - 10 years or so - this may be an alignment problem requiring tweaking of a coil in the sound IF. See your service manual. It may be possible to have similar problems with newer TVs but this is relatively rare.

There could also be bad electrolytic capacitors, probably in the power supply area. Even though you might think this would result in hum and there is none (even when there is no audio in the program or the sound is turned down) dried up caps can result in distorted sound that may sound like a sort of clipping. An ESR meter is best for testing (with power off!) but carefully jumpering known good caps across suspect ones (again with power off, then turn on the set and check), will eventually find the bad one(s).

Buzzing TV

Do you actually mean buzz - low frequency as in 60 Hz? Or, do you really mean high pitched whine. If the latter, see the section: High pitched whine or squeal from TV with no other symptoms. Or, it may be a combination of both effects. Is the buzz through the speaker or from the inside of the set?

- If it is the speaker, then it is a problem with the audio circuitry. This could be a design issue - very common or an actual fault (if it wasn't there before). It could also be interference caused by fluorescent lights or appliances like vacuum cleaners with universal motors or body massagers with vibrator interrupters (which generate sparks).

  Where the source of the problem cannot be located or eliminated, consider using a (HiFi) VCR for the tuner with an external stereo amplifier and the disable the internal speaker.

- There is a slight possibility that the AC power in your house has some harmonic content - the waveform is not sinusoidal. This might be the case if you try to run on the same circuit as an active dimmer or something else with thyristor control. Proximity to heavy industry could also cause this.

  Relocating the offending device to another branch circuit may help. You could also try a line conditioner (not just surge suppressor) which includes filtering. Or, use a HiFi VCR as your audio source (see above). Else, petition to have that metal foundry move out of the neighborhood :-).

- However, a buzzing that only occurs when the picture has sharply defined text or graphics, may be an overload problem at the source - some TVs simply handle it better than others.

  If it is a fault in the TV, an adjustment to the tuner or IF may be needed.

  (From: Paul Weber (webpa@aol.com).)

  Not to disparage proponents of the evil demon theory, but the phenomenon is more commonly known as "sync buzz". It is caused by poor performance in the TV's audio circuitry. It can usually be fixed by (1) reducing the signal strength and/or (2) tweaking the sound IF coil. Unfortunately, some of the latest TV receivers have no sound IF coil to adjust. If your TV has a sound IF coil, it can be done by ear, if you don't care about sound quality. However,I'd recommend taking it so a competent shop and describing the symptoms. Use the term "sync buzz in the audio," and they'll know what you mean. Be advised that it can't be cured in some TVs due to poor design.

- If it is from inside the set (and not from the speaker), it is in the deflection (probably vertical) or power supply. Either of these can vary in severity with picture content due to the differing current requirements based on brightness. It could be a power supply transformer, deflection yoke, or other magnetic component. Even ferrite beads have been caught buzzing when no one was looking :-). Any of these parts could vibrate if not anchored securely or as they loosen up with age.

  Some hot-melt glue, RTV silicone, or even a strategically wedged toothpick may help. A new part may or may not quiet it down - the replacement could be worse!

  See the section: Reducing/eliminating yoke noise.

- Some TVs are simply poorly designed. You cannot infer the severity of this annoyance from any specifications available to the consumer. It is strictly a design (e.g. cost) issue. The size of the TV is not a strong indicator of the severity of the problem but there will be some relationship as the power levels are higher for larger sets. The best you can do is audition various TVs very carefully to find one that you are satisfied with.

BTW, when I got my new super-duper RCA Colortrak in 1980, it had a similar annoying buzz - even had a repair guy out who behaved as though this was to be expected. I did get used to it and am not even aware of it today - and still use that set.

Additional comments:

(From: Karen (kclark9835@aol.com).)

Also for some audio buzz problems especially in the older units don't overlook the possibility of a misaligned trap. or a touch-up of the sound discriminator may prove helpful.

(From: Alan (algba@ix.netcom.com).)

If the buzz is coming from the speaker suspect a bad saw filter in the if circuit (very common).

If it is coming from elsewhere in the set it could be the flyback transformer, line input choke, or most common on those sets - the deflection yoke. I have repaired many of these yoke by using a wooden shim and some silicone rubber. In the collar of the yoke just ahead of the lock down clamp, there are some metal strips under the plastic. These are magnet that are used for convergence correction at the top and bottom of the picture. If you disturb them too much it will throw off the convergence.

Chattering yoke

This is a special case of buzzing originating from the deflection yoke.

(From: John Del (ohger1@aol.com).)

I am assuming your talking about a NAP yoke made by Panasonic/Quasar also used by them as well. The vibration comess from the metal shunt inside the yoke which is used for "self convergence". The shunts were held by a mastic material that breaks down into a powdery substance.

Remove the yoke from the tube and bore a small hole in the plastic on both halves (top and bottom). These holes will be at the 12 and 6 positions, as the 3 and 9 will have windings visible. Fill the holes with white glue and let the glue settle in, rotating the yoke as it does. The glue will soak into the powdery material and harden it. You will have to do this several times until the glue oozes out near the clamp. Give it a full day to dry. This is better than paying $60 to $80 for the yoke.

High pitched whine or squeal from TV with no other symptoms

First, make sure it is not coming from the loudspeaker itself. If it is, then we are looking at an unusual electronic interference problem rather than simply mechanical vibration.

If it is a new set and think the sounds will drive you insane, returning it for a refund or replacement may be best alternative. However, you may get used to it in time. I don't know about returning a set to a store that doesn't take refunds (I won't even ask about that!).

In most cases, this sound, while annoying, does not indicate an impending failure (at least not to the set - perhaps to your mental health) or signify anything about the expected reliability of the set though this is not always the case. Intermittent or poor connections in the deflection or power supply subsystems can also result in similar sounds. However, it is more likely that some part is just vibrating in response to a high frequency electric current.

There are several parts inside the TV that can potentially make this noise. These include the horizontal flyback transformer, deflection yoke, other transformers, even ferrite beads in the horizontal deflection circuits. In addition, transformers or chokes in the switching power supply if this is distinct from the horizontal deflection circuitry. Or even a portion of the sheetmetal used for shielding if in close proximity to a magnetic component.

You have several options before resorting to a 12 pound hammer:

- As much as you would like to dunk the TV in sound deadening insulation, this should be avoided as it will interfere with with proper cooling. However, the interior of the entertainment center cabinet can be lined with a non-flammable sound absorbing material, perhaps acoustic ceiling tiles. Hopefully, not a lot of sound energy is coming from the front of the set.

- Move the TV out of a corner if that is where it is located - the corner will focus sound energy into the room.
- Anything soft like carpeting, drapes, etc. will do a good job of absorbing sound energy in this band. Here is your justification for purchasing those antique Persian rugs you always wanted :-).

If you are desperate and want to check the inside of the set:

- Using appropriate safety precautions, you can try prodding the various suspect parts (flyback, deflection yoke, other transformers), even lowly ferrite beads, with an insulated tool such as a dry wooden stick. Listen through a cardboard tube to try to localizing the source. If the sounds changes, you know what part to go after.
- Once you have located the guilty party, some careful repositioning, a strategically wedged wooden toothpick, or a dab of RTV silicone or hot-melt glue may keep it quiet. Where the yoke is the guilty party, see the section: Reducing/eliminating yoke noise.
- It is possible to coat the flyback transformer, but this is used mostly when there a loose core or windings and you are getting not only the 15,735 Hz horizontal (NTSC) but also various subharmonics of this. This is probably acceptable but may increase the temperature of the flyback.
- A replacement flyback (or whatever part) may cure the problem unless it is a design flaw or manufacturing quality problem. However, the replacement part could be noisier. You really do not want to replace the yoke (aside from the cost) as convergence and other service adjustments would need to be performed. Other transformers can be replaced.

Note that the deflection frequency - just over 15 kHz for NTSC and PAL - is on the border of audible for adults but will likely be loud to younger people possibly to the point of being terribly annoying - or worse. If you are over 40 (men more so than women), you may not be able to hear the fundamental at all (at least you can look forward to silence in the future!). So, even sending the TV back for repair may be hopeless if the technician cannot hear what you are complaining about!

BTW, if you have a really old tube type TV, the power tubes (damper and horizontal output) can also whine but these sets are few and far between these days :-).

Reducing/eliminating yoke noise

(From: Terry DeWick (dewickt@esper.com).)

Carefully look under vertical core next to plastic liner, on top and bottom is a plate called the astigmatism shunt, it has come loose. Work RTV, epoxy, or service cement onto it to glue it down and noise should quit.

(From: TVman (tvman@newwave.net).)

I have fixed a total of 27 of these sets with noisy yokes by removing the yokes and using motor armature spray sealant.

If you carefully mark the EXACT position of everything (yoke, purity magnets), and slide the yoke off the CRT, then once the yoke has been sealed with motor armature spray sealant and has dried thoroughly, put the yoke back EXACTLY where it was, there should be no problems.

The only thing I have had to do was set the purity on one set, but it was off a little to begin with.

Whining when off?

Many TVs actually run their switchmode power supplies even when off to power the standby stuff like the remote control receiver, real time clock or timer, and channel memory. Depending on the design of the regulator, the power supply may be running at a low chopper frequency due to the light load. Some people, dogs, and rodents are then annoyed. It could also be an indication of a fault like a bad capacitor or loosened transformer core if this symptom just developed - your hearing isn't likely improving :-(.

There is so much running nowadays in 'off' electronics!

- Back to TV Repair FAQ Table of Contents.

Miscellaneous Problems

General erratic behavior

You press VOLUME UP and the channel changes or a setup menu appears all by itself just at the climax of your mystery story.

Before you break out the screwdriver (or 12 pound hammer), cover up the IR remote sensor. Some types of electronic ballasted fluorescent lights may confuse the remote control receiver. Someone or something may be sitting on the remote hand unit or it may be defective and continuously issuing a bad command. Or, the kids across the street may have nothing better to do than to drive your TV (and you) nuts with their remote!

There is also a slight chance power line interference (from a light dimmer or external sources) may result in similar symptoms. See the section: Wiring transmitted interference.

Assuming this is not the source of the problem:

Check for bad connections - see if gently whacking the TV makes any difference or triggers the errant behavior. Bad connections in the power supply, system controller, or tuner, may result in this sort of behavior. See the section: TV and monitor manufacturing quality and cold solder joints. See the sections and separate documents on problems with RCA/GE/Proscan and Sony TVs if yours is made by one of these companies.

A microcontroller or other electronic problem is also possible. If the symptoms only develop after the set warms up, it may be heat related (though simple bad connections are more likely). Use 'circuit chiller' or a heat gun to identify the bad part.

Wiring transmitted interference

The power that comes from the wall outlet is supposed to be a nice sinusoid at 60 Hz (in the U.S.) and it probably is coming out of the power plant. However, equipment using electric motors (e.g., vacuum cleaners), fluorescent lamps, lamp dimmers or motor speed controls (shop tools), and other high power devices, may result in a variety of effects.

While TVs normally include some line filtering, the noise immunity varies. Therefore, if the waveform is distorted enough, some effects may show up even on a high quality TV.

Symptoms will usually be one or two areas of noise moving slowly up the screen.

The source is probably local - in your house and probably on the same branch circuit - but could also be several miles away.

- The rate will be the difference between the power line frequency (60 Hz in the U.S.) and the scan rate (59.94 Hz for NTSC). This results in a drift of about 16 seconds for a complete cycle (8 seconds if the inteference is at 120 Hz).

    - A single bar would indicate interference at the power line frequency.

    - A pair of bars would indicate interference at twice the power line frequency.

  Either of these are possible.

- Try to locate the problem device by turning off all suspect equipment to see if the problem disappears.

- The best solution is to replace or repair the offending device. In the case of a light dimmer, for example, models are available that do a better job of suppressing interference than the typical $3 home center special. Appliances are supposed to include adequate noise suppression but this is not always the case.

  If the source is in the next county, this option presents some significant difficulties :-).

- Plugging the TV into another outlet may isolate it from the offending device enough to eliminate or greatly reduce the interference.

- The use of a line filter may help. A surge suppressor is NOT a line filter.

- Similar symptoms could also be produced by a defective power supply in the TV or other fault. The surest way of eliminating this possibility is to try the TV at another location.

Jittering or flickering due to problems with AC power

If you have eliminated other possibilities such as electromagnetic interference from nearby equipment or a faulty video cable or problems with the video input (e.g., cable or VCR) - then noisy or fluctuating AC power may be a possibility. However, most modern TVs usually have well regulated power supplies so this is less common than it used to be. Then again, your TV may just be overly sensitive. It is also possible that some fault in its power supply regulator has resulted in it becoming more sensitive to small power fluctuations that are unavoidable.

One way to determine if the problem is likely to be related to AC power is to run the TV on clean power in the same location connected to the same video input. For example, running it on an Uninterruptible Power Source (UPS) with the line cord pulled from the wall socket would be an excellent test. The output of the UPS's inverter should be free of any power line noise. If the TV's image has now settled down:

1. Large appliances like air conditioners, refrigerator, or washing machines on the same circuit might cause significant power dips and spikes as they cycle.

   Plugging a table lamp into the same outlet may permit you to see any obvious fluctuations in power. What else is on the same circuit? Depending on how your house or apartment is wired, the same feed from the service panel may be supplying power to widely separated areas.

2. For some unfathomable reason, your TV may just be more sensitive to something about the power from the circuit in that room. There may be nothing actually wrong, just different. While unlikely, a light dimmer on the same circuit could be producing line-conducted interference.

If you have a multimeter, you could at least compare the voltages between the location where it has problems and the one where it is happy. Perhaps, the TV is sensitive to being on a slightly different voltage. This might only be a problem if some circuitry in the the TV is marginal in some respect to begin with, however.

3. There could be a bad connection somewhere on the circuit. If your house has aluminum wiring, this is a definite possibility.

   Try a table lamp since its brightness should fluctuate as well. This should be checked out by a competent electrician as it represents a real fire hazard.

An electrician may be able to pinpoint the cause but many do not have the training or experience to deal with problems of this sort. Certainly, if you find any power line fluctuations not accounted for by major appliances, on the same circuit this should be checked by an electrician.

TV blows fuses or trips breakers or worse when A/V connections are made

You have sent the TV for repair and now three times, it blows something the instant anything is connected to it in your house. Other A/V equipment operates fine.

Assuming all the other stuff is plugged into the same outlet asn is 115 VAC equipment and that thsi happens instantly when the TV is connected:

Next time they bring it back, measure the voltage between the A/V connector shields and the shields on your cables - I wouldn't be surprised to find some substantial fraction of 115 VAC between them. This would mean that there is an internal short in the TV (their problem - any competent service center will routinely check for signal-AC ground shorts) resulting in a connection between the non-isolated AC ground and the signal ground. When you connect your equipment, you complete a path which results in a short circuit. Depending on the design of the TV and where the fault lies, much more than a simple fuse may be destroyed. This is similar to connecting a scope probe ground to a live chassis TV - see the section: Safety guidelines.

My TV has the shakes

You turn on your TV and 5-10 seconds later, the display is shaking or vibrating for a second or so. It used to only occur when first turned on, but now, the problem occurs 3 times in 30 seconds. Of course, many variations on this general theme are possible.

Some possibilities:

1. External interference - did you change anything or move your A/V setup recently? Do you have a computer monitor nearby?

2. Defective circuitry in TV - power supply regulation, deflection, or bad internal connections are possible.

3. Defective video cable (unlikely) - wiggle the cables to be see if you can induce the problem.

4. Loose trim magnets of other magnetic components on or near deflection yoke. This is somewhat rare but if the adhesive comes apart, the magnetic fields from the deflection current can cause the parts to vibrate which will result in a jitter or movement of the picture. There may even be audible crackling or snapping sounds associated with this vibration.

Note that many of the sources of electromagnetic interference that are problems with computer monitors like transformers and power lines will not cause noticeable shaking, wiggling, or jiggling on a TV because the power line and vertical scan are at almost exactly the same frequency and any such movement would be very slow.

TV displays black box with normal picture border

When the set is first turned on, it works fine for about 20-30 seconds, then the picture goes away - all but about 1 inch of picture all around the outer edge of the screen. The square ring of picture that is left, is dim but otherwise normal.

(The following from: (jack haney) jhaney@pacifier.com))

If this is a newer set, this sounds very much like a "closed caption" box for a captioning system not being used in your area. Newer Mitsubishis do much the same thing. If the wrong caption type is selected inadvertantly, all you'll see is a large black box on screen taking up about all but an inch each way.Try turning off all closed caption. The first time I saw this I looked like a damn fool in front of a customer, took me 30 minutes to figure it out.

Advertising overload

> "I noted the advertsing programs put in bright several frames of overshooting white signals in purpose of attracting attention which I do not want also it gets on my nerves sometimes. *flash* *flash* Ughhh! Is there a way to cutoff the "overload" or tone down that?"

(From: Jeroen H. Stessen (Jeroen.Stessen@philips.com).)

Technically, the TV takes care of its own overload protection. Or at least it *should*, on some TV's you will certainly observe the line transformer going into saturation for a while. Other than that there is not much you can do, each TV should represent its input signals with as much fidelity as possible. Change channels?

(I already suggested not watching. :-) --- Sam.)

Strange codes appearing on TV screen

> "I've seen this sort of thing on a TV I bought a couple of years ago. I only see it when Proctor & Gamble ads are on.
>
> The newer TVs are required to have Closed Caption decoding (CCD). My TV has an OFF-ON button for CCD. It also has a button labeled CH1-CH2. When pushed in I get the verbal text on the screen like I should. When the button is out, I get the funny codes from Proctor & Gamble."

(From: Tim (jollyrgr@mc.net).)

The code you are seeing is Closed Caption 2. My Zenith has CC 1, 2, 3, 4, as well as Text 1, 2, 3, and 4. I have seen CC 1 which is the normal closed captions. CC 2 is used for commercial logging/identification. There should be a way to completely turn off the captions. The TV, as you state, has a switch for turning off the captions and should solve your problem.

Releasing 'demo' mode

You really want to watch CNN but the TV insists on promoting itself:

- For Fisher TVs:

(From: Alan (algba@ix.netcom.com).)

Hold down the menu key on the remote for 8 seconds to switch it out of that mode or back in again.

- Here are several possibilities for LXI TVs:

  - Press VOLUME UP and VOLUME DOWN buttons together. Set will turn off. Then power back on normally.

  - Press VOLUME UP and CHANNEL DOWN buttons together.

  - Try holding the MENU button for 5 to 10 seconds. (Sanyo/Fisher sets manufactured for Sears.)

  - Try holding the SETUP button for 5 seconds.

- For Magnavox TVs:

  (From: L. Tankersley (boat39@mail.idt.net).)

  Try pressing both volume control buttons on the TV at the same time and releasing. The demo mode should go off and the set turn off by itself. Turn the set back on and it should be back to normal.

- For Sanyo TVs:

  (From: Bill A. (Lucy27@ix.netcom.com).)

  Try pressing the "menu" button on the unit and keep it depressed for about 15 to 20 seconds. This should release the demo mode.

TV was rained on

Was the set plugged in when the leak started? Any piece of equipment with remote power-on capability has some portions live at all times when plugged in and so there may have been damage due to short circuits etc. Substantial damage could be done due to short circuits.

Otherwise, you may just need to give it more time to dry out. I have had devices with keypads getting wet that required more than a week but then were fine. There are all kinds of places for water to be trapped and take a long time to evaporate.

If the set got wet while unplugged (in a leaky attic or wet basement), for example, or it has a pull or click knob on/off switch, then give it time to dry out - completely. Assuming all visible water is drained, a week represents a minimum safe time to wait. Don't rush it.

Generally, some moisture will not do any permanent damage unless the set was on in which case you will simply have to troubleshoot it the old-fashioned way - one problem at a time.

TV was dropped

You have probably seen the TV advertisements - I don't recall what they were for - where a late model TV is dropped out a many story window on a bunjie cord to rebound once undamaged and without hitting a baby in a stroller but then smash to smithereens on the sidewalk once the stroller had moved. Needless to say, this is generally not a recommended way to treat a TV set!

However, mishaps do happen.

Assuming it survived mostly intact - the CRT didn't implode, you could still have a variety of problems. Immediately unplug the set!

If you take it in for service, the estimate you get may make the national debt look like pocket change in comparison. Attempting to repair anything that has been dropped is a very uncertain challenge - and since time is money for a professional, spending an unknown amount of time on a single repair is very risky. There is no harm is getting an estimate (though many shops charge for just agreeing that what you are holding was once - say - a TV, or was it a fishtank?)

This doesn't mean you should not tackle it yourself. There may be nothing wrong or very minor problems that can easily be remedied. The following are likely possibilities:

1. Cracked circuit boards. These can be repaired since TVs usually have fairly wide open single or two sided boards.

2. Broken circuit components. These will need to be replaced.

3. Broken solder connections particularly to large heavy components on single sided boards. Reflow the solder. If the trace is cracked or lifted, repair as in (1).

4. Broken mounting brackets. These are usually made of cheap plastic and often don't survive very well. Be creative. Obtaining an exact replacement is probably not worth the trouble and expense.

5. Components knocked out of line on the CRT envelope or neck - deflection yoke, purity magnets, convergence magnets and coils, geometry correction magnets. These will need to be reattached and/or realigned. Some CRTs use little magnets glued to the funnel portion of the CRT envelope. If any of these have come loose, it could be quite a treat to figure out where they went and in what orientation.

6. Internal damage to the CRT - popped or distorted shadow mask, misaligned electron guns. Unfortunately, you will probably have no way of identifying these since you cannot see inside the CRT. They will not be apparent until all other faults have been remedied and the TV set is completely realigned. At that point, extremely severe purity or convergence problems that do not respond to the normal adjustment procedure would be one indication of internal damage. Give the TV a nice funeral. See the "Sony1" and "Sony2" photos in James Sweet's Sony/Trinitron Directory for some screen shots showing the symptoms resulting from a monitor falling on its face. :(For a large screen TV, the effects may be even more dramatic.

If you still want to tackle a restoration:

As noted, unplug the TV even if it looks fine. Until you do a thorough internal inspection, there is no telling what may have been knocked out of whack or broken. Electrical parts may be shorting due to a broken circuit board or one that has just popped free. Don't be tempted to apply power even if there are no obvious signs of damage - turning it on may blow something due to a shorting circuit board. If it is a portable, remove the batteries.

Then, inspect the exterior for cracking, chipping, or dents. In addition to identifying cosmetic problems, this will help to locate possible areas to check for internal damage once the covers are removed.

(At this point, most people will assume there is no interior damage and plug the set back in and turn it on. My recommendation is to resist this temptation since as noted, this could result in further damage making the repair more expensive if there are circuit problems. However, if the unit was on at the time of the "incident" or you are really determined to get to the conclusion and would just throw the thing in the trash if it doesn't work or blows up, go for it! But, if you're the more cautious type, continue with the systematic diagnosis and repair procedure that follows.)

Next, remove the cover. Confirm that the main filter capacitors are fully discharged before touching anything. Check for mechanical problems like a bent or deformed brackets, cracked plastic parts, and anything that may have shifted position or jumped from its mountings. Inspect for loose parts or pieces of parts - save them all as some critical magnets, for example, are just glued to the CRT and may have popped off.

Carefully straighten any bent metal parts. Replace parts that were knocked loose, glue and possibly reinforce cracked or broken plastic. Plastics, in particular, are troublesome because most glues - even plastic cement - do not work very well. Using a splint (medical term) or sistering (construction term) to reinforce a broken plastic part is often a good idea. Use multiple layers of Duco Cement or clear windshield sealer and screws (sheetmetal or machine screws may be best depending on the thickness and type of plastic). Wood glue and Epoxy do not work well on plastic. Some brands of superglue, PVC pipe cement, or plastic hobby cement may work depending on the type of plastic.

Inspect for any broken electronic components - these will need to be replaced. Check for blown fuses - the initial impact may have shorted something momentarily which then blew a fuse.

There is always a risk that the initial impact has already fried electronic parts as a result of a momentary short or from broken circuit traces and there will still be problems even after repairing the visible damage and/or replacing the broken components. This is most likely if the set was actually on but most modern TVs have some circuitry energized at all times.

Examine the circuit boards for any visible breaks or cracks. These will be especially likely at the corners where the stress may have been greatest. If you find **any** cracks, no matter how small in the circuit board, you will need to carefully inspect to determine if any circuit traces run across these cracks. If they do, then there are certainly breaks in the circuitry which will need to be repaired. Circuit boards in consumer equipment are almost never more than two layers so repair is possible but if any substantial number of traces are broken, it will take time and patience. Do not just run over them with solder as this will not last. Use a fine tipped low wattage soldering iron and run #22-26 gauge insulated wires between convenient endpoints - these don't need to be directly on either side of the break. Double check each connection after soldering for correct wiring and that there are no shorts before proceeding to the next.

If the circuit board is beyond hope or you do not feel you would be able to repair it in finite time, replacements may be available but their cost is likely to be more than the equipment is worth. Locating a junk unit of the same model to cannibalize for parts may be a more realistic option.

Degauss the set as any impact may magnetize the CRT. Power cycling may work but a manual degaussing is best.

Once all visible damage has been repaired and broken parts have been replaced, power it up and see what happens. Be prepared to pull the plug if there are serious problems (billowing smoke or fireworks would qualify).

If there are obvious problems with color, disconnect (or disable) two of the 3 primary colors with a B/W picture (color control turned all the way down) or solid raster displayed. If the raster is not now a pure color, you have a CRT or CRT purity adjustment problem.

Perform any purity, convergence, or other realignment as needed.

Then proceed to address any remaining problems one at a time.

Really cleaning a TV inside and out

(This was written for computer monitors but applies equally well to modern TV sets.)

(From: Dr. Ludwig Steininger (drsteininger@t-online.de).)

Often I get defective monitors, which are more than 5 years old, and have been run in offices for 8 to 10 hours/day. So, their case and pcbs usually are very dirty and dusty.

What do I do (it's no joke!): After removing the case I carefully put them in a bath (on a flexible layer) and let them have a intensive shower of pure cold water (for 1 to 2 minutes). Additionally, the case is cleaned with soap or a detergent containing liquid (being careful, not to spill to much of it onto the PCBs). After rinsing with fresh clear water, dust and other kinds of dirt are removed and the monitors look new again. Then I allow all drops of water to run off. This can effectively be supported by turning the monitor on another side from time to time (duration: approximately 1 hour). Before turning on AC again, I let the wet monitor dry in ambient air for about 2 days (in the sunshine this can be finished in 1 day only).

This procedure has been applied for many monitors. I've never had any bad experiences (it's very important to wait, until the pcbs are really dry!). Considering this experience, I just can't imagine, that it might not be possible, to "save" a TV set or computer monitor, which has been drowned or some liquid has been spilled, and AC has been plugged off ASAP (although I've never had such a case). I think, that in such a case, it's important to have a rapid shower in order to prevent corrosion and deposits.

By the way: I know a German company, which uses water from cleaning PCBs of computer hardware for cleaning them after being contaminated by smoke from a fire.

So, in case of spillage, one has nothing to loose. Just try to shower your monitor or TV set!

Setup menus will not go away or hieroglyphics on screen

Both these problems could be caused by a faulty microcontroller or its associated circuitry. However, bad connections in the vicinity of the controller logic could also be at fault.

Unless you see something obvious, you will need schematics.

Setup adjustments lost - TV service codes

Many modern TVs have RAM, somewhat like the CMOS SETUP memory in your PC, that store all factory adjustments. When power is lost, there is power surge, lightning strike nearby, nuclear detonation or EMP, it may have put bad information into the ram and thrown it out of adjustment. There is a way to get into the service mode (depress and hold a secret button down and turn set on, special combination of buttons on the remote, etc.) and then use the remote to reinitialize and adjust the problems out.

HOWEVER, IF YOU DON'T KNOW WHAT YOU DOING YOU COULD GIVE YOURSELF WORSE PROBLEMS. YOU COULD EVEN BLOW VERY EXPENSIVE PARTS WITH SOME SETS!

Try not to make any unnecessary changes and document every change you make!!! That way you can go back if you do anything wrong (hopefully). However, some changes - even if nothing fails - will result in an unviewable picture thus making it extremely difficult to see what you are doing.

The Sams' Photofact manual for your set should describe this process - you may be able to get Photofacts from a local library, or you can buy them from Radio Shack or a place like MCM Electronics or an electronics distributor. The June, 1998, issue of "Electronic Servicing and Technology" (ES&T) had an article on service mode if you have access to this publication (it won't be in your public library).

Some examples follow. You would need to check the service information for your specific model to be sure. However, trying the procedures described below probably will not hurt. The TV will just ignore you if it doesn't like your codes! However, if you do get in, make sure you know what you are doing or your original problem may be inconsequential compared to your new ones!

- Ferguson/Thomson Technology T49F television (TX91 chassis and probably others as well).

  (From: Peter Radlberger (peter.radlberger@blackbox.at).)

  1. Unplug SCART cable.

  2. Switch to Standby, then switch mains off.

  3. Hold blue button on remote, power up.

  4. Repress blue button, service screen appears.

  5. Select function with blue, adjust with Vol+/-, store new value with highlighted Memo and Vol+. Restore jumps to original value, ROM are production defaults.

  6. Leave with Standby.

- Some Hitachi models:

  (From: Kahlid Ataya (kahlidataya@yahoo.com).)

  1. Turn the TV off with the main switch.
  2. Press and hold the A/V button on the front panel and turn the TV on with the main switch.
  3. Wait about 10 seconds and the TV will go on and service mode will appear on the screen.

- Some JVC models (JA chassis):

  (From: Roger Dowling (rogerd@globalnet.co.uk).)

  Press the DISPLAY key (may look like a small TV screen with a cross in the bottom right corner) and the CINEMA/GAME key of the remote control simultaneously.

  (From: Andy Cuffe (baltimora@psu.edu).)

  I have used this on JVCs from 1995:

  1. Set the clock to 3:21 AM.

  2. Start the clock as you normally would but press MUTE while "Thank you" is flashing.

  3. Press menu up or down just after MUTE.

  4. Use up/down to select options and left/right to adjust. The settings are automatically saved when you exit.

  (From: P. White (pwhite4@aol.com) and David Rigolo (stormdav@ix.netcom.com).)

On the new line of JVC sets (some models include: AV-36850, AV-32850, AV-27850, and AV-32820), hold the "Display" and "Video Status" buttons on the remote simultaneously. The set will bring up a service menu. Good luck trying to navigate the service menus with out a manual.

(From: Yorkie (magicfriend@ntlworld.com).)

Press the MENU and INFORMATION buttons down together and then press 1 then 2 then 3 while still holding the first 2 buttons down.

- Some Magnavox models: Enter 062596 then MENU. The channels will change but when MENU is pressed, the TV will enter the service menu.

  (From: Gscivi (gscivi@aol.com).)

  Hit MENU on the remote, while the menu is still up press the numbers 061596 or 061597. One of these will bring up the service menu. Now, your right/left arrows on remote will switch between the numbers across the bottom of the screen, highlight the number set right after the 'setup or service' option. The arrow up/down will change to the next service position.

- Some Mitsubishi models: Use your remote and press MENU then 2357 use VIDEO to select service menu and ADJUST to set values.

  There is more info on Mitsubishi service modes at: Don Page's Mitsubishi Service Mode Page.

- Some Nokia (ITT) models:

  (From: Stefan Huebner (Stefan.Huebner@rookie.antar.com).)

  Press mono/stereo - Channel C - Hypersonic within 1 second, The display now shows SE. Leave the service mode with the standby button.

  (From: Janus Christian Krarup (jckrarup@image.dk).)

  Press: [OK],[MUTE],[TV/SAT]

- Nokia model 6363:

  (From: Ian Abel G3ZHI (bert@skypilot.demon.co.uk).)

  Nokia model 6363 (and probably other late model TVs) - On the remote press -/-- then menu then TV all within 1 second. When in setup mode you use channel up or down buttons on the TV set to change to whatever you need to set up. Adjustments are made with volume + and - buttons on the remote control. My advice is to make a note of all the settings before making changes then you can always go back to them.

- Some Panasonic models: A very detailed document on Panasonic Service(man) mode for some models in the GL10C family (may apply to others as well) is provided at:

  - Panasonic TV Service Modes

  This includes entering/saving/leaving, register contents and range, etc., and useful links.

- Panasonic TX-W28R3 (and similar models):

  (From: Arpad Kothai (arpadk@EUnet.yu).)

  The remote control is used for entering and storing adjustments, with the exception of cut-off adjustments which must always be done prior to service adjustment. Perform adjustments in accordance with screen display. The display on the screen also specifies the CCU variants as well as the approximate setting values. The adjustment sequence for the service mode is indicated below.

  1. Set the Bass to maximum position, set the Treble to minimum position, press the Reveal on the remote control and at the same time press the Volume on the customer controls at the front of the TV, this will place the TV into the Service mode.

  2. Press the RED/GREEN buttons to step down / up through the functions.

  3. Press the YELLOW/BLUE buttons to alter the function values.

  4. Press the STORE button on the preset panel after each adjustment has been made to store the required values.

  5. To exit the Service Mode press the Normalization button.

- Philips 29PT8303 and other similar models:

  Using the remote control, press 062596, then the MENU key.

  (From RONGYOUNG@aol.com.)

  The access code for my Philips/Magnavox model TP3281CI is: Key in 062596, then press STATUS. This will get you into the setup menu. When done exit using the MENU key back to the normal picture. (Just as you would to exit the normal menu items). To save your changes you need to turn the TV off and then UNPLUG it for 10 or more seconds.

- Some late model Philips projection (and possibly other) sets:

  (From: Keith Halonen (finearts@sonic.net).)

  1. On remote, quickly enter 062596 and press MENU. SDM will appear at top right of screen. You can enter a channel number (or select a feed with your AV button) to restore a clear picture behind the SDM menu.

  2. Go up to the set itself and simultaneously hold down BOTH front panel volume buttons for several seconds - regular menu shows up for a second or two, then the service menu appears.

  3. CLEAR ERRORS will be selected. Press your RIGHT arrow button and all error numbers will reset to zeroes. (The repairman did this BOTH times he went in to adjust my Horizontal Shift - I'm not sure it is necessary but just in case!)

  4. Press DOWN arrow button to scroll down until you get to GEOMETRY, then press RIGHT arrow button to enter that mode.

  5. Press DOWN arrow button until you see HOR-SHIFT and a number. LEFT arrow key moves the picture left (smaller number), RIGHT arrow key does opposite.

IMPORTANT! To LOCK setting in, press MENU button to back out of GEOMETRY mode. Then shut off TV and turn on again. Picture will be shifted.

NOTE: After making any changes as per the above procedure, the Closed Caption feature will be activated during normal sound settings. Enter the regular MENU mode, select FEATURES and enter CLOSED CAP to reset the CAPTION MODE to CC MUTE.

NOTE: Other features in GEOMETRY mode also influence the picture image. If you intend to tinker, first make a list of all features/numbers. Don't panic if the VER-SLOPE feature chops the screen in half when you use the L- R arrow buttons to change the number. Just press MENU to back out and the picture will restore itself as per the new setting. After backing out of GEOMETRY mode with MENU you can reenter GEOMETRY mode without having to shut off the TV - just select GEOMETRY and use the right arrow button to reenter. Backing out with MENU merely locks in the most recent setting changes.

- Some RCA models: The codes can be found pasted to the inside of the back cover. To get into the SETUP MENU, "Press and hold MENU, hit POWER and then VOL+. DO NOT set H Freq too low or you will wipe the EEPROM. Bummer. For more information, see the document: RCA/GE TV (CTC175/176/177) Solder Connection and EEPROM Problems.

  (From: David Kuhajda (dkuhajda@locl.net).)

  On the newest RCA models, the Thomson Chipper Check computer interface is required for the service mode adjustment. To get into service mode: Press and hold MENU, tap POWER, tap VOLUME UP (on TV). Then using VOLUME UP or VOLUME DOWN, move data to 200 and press CHANNEL UP.

- Some Samsung models:

  (From: Livio Belac (lbelac@efpu.hr).)

  - CHASSIS: SCT51A: PICTURE OFF (ST. BY) -> SLEEP -> P.STD -> MUTE -> PICTURE ON (PWR ON).

  - CHASSIS: SCT11A, SCT11B, SCV11A, SCV11B ST. BY -> P.STD -> MENU -> SLEEP -> POWER ON.

  Perform adjustments with VOL +/-

  Select between adjustments with CH +/-

- Some Sharp models (including 19J-M100 and 20J-M100):

  Press the 'vol up' and 'channel up' at the same time and then plug in the set to AC line. Use the 'channel up/down' buttons to select the register; use the 'vol up/down' buttons to select the values. To exit this mode, depress the 'power' button.

- Some other Sharps (e.g., model 19H-M60):

  Short TP2001 and TP2002 together momentarily to get the service menu up. The service menu shows the paramater being aligned and the value.

- Sharp 51DT-25H:

  (From: Matt (matties@btinternet.com).)

1. Power the set off.
2. Press vol- and prog+ at the same time while powering up the set. Release the buttons after 1-2 seconds (the screen is still black at this point), otherwise the television is switched on in normal mode.

- Sharp 59C5-03H and some others:

  (From: Malcolm MacArthur (malcolmm@rustic-place.demon.co.uk).)

  1. Switch on TV, get a picture up.
  2. Unplug without switching to standby.
  3. Volume down, channel up.
  4. Plug in. The TV "boots" into service mode.

  To change values:

  1. Channel up/down (on set or remote): Select value to edit.
  2. Volume up/down: Edit value.
  3. Standby button: Store value (it took an hour to figure out the last one!)

  When finished, unplug. The TV will restart in normal mode.

- Some Solar/Finlus/ITT TVs:

  (From: Janus Christian Krarup (jckrarup@image.dk).)

  Salora 28F8C: Within 6 seconds from a cold-boot press [pause],[stop],[play] and [fast forward] quickly after each other. The TV will then enter the setup mode by displaying "SA" in the LED display. The user interface for this is an absolute nightmare. You input via the remote control (the layout is in no way intuitive!) and all the feedback you get is via the small LED display. I started navigating the mode and quickly figured out that [+] and [-] are used to navigate between different entities. You always start in "SA" and can cycle through 15 different entities before you end back in "SA". There are some basic and some very hardcore functions. (At the moment I have managed to mess my TV up really well, with the primary colours mis-aligned - which also seems to affect the AFC somehow.) [VolUp] and [VolDn] adjusts the "primary property" of the entity.

  SA: Horizontal adjustment, [VolUp]/[VolDn]: position A0: Vertical adjustment, [VolUp]/[VolDn]: position Y0: Trapezoid adjustment, [VolUp]/[VolDn]: +/-

- Various Sony models: Service mode adjustments can be found at:

  - Sony Service Mode

- Another Sony:

  (From: Trygve Pedersen (trygve-p@netpower.no).)

  To enter service mode turn off power push both + and - buttons on front of TV while you powers up you get TT on screen, and then you enter 34 (TT34 on screen), press the left arrow twice on remote, and you are in service mode.

- Some Sony UK models: Fast text buttons operate service mode.

- Sony KV-X2571 and similar models:

  (From: Peter & Jolanda Faber (pfaber@worldonline.nl).)

  Switch TV off. Press and hold two switches (center & right) under front panel. Switch set on with main switch. Wait a few seconds. Release two switches again.

- Some Toshibas:

  (From: Bill A. (Lucy27@ix.netcom.com).):

  1. Press the mute button on your remote and release (put unit in mute).

  2. Press and hold mute button on remote.

  3. At the same time while holding mute button on remote, press the menu button on the TV itself.

  If done correctly an "s" should show up on the screen to determine that you have successfully entered the service mode.

  5. Now, I believe if you press the menu button again on the unit some microprocessor data should be showing up on screen i.e. current micro part# etc.

  6. Press #9 on remote to enter various modes of operation. Here is where you really need the service manual, too much info to show here.

  Once in Service mode be very careful!!!

- Zenith System 3:

  (From: Raymond Carlsen (rrcc@u.washington.edu) and jollyrgr@mc.net).

  Hold the MENU button down for about 5 seconds... until the currently displayed menu disappears. Then press 9 8 7 6, then ENTER. There are two menus in the service mode. Use the MENU to toggle between them. Press SELect until the item you want is highlighted, then the ADJ button (left or right) for the submenu or the adjustment. Press SELect for the next item and MENU for the alternate menu. Press ENTer to exit the service mode.

  Some other Zenith TVs:

  On the TV itself, press MENU until it disappears, then ADJUST RIGHT and CHANNEL UP at the same time.

Service menu caution

Even changing a parameter which results in the loss of the picture could require replacing the EEPROM if you cannot get the set to come on and view the service menu to reset!

However, it may be possible to drive the HOT with an external source so you can see the menus for setup.

CAUTION: there is some risk. Should drive the HOT with too low a frequency, it may blow due to flyback core saturation. Use a series light bulb to minimize this possibility.

Strange number in upper left corner in Magnavox service mode

> "When I put my Magnavox in service mode a number comes up on the top left of the screen. I see no description of it in the service manual. Is this an hours used timer? Is it actually in hours?"

(From: Mister M. (mister-m@ix.netcom.com) and zapper (zap@mhv.net).)

This is actually a usege timer in hexidecimal.

(Hey, at least it is not binary. :-) --- Sam.)

TV doesn't work after being in storage

So the TV you carefully stuffed in a corner of the garages is now totally dead. You swear it was working perfectly a year ago.

Assuming there was absolutely no action when you turned it on, this has all the classic symptoms of a bad connection. These could be cold/cracked solder joints at large components like transformers, power resistors, or connectors and connectors that need to be cleaned or reseated. By 'no action' I mean not even a tweet, bleep, or crackle from anything.

To narrow it down further, if careful prodding of the circuit board(s) and various large components with a well insulated stick does not induce the set to come on, even momentarily, check the following:

1. Locate the horizontal output transistor. It will be in a TO3 metal (most likely on an older set) or TOP3 plastic package on a heat sink. With the set unplugged, confirm that there is no voltage across C to E and then measure between them with an ohmmeter. In at least one direction it should be fairly high - 1K or more. This confirms that the HOT is probably good.

   (There is also a slight chance that there is a low voltage regulator in addition to the horizontal output, so don't get them confused. The horizontal output transistor will be near the flyback transformer and yoke connector.)

2. Trace back from the HOT collector to the flyback and through the flyback to the B+ feed from the power supply. Clip a voltmeter between this point and the HOT emitter. Make sure the leads are well insulated and can't accidentally short to anything. (This test can be performed across C to E of the HOT but if the horizontal deflection were to start up unexpectadly, the meter could be damaged by the high voltage pulses on the HOT collector. But if you can't find the B+ source, it may be worth the risk.) Plug it in and turn it on.

   - If the problem is in the low voltage (line) power supply, there will be no substantial voltage across C to E.

     You should be able to trace from the power line forward to find the bad part though a schematic will help greatly.

   - If the problem is in the startup circuit or horizontal oscillator/driver, then there will be something on the order of 100 to 160 V across C to E.

     In this case, a schematic may be essential.

   There is also a slight chance that there is a low voltage regulator in addition to the horizontal output, so don't get them confused. The horizontal output transistor will be near the flyback transformer and yoke connector.

Older TVs with multiple intermittent problems

If the set is say, a GE, with a manufacturing date around 1980, it is possible you have one of those circuit boards best described as bad solder joints held together with a little copper. In this case, prodding may get the set started. The circuit boards in these sets were double sided using what were called 'rivlets' for vias. The rivlets were relatively massive - literally little copper rivets - and they were not adequately heated during assembly so there were bucketloads of cold solder joints that showed up during middle age. I repaired one of these by literally resoldering top and bottom of every one of the darn things with a high wattage iron.

TV has burning smell

Assuming there are no other symptoms:

If this appears after extended operation - an hour or more - it may just be a build up of dust, dirt, and grime over the years. After understanding the safety info, some careful vacuuming inside may help. Just don't be tempted to turn any screws or adjustments!

Dust is attracted to the high voltage section in particular - even the front faceplate of the CRT collects a lot and should be wiped with a damp cloth from time to time.

If the symptoms develop quickly - in a few minutes or less, then there could still be a dust problem - a power resistor may be heating a wad of it but other possibilities need to be considered.

If not dust, then probably in the power supply but realize that TVs don't have a nice metal case labeled 'power supply'. It is just a bunch of stuff scattered around the main board. Without identifying the part that is heating, a diagnosis is tough especially if the set really does work fine otherwise. However, if a series regulator were faulty and putting out too much voltage, the set could appear to work properly but in fact have excessive power dissipation in certain components. If cleaning the dust does not solve the problem, you will probably need a schematic to identify the correct voltages.

Static discharge noise and picture tube quality

> "I bought a 29" TV a couple of weeks ago and I have noticed that after being switched on for > about 15/20 minutes, whenever the picture changes from a "light" scene to a darker scene, the set makes a crackling noise. It sounds as though there has been a build-up of static and it is being discharged. I have never noticed this in a TV before and I was wondering if this is normal and acceptable behaviour for a large-screen TV?"

(From: Jeroen H. Stessen (Jeroen.Stessen@philips.com).)

It probably is normal. Whether it is acceptable is a personal matter. In some geographic areas no countermeasures are taken at all...

When the scene changes from bright to dark, the beam current is reduced to practically zero. As a result, the high voltage rises. (The high voltage supply has a relatively high internal impedance.) The high voltage is connected to the inside layer of the picture tube. A voltage change on the inside will also cause a voltage change on uncovered parts of the outside, especially on the part of the picture tube that is hidden under the deflection coils. This causes little sparks between the picture tube surface and the inside of the deflection coils and this is accompanied by a crackling sound.

On the better picture tubes, a dark "anti-crackle coating" is painted on the picture tube near the deflection coil. This is a very high impedance coating, dark black, much darker than the usual aquadag coating over the rest of the picture tube. You should be able to see the difference.

If, on the other hand, the outside of the picture tube near the deflection coil is not coated then you have a problem. Then you will hear strong crackling also at switch-on and switch-off. Normally you shouldn't see such a 'cheap' picture tube on the European market...

The area of the picture tube around the anode connector is also not coated, for obvious reasons. Normally that should not cause any significant sound. Same goes for the front of the screen and neither should the anode cable crackle.

In a dark room you should be able to see from the tiny blue flashes where the sound comes from. This is perhaps best observed at switch-on and switch-off (with a black picture on the screen). Try and keep the back cover mounted !

Revival of dead or tired remote control units

There are two types of problems with hand held remote controls: they have legs of their own and they get abused or forgotten. I cannot help you with walking remotes.

Where response is intermittent or the reliable operating distance is reduced, first check the batteries and battery contacts. If some buttons are intermittent or dead, than the most likely cause is dirty or worn contacts under the rubber buttons or on the circuit board.

If there is no response to any functions by the TV or VCR, verify that any mode switches are set correctly (on both the remote and the TV or VCR). Unplug the TV or VCR for 30 seconds (not just power off, unplug). This sometimes resets a microcontroller that may have been confused by a power surge. Confirm that the remote has not accidentally been set to an incorrect mode (VCR instead of TV, for example). If it a universal type, it may have lost its programming - reset it. Make sure you are using the proper remote if have multiple similar models.

Test the remote with an IR detector. An IR detector card can be purchased for about $6. Alternatively, build the circuit at the end of this document. If the remote is putting out an IR signal, then the remote or the TV or VCR may have forgotten its settings or the problem may be in the TV or VCR and not the hand unit. The following is just a summary - more detailed information is available in the companion document: Notes on the Troubleshooting and Repair of Hand Held Remote Controls.

Problems with remote hand units:

All except (1) and (2) require disassembly - there may be a screw or two and then the case will simply 'crack' in half by gently prying with a knife or screwdriver. Look for hidden snap interlocks.

1. Dead batteries - solution obvious.

2. Corroded battery contacts, Thoroughly remove chemical deposits. Clean contacts with pencil eraser and/or sandpaper or nailfile.

3. Broken connections often between battery contacts and circuit board, possibly on the circuit board - resolder.

4. Bad resonator or crystal - replace, but diagnosing this without an oscilloscope may be tough. Broken

connections on resonator legs are common.

5. Dirt/spills/gunk preventing keys from operating reliably. Disassemble and wash rubber membrane and circuit board with water and mild detergent and/or then alcohol - dry completely.

6. Worn or corroded contact pads on circuit board. Clean and then use conductive Epoxy or paint or metal foil to restore.

7. Worn or dirty pads on rubber keypad. Clean. If worn, use conductive paint or metal foil to restore.

8. Cracked circuit board - can usually be repaired as these are usually single sided with big traces. Scrape off insulating coating and jumper breaks with fine wire and solder.

9. Bad LED. If IR tester shows no output, remove LED and power it from a 9 V battery in series with a 500 ohm resistor. If still no output, replace with readily available high power IR LED. Otherwise, check driver circuits.

10. Bad IC - if it is a custom chip, forget it! Failure of the IC is usually quite unlikely.

    (The following is from Duane P Mantick:)

    An awful lot of IR remotes use IC's from the same or similar series. A common series comes from NEC and is the uPD1986C which, incidentally is called out in the NTE replacements book as an NTE1758. A lot of these chips are cheap and not too difficult to find, and are made in easy-to-work-with 14 or 16 pin DIP packages. Unless you have no soldering or desoldering skills, replacement isn't difficult.

There are a large variety of universal remotes available from $10-$100. For general TV/VCR/cable use, the $10 variety are fine. However, the preprogrammed variety will not provide special functions like programming of a TV or VCR. Don't even think about going to the original manufacturer - they will charge an arm and a leg (or more). However, places like MCM Electronics do stock a variety of original remotes - prices range from $9 - $143 (Wow $143, for just a stupid remote! It doesn't even have high definition sound or anything exotic). The average price is around $40.

Problems with the IR remote receiver

Although the hand unit is most likely to be the cause of any problems with the remote control, it is also possible for the IR receive module to fail or for power to it to be missing. Microcontroller problems as well can result in similar symptoms.

First confirm that the hand unit is putting out the correct code. If it is a programmable type, try re-entering the settings for your TV. Install a set of fresh batteries. Try a different remote if possible. Use an IR detector to verify IR emissions (see the section: Revival of dead or tired remote control units).

The IR receiver is often a self contained module connected to the rest of the TV's circuitry by 3 wires: Power (+12 V typical), Ground, and Signal Out.

The IR receiver module will be located directly behind the IR window. Test by confirming that DC power is present. A schematic will tell you exactly what it should be but figure on 6 to 12 V if you do not have one. If this is present and you have an oscilloscope, put is on the Signal Out. You should see the demodulated data stream corresponding to whatever key is pressed on the hand unit. It should be a logic level signal swinging between 0 and the supply or +5 volts.

If there is no power, then a bad cable connection or blown fusable resistor may be the cause. If there is correct power but no signal, a fault internal to the IR module is likely. The internal circuitry may be a combination of special ICs and discrete components. The Sams" or service manual may or may not provide the details. There may be an adjustment for the carrier frequency but don't be tempted to touch this unless you have exhasuted other possibilities - and them mark it first!

If the signal is present, then there may be a problem in the microcontroller or other logic on the mainboard. This will require a schematic to proceed further.

So you lost your original remote (or it fell in the toilet)

An exact replacement remote will be easiest to use but may do significant harm to your bank account.

For example, you cannot add or remove channels from a typical Sony TV using the common universal remotes.

(From: Ed Ellers (edellers@delphi.com).)

Universal Electronics' "One For All" remote controls can reproduce these codes, and any others on any Sony TV (among others). Typically you'd press [MAGIC] and then 1-9-4 to add a channel or 1-9-0 to erase one; to start the auto program mode you'd press [MAGIC] and then 1-2-4.

Loudspeakers and TVs

Loudspeakers incorporate powerful magnets - the larger the speaker, the larger the magnet. However, anyone who goes ballistic when the mention is made of a loudspeaker near a TV or monitor, should take their Vallium.

The fringe fields outside the speaker box will not be that great. They may affect the picture perhaps to the point of requiring degauss. The normal degauss activated at power-on will usually clear up any color purity problems (assuming the loudspeakers have been moved away). At worst, manual degauss will be needed. The CRT will not be damaged. The maximum field - inaccessible at the voice coil - is quite strong. However, even for non-shielded loudspeakers, the magnetic field decays rapidly with distance especially since the core structure is designed to concentrate as much of the field as possible in the gap where the voice coil travels.

However, keeping speakers away from CRTs is a good idea.

Now, you really should keep your superconducting magnetic resonance imager magnet at least in the next room.....

Should I replace all the electrolytic capacitors if I find a bad one?

When a bad capacitor is found in a TV, the question of course arises as to the likelihood of other capacitors going bad in short order. It might be worth checking (other) caps in the power supply or hot (temperature) areas but you could spend you whole life replacing **all** the electrolytics in your older equipment!

Sweet little old ladies and TVs from attic

Always confirm the customer's complaints first!! Then verify that everything else works or you will never know if your efforts have affected something unrelated.

(Original request from rogerj@apex.com):

> "A sweet little old lady has duped me into repairing her old GE 13" color TV. She wanted me fix a bad volume pot. "Oh it has such a good picture", she says.
>
> Stupidly without even turning it on, (big mistake) I begin to open the set. After 15 to 20 min. of travail, I discover that a previous "repairman" has glued the case shut! (I wonder the sweet little old lady was in the habit of tweaking everything inside!:) --- Sam.)
>
> Now with the set open, I turn it on and this picture is LOUSY. Bad color, and very poor convergence. But I don't know if I'm to blame for banging it around trying to open it up. Also, no horizontal or vertical hold. (fixed that with a few caps). This thing has probably been sitting around for a few years."

Well, you certainly did not kill the caps. Anything that sits for a few years - probably in a damp unheated attic - is suspect.

Did you find the adjustments on the yoke assembly tight? If so, you probably did not move anything very much either. She may remember the good picture it produced before being stuffed away in the attic.

(From: Roger.)

> "Anyway after going through all the adjustments, the convergence at the sides is still bad and the horizontal size is a tad insufficient (and no adjustment available)."

It could be that the convergence (including pincushion) circuits are still faulty - not just misadjusted.

Other things that can effect horizontal size while still giving you a complete picture:

1. Voltage to horizontal output transistor low. Is there a voltage regulator in your set? The one I have has none. I assume your line voltage is ok.

2. Increased resistance or inductance of the yoke windings. For all you know, the yoke may have been replaced with the wrong part.

3. Yoke improperly positioned on tube neck.

4. Excessive high Voltage. This is usually not adjustable.

I bet the thing hasn't worked properly in 10 years! :)

Phantom spot or blob on CRT after set is shut off

(Portions of the following from a video engineer at Philips.)

Why is there a splotch of colored light at the center of the CRT after I kill power to my TV? Why does this not happen if the plug is pulled instead? It seems to last for hours (well maybe minutes at least).

A broad diffused glow (not a distinct spot in the middle of the screen) that lasts for a few seconds to minutes is called 'afterglow' and may be considered 'normal' for your model. The warm CRT cathodes continue to emit electrons due to the high voltage that is still present even though the signal circuits may have ceased to operate.

For more sharply defined spots there are two phenomena:

1. Thermal emission from a cathode that has not yet cooled off (and this could take several minutes) gives a more or less circular spot near the centre. It is actually 3 spots from the 3 cathodes, we at Philips call them 'Christmas balls'.

2. Field emission from sharp whiskers on any electron gun part gives a much sharper spot, sometimes with a moon-shaped halo around it. Even with the filament off, there may be some electron emission from these sharp points on the cold cathode(s) due to the strong high voltage (HV) electric fields in the electron gun. I do not know how likely this is or why this is so.

The shape of the spot is an inverted image of the shape of the emitting area(s) on the electron guns cathodes.

The visibility of both effects depends in the same way on the decay time of the high voltage (HV/EHT) on the anode.

When turned off with the remote or front panel button, you are not actually killing AC power but are probably switching off the deflection and signal circuits. This leaves the HV to decay over a few minutes or longer as it is drained by the current needed to feed the phantom spot or blob.

When you pull the plug, however, you are killing AC input and all the voltages decay together and in particular, the video signal may be present for long enough to keep the brightness (and beam current) up and drain the HV quickly. Whether this actually happens depends on many factors - often not dealt with by the designers of the set.

A proper design (who knows, yours may simply have been broken from day 1 or simply be typical of your model) would ensure that the HV is drained quickly or that the other bias voltages on the CRT are clamped to values that would blank the CRT once the set is off. If the problem developed suddenly, then this circuitry may have failed. On the other hand, if it has been gradually getting more pronounced, then the characteristics of the CRT or other circuitry may have changed with age.

In most sets it is left to chance whether the picture tube capacitance will be discharged by beam current at switch-off. It may simply be due to the behaviour of the video control IC when its supply voltage drops that causes the cathodes to be driven to white and this may not be formally specified by the manufacturer of the IC. Some of of the latest sets have an explicit circuit to discharge the EHT at shutdown.

As noted in the section: Safety guidelines, the HV charge on the CRT capacitance can be present for a long time. A service technician should be very aware of that before touching HV parts!

Interestingly, most sets for the Asian Pacific market have a bleeder resistor built in that will discharge the EHT without the need for a white flash at switch-off. These will in fact drive the beam to black at switch-off via a negative voltage to the CRT G1 electrode. The AP market is very sensitive to proper set behaviour, they don't like a white flash.

In short, it all depends on the demands of the particular market, the chance of the picture tube producing a spot/blob, and the mood of the designer.

So, it may not be worth doing anything to 'fix' this unless the splotch is so bright (more so than normal video and for an extended time) that CRT phosphor damage could result. This is usually not a problem with direct view TVs but would definitely be a concern with high intensity projection tubes.

On the other hand, your phantom blob may provide for some interesting conversation at your next party!

Comments on bright spot at power-off

With really old TVs, it was almost expected that when shut off, the raster would collapse to a spot which would then gradually fade away. If severe enough, the result after awhile would be a permanent dark spot in the center of the screen. Modern sets usually avoid this by forcing the CRT to be blanked for a few seconds after power-off while the high voltage decays or unblanked as the raster collapses to discharge the high voltage quickly with a white flash. However, claiming they all do this by design may be optimistic! :)

The following was in response to questions about a Sony TV but should apply in general.

(From: JURB6006 (jurb6006@aol.com).)

I think in this case the filter for the supply to the final video outs has gotten to a point where is discharges faster than the tube. Sony designs usually use fast blanking at power down, but it can only blank while the +220 VDC line is alive. There might also be a cap between the 220V line and the G1 biasing circuit. Also Sony's almost always incorporate some sort of HV bleeder but if it opens up usually there is a convergence problem. If it's not any of the above, the plot thickens. Look for a bad diode, or even an active spot killer circuit that has failed.

You might want to look into this, as I tell customers, when it collapses to a line it is 480 times as bright, it won't *look* 480 times as bright because the phosphor simply cant put out that much light. I've also made comments in here on how fast a CRT will burn if the yoke is unplugged. It's then the original 480X multiplied by 640. If that beam is in focus that means the "drive" to the phosphor is over 300,000 X what it should be. Even if the spot is defocused to 100X it's normal size, that is still 3,000X the current on that part of the screen. Even if yours doesn't burn the screen, in time you might expect a minor purity problem in that area on a fine pitch color CRT. This is an effect known as "doming", and it happened even on some low resolution NTSC TVs! It usually happened more at the sides, and if it became permanent you could fix it up if you used enough stick-on magnets, but you can't do that in the middle.

I bet the thing is a real pain to work on too, so I might consider just never shutting it off, or a simple modification. If G1 is grounded, it is easy. One resistor, a cap and a diode, ba-da-bing ba-da-boom. Two caps if you like to be fastidious. There are some designs in which this will not work. It does work 99% though, if the vidouts are driven they will discharge the +220 VDC supply, what I do is to AC couple the supply to the G1. It can be done with three component, but there are enhancements I recommend to protect the CRT from excessive K-G1 voltage. Don't want to cause a short there. Five or six components will do it on almost anything.

Disposing of dead TVs (CRTs and charged HV capacitors)

I don't know what the law says, but for safety, here is my recommendation:

Treat the CRT with respect - the implosion hazard should not be minimized. A large CRT will have over 10 tons of air pressure attempting to crush it. Wear eye protection whenever dealing with the CRT. Handle the CRT by the front - not the neck or thin funnel shaped envelope. Don't just toss it in the garbage - it is a significant hazard. The vacuum can be safely released (Let out? Sucked in? What does one do with an unwanted vacuum?) without spectacular effects by breaking the glass seal in the center of the CRT socket (may be hidden by the indexing plastic of the socket). Cover the entire CRT with a heavy blanket when doing this for additional protection. Once the vacuum is gone, it is just a big glass bottle though there may be some moderately hazardous materials in the phosphor coatings and of course, the glass and shadow mask will have many sharp edges if it is broken.

In addition, there could be a nice surprise awaiting anyone disconnecting the high voltage wire - that CRT capacitance can hold a charge for quite a while. Since it is being scrapped, a screwdriver under the suction cap HV connector should suffice.

The main power supply filter caps should have discharged on their own after any reasonable length of time (measured in terms of minutes, not days or years).

Of course around here, TVs are just tossed intact which is fortunate for scavengers like me who would not be happy at all with pre-safed TVs!

Shock and/or spark when connecting cable or other A/V components

TVs with hot chassis - where signal ground is actually line connected and at some intermediate (and dangerous) voltage - will have an isolation block in between the tuner and antenna/cable connections. TVs with isolated power supplies may have some bypass capacitors between the power supply and signal grounds (including the A/V shields if there are A/V connectors). It is possible for a failure to result in a serious safety hazard where the RF (antenna/cable) or A/V connectors become electrically live.

However, a tingle or small spark might be normal. RFI bypass caps between the AC input and shield on the connector could result in some leakage - 50 V or more might be indicated using a high impedance multimeter. This is harmless. Reversing the plug in the AC socket (if it is not polarized or if you are using an unpolarized extension cord) might eliminate or greatly reduce the effect.

Nonetheless, it should be checked out. Measure the resistance between each side of the AC plug and the RF and AV connector shields. It should be 1 M ohm or more. Test for voltage between the cable (or other device) connector and earth ground. If there is anything significant, test the resistance on the device between its shield and its power plug as above - other devices may have RFI bypass caps or be defective as well.

What is the deal with Macrovision copy protection?

(From: Jeroen H. Stessen (Jeroen.Stessen@philips.com).)

JVC owns the patent for VHS. JVC has made a deal with Macrovision that from a certain date in the past *no* VHS recorder licenced by JVC shall be able to record any video signal that contains Macrovision's copy protection pulses. Any video recorder from before that date (VHS or other) might well work OK on the altered video signal ! The copy protection pulses upset the video-AGC and H-sync. TV's usually don't have a video-AGC. The stabilizer box removes the extra pulses and makes it into a normal video signal again. No VCR should ever know the difference, so they should all record properly again.

At the same time, all TV's are required to ignore the copy protection pulses. As a TV-designer I can tell you that this is sometimes far from trivial. Not in the least because in the beginning we were not included in "the deal". There may be TV's around whose brightness and/or sync will be disturbed by the Macrovision pulses. Officially, this is the reason for existance of the stabilizer boxes: to view better, not to copy better. Unofficially, they are sold for copying, of course.

The next step will be that digital-TV decoders will output an analog TV signal with Macrovision copy-protection pulses so that you may watch but not record your pay-per-view program. Same problem, same solution ...

And I thought that PAL/Secam/NTSC were *standards*, sigh ...

Whether they like it or not (and from personal experience I can tell you that we don't like it) it is the responsibility of the TV set-maker (in your case Sony) to build a TV that takes the Macrovision copy protection pulses without showing any side effects on the screen. Seems like they didn't do a good job on your TV :-). But they will have to fix this, your complaint is valid. I think in this case it may be the dealer's responsibility too, maybe you can trade it for a different brand ? And do try it out first ...

Sadly, more complex TV's seem to suffer more than the simpler, old-fashioned, designs. Unfortunately, Macrovision seems to be satisfied when their pulses do not affect the majority of (mostly older) TV's. In your Sony TV, the clamping circuit seems to be affected by some ultra-black pulses in the signal. Maybe an anti-Macrovision decoder can help you, officially they are designed for *this* purpose.

AGC and copy protection

(From: Jeroen H. Stessen (Jeroen.Stessen@philips.com).)

1. RF-AGC which compensates for different signal strength at the aerial, it measures RF amplitude and is *not* sensitive to video contents because with negative modulation the sync is the peak and is constant, this AGC will not work on CVBS (baseband video) inputs.

2. Video-AGC which normalizes baseband signals which enter *after* the tuner-IF. A.o. this compensates for different signal strengths when you connect two VCRs together. It measures peak-white, so it *is* sensitive to video content and thus to the Macrovision pulses.

And: A television does NOT have a video-AGC, unless you want to call the beam current limiter circuits an AGC. (Exception: the Secam-L system with positive modulation requires an RF-AGC which measures peak-white instead of peak-sync.)

The RF-AGC does not see the peak-white of the anti-copy pulses. If you connect the VCR to the TV via the CVBS (baseband) input, then the RF-AGC is not even in the path. Still, it may be disturbed. But the sync separator may see the extra inserted Hsync pulses, and due to the phase disturbance the video clamping may be disturbed too.

On-screen clock runs slow or fast

- If the TV was purchased in another country (most likely it is a "multi-system TV), then the power line frequency may be different. There could be a switch or menu setting for this.

- If the clock reference is power line derived, noisy power can sometimes result in erratic timekeeping though running fast is probably more common than running slow. This could be a result of a lamp dimmer or compact fluorescent on the same circuit.

- If the time reference is a separate crystal, that or its circuit could be faulty.

Now think about it: Do you absolutely need the TV's clock??? After all, there are probably a half dozen other clocks in the same room! :)

Cold problems with cold TVs - or - an unhappy Christmas

(From: Ren Tescher (ren@rap.ucar.edu).)

My Christmas repair story wasn't so happy.

I worked as TV repairman for an appliance store.

On a very cold (20 below zero Fahrenheit) evening a man bought a new 25" console for the family.

As we loaded it into the back of their pickup truck, we *told* them. "Do not plug this in until it warms back up to room temperature." They nodded and said "uh-huh, okay".

They lived about 15 minutes away.

25 minutes later we get a telephone call...

"Hey! that TV you sold us don't work!"

So we ended up loading another TV into our delivery van, drove out to their place. Unloaded it, and WAITED until the thing was warm enough to plug in.

Needless to say, I got home late that Christmas Eve and had brand new TV console waiting for my repair back at the shop.

F-connector broken off rear of TV or VCR

Sometimes this just happens due to poor manufacturing and a slight tug. However, usually, there has been some severe trauma - like the TV or VCR falling off a shelf while still attached. When else would it fall off a shelf? :-)

I recently repaired a Panasonic VCR with a dangling F-connector. It required removing the cover, main board, unsoldering the A/V block and part of the power supply, just to get at the RF modulator. Then it was a simple matter of resoldering the center conductor to the printed circuit board (fortunately, nothing else was damaged) and the shell of the F-connector to the metal box.

From: Glenn Watkins

We get a lot of sets with broken "F" connectors broken off - both VCR's and TV's. The job can be quite involved depending on the exact set. It may take an hour just to open it, remove the tuner or RF modulator and open the case. Then if you're lucky, there is no additional damage inside the unit due to people probing with pencils, screwdrivers, etc.

On some TV's including Sharp, there is a antenna(cable) isolation device that connects between the tuner and antenna. This device comes in a few flavors and is very easy to install if broken. I've seen them as cheap as $4.95 each mail order.

---

3. Back to TV Repair FAQ Table of Contents.

Some Model Specific Problems

Erratic problems with older GE TVs

Older GE TVs used double sided circuit boards with poor-man's vias - rivets soldered to the traces top and bottom. These have been called 'Rivlets' and 'Griplets'. Unfortunately, whoever did the design didn't realize that (1) the the rivets did not heat adequately during soldering and (2) the expansion coefficients of the rivets and circuit board were not qutie identical.

Thus, erratic problems are almost a certainty with these TVs. Normal logical troubleshooting is useless. The only solution is to repair every !@#$ Griplet on all circuit boards in the TV.

I have repaired these with a high power soldering gun used on both sides with liberal application of solder and flux.

However, I do not recommend this shortcut unless you are willing to redo the repair every couple of years.

(From: Mr. Caldwell (jcaldwel@iquest.net).)

There are two methods of repair.

4. Method 1: Clean the paint from around each griplet on both sides of the board to expose the surrounding copper pad. Apply liquid solder flux to the cleaned copper. Solder so as to bridge the griplet to the cleaned copper.

5. Method 2: Do the above but desolder the griplet and place a wire through it so that the wire extends beyond the griplet to the copper foil and solder the wire on both sides (this was the final fix GE used in this chassis).

If done carefully Method 1 works and is reliable.

I would normally do this prior to any troubleshooting, it repairs most problems in this chassis. While you have the board out working on it be sure to also clean and resolder high temperature components and connections that look bad. These griplets can be on all boards, even the tuner control board.

Erratic problems on late model GE, RCA, or ProScan TV

Problems with bad solder connections, mostly in and around the tuner are very common with several series of late model (e.g., CTC175/176/177 chassis) RCA/GE/Proscan TVs. Ignoring these erratic and intermittent problems can lead to serious damage including failure of the EEPROM and possibly other expensive ICs. Therefore, it is essential to deal with the solder connections as soon as these symptoms appear. The repairs are straightforward though perhaps tedious. Thomson may reimburse for reasonable cost of repairs.

Some of the common symptoms include:

- Random power cycling. It may come on in the middle of the night!
- Picture shifts or changes size vertically or horizontally.
- Picture turns to snow or shows other reception problems.
- Picture turns to random display of time or other data.
- Noisy or muted sound, volume buttons have no effect.
- Remote has no or unexpected effect.

See the document: RCA/GE TV CTC175-187+ Solder Connection and EEPROM Problems for additional information on these types problems including repair procedures and approaches to getting coverage from Thomson Electronics.

Sylvania/Magnavox/Philips - no startup

Check the resistor supplying initial base current to the horizontal driver (not HOT) transistor. On many chassis, it is R502, 47 K. It opens for not good reason. Why it fails is a mystery as its power rating should be adequate.

Sony TVs/monitors and Hstat

Symptoms are that the TV or monitor will shut down possibly after a warmpup period. There can be other causes but failure of the Hstat module HV sense wire is quite likely on many Sony models.

(From: Mr. Beanz (slin01@mail.orion.org).)

If you've determined that the HV is fine, and the H-STAT is shutting down for no reason, it's possible to bypass. There is a little brown wire coming out the bottom of the H-STAT which goes to a 3-pin connector. Two wires have a jumper, and the brown wire goes to the other. Snip the brown wire at the H-STAT and the TV will continue to function normally. Measuring the regulated B+ to the flyback will give you a pretty good indication of the condition of the HV output. If it remains steady at rated voltage (I forget what it was, 130V or 135V) then HV is A-OK. If it slowly creeps up or is too high to begin with, you have a problem. The voltage will normally jump to 150V or so after HV shutdown is tripped.

Ideally, you should replace the H-STAT in this case. Although taking the poor man's route will WORK, you lose any protection in the event that the HV circuitry should malfunction.

More on Hstat

(From: Shawn Lin (slin01@mail.orion.org or lin@science.smsu.edu).)

The H-STAT is a plastic box that sits mounted to the picture tube's shield. It's red in color (for every SONY TV that I have owned) and has a single knob on it. The flyback's HV output wire goes into the H-STAT and another HV wire exists the H-STAT and connects to the anode cap on the picture tube. It has a dual purpose, horizontal static convergence (the control adjusts this) and HV overvoltage shutdown protection. Chances are, your HV is within spec and the H-STAT is bad, but you should make sure the regulated voltage to the flyback is steady and doesn't fluctuate before assuming the H-STAT is bad.

H-STAT is expensive, and may not be worth replacing. My kV-1952RS is old and as a whole, not worth the cost of a new H-STAT, so I just bypassed it and didn't bother replacing it. The TV's been working great for over a year and the picture is still excellent.

Note: On some models, the sense wires need to be connected during startup or else it will never come on.

CAUTION: On some monitors (like the Sony CPD1302), the sense signal may be used for actual HV regulation. Thus, if the sense wire is disconnected, (or the divider inside the Hstat block fails open) there is no feedback and it is possible for the high voltage (and probably B+) to increase until the HOT (and possible other components) blow. I do not know if this applies to Sony built TVs as well.

No video on late model Sony TVs

(From: David Kuhajda (dkuhajda@locl.net).)

This following assumes that the more basic TV troubleshooting has already been performed and resulted in no solution - i.e., filaments are lit up, CRT voltages are all correct but the cathodes are all in cutoff, main power supply voltages are present, etc

The 3 most common causes of no video, but good audio are as follows:

1. AKB blanking due to either a fault in the AKB circuit or the CRT has one gun that is too weak and the AKB won't unblank the CRT.

2. Loss of vertical deflection. The system control must see the vertical return pulse to unblank the video.

3. Loss of data bus communication with the Jungle IC. The Jungle IC must send the all OK signal to the micro before it will unblank the video.

To troubleshoot:

1. Try changing the volume with the volume control. If it changes the data bus is not the problem. This is assuming the TV is tuned to a good TV station.

2. Mark the EXACT position of the screen/G2 control with a marker. Then turn the G2 control up.

    - If the picture unblanks and a gray scale bar pattern is used, you can usually see which CRT gun is weak. Time to replace the CRT for a long term fix. All of the temporary fixes I have tried resulted in only a few months extra life out of the tube.

    - If the picture does not unblank and it looks kind of like there is a halo near the top of the screen. The vertical circuit needs checked for proper operation and repaired. WARNING do not continue to operate the TV set in this mode for any length of time, it will crack the CRT from localized heating!!!! (because the guns are shooting into the extreme top of the tube and possible the neck of the tube) RETURN the G2 control to the exact position that was marked before you started.

The typical failure mode of the vertical circuit in a Sony causes only one of the vertical supply resistors to open usually. Either the +15 V or -15 V. This puts a full + or -15 V on the yoke which deflects the guns into the glass envelope of the tube.

An informal history of X-ray protection

(The following is from: Marty).

Most of the old tube type color TV sets used a shunt HV regulator tube, usually a 6BK4. If it failed, or some component in the HV circuit failed, the high voltage, normally 25kV, could go up to 35kV or more, causing some X-Ray leakage from the CRT. In the early 70s when news of this radiation scare was first announced, there was a public outcry to immediately fix the problem. The feds hastily imposed a requirement on manufacturers of TV sets to somehow render a TV set "unwatchable" if the HV exceeded rated limits.

The manufacturers first response was to follow the letter of the law and the first "HEW" circuit simply blanked the video when the HV exceeded a setpoint to make the set "unwatchable".

It was quickly noticed that the HV was not turned off with this circuit and the CRT still could emit some radiation. Many TV sets with this feature were left on so the consumer could listen to the sound, so the feds tightened the requirement.

By this time new TV sets were all solid state and some manufacturers experimented with HV shutdown circuits, but most of these circuits were poorly designed and not reliable.

Zenith thought they had the answer by regulating the HV with a bank of 5 capacitors across the horizontal output transistor to "hold down" the HV to 25kV. If one capacitor opened, the HV would only rise about 2kV, not a dangerous situation. This wasn't good enough for the feds.

The "fix" that Zenith finally came out with, was a "4 legged capacitor". Two legs were the emitter return for the horizontal output transistor, & two legs were the HV holddown capacitor (the equivalent value of the bank of 5 caps). This "fix" was accepted by HEW and millions of TVs were produced. It worked so well, that other manufacturers soon followed the lead (Magnavox, GE, etc.).

Then the worst happened! The 4 legged monsters started failing in a large numbers. Not opening completely & not shorting out. They sometimes allowed the HV to skyrocket to over 50kV. Some of them even cut the necks off of the CRTs.

Zenith issued a recall on those models with the problem (more than one entire model year). After several "improved" versions of the capacitor, the problem was fixed but that recall almost bankrupted the company. Other companies had failures too, but usually not as dramatic as Zenith's.

Magnavox used the HV holddown capacitor, both single & 4 leg version in several 70s era TV sets and is a good candidate for fireworks as well.

(From: Roy J. Tellason (rtellason@pa.net).)

The problem was reputedly due to a capacitor maker substituting a different (cheaper) material for the one that Zenith originally specified, leading to the failures. I can't recall who the cap maker was (some company in Taiwan?) but remember hearing as to how they were the ones who ended up having to pay for all those warranty repairs, including CRT replacements.

What is this goop around some electrolytic capacitors and other components?

That goop is probably glue and generally harmless - it is there to hold down the components aganst vibration. I have heard of it sometimes decomposing and shorting stuff out but I doubt you have that problem.

Therefore, unless you find a bad cap in the focus or related circuit, we are still looking at a flyback problem.

What does the flyback (LOPT) transformer do?

The typical flyback or Line OutPut Transformer (LOPT) consists of two parts:

1. A special transformer which in conjunction with the horizontal output transistor/deflection circuits boosts the B+ (120 V typical for a TV) of the low voltage power supply to the 20 to 30 kV for the CRT as well as provide various secondary lower voltages for other circuits.

   A HV rectifier turns the high voltage pulses into DC and the CRT capacitance smooths it. The HV may be developed from a single winding with many many turns of wire or a lower voltage winding and a diode-capacitor voltage multiplier.

The various secondary voltages power the logic, tuner, video signal, vertical deflection circuits, and CRT filament. In fact, with many TV designs, the only power not derived from the flyback is for the keep-alive circuitry needed to maintain channel memory and provide startup drive to the horizontal deflection/high voltage system.

2. A voltage divider that provides the focus and screen supplies. The pots are in this divider network - and these things fail resulting poor focus, uncontrolled brightness, or fluctuating focus and/or brightness. A total short could also result in failure of other components like the horizontal output transistor. In some TVs, the focus and screen divider and/or controls are external to the flyback and susceptible to dust and problems particularly on humid days. The resistance of these circuits is so high that dirt or other contamination can easily provide a bypass path to ground especially when slightly damp.

Why do flyback (LOPT) transformers fail?

While flyback transformers can on occasion be blown due to a failure elsewhere in the TV or monitor's power supply or deflection circuits, in most cases, they simply expire on their own. Why?

Flybacks are wound with many layers of really really fine wire with really really thin insulation. This entire assembly is potted with an Epoxy resin which is poured in and allowed to cure.

In some ways, these are just short circuits waiting to happen.

Flybacks get hot during use and this leads to deterioration of the insulation. Any imperfections, nicks, scratches, etc. in the insulation contributes to failure. Temperature cycles and manufacturing defects result in fine cracks in the Epoxy potting material reducing the insulation breakdown particularly in the area of the high voltage windings, rectifiers, and focus/screen divider network.

It is amazing they last as long as they do with the stress they are under. They also physically vibrate to some extent. A whole bunch of other factors are also no doubt important.

Brief comments on testing the HOT

For a TV with no blown fuses that will not start, here are two quicky checks to see if the HOT is good and has power and drive:

- HOT tests - check across each pair of pins for shorts (preferably removed from the circuit board). No junction should measure less than 50 ohms or so. Lower readings almost certainly indicate a bad HOT. If in-circuit, however, the reading between base and emitter will be near zero due to the secondary of the driver transformer. See the document: Basic Testing of Semiconductor Devices. Don't be confused by internal damper diodes and B-E resistors.

- Power - measure across the collector to emitter with a multimeter (with the HOT removed or if there is no deflection, this is safe with it in place). There should be solid B+ - typically about 100 to 160 V (115 VAC sets - possibly higher for 220 VAC sets). If this is missing, iether there is a problem with the power supply or the emitter fusable resistor has blown (probably in addition to the HOT) and there is no return.

- Drive: put an oscilloscope on the base - there should be pulses around 0.7 V for most of the scan (~50 microseconds) and probably going negative a couple volts at least for retrace (~12 microseconds). If drive is weak or missing, determine how startup is implemented as there may be a problem in the startup power supply or deflection IC.

WARNING: use an isolation transformer for the oscilloscope tests (and whenever you are probing a TV in general)!!! This part of the circuit, in particular, is usually line connected. See the sections on safety.

CRT rejuvenation

Where one or more electron guns in the CRT have deteriorated due to wear and tear, it is sometimes possible to give them a new, but possibly, temporary lease on life through rejuvenation using a special piece of CRT service equipment.

(From: Gary Klechowitz (klechowi@execpc.com).)

When I rejuvenate a tube I inform the customer that there is no warranty on the job. Rejuvenating a CRT is like when Clatuu was brought back to life by Gort in "The Day The Earth Stood Still". When asked "How long will you live"? he replied: "no one knows".

I use a Sencore Beam Builder. If your tube is just moderately dim and blurry but still shows good cut off threshold, I would just use the auto restore mode on the beam builder rather than using the restore button. If the tube is really bad with little or no cutoff threshold, then the rejuvenator is needed but that has less than a 50% chance of fixing the tube and in many cases the tube gets worse to trashed in the process.

Memory chips in TVs

(From: Mark Zenier (mzenier@eskimo.com or mzenier@netcom.com).)

Actually, they are EEPROMs. A modern TV has integrated the circuitry so that the microprocessor that controls it also sets the various adjustments like vertical height and other characteristics. The same memory that knows what channels are valid and what the brightness and other user adjustable settings are is used for factory adjustments that are set when the TV is first turned on. It's a lot cheaper to use the remote control signals that are already there than add a handful of trimmer resistors.

For service purposes there is often a magic key sequence used with your remote control to access a service page in the on screen display than can change these. Since you can easily set something that could fry the various high power deflection circuits, getting a little too curious can void your warranty, and toast your set.

How does Picture-In-Picture (PIP) work?

A separate video input or tuner provides the PIP baseband signal which is then resized and stored in a frame buffer large enough to hold the X and Y dimensions of the PIP image. Readout is timed to place the PIP image in the selected area of the screen and it is substituted for the main video. What could be simpler?!

Tony's notes on setting convergence on delta gun CRTs

(This section from: ard12@eng.cam.ac.uk (A.R. Duell))

The older delta-gun tubes (3 guns in a triangle, not in a line) can give **excellent** pictures, with very good convergence, provided:

1. You've set those 20-or-so presets correctly - a right pain as they interact to some extent.

2. The CRT is set up in the final position - this type of tube is more sensitive to external fields than the PIL type.

Both my delta-gun sets (a B&O 3200 chassis and a Barco CDCT2/51) have very clearly set out and labeled convergence panels, and you don't need a service manual to do them. The instructions in the Barco manual are something like:

"Apply crosshatch, and adjust the controls on the convergence board in the numbered order to converge the picture. The diagrams by each control show the effect".

Here's a very quick guide to delta gun convergence where the settings are done using various adjustments on the neck of the CRT (if you don't have a service manual but do know what each control does, and where they all are - otherwise, follow the instructions in the service manual --- sam):

1. Apply a white crosshatch or dot pattern to the set. Don't try and converge on anything else - you'll go insane. It's useful to be able to switch between those 2 patterns.

2. Before you start, set the height, width, linearity, pincushion, etc. They will interact with the convergence. Also check PSU voltages, and the EHT voltage if it's adjustable. That's where you do need a service manual, I guess.

3. Turn off the blue gun using the A1 switch, and use the red and green static radial controls to get a yellow crosshatch in the middle of the screen. These controls may be electrical presets, or may be movable magnets on the radial convergence yoke (the Y-shaped think behind the deflection yoke).

4. Turn on the blue gun and use the 2 blue static controls (radial and lateral) to align the blue and yellow crosshatches at the center of the screen. Some manufacturers recommend turning off the green gun when doing this, and aligning red with blue (using *only* the blue controls, of course), but I prefer to align blue with yellow, as it gives a check on the overall convergence of the tube.

5. Turn off the blue gun again. Now the fun starts - dynamic convergence. The first adjustments align the red and green crosshatches near the edges - I normally do the top and bottom first. There will be 2 controls for this, either a top and a bottom, or a shift and a linearity. The second type is a *pain* to do, as it's not uncommon for it to affect the static convergence.

6. Getting the red and green verticals aligned near the edges is a similar process.

7. You now have (hopefully) a yellow crosshatch over the entire screen.

8. Now to align the blue. This is a lot worse, although the principle is the same. Turn on the blue gun again, and check the static (center) convergence

9. To align the blue lines with the yellow ones, you'll find not only shift controls, but also slope controls. Use the shift controls to align the centers of the lines and the slope controls to get the endpoints right. These interact to some extent. You'll need to fiddle with the controls for a bit to work out what they do, even if you have the manual.

The convergence over the entire screen should now be good....

A word of warning here... The purity is set by ring magnets on almost all colour CRTs, but on PIL tubes, there are other ring magnets as well - like static convergence. Make sure you know what you are adjusting.

Saga and general setup for large CRT TVs

(Panic from: V. K.)

> "I'm having problem(s) with a brand new 40" Mitsubishi tube (direct view) TV. I'm writing this with hopes of getting some basic information so that the dealer doesn't bamboozle me.
>
> From first viewing (5 minutes after the delivery man departed). I noticed a discoloration patch in the top right hand corner (purple when the background is blue/greenish when background is white)."

(From: Tony (ard12@eng.cam.ac.uk).)

As you probably know, a colour TV produces a red picture, a green picture and a blue picture on the screen at the same time. You eyes interpret that as a coloured picture. If you look at (a normal, non-projection) TV screen through a magnifying lens, you should be able to see red, green and blue dots, and no other colours.

Now, there are 3 basic adjustments to getting a good colour picture :

1. Purity. This means that the red picture is only red, the green picture only green, etc. This is the one that needs setting up on your set - you have a purity problem

2. Convergence. This means that the 3 pictures line up over the entire screen (or as much of it as possible). If this one is wrong, you'll see coloured fringes around objects in the picture.

3. Grey scale. This sets the overall colour of the picture - it means that white is really white, etc. It varies the relative intensities of the red, green and blue pictures.

(From: VK.)

> "I called the store in a panic and they calmly told me to press the "degauss" button to eliminate the problem (which I quickly learned was spurious magnetization, caused perhaps by storage near a speaker in the warehouse?). Result? Better but not cured."

(From: Tony.)

Yes, spurious magnetization (or more correctly a different magnetic field around the tube from the one present when it was set up) will cause purity problems.

(From: V. K.)

> "The next day I visited the store, and the manager said (again) that this was an easily fixable problem, requiring a few waves of a degaussing coil. To appease me, he sends the salesman home with me with small (1 foot diameter) coil in tow. Salesman (boy, actually) waves the coil in front of and around set but can't seem to remove the discoloration."

(From: Tony.)

Argh... Here's what should have been done IMHO.

1. The set should have been degaussed (a fancy word for demagnetized).

2. They should have connected a 'pattern generator' to the set. This is a piece of equipment that generates various test signals. They should have selected 'red raster' (which will appear to you as a pure red screen), and set up the purity adjustments on that. You should ask to see the pure red raster (and pure green and pure blue if the generator will allow it), and make sure there are no strange-coloured patches. If you like, you can examine the screen through a magnifying lens to check that there are no dots of other colours appearing - I do that when I'm setting up a new TV or monitor.

3. They should then have displayed a 'cross hatch' on the screen. This is a grid of white vertical and horizontal lines. Convergence errors are shown by the lines splitting into 2 or more colours (normally one of the 'primary colours' - red, green, or blue, and its complementary colour (cyan, magenta, and yellow).) Note, however, that it's _very_ difficult or even impossible to get perfect convergence over the entire screen on a modern tube, and that you'll not notice small errors near the corners on a TV screen. Note that some engineers prefer to set up the convergence on some other type of display (dots, for example), but you should at least be able to see a cross hatch pattern (all pattern generators provide that one)

4. They should have then displayed a 'grey scale' test display. This is a pattern of vertical grey bars of different brightnesses, from black to white. They should all have been a neutral grey, without colouration.

Note that convergence and purity interact to some extent, and thus if either is adjusted, both must be checked (and rechecked). Grey scale adjustments interact with nothing else.

I would want to see the set on a pattern generator (at least the patterns I've mentioned above) and identify the problems.

(From: V. K.)

> "To demagnetize the TV, he says that a large coil is required, that encompasses the whole unit; service rep will 'be in touch'."

(From: Tony.)

I've never heard of that - the correct procedure is to wipe the coil around the front, top, sides and bottom _NOT the back_ and then move it 2-3m from the set before turning it off. It doesn't matter whether the set is on or off for this, btw. I've not heard of putting a large coil round the entire set. (See the section: Degaussing (demagnetizing) a CRT.

(From: V. K.)

> "After the sales boy leaves, I could SWEAR that the picture quality in general is decreased, with people (especially their extremities like lips and ears) appearing pinker than before, and also more general interference (fringes/noise) noticeable."

The convergence and purity are set by ring magnets on the neck of the tube. It's possible that the degaussing procedure has slightly demagnetized these, and if so, the whole set will need to be set up. Similarly, if any part of the set was magnetized at the factory, then the adjustments may have been set up to compensate, and then after demagnetization, they'll need to be reset.

(From: V. K.)

> "So my questions are these. Can the original problem truly be FIXED with proper sized coil and application?

(From: Tony.)

I don't think the size of the coil will make any difference. I would want to see that set on a pattern generator, so I could be _sure_ as to what the problems are. If the dealers don't have a pattern generator, then they're not fit to be fixing TVs IMHO.

(From: V. K.)

> "Could I be imagining that the waving of the small coil degraded the picture quality?"

(From: Tony.)

It's possible, but fairly unlikely. See above

(From: V. K.)

> "Should I demand replacement to a new set? Can I legally ask for this, or is it like a new car...you own it, now you deal with the service guys forever.

(From: Tony.)

I don't know US law, but in the UK, if a product is defective, you can demand a refund of the money paid (not a replacement or a repair, a refund). IMHO, a TV with incorrect colours is defective...

Liquid coupling fluid for projection TVs

(From: Jeroen H. Stessen (Jeroen.Stessen@philips.com).)

The liquid serves two purposes:

1. It conducts the heat away from the surface of the tiny picture tube.

2. It couples the light from the glass surface of the picture tube to the glass surface of the projection lens. Using air instead of liquid would give too much unwanted refraction at the glass-air interfaces

I believe that the composition of the liquid is mostly water + glycol, quite similar to the anti-freeze liquid in your car's radiator, but without the colorants added that should warn you against drinking it.

A good replacement kit contains not only a plastic bottle of liquid but also new rubber sealing rings to keep it in, where it belongs. It's always recommended to buy the original stuff, if you can find it.

(From: markmtf@earthlink.net). I just wanted to throw my $.02 in since I was one of the original members of the design team for the first Magnavox and Sylvania PTVs.

I don't recall the models, but essentially, there are several generations of liquid cooled/coupled PTV designs. One type consists of a set of CRTs with a liquid cell as part of that component. The other type consists of a liquid cell that directly couples the CRT faceplate to the lens.

The liquid is a solution of DI (deionized) water and propylene glycol, with a small amount of surfactant to eliminate bubbles sticking to the glass and plastic surface. Distilled water can be used. The propylene glycol is USP grade, not commercial grade for clarity reasons. You need to order this through a lab supply company and specify USP grade. If you use a cheaper grade, the solution may become cloudy. The mixture of your solution should be somewhere between 50/50 to 80/20 water/glycol. The are many kinds of surfactant which can cause cloudiness or foaming. You should probably leave this step out if you are just adding rather than replacing liquid. If you want to experiment, you might try some fluid from a photographer darkroom supply store that is used for eliminating water marks during the film drying process. Just add a few drops to 1/2 liter. Then heat it up to check for cloudiness. If it works, then you are in business. Again, if you are careful with filling the cell so that you don't mix in air, you probably don't need any surfactant.

I probably can't help you too much on the seals or gaskets. It is very dependent on the specific model. Both types of liquid cells loose the liquid over time due to vapor traveling through the silicone seals. The CRTs with the cooling cell used a special RTV for a seal. The CRT/Lens cooling cell used silicone gaskets. There is a tradeoff on how tightly the gaskets can be tightened down due to CRT specifications. Some manufacturers were also working on a expandable chamber to reduce buildup of pressure when the liquid expanded due to heat. The higher the pressure, the faster the liquid would evaporate through the gaskets.

Origin of burn spot/line on projection set

This may be an issue where a set was repaired but with a blemish that you didn't think was there before.

(From: JURB6005 (jurb6005@aol.comtere).)

1. If you fire a projection set up with one yoke disconnected AND the yoke windings are in series, unless you are quick, you will have a horizontal line burnt in all three tubes.

2. The shop may have been less than 100% competent, and even if they were 100% competent, it could have happened at the actual time of the failure, before they ever saw it.

3. If the set was fired up by ANYONE with any of the yokes disconnected, the vertical blanking circuit should have cut off ALL beam current, preventing the burning of the CRT screens. Two exceptions apply;

    - YOU were already watching the TV with a fault, or the burn happened really quickly and you didn't notice the spot.

    - The technician turned up the G2 to the point where it overrode the blanking.

Blue focus different for projection sets?

On some 3-tube projection sets, you may find the blue tube to have poorer focus than red and green. Don't touch it!

(From: Dakuhajda (dakuhajda@aol.com).)

What you are describing is completely normal. The manufactures design in the blue picture tube so that it will not focus completely.

In fact the service literature lists exactly how much and which way it should be out of focus. In fact the picture generally looks better with the blue CRT slightly out of focus per specification - slightly wider than the scan lines so that it completely fills in the scan lines. The slight out of focus is designed to blend in the scan lines so they are not as noticeable on the big screen.

This is because when the standard TV signal with 262.5 lines being displayed at any given time, it looks bad to see the scan lines. The standard TV signal was never designed to be viewed on a screen larger than 25".

It also is the nature of the phosphor that makes blue not to allow a good focus. Especially in the older sets. I have not seen any early blue projection tubes focus well even when they were new.

Comments on color purity, set orientation, and doming

> "The problem with my TV is that bright parts of the picture change color. For example, white areas may shift towards yellow or blue depending on the orientation of the set.
>
> What are the possible causes of doming? I have noticed that the magnitude of the doming effect varies with TV orientation even after degaussing several times at the new orientation. Does this help identify the cause of the doming in my case?"

(Portions from: Jeroen H. Stessen (Jeroen.Stessen@philips.com).)

The problem with regular shadow masks is 'doming'. Due to the inherent principle of shadow masks, 2/3 or more of all beam energy is dissipated in the mask. Where static bright objects are displayed, it heats up several hundred degrees. This causes thermal expansion, with local warping of the mask. The holes in the mask move to a different place and the projections of the electron beams will land on the wrong colours: purity errors. The use of invar allows about 3 times more beam current for the same purity errors.

Both local doming and magnetic fields compete for the remaining landing reserve. Due to improper degaussing, the doming problem may be more visible. And applying a tube designed for the wrong hemisphere may very well increase the doming complaints. It is possible to deliberately offset the nominal landing in order to get more doming reserve (the shift due to doming is always to the outside of the tube). You would do this using spoiler magnets put in the right places.

Permanently setting the contrast lower is not a real cure because the customer might not like such a dark picture. A better picture tube (Invar shadow mask) *is* a good cure (in most cases) but there is the cost price increase. (This is mainly due to the fact that Invar metal is harder to etch.)

Also see the section: Comments on color purity, set orientation, and doming.

About instant-on TVs

Most TVs built since, say, 1980 have only the microcontroller powered from a small transformer when the set is off. This permits the remote control or front panel pushbutton to switch the set on. This circuitry should be no more prone to catastrophic failure than what is in a VCR or digital clock.

Historically, there were 'instant on' TVs which kept a substantial portion of their circuitry live all the time - especially those using vacuum tubes in at least part of the circuitry (other than the CRT). In these, there was a lot more to fail. Those tubes would continue to change their characteristics for many minutes when warming up. Circuits were also much more touchy - remember all that constant tweaking! Thus, it made sense from the users's perspective to eliminate the warmup period and keep those tubes toasty all the time.

In modern solid state TVs, the only component to really need a warmup period is the CRT. All this means is that you have to wait 20 seconds for the picture to appear.

About gadgets to use house wiring as TV antenna

Note that these $10 devices usually contain a single 5 cent ceramic capacitor as their 'sophisticated electronic circuitry'. The rest of the fancy plastic case is just for show.

(The following is from: Greg Smith (LiveTV@en.com).)

Most people mistakening believe that the larger the antenna the better the received signal. The truth of the matter is that each element of the antenna must be cut to a precise length depending upon the frequency of the signal you are attempting to receive. Further more, each element must also be spaced a precise distance away from the others. This creates what is commonly called a "directional array". (see diagram below) By providing enhanced reception (gain) in the direction the antenna is pointed, it also provides decreased reception from the sides and back. (directivity) This prevents "ghosting" which is caused by the same signal arriving at the TV at a slightly different time because the signal bounced off of some structure on it's way to your set.

If you use the house wiring as the antenna, the length will be random and the orientation to the received signal will also be random. Therefore it will pickup the bounced/reflected signals just as well as the primary signal. IE: lots of ghosting = very poor picture quality.

Any kind of directional antenna, even a small one, whether inside or outside, should provide a superior quality picture to that from the device you are talking about. Even a cheap "rabbit ear" antenna mounted on top of the set allows you to orient it in the best direction.

If you only receive the VHF channels (2-10) in your area then buy a VHF ony antenna. If you only receive the UHF (19-60+) then buy a UHF only. If you get some of each then make sure that it is a combination antenna. If your set has separate inputs for VHF/UHF make sure you also get one with the proper splitter.

```
      -------------------
        ------()-------
           --------
             ----

              ^
              |
     direction of signal
```

Can I add an S-Video input to my TV or VCR?

Possibly, but why bother? You will most likely be limited by the TV or VCR's circuitry anyhow.

All S-Video means is (1) a special connector and (2) separate luminance (Y) and chrominance (C) rather than composite video.

In a VCR, you will need to bypass the input circuitry and get to the place where Y and C are separate. This may or may not be possible depending on its design.

In a TV, they may never be separate and you will need to substitute your own circuitry for the chroma demodulator.

It is probably not worth it as you will likely not gain much in picture quality but if you really are determined, a schematic will be essential in either case.

If all you want to do is allow for an S-video input, there are single chips which will combine the Y and C into a normal composite video signal.

Also, see the section: How do I add A/V inputs or outputs to a TV which does not have them built in? since there may be safety implications in the case of adding S-Video to a TV without any A/V jacks.

How do I add A/V inputs or outputs to a TV which does not have them built in?

For A/V inputs (video and audio) The place to do this is after the video and audio IF where baseband signals are normally separate.

For audio, in particular, an alternative is to tap into the audio circuitry which may be elsewhere. Even the loudspeaker outputs can be used but then without additional switching, you cannot disable the internal speakers when you are using your stereo system.

Depending on the model of TV, doing any of this may be trivial to impossible - or a serious safety hazard.

- Trivial: many low-end models use the same chassis (read this: circuit board) as the high end A/V receivers. Either there will be some parts missing, a cable connection to the missing A/V panel, or a missing auxiliary board which would have the A/V interface and jacks. If this is the case with your model, then it should be straightforward and safe to tap into the circuits at that point.

  A service manual or Sams' Photofact for the set will probably even identify the additional circuitry present in the higher priced models with A/V inputs.

  If, on the other hand, everything is crammed onto a single circuit board with no evidence of A/V signals, it may be very difficult as suitable tap-in points may simply not be available.

- Hazardous: many TVs have circuitry which is not isolated from the AC line. If this is the case with your set, then it may be more trouble than it is worth to provide the essential isolation barrier between the TV and your external A/V equipment. The only 'easy' solution for audio at least is to include an isolation transformer RATED FOR LINE VOLTAGE ISOLATION in each signal path to the outside world. A means of isolation can be provided for video as well but it has to be able to handle the 6 MHz or so bandwidth of the video signal. A simple capacitor even if rated for sufficient voltage will probably not work and could be hazardous since it would need to have a high uF value to pass the lower frequency end of the video signal.

If what you are really after is replacing a dead tuner/IF with your own tuner or converter, this may be possible but, again, may not be worth the trouble. The antenna isolation circuitry is probably external to the TV's tuner so yours could be substituted in its place. Of course, any user contact with the transplanted device would then have to be TOTALLY prevented since a serious shock hazard would be present for all metal parts and connections including shield grounds. In addition, many components would likely blow the instant power was applied if this were not done perfectly.

Unless you intend to always use the direct A/V inputs and forgo the tuner, you will need some way of selecting between them - a switch or relay. This could be manual - you push a button or flip a switch - or automatic. There are all kinds of ways to doing the detection - mechanical, checking for a low impedance connection, looking for a signal, using a switch, etc.

You will need a schematic - don't attempt this without one (for safety, if no other reason). Even some TVs that have A/V jacks use a live chassis and provide isolation for each signal (though this is the exception rather than the rule). So, even adding another A/V jacks to one of these would be hazardous!

Can I add direct RGB inputs to a TV?

The signals going into the CRT neck board are separate RGB, possibly a somewhat higher voltage level, but otherwise similar to those sent to a computer monitor. So, would it be possible to bypass the tuner and color decoding and go direct for better picture quality? After all, RGB SCART inputs are common on PAL TVs.

Assuming the scan rate of your source is NTSC (or PAL as appropriate), in principle, yes. The RGB signals may have to be amplified from the normal .7 to 1 V p-p used for monitors to whatever is required by your TV's final video amps (unless you can find a location on the mainboard where the levels are lower) and composite sync would need to be injected separately.

However, there are some serious safety issues. Many TV are designed with a chassis that is electrically live - not isolated from the AC line so unless an isolation transformer is used to power the TV or some means of isolation is used in the coupling of the signals, you could end up with a very shocking situation and/or blown parts all over the place. I wouldn't recommend it unless you have the complete schematics and really know what you are doing.

Adding variable volume headphones to a TV

> "My Mother-in-Law is hard of hearing. He is not. Is there such a thing as a variable volume headset that can hooked up while maintaining normal volume on the main speakers?"

(From: Filip "I'll buy a vowel" Gieszczykiewicz (filipg@repairfaq.org).)

Greetings. But of course... The cost is $9-ish per set and it includes a 9 foot (yup, 9 foot) cable and a handy, in-line volume control. The setup requires an audio output somewhere on the TV itself - is there a headphones jack? If yes, all you need is a "Y" (splitter) and two sets of headphones. If not, hmmm.... Either you or the local TV repair shop will need to add one. Depending on the circuitry of the speaker amplifier inside the TV, this may be as easy as splicing in a headphone jack and drilling a hole for it on the case, or as hard as somehow matching the impedance of the speaker to that of the headphones. You *will* need to look at the schematic or measure the speaker/signal. See the section: How do I add A/V inputs or outputs to a TV which does not have them built in? for the very important safety issues.

First, however, make sure they have a TV with a headphones jack or have one put in (or get a TV that *does* have one). The 'Y' adapter can be purchased in any Radio Shack. Any cheapo one will do - no need for gold plating (they will try to sell it to you ;-) should be under $5.

Building a Frankenstein TV

Here is an interesting questions:

> "I got a lot of partially gutted TVs at an auction (All the same brand) and I'm trying to build a 'Frankenstein TV'.
>
> I have a 13" unit with a working power supply board and tuner board in one set. I have another set with a 25" picture tube in it. I'd like to drive the big tube with the guts from the small TV. Does anyone know If I'll blow up my workbench if I attempt this sort of transplant?"

It won't blow up your workbench but the differences are probably significant enough that the performance would be unsatisfactory if it worked at all.

In addition, this may blow up the power supply board - kill the horizontal output transistor and/or low voltage power supply itself - as the required power levels are higher. If you have nothing to lose, power your Frankenstein initially through a series 100 W light bulb and Variac. Then you will be able to tell if you are even close with less risk of blowing expensive parts.

Of course, this does assume that all the organs your are merging are actually good to start with. Why do you you think they unloaded those TV carcasses?

While the same chassis may be used for 19" and 25" sets, going from 13" to 25" is likely to have many differences.

Turning a TV (or monitor) into an oscilloscope?

This question comes up so often and it does sound like a neat project to give a defunct TV a second life. Don't expect to end up with a Tek 465 on the cheap when you are done. However, it could be a fun learning experience.

CAUTION: See the safety recommendations below.

You will be severely limited in the performance of such a scope. TVs and monitors are designed to operate at a very narrow range of horizontal scan rates and the high voltage is usually derived from the horizontal deflection. So, you would need to retain the original deflection system for this purpose at least.

1. You will need to disconnect the deflection yoke from the horizontal and vertical deflection circuits of the TV or monitor without killing the HV. (also, doing all this without killing yourself as well). Depending on the design, this may be as simple as unplugging the yoke connector. More than likely, you will need to substitute a load for the horizontal deflection coil. A coil from another sacrificial similar TV or monitor would probably suffice.

   Warning: at this point you have a really bright spot in the middle of the screen which will turn to a really black spot if the brightness is not turned way down really really quickly.

2. For the horizontal, you need a ramped current source. You are driving a non-ideal inductor (the deflection coil) so it has both inductance and resistance. Thus the waveform is a trapezoid - a voltage ramp (for the resistive part) superimposed on a voltage step (for the inductive part). This should not be too difficult. Don't expect to be able to achieve really fast sweep. Even running at normal TV rates is non-trivial.

3. Similarly, for the vertical you need to drive with a voltage (your signal) controlled current source. However, if you are just screwing around, then the linearity etc. for the vertical may not be that important. In this case, one way is to put a current sensing resistor in series with the deflection coil and use this in a power op amp type of feedback arrangement. (You could do this for (2) as well.

4. There is a good chance that the original brightness control will work as an intensity adjustment. However, with some TVs and monitors, this depends on receiving a valid video signal. You may need to improvise. If you do want to control the intensity from a signal source, you should be able to tap into the drive signals going to the little board on the neck of the CRT.

5. Don't expect high bandwidth, uniform response, or any of the other things you take for granted with a decent scope. That takes work. However, as a fun project, this certainly qualifies. Interchanging the functions of the horizontal and vertical deflection yoke (and rotating it 90 degrees) may provide a better match of horizontal and vertical bandwidth to your intended applications or experiments.

6. With a color TV or monitor, these experiments could be quite interesting and educational but there may be color fringing effects since you are not compensating for certain aspects of dynamic convergence at all.

7. SAFETY: Once you disconnect the deflection yoke from the TV or monitor's circuits, move the original circuits out of the way and put a barrier between between you and the rest of the TV or monitor. All you will need are connections to the deflection yoke on the CRT (unless you want to do intensity modulation in which case you will need to drive the video output(s) to the CRT cathodes. I would recommend against doing this if your unit is one of those with a totally 'live' chassis as there would be additional safety hazards and circuit complications).

(From: Chris Crochet (ccrochet@premier.net).)

Hehehe... Actually, I've done this one. :)

I've got two old IBM mainframe terminals, painted like charred metal, hooked up to each channel of the 'B' speaker outputs on my stereo. It's strange looking and always an attention getter when I have guests. Not to mention, the long-persistence phosphor they use makes interesting tracers :)

One caveat, at least on these monitors (I don't know what other monitors this might apply to). When you turn them off, the circuitry shuts down in the following order: horizontal drive first, electron gun second, and vertical drive last. Therefore, if there is no vertical deflection, which would be the case if the stereo is quiet, the active electron beam becomes perfectly stationary during the course of shutdown, thus burning a hole in the phosphor. Oops :) I found it more effective to hook the stereo into the HORIZONTAL drive, thus avoiding this problem. Not quite like your average oscilloscope.

Another interesting effect -- if the electron gun is active during vertical blanking interval, it seems to deflect so far that it bounces off the SIDES of the picture tube, and sprays all over the phosphor, making some interesting images.

(From: Lance Edmonds (lanceedmonds@xtra.co.nz).

Some years ago ELEKTOR and Electronics Australia magazines published articles on a design for this. Dick Smith Electronics in both NZ & Australia used to sell the kit.

Max Bandwidth was a startling 10 or 15Khz. Enough for elementary audio servicing.

Those magazines also published designs for delayed sweep & trigger modules as additions to any basic 'scope. Plus, a storage scope design, logic analyzer design, and a Dual trace emulator design.

Enough to keep the average hobbist/experimenter happy for quite a while (g).

(From: Dale H. Cook (dhcook@rev.net).)

Every few months someone will pop up with this question. A TV would not make a very good scope. Bandwidth would be limited and the amount of work needed to build the horizontal and vertical amplifiers, sweep and triggering circuits and so on wouldn't be worth the effort. You'd need even more work to add modern features such as delayed triggering and variable hold-off. Don't even think about multiple channels and the advantages they offer. In a time when I see used Tek 465s offered for $200 it certainly doesn't pay to try to convert a TV. If you are just looking for a challenging electronic project I can think of several that have a far better chance of yielding something useful. Now, if you were starting with an antique set that used an electrostatic CRT you might do a bit better, but a 1937 Dumont will set you back about $3,000.00 or so - a little too much of an investment.

(From: Tony Duell (ard@p850ug1.demon.co.uk).)

I've worked on the vector monitors that were used on some of the 1970's minicomputers. These are essentially X-Y displays (not raster scanned), and would make audio-bandwidth 'scopes if given a timebase. I would guess at a bandwidth of the order of 100kHz.

Some of them (DEC, certainly, maybe Tektronix) were electromagnetically deflected like a TV. However, there are a couple of things to be aware of. Firstly, the output amplifier, which drives the yoke at constant current, is pretty complex. Secondly, the yoke is specially made - the 2 sets of coils are pretty similar (unlike those in a TV), and the inductance is critical.

So, while I'll keep these monitors running, I'd not want to have to covert a TV into one :-).

(From: David Katz (DAVEkATZ@prodigy.net).)

If by chance what you want is an X-Y display for audio, not a (more typical) X-T, it's easy. Just put a resistor in series with each yoke (about 100 ohms, 5 W) and drive them with a stereo amp.

(From: Steve Roberts (osteven@akrobiz.com).)

Your best hope might be to get a older generation heart monitor from a hospital, these have a professional X-Y display module to begin with, and are surprisingly easy to hack, mine was $10 at the local surplus shop. The ultra long persistence phosphor is a pain/blessing depending on what you are doing.

For a description of what one person did, see: Dan's Home-Built O-Scope Page.

(From: Alan (revidyks@rocketmail.com).)

Apparently it's pretty hard to produce a decent scope.

It is, however, pretty easy to use the CRT as something like a scope, which I did recently with the built-in green screen monitor of a thing called a Kapro 2X. It was being thrown away, so I said I'd take it and have a look inside before throwing it away.

I wondered what if it was possible to drive the CRT from a source other than the computer video circuitry, so I did some tests, worked out how and by what voltage the deflectors were driven, (about 1v, 0.3A measured as an AC voltage).

Once I'd worked out that this was about the same as the output from a small stereo amp, I removed the horizontal signal from the CRT and hooked one channel of my stereo across the horizontal deflector , left the vertical deflector hooked up to it's (60Hz?, 30Hz?) signal, and switched it on. The results look pretty good, I get a full-screen moving trace of the sound wave. One other thing that I did was make the beam intensity constant by turning a knob marked 'B-SUB' a bit, this would have flooded the screen with 'white' ordinarily, but was perfect for me as I could now remove the computer motherboard all together.

I also tried connecting the left and right channels across the horizontal and vertical deflectors respectively (first disconnecting them from their normal inputs), which produced some really cool looking lissijous (sp?) figure type things, that change and throb with the music- each CD seemed to have distinctive characteristics. Maybe I'll try two different pieces of music across the axes, could be interesting...

I'd love to try throwing some different signals of different frequencies and shapes across the axes too, especially in combination a with musical one. The 'best' results so far, have been from music with a strong bass, simple beat (cymbals with a bass drum look great), and not too many layers of guitars, vocals, etc. (too many sounds and it's an uninteresting mess...)

If you want more information or have any advice on or experience with this sort of thing, mail me...

If you're thinking of trying any of this, remember (in case you don't know) that TVs/Monitors can be REALLY dangerous even when switched off and unplugged. See the section: SAFETY.

Displaying a video signal as a picture on an oscilloscope

I am not sure why anyone would really want to do this other than as an experiment - it would be interesting one.

If a composite video signal is the input, you will need a sync separator.

You will have to construct a vertical deflection voltage ramp generator which can be locked to your vertical sync signal.

The horizontal timebase of the scope will be fine for the horizontal deflection and should easily lock to your horizontal sync pulse or (if the scope has a TV trigger mode) directly to the video signal.

A video amplifier will be needed if your Z axis does not have an internal amplifier (you need .7 V p-p to be full brightness range.) Unless you provide automatic gain control, this will need to include offset (brightness) and gain (contrast) adjustments. Even if there is an internal amplifier, it may not have the required bandwidth for the video signal.

However, the overall brightness may be disappointing - a scope is not designed for overall high brightness. The beam focus will not be as good as that on a little TV either.

Use of surge suppressors and line filters

Should you always use a surge suppressor outlet strip or line circuit? Sure, it shouldn't hurt. Just don't depend on these to provide protection under all circumstances. Some are better than others and the marketing blurb is at best of little help in making an informed selection. Product literature - unless it is backed up by testing from a reputable lab - is usually pretty useless and often confusing.

Line filters can also be useful if power in you area is noisy or prone to spikes or dips.

However, keep in mind that most well designed electronic equipment already includes both surge suppressors like MOVs as well as L-C line filters. More is not necessarily better but may move the point of failure to a readily accessible outlet strip rather than the innards of your equipment if damage occurs.

Very effective protection is possible through the use of a UPS (Uninterruptible Power Supply) which always runs the equipment off its battery from the internal inverter (not all do). This provides very effective isolation power line problems as the battery acts as a huge capacitor. If something is damaged, it will likely be the UPS and not your expensive equipment. Another option is to use a constant voltage transformer (SOLA) which provides voltage regulation, line conditioning, and isolation from power spikes and surges.

It is still best to unplug everything if the air raid sirens go off or you see an elephant wearing thick glasses running through the neighborhood (or an impending lightning storm).

Comments on lightning damage

Unfortunately, lightning or similar surge related damage can happen to any equipment that is plugged into

ANYTHING - AC line, antenna, cable, phone. Symptoms can be almost anything but often run along the lines of the following:

> "I just recently bought a new JVC TV, about 5 months ago to be exact. A few weeks ago it got hit by lightning. Not directly though. I am trying to figure out why it will not power up now. I traced as far as I could into the power and it seems to be getting 120 all the way to some sort of parts. I know at least that it is going past the fuse, and the fuse did not even blow. But when I press the on switch still nothing happens. The switch is good, as is the wiring leading to the mainboard. From there I don't know. Does anyone know of any VERY common things to go when hit by lightning? I really don't know much about TV repair, but I feel like trying to fix it myself. I just have no idea where to look now. It is getting power, but I don't know where exactly it is stopping. Any ideas would be greatly appreciated."

(From: Brian Frank" (jambfrank@erols.com).)

When I was in trade school the instructor who taught the TV/VCR. repair course also had a fixit place on the side. This man knew everything about TVs, he could almost tell you what was wrong with a set by just smelling it. Once I brought a set to class that had been struck indirectly as well, the instructor told me the best thing to do was to tie a rope around it an use it as an anchor for a boat. He further went on to explain that a set struck in any way usually has so many problems that it is not worth getting in to. The one time he did try to fix a particularly expensive set it took him and two other employees three weeks to get it going. And he said there were still some problems.

As for tips on actually fixing it you might want to ask around for junkers and cannibalize them into one set.

GFCI tripping with TV, monitor, or other high tech equipment

Ground Fault Circuit Interrupters (GFCIs) are very important for minimizing shock hazards in kitchens, bathrooms, outdoors and other potentially wet areas. They are now generally required by the NEC Code in these locations. However, what the GFCI detects to protect people - an imbalance in the currents in the Hot and Neutral wires caused possibly by someone touching a live conductor - may exist safely by design in high tech electronic equipment. The result - false tripping - is mostly a problem with 3 wire grounded devices with built in line filters having capacitors between Hot and Ground but may also occur with 2 wire ungrounded TVs due to the power-on surge into the highly capacitive or inductive loads of their power supplies.

However, it's also possible for this to happen when a TV is hooked to a cable system because it's cable shield is connected to Earth ground. In such a case, this may or may not be a cause for concern.

TVs using Hot chassis designs couple the antenna and its cable shield to the tuner with small coupling capacitors. A side effect is that some AC leakage current can flow through these capacitors, possibly enough to trip the GFCI. If the TV's plug isn't polarized, try reversing it and see if the problem goes away. If it is polarized, make sure your outlet is wired properly and you aren't using a non-polarized extension cord with the TV plugged reversed.

It's also possible the TV is faulty and the tripping is actually taking place as a result of a legitimate problem.

To assure the set is safe, (whether reversing the plug helps or not), a leakage test should really be performed by measuring the AC current between the TV's antenna shield and an Earth ground. Try it with both polarities of the wall plug. Anything over about 8 mA will trip a GFCI. If the leakage current is less than this with either polarity of the wall plug, the GFCI is overly sensitive. If the leakage current is much more with either polarity of the wall plug, the set is defective and should be serviced immediately. It should not be used until the problem is corrected as a serious shock hazard exists.

Multisystem TVs

The question often arise: can my NTSC TV modified to display PAL signals (or vice-versa). Unlike a VCR where there are substantial differences between recording of NTSC and PAL, the problem of displaying the picture is much simpler.

The following assumes 525 line NTSC and 625 line PAL:

The horizontal scan rates are nearly identical (15,734 Hz for NTSC and 15,625 Hz for PAL), so this is not likely to be a problem. If these differed significantly, then there would be design issues similar to those for multisync computer monitors and this would drive up cost.

The vertical scan are slightly more of a problem with 525 line/60 Hz NTSC and 625 line/50 Hz PAL. But it is a lot easier to design vertical deflection to accommodate a modest variation in rates. TVs could be easily designed or modified to accept either.

The color encoding techniques differ but inexpensive ICs exist that can deal with either standard. In fact, many are programmable to do either with a jumper and slight modifications to the external components.

Displaying a monochrome - B/W - picture on the other kind of set is usually possible if the set has a vertical hold control or enough vertical range. Modifying the chroma circuitry is more complicated but it should be possible to substitute a second IC and patch it into the existing video chain.

As far as commercial multisystem TVs are concerned, the real reason we do not see many of these (at least in the U.S.) is lack of demand. They are available if you look hard enough and are willing to pay a premium. They are readily available on the international market.

Playing NTSC videotape on a PAL TV

Note that you will probably need an adapter at the very least to connect a PAL TV to an NTSC RF cable. This, at least isn't a problem as suitable devices should be readily available for a couple dollars. However, that may be the easy part if the VCR doesn't do enough of a conversion!

> "Does anyone know if NTSC VCRs (NTSC is a special feature in Ireland) require an NTSC capable television too, or can they convert NTSC signals to PAL (seems unlikely)?"

(From: Jeroen H. Stessen (Jeroen.Stessen@philips.com).)

There are 4 possible answers:

1. The VCR does not convert an NTSC signal to PAL, it outputs pure NTSC and you need an NTSC-compatible TV to view it.

2. The VCR converts NTSC 3.58 to NTSC 4.43 and you need a PAL-TV adapted to NTSC 4.43 to view it (relatively minor adaptation).

3. The VCR converts NTSC 3.58 to PAL 4.43 but keeps the field rate at 60 Hz. That is definitely not a standard signal! Some standard PAL-TV's will permit viewing it, and some Won't! At least be prepared to see interesting artifacts and crosstalks.

4. Conversion to real standard PAL is very expensive, thus unlikely.

The most likely answers are (1) and (3), check the spec of the VCR. The NTSC 4.43 system has been sold to middle-east and maybe US-military.

Buying a TV in Europe

> "I have the following question for you specialists:
>
> Can I buy a TV in any west-european country and use it in any other west-european country? For example, buying a TV in the Netherlands and use it in Greece or buying in France and using in England."

(From: Jeroen H. Stessen (Jeroen.Stessen@philips.com).)

The general answer is: NO.

There are multi-standard TV's that cover more countries, but a TV that covers them all is extremely rare. Most countries now have PAL-BG, including all of Germany. England has PAL-I, the analog sound is at a different frequency and the digital sound is their own variety of Nicam. France has Secam L-L', mostly incompatible with anything else. I don't know about Greece, probably PAL-BG. Most Philips high-end sets can do PAL-BG, Secam-BG and NTSC (the latter from the baseband video inputs only).

(From: Allan Mounteney (allan@amounten.demon.co.uk).)

The answer is YES. Well, at least one.

Reason I know is that I was with a company that made computers with TV-OUT for world wide use and wanted something that could show that the TV Out worked for various countries.

This ONE and ONLY one we could find Three years ago came from Germany and covered PAL, SECAM and the American NTSC systems and came with a note that said from the time of making/selling that set it would not work in just one small country in South America. All features (including audio) were adjustable from the front panel Menu and it was a Grundig 17" job. I am advised that there is a load of others on the market now.

The company who seemed to know all about these international sets and gave us good service at that time was Andrew McCulloch Ltd in Cambridge UK. Phone #44(0)1223-351825

Could a TV be modified for 3D (stereo) display?

The whole idea of stereo 3-D vision to put the left and right views to the appropriate eyeball. There are two common ways of doing this:

1. Use different colors for the two views with color filters in from of each eye to separate the views. This is what were often used for the really bad (content wise) sci-fi movies of the '50s.

2. Display alternate views on the same monitor screen but use LCD shutter glasses to allow each eye to only see the appropriate view. This requires increasing the refresh rate to avoid unacceptable flicker.

The first approach can be used with any TV and a pair of monochrome video cameras. Of course, true color cannot be used since pure colored images are needed to separate the stereo views.

Alternating views with synchronized LCD glasses is a possibility but on a standard TV, the resulting refresh rate would be 30 Hz with a 50% duty cycle which is likely to be useful only as a short experiment - else your viewers will likely develop splitting headaches.

Displaying TV on a computer monitor

My general recommendation is that if you have the space, buy an inexpensive TV - the quality in the end may in fact be better. And, it will be usable without tying up your expensive monitor and (maybe) PC.

While various convertors are advertized to use a computer monitor with video from a VCR or other source, keep in mind that if it sounds too good to be true, it probably is like the claim of a $200 box for this:

OK, let me get this straight - this card/box will enable a 31.4 kHz horizontal scan rate monitor (VGA) be used as a TV - yes or no? It thus includes a video A/D, full screen frame buffer, D/A, and all the other tuner stuff for under $200? I don't think so. A scan doubler - which is a subset of the above - will not result in a high quality picture since it will display pairs of lines interleaved. Or does the impressive advertisement leave out the key requirement that the monitor sync at the NTSC horizontal scan rate of 15.734 kHz (most newer monitor do not)? Or is it a board that plugs into a PC and indeed does use the resources of the PC including the VGA card and bus?

In any case, get a written money back satisfaction guarantee.

Displaying computer video on a TV

Assuming this means NTSC:

1. You need to convert RGB to NTSC - there are single chips for this. Try Sony, Philips, Motorola, and others. These will combine the R, G, B, H sync, and V sync into a single composite video signal using a minimum of additional components.

2. You need to match the scan rate to NTSC - 15.734 kHz horizontal. Even basic VGA is twice this - 31.4 kHz. If your video card can be programmed to put out interlaced NTSC rate video then this is easy. If not, it is more difficult. If you want to use anything higher res than VGA, it is a very non-trivial problem requiring the construction of a scan convertor which includes a video A/D, full frame store, interpolator/readout timing, video D/A. Unless you are an experienced digital/analog designer, you really do not want to tackle any of this.

For the special case of VGA->NTSC, you may be able to get away with just storing a single scan line since the horizontal frequency is (almost) exactly twice the NTSC horizontal of 15.734 kHz. A double buffer where one buffer is storing while the other is reading out at approximately half the VGA pixel rate should work. With appropriate timing, even lines become the even field for NTSC and odd lines become the odd field (I may have this backwards). It is still not a trivial undertaking. Also, keep in mind that the quality you will get on NTSC will be poorer than the VGA due to fundamental NTSC bandwidth limitations. Also, flicker for line graphics will be significant due to the interlacing at 30 Hz. Even this is a non-trivial undertaking.

The requirements for PAL are very similar. For 625 lines systems, the 800x600 is the format that most closely matches the TV resolution.

You can also buy little boxes to do this. Quality is general not great as you are seriously limited by NTSC/PAL and the VCR. Except for presentations on existing TV rate equipment, it is probably not worth the effort. This is totally useless for any serious computer applications.

For professional presentations, modern video projectors are available that use high resolution LCD panels and real-time scan conversion. However, they are still relatively expensive).

How can I couple 4 TV screens to make them act like only one?

> "I've being thinking about how people do these kind of things? Is this analog stuff or do they use some kind of digitized signal which is then divided to each TV?"

It is mostly digital. The original master signal is digitized and stored in memory. Control codes specify the readout of a (probably double buffered) frame store. 9 and 16 screen versions are common. If you look closely, you will note that the resolution of pictures that differ is always lower indicating that the whole affair is driven from a single tape source with appropriate decoding. Where the pictures are the same, they may be at full resolution. Sub blocks of identical pictures may be at some intermediate resolution.

What is Scan Velocity Modulation?

(From: Jeroen H. Stessen (Jeroen.Stessen@philips.com).)

Scan velocity modulation occurs around the transients in the luminance signal. The beam is sped up just before and just after the edge and it is slowed down during the edge. This makes for a sharper edge. On an alternating B/W pattern (stripes, checkerboard) you will see that the white parts get smaller and the black parts get whiter. This geometry error is a side-effect. Some say that this is the main intended effect of SVM.

SVM is *supposed* to be used to compensate for the spot blowup at high beam current. Peaking does not help to improve sharpness because the higher peak beam current also gives a fatter spot. SVM *can* work in that case. Unfortunately it is often misapplied, too much SVM will give a very unnatural picture, with obvious horizontal geometry errors.

If applied properly, SVM can improve the picture. Unfortunately there has been a rat race, led by Japanese, suggesting that more is better.

Some people will simply advise turning the contrast down. At low beam current the spot size will be acceptably small and SVM is not needed. In most, if not all, cases they will disable the SVM circuit, usually by pulling the supply connector to the SVM panel. That panel is often fixed to the neck of the picture tube, behind the video amplifier panel.

About Automatic Black Level Stabilization and possible problems

This is how some Philips TVs automatically compensate for component drift.

(From: Jeroen Stessen (Jeroen.Stessen@philips.com).)

Check datasheets of TDA4580, TDA4680, TDA4780, TDA8390:

These video control ICs have automatic black level stabilization. At the top of each field it generates 3 measurement lines (R,G,B). Through a BCI beam current info wire it measures the beam current. It adjusts the amplitude of the measurement pulses so that it gets a fixed current level back, usually around 10 uA. Actually it measures a delta-voltage, the current is determined by resistors on the picture tube panel. The result is used as an offset for the video signals so that black voltage is put at zero beam current. (3 capacitors near the IC store 3 voltages, a 4th capacitor is used to store an ultra-black reference to compensate for leakage current.)

The pulses are easily seen on the screen if you turn down the vertical amplitude (height), you'll see 3 dim lines at the top.

When the set first starts up, the measurement loop can not close because cold cathodes can not produce any beam current. That would cause the loop to increase the black level to maximum. To prevent that, first it is measured whether the cathodes are warm yet. Instead of the 3 small measurement pulses a much larger (peak-white level) warm-up pulse is generated. This looks like a big fat white line at the top (above the screen edge).

The video control IC waits for the beam current to increase (to approx. 5 mA for the 3 guns together) before it will release the black level control loop. This is measured over the same BCI line, a diode adds an extra load resistor to this line so that a large beam current is required to cross the detection level. After this level is reached (was it +8 or +9 V ?) the black level stabilization starts, and after almost a second the picture is unblanked. It should be correct at once.

(I have often argued that this long delay is not pleasing to the customer who would rather have a faint picture earlier.)

Reasons why the warm-up trip level may not be reached are:

- The pulse is not strong enough, sometimes it can be adjusted via the same pin on the IC that adjusts the peak drive limiter,
- The emission of the cathodes is not enough (too cold, worn out cathode surface or too low VG2 voltage = screen voltage),
- The measurement resistor is too low value (via that diode),
- The beam current info circuit at the video output amplifiers does not work well, often because the CRT cathode voltage goes too low and the voltage on BCI can not be higher than that.

If there is too little beam current in general then I would start with re-adjusting the VG2 screen voltage. Because of the automatic black level stabilization this will NOT have any obvious effect on the picture. The stabilization just follows the VG2.

If VG2 is too low then the peak drive limiter will kick in too early and you can't get a decent contrast. Also the picture will be less sharp because at a lower cutoff voltage a smaller cathode area is used plus there's your problem with the warm-up detector.

If VG2 is too high then the video signal can not achieve blanking level anymore and you will see retrace lines. Also the cathodes will wear out faster because at a higher cutoff voltage a smaller cathode area is used, you'll have a sharper picture but not for long.

The proper adjustment procedure for VG2 is in the service doc, you need to observe the measurement pulses on an oscilloscope. But a little twist won't hurt too much, especially if you have already written off the CRT.

(I have the advantage of having known the people who invented this system many years ago, they were once my teachers.)

What is Kell factor with respect to interlaced displays?

(The following is from Bob Myers (myers@fc.hp.com).)

The Kell factor - which has to do with the fact that we're often undersampling an image from the standpoint of the Gospel According to St. Nyquist - IS a factor in the reduction of vertical resolution, but interlacing plays a part as well. This comes from at least two factors:

1. The receiver usually cannot precisely interleave the two fields.

2. More importantly, there are steps taken to reduce the interline flicker which reduce the effective vertical resolution. This includes running the line width of the display somewhat larger than would otherwise be the case, and in interlaced cameras, discharging the entire screen (including the lines from the "other" field) after every field scanned.

Interlace is particularly troublesome on moving images, where you will often perceive momentarily "missing" details. There was a LOT of discussion regarding the gory details of interlacing in the recent HDTV debates within SMPTE and other groups.

Homemade V-chip (or at least viewing limiter)

Here is an interesting questions:

> "I would like a control box of some sort that controls the cable signal that comes into the TV. I want to be able to control the total time a particular child has in his account to watch, plus the actual channels that he is allowed to watch (no Playboy or MTV), PLUS the time of day that he can watch (not during home work time). Programmable by channel, cumulative time, hour of the day, and day of the week. I also need a master pass word for parental programming of the kids accounts, plus be able to watch what I want to at any time. The kids could use either an individual account number or an individual "card" of some kind with a PIN like our ATM cards. This "box" should be secure so that a 14 year old boy can't bypass it very easily. At least without doing come major damage so that I'd know it when he did it. I know that this is a lot to ask, but I'm very familiar with computer programming and chipset technology, I do know that such a thing can be done. I just don't have the electronics knowledge to do it."

The following probably won't help you build such a gizmo but here are some thoughts:

First, I would not attempt to build any of the RF/cable switching stuff - there are too many variations. I would suggest trying to control the control of what you have. With a cable box, this would be relatively easy - just put the box and an IR transmitter in the same sealed enclosure. If you have only a cable ready TV, you could substitute or intercept the remote detector signal inside the set and disable the front panel controls.

Then you need:

- An input devices - keypad for example.

- A display - a 1 line LCD.

- A microprocessor. This doesn't need to be much - just to store the 'account information' including balance, allowable channel and time slot map, passwords. It would need a real time clock.

- An IR remote code transmitter. This could probably be directly programmed by the micro to control your cable box.

Each account would have a means of adding to the balance, password authentication, etc.

You would have a superuser account for your own watching as well as changing any of the individual account settings.

Too bad I don't still teach my intro to computer design courses - this would make a nice term project.

If you have a junker PC, this would be a simple bit of programming (but quite wasteful of power even for an 8088 based PC).

What is Aquadag?

You may see the term 'Aquadag' referring the the black paint covering the outside of most of the funnel section of the CRT.

(From: Nicholas Bodley (nbodley@tiac.net).)

Aquadag used to be a trademark of Acheson Colloids [Corp.?], I think around Niagara Falls or Buffalo, NY. It was one of many "-dag" colloidal graphites; they also made Oildag, Gredag (grease), and Alcoholdag, as I recall. Unfortunately, it's probably sold in 55-gallon drums minimum. I hope you can find smaller quantities. Are there any CRT rebuild shops around the USA? See the Thomas Catalog (ThomCat) in a library to find Acheson.

I am pretty sure there's nothing magic about the graphite. If you can find some reasonably-priced nickel-flake or copper-flake paint (be sure it's conductive!), you might have an affordable (?) coating. How about plain metal foil, maybe even ordinary aluminum foil? You surely don't need current-carrying capacity; you would need a decent adhesive, though. How to make sure you have continuity between pieces, I'm not so sure; shoot for really tight crimps that deform the metal and are gas-tight. (This might, however, be quite unnecessary.)

Combined computer monitor and TV

> "This is a 27" VGA monitor which should also be able to be used as an NTSC television monitor. Can anybody comment on it?"

IMO, I think the entire idea of a combined TV/computer monitor is silly especially when the likely cost premium is taken into account. Watching the boob tube will tie up your entire PC. The optimal size for TV and computer use is not the same nor are the requirements in terms of scan rate, resolution, brightness, and sharpness. Thus, the design will be inherently more expensive and include more compromises. So, I will probably be proved wrong by record sales of these things but my only justification for such a hybrid would be if there were absolutely no space for both.

Interesting TV Switch Mode Power Supply

The following was found in a Sony TV:

```
                         Q1 switching/reg
                            transistor
                 (+)             ---
              +---+-------------| |---------------+-----------+
        +--+  |  _|_             ---              |          _|_
  AC >--|  |--+  --- C1           |               |    diode /_\ D2
        |  |      |               |               |           |
  AC >--|  |------+---+    +-----+------+         |           |
        +--+     (-)  |    | Reg. Drive |         C           |
         D1           |    +-----+------+         C choke     +---- gnd
```

```
                |          |                C           _|_
                |          |                | +135 cap --- C2
                |          |                |  I--->    |+
                +----------+----------------+-----------+---> + 135
```

Although at first this appears to short out the line supply, when drawn like this it turns out to be a valid switching regulator:

- Q1 is driven by a pulse width modulated signal a the horizontal rate.
- Q1 turns on putting 150 V across choke. Current ramps up in choke - more or less linear until saturation which should not occur. This time increases with increasing load.
- Q1 turns off. Since current in an inductor cannot change instantly, current continues to flow, now through D2, C2, and +135 load. LCR (R of load, diode) time constant - charges capacitor and powers load.

It would appear to fail and run away under the following circumstances:

1. Inductance is too low and choke cannot store enough energy even at high duty cycle to supply load. Too high a duty cycle and core saturates at which point transistor blows up.
2. Inductance is too high relative to switching frequency so that choke does not have time to discharge (its current) before next current pulse - DC current will just keep increasing until core saturates. This could only really happen if the switching frequency were too high for some reason unless someone changed core material or something like t.
3. Load is too great due to fault elsewhere.

Unfortunately for reliability and troubleshooting, many modern power supply designs have similar failings.

When attempting to diagnose problems with these types of circuits where the natural outcome of a fault is for one or more expensive parts to fail catastrophically, it is wise to either use a Variac to bring up the input voltage slowly and carefully observe the behavior hopefully before too late or put a load in series with the line such as a 100W light bulb to limit the current (though this will change the behavior in various ways).

The horizontal output transistor substitution jig trick

(From: penguin@datastar.net).

Okay, here's a good trick you can use for almost all TV work. Mount a TO-3 transistor socket on a heatsink that has about as much surface area as the skin of both fists balled up, actually the bigger the heatsink the better. Then mount a horizontal output transistor in the socket. Use an ECG238 or equivalent. Make sure you use a good mica insulator, as there will be over a thousand volts on the collector.

Solder a 1.5 foot red wire (18 gauge or bigger) to the collector, an equal but yellow wire to the base and an equal but green wire to the emitter (or use your own color codes). You may be able to salvage a ready made heatsink with socket out of an old receiver or TV. Mine came out of some old Curtis Mathes TV's. Solder a damper diode with the cathode to the collector and the anode to the emitter. Add a 200 ohm 1/4 watt resistor from base to emitter. Add these parts to the socket not the transistor, so the transistor can easily be changed if you ever need to.

Now you have a very useful test jig. If you are ever working on a TV that has a blown HOT (horizontal output transistor) you can pull out the bad part and connect this jig. Then you can run the set at low voltage.

If you have a set where the HOT is running too hot, this method often will give you some running time, hopefully enough time to find out what the problem is. Often the bad parts themselves will self destruct or heat up to where identifying them is easy. Usually a bad flyback will crack and smoke proving itself to be bad. Once your satisfied that the problem is cured, you can put the original HOT in knowing it will be safe.

Usually when I power a TV in this way (using a Variac) I'll bypass the series pass regulator with a jumper. This is easily done by finding the 180 to 330 ohm 15 to 20 watt regulator bypass resistor and putting a jumper across it. With the regulator bypassed the power supply will go to 160 volts this is why it is necessary to use a Variac and only run it at about 60 volts. It is necessary when using this brute force approach, to make sure that all of the low voltage supplies coming off the flyback are fused with fusible resistors. Most models do fuse the LV supplies, but some don't. (One particular RCA comes to mind.) Another good trick, if your out in the field and don't have a varactor handy, is to simply pull the series pass regulator (e.g. STR30130 etc.) and let all the power just come through the 20 w bypass resistor. If the flyback is okay the B+ to the flyback will come up to about 60 to 90 volts, and in many cases you can even see a dim picture. Anything less than 50-60 volts and the flyback is probably bad. Don't run it this way for more than a minute or two as the the resistor will be dissipating close to or more than its rated power under these circumstances. Of coarse you obviously can't use this method with switching power supplies.

Here's a good trick for the Sony TVs that use the SG-613, even though this device is a gate controlled SCR you can sub a regular HOT like the ECG238 on your test jig. I used to blow out these buggers to the tune of about $20 dollars a pop til I figured out how to use the "HOT Heatsink Jig". Now with the jig connected, the horizontal width may not open up all the way, but you can run these old Sony's like this for about 5 minutes before the HOT jig starts to get too hot. Usually if they run this long they're ok and then you can put the SG-613 in knowing that you aren't going to see a bunch of $$$ go up in smoke. I had a Sony that would run for weeks then blow the SG-613 finally put this one to rest when I changed out the horizontal output transformer which was separate from the flyback on this oldie.

Always be cautious of the high voltage on the collector of the HOT JIG.

Ken's comments on (TV) SMPS repair

(From Kenneth Aaron (kennetha@geocities.com).)

1. NEVER NEVER NEVER power on a SMPS without load, the newer ones especially in TVs (not so much VCRs) self destruct when not loaded.

2. The light bulb test is great to see if your SMPS can handle the load of the horizontal circuits - when the set does not turn on - you get the initial power on then it goes off - best is to disconnect the collector of the horizontal output transistor and plug in a light bulb and see if it goes on.

3. Chinese TVs have poor quality capacitors - the latest models mostly have the same SMPS so this applies for all. There is a small electrolyte cap in the supply feedback about 22 to 47uF at 50V. This dries up real fast and after 2 years or so the voltage B+ goes up from 110 V to anything up to 300 V! (not joking here). I got a TV where the end of the tube was blown off from a supply that reached 296 V instead of 105 V. that's over 75kV into the screen!

4. The newer Philips and copycat Chinese models use the main supply to power the horizontal. The flyback is driven by a transistor which has over 2500 V on it's collector. The flyback is built differently as well. These transistors are called 2DS... - do not use a replacement - I did use one with a higher voltage and it fried - this

is because the ceramic capacitors around it along with it's different characteristics changed the 'on' time and it overheated after a few minutes.

5. You can always use a BU208D instead of a BU208A, BU508D instead of BU508A, etc, the extra diode will do no harm.

IR detector circuit

This IR Detector may be used for testing of IR remote controls, CD player laserdiodes, and other low level near IR emitters.

Component values are not critical. Purchase photodiode sensitive to near IR - 750-900 um or salvage from optocoupler or photosensor. Dead computer mice, not the furry kind, usually contain IR sensitive photodiodes. For convenience, use a 9V battery for power. Even a weak one will work fine. Construct so that LED does not illuminate the photodiode!

The detected signal may be monitored at the collector of the transistor (Q1) with an oscilloscope.

International Color Television Standards

Brief description of international color TV standards

(The following is from Bob Myers: (myers@fc.hp.com).)

Well, the joke was that SECAM stands for System Essentially Contrary to the American Method....:-)

The basic, oversimplified description of the three common encoding methods is as follows:

NTSC: Used in North America, Japan, and a few other areas. Luminance ("black and white" information) is sent just as it was before color, and color information is provided in two "color difference" signals (actually, derived along with the luminance (Y) signal) via matrix multiplication) which are carried on a "color subcarrier". The chroma (color) signals are severely band-limited compared to the luminance signal, which is one reason you can never fully recover proper RGB from an NTSC-encoded signal. The color information itself is encoded such that the PHASE of the chroma signals, relative to the reference signal, is important in recovering the color. As used in the U.S., the broadcast standard provides a line rate of approx. 15,734.26 Hz, and a field rate of 59.94+ Hz*

PAL: Very similar to NTSC, with the exception that the phase of the color subcarrier is reversed on alternate lines; this tends to cancel some of the more common color errors seen in the NTSC system. (The color signals of PAL are also simple color-difference signals, rather than using the more involved RGB -> YIQ matrix of NTSC). In the most common European PAL broadcast systems, a line rate of 15,625 Hz and a field rate of 50.00 Hs are used*.

SECAM: This system is very different from both NTSC and PAL. Luminance and color-difference signals are still used, but the color difference signals are sent separately, on successive lines. This requires at least a one-line memory or delay line be provided in the receiver for proper color decoding. The broadcast SECAM systems usually use similar line/field rates as for the PAL broadcast standards noted above*.

Note: In all three cases, the terms "NTSC", "PAL", and "SECAM" technically refer only to the COLOR-ENCODING systems described above; they do not specifically imply a set of timing standards or frequencies. The one possible exception to this is the use of the term "NTSC", since the U.S. National Television Standards Committee ALSO came up with various timing standards for U.S. television. But in all cases, the color encoding method is not *strongly* tied to a specific line/field timing. For example, there is at least one broadcast system (Brazil's) which uses NTSC encoding, but at the line/field rates more commonly seen in the European systems.

Some questions and answers about TV standards

(Responses from: Steve McKinty: (smckinty@france.sun.com))

1. What are the most common TV standards in the world?

NTSC: National Television Standards Committee PAL: Phase Alternate Line SECAM: SEquential Couleur Avec Memoire (Sequential colour with memory)

There are other differences though. Strictly they are just different colour systems, but most countries which use PAL have 625 lines in a picture and send 25 full pictures/second, most NTSC countries have 525 lines and send 30 full pictures/second (mostly for historical rather than technical reasons). That complicates things.

2. Who devised them, and when? and why? Are they as old as television?

The first serious TV experimenting was done in several countries around the period 1900-1930, mostly black & white. The BBC started a regular service in 1936, other countries followed soon after, but since the technology was developing very rapidly there were always improvements being made. The BBC started with 405 lines, the US started a service a couple of years later with 525, by the time other European countries started the technology allowed 625 lines. France even tried 819 lines.

All those system were black & white, but people wanted to have colour. During the 1940's much of Europe was at war, and technological development for entertainment slowed down, but in the US they were able to continue and devised a colour system which was compatible with the existing black & white one.

By compatible I mean that a black & white TV got a black & white picture, a colo(u)r one got a colour picture. No need to make people throw away their B&W TVs. This system was endorsed by the American National Television Standards Committee, and was named after it => NTSC.

After the war other countries started to look at colour. NTSC was a very clever system, but it had some flaws. Engineers in various countries tried to improve on it, and Telefunken in Germany came up with a simple modification which improved colour stability. It was named PAL because they reversed the Phase of the colour signal on Alternate Lines.

At the same time Henri de France, in France, fixed the same flaw in a different way. His design (SECAM) needed a memory inside the set which made it more expensive. PAL gave as good a result, so most countries opted for that. France stayed with SECAM, possibly because in the De Gaulle era of the 50's memories of German occupation were still fresh, and dropping a French system in favour of a German one would have been unpopular. Rumour has it that the French government subsidized Thomson to make memory affordable.

Since Britain went PAL, France went SECAM, and the US went NTSC, any colonies or dependencies of those countries tended to get the same system. India/Pakistan got PAL, Algeria got SECAM, and since the US helped rebuild Japan after WW2 it got NTSC, etc.

3. What's the difference?

To squeeze a colour signal into the same space as a black & white one, and stay compatible, the NTSC designers separated the colour and brightness information. The human eye is less sensitive to colour, so they were able to reduce the bandwidth of that signal (make it take up less space in each channel), 'hiding' it at the high-frequency end of the video. That meant they didn't need to make the channels bigger, and incompatible.

To do that, they used the fact that you can represent most colours with a combination of Red, Green and Blue. If you film a scene with three cameras, one for each colour, then add all the outputs together you get a black & white image. This signal is called luminance, usually represented by 'Y'. Mathematically Y = R + G + B. (Actually, not all the contributions are equal).

They then transmitted the Y signal just as for a black & white TV, and also transmitted the R and B in the extra colour signal. B&W TV's only saw Y, and colour TV's got Y, R and B. Since Y = R + B + G, G can be obtained as Y - (R+B), so they didn't need to transmit all three.

To get both R and B into one signal, they use a combination of Phase and Amplitude modulation (think of it as AM and FM at the same time). Its called quadrature modulation, and works very well, but is susceptible to phase changes as it passes along cables, etc. If the signal gets +10 degrees phase change the colour will visibly change, which is why NTSC TV's have a tint control.

PAL overcomes that by sending R and +B on one line, then R and -B on the next. That way a +10 phase shift on one line becomes -10 on the next, and small differences will cancel out. PAL TV's don't need tint controls. (Some old PAL sets may have a one, however).

SECAM doesn't send both R & B together, it sends R on one line, B on the next. No fancy modulation, so no phase problems, but you need a 'memory' in the set to save up the signal from the previous line, since both R & B are required together for processing.

4. Why do you need different TVs?

Mostly because of the different numbers of lines. Its quite easy to make one colour decoder which can cope with all the systems, but making a TV which can do 625 and 525 lines, 25 and 30 pictures/second, gets expensive. Consumers shop on price, no-one will buy a SECAM TV in the USA even if it only costs $20 more, since there aren't any SECAM channels.

5. Why do you need different VCRs? Why can't one VCR record the same "output"?

Some can, but like TVs it costs more to make them adjust. The motor speed varies with the number of pictures transmitted per second, for example. (This is covered in more detail in the document: Notes on the Troubleshooting and Repair of Video Cassette Recorders.)

6. Why did different systems evolve? Is one cheaper? Is one better?

When originally developed, expense was considered based on contemporary technology. As noted, politics may have been equally important.

As to which has better quality, its all rather subjective. The 625-line system adopted in Europe has better vertical resolution than the 525-line US system, but some people find the 50Hz field rate still produces some flicker. NTSC/PAL/SECAM are all equally capable of excellent colour reproduction, but under poor signal conditions NTSC can degrade more quickly.

7. Are there other systems besides the ones I've mentioned? Why?

Some others, like MAC where the colour and luminance are completely separated. That gets rid of interference (ever see the strange colours which appear on very fine check patterns?) but is more expensive and really only possible due to modern electronics.

8. Are there going to be more or less systems in the future?

That is THE question! There are certainly going to be different systems, more lines, better sound, etc.

9. Is there any way to convert a PAL tape to NTSC or vice versa?

Yes. If the PAL tape has 625 line pictures and the NTSC one has 525 line then you normally need a computer which can read in one format and re-adjust things. Not cheap, but becoming cheaper, several companies offer that sort of service. Some PAL VCRs can do a half-conversion, enough to fool most PAL TVs into thinking its got a PAL signal.

10. Do they teach this stuff in electrical engineering courses?

Sometimes. Some of it, depends a lot on the course and school.

Politically Correct TV Standards

(The following is from: Robert Rolf).

```
    SECAM:
            Used by France and the former Soviet union.
            No tint control. No color control.
            Full socialism. The state knows exactly what color you
            should see, and how strong that color should be.

    PAL:
            Used by Germany & UK, Australia etc.
            No tint control. A color control.
            Partial socialism. The state knows exactly what color you
            should see, but you get a choice as to how strong it can be.

    NTSC:
            Used in USA and Canada, Japan etc.
            A tint control, A color control.
            Uncontrolled socialism. The state lets you chose what color you
            see and how strong it can be. They then tax you regardless.
```

Just another way of looking at it....

Variations on a 'standard' - the PAL system

In the U.S., when PAL is mentioned, it is usually assumed to be 625 line/50 Hz as used in the UK and man other places. However, there are several variations on the PAL system.

(The following from: Ed Ellers I can think of five major groups right off:

PAL B/G/H - 625-line 50 Hz systems used in most European countries and many countries in Africa, the Middle East and Asia.

PAL I - Again 625 lines at 50 Hz, but with a different sound carrier frequency. Used in the United Kingdom, the Republic of Ireland, Hong Kong, South Africa and a few other places I've forgotten.

PAL D/K - Yet another 625-line system with a different sound carrier. Used in some former Warsaw Pact countries as well as mainland China; this may become more popular as PAL/SECAM receivers become common in the CIS republics and other former Soviet bloc countries, since those countries now use SECAM D/K.

PAL M - This one's 525 lines at 59.94 Hz; it's just like NTSC except for PAL-type color encoding. It's used mainly in Brazil.

PAL N - A real oddity, with 625-line 50 Hz video but a *lower* sound carrier and a lower color subcarrier than the B/G/H, I and D/K varieties. It's used in Argentina and a few other places.

What about PAL sets WITH a tint/hue control?

Here is one for the record books - a Sony PAL TV that really wants to be NTSC!

(From: Tony Duell (ard@p850ug1.demon.co.uk).)

Although this very old Sony set (KV-1300) receives PAL signals, it's much closer to an NTSC set inside. In fact it's one of the strangest PAL decoders that I have ever seen. As you know, in the PAL system, the phase of one of the colour signals is inverted on each line, and in the receiver there's a bistable which switches at half the line rate to re-invert the colour signal on alternate lines. Well, to avoid a patent, the Sony set only uses (say) the in-phase colour signal that's received on alternate lines. For the lines in between it uses the previous line's colour signal (ignoring the incoming inverted one), which has been stored in a delay line.

This approach avoids the main patent on the PAL system. It also means that this set doesn't automatically correct for phase errors in the colour signals - it's almost an NTSC decoder. Hence the hue control (which is also on my kV1320UB schematic). It's just about the only set like that.

TV, shortwave, power worldwide

(From: Mark Zenier (mzenier@netcom.com).)

A book, "The World Radio TV Handbook" published by Billboard that covers TV, along with where all the world's shortwave radio transmitters are, and what sort of power comes out of the wall plug all around the world. It has a new edition each year and costs around $25 to $30.

Color television standards worldwide

(The following is from EDMUNDO, Design Engineer Ten-Lab. This and additional information are available at: http://www.tenlab.com/format.htm).

We at Ten-Lab have put together the following chart listing countries and their corresponding color TV standards.

We are trying to be as accurate as possible, but we need your feedback to refine and correct the information. We are doing the best we can in spite of inherent problems such as:

1. Some of the literature and charts are contradictory; even some books and manuals contradict each other more than they agree.
2. Many countries have changed their names during the last few years.
3. Some countries have one broadcast TV system, but also receive programs in a different system from beyond their borders. This creates some confusion about the format(s) used locally.

```

Notes on cable and broadcast frequencies

(The following is from: (kruskal@watson.ibm.com (Vincent Kruskal).)

RF band: To get the band, subtract 1.25 from picture carrier (low end) and add 4.75 (high end).

Color subcarrier: Add 3.58... to picture carrier.

Sound carrier: Add 4.5 to picture carrier.

HRC: Harmonically Related Carrier. Makes both second- and third-order beats invisible by making them fall directly on the picture carrier of other channels. That is, multiplying the picture carrier by two or three will yield exactly another picture carrier.

IRC: Incrementally Related Carrier, add 1.25 to HRC frequency. A General Instruments (Jerrold) catalog said that IRC makes third-order (more important than second-order) beats invisible by making them fall directly on the picture carrier of other channels. But it is not true that multiplying an IRC picture carrier by two or three yields another IRC picture carrier. This contradiction has not been resolved. The reason third-order harmonics are more important is that oscillators and amplifiers tend to generate odd-order harmonics far more than even-order ones.

Broadcast frequency: Add 1.25 to HRC frequency except for channels 5 and 6. For them, subtract 0.75. But these are just nominal frequencies. The FCC actually has three channel designations for each number as in 5, 5- and 5+. The minus channels are 10 kHz below the nominal value and the plus channels are 10 kHz above. For example:

How did the (vertical) frame rate get chosen

Some people think that TVs are synchronized to the local power line since the vertical scan rate is around 60 Hz (or 50 Hz). This is not correct.

No TV (at least once the broadcast standards were defined - some experimental schemes did) ever used the power line for synchronization. However, older TVs had line frequency power transformers (no SMPSs) whose stray magnetic fields could affect the CRT deflection slightly. So it made sense (well, this is one justification at least) to make the vertical scan rate (field rate) equal to the power line frequency. Otherwise, there would be a jiggle or wiggle in the picture due to the stray magnetic field affecting the deflection of the beam inside the CRT. Since it was thought at the time (and for other reasons as well like cost) that 60 Hz was adequate to produce an acceptable amount of flicker, this all fit together nicely.

In the good old days before color TV, the frame/field rate was exactly 30/60 Hz (or 25/50) Hz. With color, it had to be changed slightly (see the section: Why is the NTSC color subcarrier such a weird frequency?) but since TVs no longer use line power transformers, there would not even be a slow position shift (period of several seconds) due to this so it didn't matter.

Why is the NTSC color subcarrier such a weird frequency?

(The following is from Bob Myers (myers@fc.hp.com).)

Actually, if we wanted to define the rates to the Nth degree, the important starting point is the field rate. The NTSC color frame rate was defined as (60 * 1000/1001) Hz, which is a bit more than 59.94 Hz. From this rate, all the others in the system are defined. The line rate is 262.5 times this, and the color subcarrier is defined as 455/2 times the line rate. This is often given as simply 3.579545 MHz, but the the color subcarrier was actually derived from the line/field rates rather than the other way around.

The whole thing was done so as to avoid (or at least minimize) interaction between the luminance, chrominance, and audio subcomponents in the standard color signal. This could have been achieved by moving either the audio subcarrier or adjusting the line and frame rates as described above. Unfortunately, the latter route was chosen, leaving us with this very strange looking set of rates.

The precise color burst frequency winds up being 3.579545.4545... under this definition, but giving it to the nearest Hz is within the tolerances of the system.

What is the maximal allowed deviation of the horizontal frequency?

(The following is from: Peter Bennett VE7CEI (bennett@triumf.ca))

In Canada and the US (525 line, 60 HZ, NTSC), the horizontal frequency is 15,734.264 Hz. The colour subcarrier is 455/2 times the horizontal frequency which should come to 3.579545 MHz. I believe the tolerance on the subcarrier frequency is +/- 10 Hz.

Informal comparison of TV standards

Q: I heard that TV in certain part of Europe has more quality in Europe then here in North America. I'd like to know the differences between the two systems. Is that why we cant use video tapes from there?

(Responses from: Mark Zenier (mzenier@netcom.com or mzenier@eskimo.com))

The first difference is that a lot of the world runs on 50 Hz power as opposed to North America's 60 Hz power. In the olden days, before active power supply regulators got cheap, it was decided that the vertical scan rate match the power supply frequency, so that ripple in the power supply wouldn't produce obnoxious visual effects.

So the PAL/SECAM signals have 50 vertical scans per second.

I don't know the exact reasoning, but the horizontal scan rate is close to the same. 15750 (now 15734) for 60 Hz, and 15625 for 50 Hz systems. My guess is the tradeoff between cost (50 years or so ago) and audibility for a large portion of the population.

So 50 Hz systems have more lines - 625 vs. 525 lines for 60 Hz systems.

The second difference is that European TV channels are wider. 7 or 8 MHz compared to the North American 6 MHz. Video bandwidth is limited to 4.2 MHz in a 6 MHz channel, but can be as much as 6 MHz in some of the 50 Hz systems. (Note: Systems is plural. There are many different European systems with incompatible color and sound transmission methods.)

As for the quality, if you move a little farther away, so that a pixel on each system subtends the same angle, NTSC doesn't have a poorer picture, just a smaller one.

PAL-plus

> "I wonder if you could tell me about PAL-Plus. The last time I was in Germany was in '84 so I've been out of touch with them."

(From: Jeroen H. Stessen (Jeroen.Stessen@philips.com).)

Oh boy, here goes another long story:

PAL-plus is an attempt to extend the life-cycle of terrestrial PAL transmissions by including compatible wide-screen (16:9) transmissions. It is an advanced variant of the letterbox format, this means that when you receive a PAL-plus widescreen program on an older 4:3 receiver you will see black bars top and bottom. It was originally developed in Germany (university of Dortmund in cooperation with German terrestrial broadcasters and some setmakers). Later a large consortium of European and Japanese setmakers took over and finished the job. Strangely, the German broadcasters seem to use PAL-plus only very rarely.

The PAL-plus standard comprises three extensions to the PAL-standard:

1. Vertical helper. In order to compensate for the fact that 1/4 of the video lines are not used, which would deteriorate vertical resolution for the widescreen viewer, the missing vertical information has been coded into the black lines in a manner as to be nearly invisible on a 4:3 receiver (you see some dark blue). The 16:9 PAL-plus receiver combines 432 visible lines plus 144 helper lines into 576 new visible lines.

2. Colour-plus. The PAL colour carrier is modulated in a slightly different way (making use of correlation

between 2 fields) in order to give a cleaner Y/C separation in the PAL-plus receiver.

3. Signaling bits from which the receiver can conclude whether the transmission is 4:3/16:9/PAL-plus and adapt the display format accordingly. The bandwidth of these bits is low enough to survive recording on a VHS recorder.

In order to enable a poor-man's PAL-plus receiver, the standard permits using the mark "PAL-plus" if at least the vertical helper reconstruction is included. Colour-plus is optional, so you will find sets on the market with only half of the PAL-plus extension.

PAL-plus may also be combined with teletext, ghost cancellation reference, digital Nicam stereo, VPS, PDC and what-you-have more. Theoretically it can be broadcast over a satellite channel too, but it was not designed for that and some aspects of a satellite channel do indeed give interesting technical problems.

There are also sets marketed as "PAL-plus compatible". These are mostly widescreen sets without any PAL-plus processing at all, but they allow switching of the display format between 4:3 and 16:9. They may well do that automatically, based on the signaling bits.

There are 2 methods for displaying a 4:3 letterboxed signal on a 16:9 display, without using the PAL-plus helper lines:

1. Increase of the vertical deflection amplitude to display only the centre 432 lines.

2. Vertical interpolation without using the helper, to convert 432 lines into 576 lines and display on a 576 lines display.

Both modes may be called "movie expand". Only when you really convert to full-resolution widescreen will it be called "widescreen".

And there are 4 methods for displaying a regular 4:3 signal on a 16:9 display (regular PAL, has nothing to do with PAL-plus):

1. Decrease of the horizontal deflection amplitude, this gives black bars left and right.

2. Horizontal interpolation, to convert N pixels to 3/4*N pixels. Both modes may be called "4:3" or "normal".

3. Non-linear horizontal deflection waveform, called "Panorama mode" by JVC, works by increasing the S-capacitor value.

4. Non-linear horizontal interpolation, called "Superwide" by Philips, works with an advanced sample-rate converter.

With both modes, the left and right edges of the picture will be stretched to fill the left and right bars, but the aspect ratio of the centre part of the picture will hardly be affected.

Interesting, huh?

More information about watching NTSC video on PAL systems

(From: Aaron Smart (spectrum_kid@hotmail.com).)

Most VCRs of remote quality sold in the British Isles (UK & Ireland) and probably other PAL regions (and definitely in the Middle East) in the past few years say something along the lines of "NTSC playback on PAL TV". It's usually automatic (it often takes the VCR about a second to adjust to NTSC speed), but some older VCRs have a switch. They don't usually go into much detail about how it's done in the manuals, but I'm pretty sure they usually just convert the signal to NTSC 4.43. Many decent TVs made in the last decade or so can handle this well enough, but some (most noted are Philips sets) will only display it in a kind of 'meshed' black and white. However, use of an RGB connection (e.g. SCART) removes this problem.

All DVD players sold in PAL regions (I think) are equipped to play NTSC video (too bad that most of them only play Region 2 discs, which means the only NTSC discs they can play are Japanese or region-free titles). I don't know exactly how every player works of course, but with ones I have used, they either just play NTSC discs in NTSC 4.43 or have the option to do that or play them in 'PAL' which I assume is PAL 4.43 at 60Hz which seems to be the same, except it won't turn out in blank and white with a composite connection as it does on some sets.

Also, certain newer videogame consoles (Sega Dreamcast and Nintendo Gamecube mostly) have many games that are allowed to be played in either 60 or 50Hz modes (since most games originate from NTSC regions, and 50Hz versions are usually slowed down and contain sometimes MASSIVE 'letterbox' borders). I don't know about other consoles, but the Dreamcast displayed the 60Hz video modes in PAL.

Panasonic TV manuals call this system "PAL 60/525", and I've heard it called "PAL 60" before, so it must be standardised to some extent.

I've tried a few PAL TVs with displaying 60Hz (PAL or NTSC), and here's some vague results of what happened: (O = yes, X = No. 'M' under NTSC only means black and white with composite or RF connection - not tested with RGB. Sorry I don't know the model numbers for all the tested sets. All models are Irish models unless stated)

TV Make/Model (if known)	PAL 60	NTSC 4.43
Panasonic TX-21S4TL (1998)	O RGB only	
Panasonic TC-14JR1L (2000)	O	?
Hitachi C1405R (UK, 1994)	O	?
Philips 21"(mid 90s)	?	M
BPL 14" (early 90s)	X	X
Panasonic 21" (early 90s?)	O	?
Mitsubishi 21" (late 80s?)	X	X
Ferguson 14" (late 90s)	O	O
Akura 14"(Daewoo tube, early 90s)	X	X
Salora 21" (circa 1990)	O	?
Philips 28" (circa 2000)	O*	?

* The colour was screwy at the top of the screen and was kind of unstable.

I've noticed that on a lot of sets that 60Hz pictures go off the screen a bit (vertically), and the OSD is stretched with it.

As for multi-region TV sets, most sets sold in the British Isles only receive PAL I RF transmissions, but I've seen some cheaper TVs sold in Ireland with PAL G as well. However, I have seen a widescreen Philips set (circa 2000, 32"?) that actually had a country selection menu - and it was definitely changing to the different PAL systems and to SECAM when I put it on France. I personally haven't seen other TVs like this, but there probably are others.

In the Middle East, though, it's a totally different story. In Saudi Arabia, anyway, all TV sets and VCRs had at least PAL (dunno which one) and MESECAM support. Most VHS VCRs had NTSC 4.43 playback, you could get multi-region TVs which had support for PAL, SECAM, NTSC 4.43 and NTSC 3.58. I had a multi-region Daewoo TV which had 4 LEDs below the screen to tell you which system you were watching - how nice!

Service Information

Advanced TV troubleshooting

If the solutions to your problems have not been covered in this document, you still have some options other than surrendering your TV to the local service center or the dumpster.

Also see the related document: Troubleshooting and Repair of Consumer Electronic Equipment.

Manufacturer's service literature: Service manuals are available for a great deal of consumer electronics. Once you have exhausted the obvious possibilities, the cost may be well worth it. Depending on the type of equipment, these can range in price from $10-50 or more. Some are more useful than others. However, not all include the schematics so if you are hoping to repair an electronic problem try to check before buying.

Inside cover of the equipment: TVs often have some kind of circuit diagram pasted inside the back cover. In the old days, this was a complete schematic. Now, if one exists at all, it just shows part numbers and location for key components - still very useful. Some TVs - as late as 10 years ago, maybe even now - included a complete schematic with the product information and owner's manual. I have a 1984 Mitsubishi which has this. It is, however, the exception rather than the rule anymore.

Sams' Photofacts (http://www.samswebsite.com/): These have been published for over 45 years (I don't know for how long but I have Sams' for a 1949 portable (3 inch) Pilot TV - about as portable as an office typewriter (if you remember what one of those was like) and are generally the best most consistent source of service info for TVs (nearly every model that has ever been sold), radios, some VCRs and other consumer electronics. For TV servicing, they are indispensable.

There are some Computerfacts but the number of these is very limited. The VCRfacts are also somewhat limited and the newer ones tend to have strictly (obvious) mechanical information.

Even if they don't list your model, they may have a folder for one using the same chassis so search by chassis number as well. Even if this doesn't help, there still may be a folder for models that are similar enough to be of value (though you really have to be in the library to be able to determine this by looking at the circuit diagrams or photos) so check out folders for other model numbers that are close to the one you really want.

You can search this site to determine if they have a folder for your model. Service info (EFacts) for most models manufactured after 1992 is available in electronic form (currently) about $11. These are similar to the print PhotoFacts but may be ordered on-line and will arrive via email within 1 business day. The hard copy versions are also available from major electronics distributors but may be more expensive than the EFacts. However, I don't know how quickly the Photofact is created after a new model is introduced. So, if your set is just out of warranty, it's possible that none is available.

Sams' Photofacts are also often available (for photocopy costs) from your local large public library which may subscribe to the complete series.

One advantage of the Sams' info is that it is compiled in a very consistent format so that once you are familiar with one model TV, it is easy to transfer that knowledge to any other. They provide waveforms at key locations and DC voltage measurements almost everywhere. Additional info such as IC pin to ground and coil resistances are often provided as well. The manufacturer's service manuals are generally not nearly as complete.

Note that I have no connection with Sams Technical Publishing (formerly Howard Sams).

Elsewhere around the world, libraries may also have Sams' or other service information:

(From: Chris Laudan (chris.laudan@zetnet.co.uk).)

This is true here in UK too, though not Sams photofacts, just schematics issued by manufacturers. Go to the reference library and ask for Video and TV service manuals, most main libraries carry a good selection.

(From: Michael Covington (mcovingt@ai.uga.edu).)

Concerning Sams' Photofacts, here is a bit of history that seems to be very little known:

The name "Sams" is not an acronym, nor is it "Sam." It's the last name of Howard W. Sams, who founded the Howard Sams publishing company (now Sams Technical Publishing). Accordingly, they are "Sams' Photofacts" rather than any of various other spellings that we often see on the net.

And they're a great product. Apparently "Howard W. Sams & Co., Indianapolis, Indiana" is a sufficient address to reach them. So is 1-800-GAT-SAMS.

Service manuals for really old TVs

Try your large public library for Sams' photofacts. I found a 3" TV of from around 1948 at a yard sale. There was no problem finding a complete set of Sams' service information including full schematics, parts list (of course, finding suitable parts like tubes in the 1990s may be a bit more difficult than when this set was new!), troubleshooting procedures, etc. Someday, I may even get around to fixing it. All the paper capacitors are leaky (for starters).

BTW, the case for this 3" TV is about 18" x 10" x 15" and it includes a handy option: a 6 inch semispherical water filled magnifier. The CRT is an oscilloscope tube. Not your modern portable!

How to locate service info when all the little stickers have fallen off

On newer TVs, the chassis number may be printed on the mainboard.

(From: "Clifton T. Sharp, Jr."

Somewhere on the chassis there may be an inked chassis number; an example for one color set was TS-914. A chassis number will at least get you some service information, and should be all you need unless you plan to try to get cabinet parts for it (chortle guffaw titter). Number should be findable on the back of the chassis (i.e. where the pots are mounted through the chassis).

Techical assistance help numbers

Here are contact numbers for some TV manufacturers:

```
Curtis Mathis                  1-800-949-4999  Steve Long
```

```
Mitsubishi                 1-800-552-8324

NAP                        1-900-896-8324

Zenith                     1-800-874-1930  ext 1065 or 1066
                           1-800-856-0981
                           1-312-745-5154

Sanyo                      1-800-877-5032

Panasonic                  1-201-348-7957
                           1-201-348-7958
                           1-201-392-6961
                           1-201-392-6992
```

Web resources

Many manufacturers are now providing extensive information via the World Wide Web. The answer to you question may be a mouse click away. Perform a net search or just try to guess the manufacturer's home page address. The most obvious is often correct. It will usually be of the form "http://www.xxx.com" where xxx is the manufacturers' name, abbreviation, or acronym. For example, Hewlett Packard is hp, Sun Microsystems is sun, Motorola is, you guessed it, motorola. Electronic parts manufacturers often have detailed datasheets for their product offerings.

Radio Shack (Tandy) has a nice web resource and fax-back service. This is mostly for their equipment but some of it applies to other brands and there are diagrams which may be useful for other manufacturers' VCRs, TVs, CD players, camcorders, remote controls, and other devices:

- Hitachi Service Manauls (Requires registration but should be free)
- Radio Shack Product Support

In addition to Tandy products, there is at least one Sony model. Furthermore, since Tandy does not manufacture its own TV sets - they are other brands with Realistic, Optimus, or other Radio Shack logos - your model may actually be covered. It may just take a little searching to find it.

Parts information

I have found one of the most useful single sources for general information on semiconductors to be the ECG Semiconductors Master Replacement Guide, about $6 from your local Philips distributor. STK, NTE, and others have similar manuals. The ECG manual will enable you to look up U.S., foreign, and manufacturer 'house' numbers and identify device type, pinout, and other information. Note that I am not necessarily recommending using ECG (or other generic) replacements if the original replacements are (1) readily available and (2) reasonably priced. However, the cross reference can save countless hours searching through databooks or contacting the manufacturers. Even if you have a wall of databooks, this source is invaluable. A couple of caveats: (1) ECG crosses have been known to be incorrect - the specifications of the ECG replacement part were inferior to the original. (2) Don't assume that the specifications provided for the ECG part are identical to the original - they may be better in some ways. Thus, using the ECG to determine the specifications of the parts in your junk bin can be risky.

Other cross reference guides are available from the parts source listed in the section: Repair parts sources.

Suggested references

Some good sources for technology information:

- Basic Theory of Colour Television
  Philips

  Ask for this book from your local technical bookstore.

- Basic Television & Video Systems, 5th ed.
  Bernard Grob
  McGraw Hill

For a technical reference on the various flavours of NTSC, PAL, and SECAM used around the world, I suggest:

- Recommendations and reports of the CCIR
  volume XI, Part 1

  Available from Omnicom, 115 Park St. S.E. Vienna, VA 22180 (703)281-1135

The following book is for PAL TV-standard specifications:

- Colour Television (With particular refererence to PAL)
  G.N. Patchett
  Norman Price (Publishers) Ltd.

  It has three heavyweight chapters describing NTSC/PAL/SECAM and has a decent amount of math content.

The following is more directed toward digital video but may still contain some information useful for understanding analog TV technology:

- Video demystified: A handbook for the digital engineer
  Keith Jack
  Brooktree Corporation, 1993
  ISBN 1-878707-09-4

There don't seem to be nearly as many TV repair books for modern solid state TVs as I recall for old tube sets. Here are a couple which you may find (or its predecessor) at your local public library (621.384 if you library is numbered that way) or a technical book store. MCM Electronics has the Davidson as well.

- Troubleshooting and Repairing Solid State TVs
  Homer L. Davidson
  2nd Edition, 1992 (The 1st edition is also useful)
  TAB Books, Inc.
  Blue Ridge Summit, PA 17214

- Lenk's Television Handbook: Troubleshooting and Repair
  John D. Lenk
  McGraw Hill, 1994
  ISBN 0-07-037517-8

  (Recommended by: Larry Sabo (sabo@storm.ca).)

- Color and Black & White Television Theory and Servicing
  Alvin A. Liff and Sam Wilson.

  (Recommended by: Michael Caplan (cy173@freenet.carleton.ca) who has the following comments.)

  There are three editions, the first going back to 1979. I've used both the second (1985) and third (1993) editions (ISBN 0-13-150012-0). The latter incorporates more digital circuitry and virtually no tube systems. The second has somewhat more tube-based information, but still focuses on semiconductor circuits. The first edition, I understand, had far more tube system detail.

- Basic Television Principles & Servicing
  Bernard Grob

- Complete TV Servicing Handbook
  Walter H. Buchsbaum
  Prentice-Hall, Inc., 1985

The following is a recent publication:

- Troubleshooting and Repair Guide to TV
  PROMPT Publications (Howard W. Sams), 1-800-428-7267
  ISBN #0-7906-1077-9, $29.95.

  From the advertising blurb for this book:

  "This book, 300 pages of detailed photos, schematic diagrams, and text explains in easy to understand language how TV works, how to troubleshoot problems, and advice on how to fix them. The Howard W. Sams Troubleshooting and Repair Guide to TV is the perfect reference book for technicians, instructional guide for students and hobbyists."

FCC ID Numbers of TVs

Only a few manufacturers actually produce the vast majority of TVs. For example, Radio Shack, Magnavox, and Emerson do not make their own TVs (I can tell you are not really surprised!).

How do you determine the actual manufacturer? For most types of consumer electronic equipment, there is something called an 'FCC ID' or 'FCC number'. Any type of equipment that may produce RF interference or be affected by this is required to be registered with the FCC. This number can be used to identify the actual manufacturer of the equipment.

A cross reference and other links can be found at:

- S.E.R FCC ID FAQ

Interchangeability of components

The question often arises: If I cannot obtain an exact replacement or if I have a monitor, TV, or other equipment carcass gathering dust, can I substitute a part that is not a precise match? Sometimes, this is simply desired to confirm a diagnosis and avoid the risk of ordering an expensive replacement and/or having to wait until it arrives.

For safety related items, the answer is generally NO - an exact replacement part is needed to maintain the specifications within acceptable limits with respect to line isolation, X-ray protection and to minimize fire hazards. Typical parts of this type include flameproof resistors, some types of capacitors, and specific parts dealing with CRT high voltage regulation. However, during testing, it is usually acceptable to substitute electrically equivalent parts on a temporary basis. For example, an ordinary 1 ohm resistor can be substituted for an open 1 ohm flameproof resistor to determine if there are other problems in the horizontal deflection circuits before placing an order - as long as you don't get lazy and neglect to install the proper type before buttoning up the monitor or TV.

For other components, whether a not quite identical substitute will work reliably or at all depends on many factors. Some deflection circuits are so carefully matched to a specific horizontal output transistor that no substitute will be reliable.

Here are some guidelines:

1. Fuses - exact same current rating and at least equal voltage rating. I have often soldered a normal 3AG size fuse onto a smaller blown 20 mm long fuse as a substitute.

2. Resistors, capacitors, inductors, diodes, switches, potentiometers, LEDs, and other common parts - except for those specifically marked as safety-critical - substitution as long as the replacement part fits and specifications should be fine. It is best to use the same type - metal film resistor, for example. But for testing, even this is not a hard and fast rule and a carbon resistor should work just fine.

3. Rectifiers - many are of these are high efficiency and/or fast recovery types. Replacements should have at equal or better PRV, Imax, and Tr specifications.

4. Posistors - many of these are similar. Unfortunately, the markings on the devices are generally pretty useless in determining their ratings. Note, however, that the prices for replacement posistors may be quite reasonable from the original manufacturer so it may not make sense to take the risk of using an unknown part.

   (From: Stefan Huebner (Stefan.Huebner@rookie.antar.com).)

   In most cases you can use a standard 3-terminal-device, the resistance of the temperature dependent resistors in it are nearly identical. Here is a list of possible replacement devices:

   380000-01, 24340521, 2199-603-1201, 163-024A, 163-035A, CO2200-N66, C8ROH, QX265P05503, 32112026, 4822-A1-11240148, 02199-003-120, 15-08-001A, 5391560067, F400001.

5. Transistors and thyristors (except HOTs and SMPS choppers) - substitutes will generally work as long as their specifications meet or exceed those of the original. For testing, it is usually OK to use types that do not quite meet all of these as long as the breakdown voltage and maximum current specifications are not exceeded. However, performance may not be quite as good. For power types, make sure to use a heatsink.

   Also see the section: Replacement power transistors while testing.

6. Horizontal output (or SMPS) transistors - exact replacement is generally best but except for very high performance monitors, generic HOTs that have specifications that are at least as good will work in many cases. Make sure the replacement transistor has an internal damper diode if the original had one. For testing with a series light bulb, even a transistor that doesn't quite meet specifications should work well enough (and not blow up) to enable you to determine what else may be faulty. The most critical parameters are Vceo/Vcbo, IC, and Hfe which should all be at least equal to the original transistor. I have often used by favorite BU208D as a temporary substitute for other HOTs and SMPS (chopper) transistors. Make sure you use a heatsink and thermal grease in any case - even if you have to hang the assembly by a cable tie to make it fit.

For that matter, you can usually substitute a similar HOT with the D suffix instead of the A (or no) suffix. These have a built-in damper diode and two in parallel (the external one) will not hurt (or remove it). Naturally, the reverse is not true since a damper diode IS essential and the HOT will probably not last beyond the click of the power relay without one!

On SVGA monitors, there will likely be additional circuitry between the HOT and the damper so this trick doesn't work for them.

However, using a HOT with much better specs may actually result in early failure due to excessive heating from insufficient and/or suboptimal base drive. See the document: "TV and Monitor Deflections Systems" for more info.

For more information, see the document: TV and Monitor Deflection Systems.

7. Deflection yokes - in the old days, particularly for B/W TVs, all of these were quite similar. It was common to just swap with one that fit physically and at most need to adjust or change a width coil. With color TVs and high performance multiscan monitors, this is no longer the case. Sometimes it will work but other times the power supply won't even be able to come up as a result of the impedance mismatch due to different coils and pole piece configurations. In addition, there may be other geometry correction coils associated with the yoke that could differ substantially.

   However, if you are really determined, see the section: Swapping of deflection yokes.

   Also see the section: Replacement power transistors while testing.

8. Standby power transformer - this most likely only has a single secondary so locating a standard UL approved (for safety reasons) power transformer with the same output voltage should not be difficult.

   Check the service manual or the Sams' Photofact for the set to determine the required output voltage and if a centertap is needed. Current should be quite low.

9. CRTs - aside from the issues of physical size and mounting, many factors need to be considered. These include deflection angle, neck diameter, base pinout, focus and screen voltage requirements, purity and convergence magnets, etc. Color CRT replacement is rarely worth the effort in any case but trying to substitute a different CRT is asking for frustration. For monochrome CRTs, there is less variation and this may be worth a try.

10. The following are usually custom parts and substitution of something from your junk box is unlikely to be successful even for testing: flyback (LOPT) and SMPS transformers, interstage coils or transformers, microcontrollers, and other custom programmed chips.

Horizontal output transistor pinouts

You will nearly always find one of two types of horizontal output transistors in TVs and monitors:

9. Metal can - TO3 package:

```
          _
        / O \         View from bottom (pin side)
      / o   o \
```

```
        (  B   E  )      B = Base, E = Emitter, C = Collector
         \       /
           \ O / C       The metal case is the Collector.
```

10. Plastic tab - TO3Pn (n = several suffixes) package:

```
           _____
          /     \
         |   O   |      View from front (label side)
         |       |
         |       |      B = Base, E = Emitter, C = Collector
         |_______|
           | | |        If there is an exposed metal tab, this is the
           | | |         Collector as well.
           B C E
```

Some other transistor types use the same pinout (TO66 for metal can, TO218 and TO220 for plastic tab) but not all. However, for horizontal output transistors, these pinouts shouuld be valid.

Note that those with a built in damper diode may read around 50 ohms between B and E (near 0 on the diode test range) - this is normal as long as the resistance is not really low like under 10 ohms.

How do you locate the HOT

Well, it is usually the LARGEST transistor in the set near the LARGEST transformer in the set (flyback - the thing with the FAT red wire connecting to the picture tube) on the LARGEST heat sink in the set.

Got that? :-)

Or, in the good old days....

(From: Don Wall (d.wall@nunet.neu.edu).)

Sure, it's usually the largest tube in the set, has a top cap, runs very hot, and is often a 6BQ6G or some such. (tongue firmly in cheek) Actually, back in the days of yore, the Horizontal Output Tube was frequently referred to as the HOT; guess some things don't change!

Replacement power transistors while testing

During testing of horizontal deflection circuits or switchmode power supplies, particularly where the original failure resulted in the death of the HOT or chopper, overstress on replacement transistors is always a possibility if all defective components have not be identified.

Therefore, using a part with better specifications may save you in the long run by reducing the number of expensive blown parts. Once all other problems have been located and repaired, the proper part can be installed.

However, this is not always going to work. In a TV and especially a high performance monitor, the HOT may be closely matched to the drive and output components of the deflection circuits. Putting in one with higher Vce, I, or P specifications may result in overheating and failure due to lower Hfe.

Where possible, a series load like a light bulb can be used limit the maximum current to the device and will allow you to power the equipment while checking for other faults. Some designs, unfortunately, will not start up under these conditions. In such cases, substituting a 'better' device may be the best choice for testing.

(From: Glenn Allen (glenn@manawatu.gen.nz).)

I been repairing SMPS of all types but when I started on those using MOSFETs I was blowning a few of them when replaced because something else was faulty.

Ever since I have been using a BUZ355 on a heat sink I haven't blown it. It is rated at 800 V, 6 A, and 220 W. it is a TO218 case bigger than a T0220. It seems the higher ratings allows you to do repair where as a something like a 2SK1117 or MTP6N60 will just blow.

Testing of replacement HOTs

The following is useful both to confirm that a substitute replacement HOT is suitable and that no other circuit problems are still present. However, single scan line anomalies (particularly when changing channels and/or where reception is poor with a TV or when switching scan rates and/or when no or incorrect sync is present with a monitor) resulting in excessive voltage across the HOT and instant failure are still possible and will not result in an HOT running excessively hot.

(From: Raymond Carlsen (rrcc@u.washington.edu).)

After installing a replacement HOT in a TV set or monitor, I like to check the temperature for awhile to make sure the substitute is a good match and that there are no other problems such as a weak H drive signal. The input current is just not a good enough indicator. I have been using a WCF (well calibrated finger) for years. For me, the rule of thumb, quite literally, is: if you can not hold your finger on it, it's running too hot, and will probably fail prematurely. Touching the case of the transistor or heat sink is tricky....

Metal case transistors will be connected to the collector and have a healthy pulse (>1,200 V peak!) and even with plastic case tab transistors, the tab will be at this potential. It is best to do this only after the power is off and the B+ has discharged. In addition, the HOT may be hot enough to burn you.

A better method is the use of an indoor/outdoor thermometer. I bought one recently from Radio Shack for about $15 (63-1009). It has a plastic 'probe' on the end of a 10' cable as the outdoor sensor. With a large alligator clip, I just clamp the sensor to the heat sink near the transistor and set up the digital display near the TV set to monitor the temperature. The last TV I used it on was a 27" Sanyo that had a shorted H. output and an open B+ resistor. Replacement parts brought the set back to life and the flyback pulse looked OK, but the transistor was getting hot within 5 minutes... up to 130 degrees before I shut it down and started looking for the cause. I found a 1 uF 160 volt cap in the driver circuit that was open. After replacing the cap, I fired up the set again and monitored the heat sink as before. This time, the temperature slowly rose to about 115 degrees and stayed there. I ran the set all day and noticed little variation in the measurement. Test equipment doesn't have to cost a fortune.

Removing and replacing the deflection yoke

Should you need to remove the deflection yoke on a color CRT, some basic considerations are advised both to minimize the needed purity and convergence adjustments after replacement as well as to prevent an unfortunate accident.

The position and orientation of the yoke (including pitch and yaw) and magnet assembly (purity and static convergence rings, if used) are critical. Use paint or White-Out(tm) to put a stripe across all of the magnet rings so you will know their exact positions should they accidentally shift later. If there are rubber wedges between the yoke and the funnel of the tube, assure that they are secure. Tape them to be doubly sure as adhesive on old tape dries up with age and heat and becomes useless. This will avoid the need for unecessary dynamic convergence adjustments after reassembly.

The neck is the most fragile part of the CRT so do not apply any serious side-ways force and take care not to bend any of the pins when removing and replacing the CRT socket.

The yoke and purity/static convergence assemblies will be clamped and possibly glued as well. However, the adhesive will probably be easily accessible - big globs of stuff like hot melt glue and/or RTV silicone. Carefully free the adhesive from the glass neck of the CRT. Loosen the clamps and gently wiggle the magnets and yoke off the neck. They may appear stuck from age and heat but should yield with gently persuasion.

Once the yoke is replaced, some fine adjustments of the picture rotation, purity, and static and dynamic convergence may be needed but hopefully with your most excellent diagrams, these will be minimal.

Similar comments apply for monochrome CRTs but there are far fewer issues as the yoke is positioned firmly against the funnel of the CRT and rotation and centering are usually the only adjustments. However, there may be magnets located on swivels or glued to strategic locations on the CRT envelope to correct for geometric distortion.

Swapping of deflection yokes

This should work with identical TVs or monitors. Your mileage will vary if you are attempting a swap between monitors with similar specifications. Chances of success for monitors with widely different screen sizes or scan rate specifications is close to zero.

One indication of compatibility problems would be major differences in resistance readings for the corresponding yoke windings, CRT HV and other bias levels, etc.

Before you do the transplant, see the section: Swapping of deflection yokes for procedures and precautions to minimize problems in realignment.

Make a precise diagram of everything you do.

Keep the purity/static convergence magnet assembly with the original CRT if possible and install it in the same or as nearly the same position as possible when you replace it.

Once you are sure of the connections, power it up carefully - there is no assurance that your yokes are compatible. A yoke with a much lower resistance or inductance than the original may overstress components in the power supply.

You will then need to go through all the adjustments starting with purity and convergence.

Swapping of CRTs

Given the problems of just replacing a CRT with an identical new one, it isn't surprising that attempting to substitute a CRT which is not the same type will result in difficulties - to say the least. Obviously, the closer in size, scan rate (for monitors), and deflection angle, the more likely the chances of success. Where the alternative is to junk the TV or monitor, it may be worth a shot - and you may get lucky!

It may be best to transfer as much as possible with the CRT - yoke and purity and convergence magnets. The connectors to the yoke may need to be changed but this may be the least of your problems. Difference in yoke impedance and other characteristics may result in anything from incorrect size to a truly spectacular melt-down! The latter is much more likely with SVGA monitors compared to similar size/deflection angle TVs.

Where the neck size is the same, the yoke can be moved from one CRT to the other but you will have to do a complete purity and convergence set up and even then you may have uncorrectable convergence errors. See the section: Swapping of deflection yokes.

(From: J. G. Simpson (ccjgs@cse.bris.ac.uk).)

Monitors are generally designed by choosing a CRT, then the EHT, then designing a yoke to scan the CRT, then designing a driver circuit to drive the yoke.

In a CRT test lab it's common to have variable supplies for EHT and other voltages, a small selection of yokes, and variable amplitude drive circuits.

EHT affects scan sensitivity, brightness, spot size. You can't get high brightness and small spot size on a large monitor with 3 kV of EHT. Virtually every variable has some effect on convergence. Spot size is important, in as much as you want most of it on the phosphor and not the shadow mask.

Provided the neck size is the same you can swap tubes in yokes but don't expect it to work very well. Different tube manufacturers may use radically different gun structures. A given yoke and its driver may give underscan or overscan and it's pretty well certain that convergence will be way off.

The military spends a small fortune on trying to get the drop into the yoke and it flies with no adjustment or convergence CRT. For the rest of us swapping a CRT is a pain in the butt.

Decayed glue in electronic equipment

Larger components like electrolytic capacitors are often secured to the circuit board with some sort of adhesive. Originally, it is white and inert. However, with heat and age, some types decay to a brown, conductive and/or corrosive material which can cause all sorts of problems including the creation of high leakage paths or dead shorts and eating away at nearby wiring traces.

The bottom line: Most of the time, this stuff serves no essential purpose anyhow and should be removed. A non-corrosive RTV or hot-melt glue can be used in its place if structural support is needed.

Repair parts sources

For general electronic components like resistors and capacitors, most electronics distributors will have a sufficient variety at reasonable cost. Even Radio Shack can be considered in a pinch.

However, for consumer electronic equipment repairs, places like Digikey, Allied, and Newark do not have the a variety of Japanese semiconductors like ICs and transistors or any components like flyback transformers or degauss Posistors.

See the document: Major Service Parts Suppliers for some companies that I have used in the past and others that have been recommended.

For those hard-to-find or overpriced TV replacement boards, modules, or other parts, try:

Introduction

Scope of This Document

This document contains a collection of information relating to CRT (picture tube) construction, characteristics, problems, maintenance, troubleshooting, and repair. This was originally from the TV and monitor repair guides of the Sci.Electronics.Repair FAQ but has been moved here due to its being of general interest.

Most new CRT related information originating on the sci.electronics.repair, comp.sys.ibm.pc.hardware.video, or other USENET newsgroups will be included here rather than in those other documents.

Related Documents

The following may be of interest and cover many relavent topics related to CRT based equipment:

- Safety Guidelines for High Voltage and/or Line Powered Equipment.
- Notes on the Troubleshooting and Repair of Computer and Video Monitors.
- Notes on the Troubleshooting and Repair of Television Sets.
- Performance Testing of Computer and Video Monitors.
- Notes on Approaches to using Fixed Frequency Monitors on PCs.
- Notes on Video Conversion.

Additional Information on CRTs

The PC Technology Guide has some information with nice diagrams on both CRT and flat panel displays. This site is well worth visiting to get an idea of the construction, operation, and problems for a variety of display technologies.

(From: David Moisan (dmoisan@shore.net).)

I've seen a few such pictures and I was fortunate enough to find a book on color CRTs that explained quite a few things:

> Color Television Picture Tubes
> Morell, Law, Ramberg, Harold
> ISBN 0-12-022151-0.

I'm not sure if its still in print but you might check out your local university library.)

If you are lucky enough to see "The Secret Life of Machines" on The Learning Channel (or was, last time I saw it), there's an episode on the secret life of the TV. It's excellent! The creator and presenter, Tim Hunkin, has a weird sense of humor but he's very well informed and quite gifted in the way he demonstrates difficult-to-explain concepts. In the opening scene, he showed off a TV that he sawed in half, showing the CRT construction very clearly. (He must have let the air into the tube, then used a diamond saw to cut it; that's the only way it could be done without glass everywhere!)

(Of course, he may not *actually* have cut a TV in half - manufacturers no doubt maintain props of this sort!)

- Back to CRT FAQ Table of Contents.

CRT Safety Issues

Electrical Safety

TVs and computer or video monitors are among the more dangerous of consumer electronic equipment when it comes to servicing. (Microwave ovens are probably the most hazardous due to high voltage at flesh frying and cardiac arresting high power.)

There are two areas which have particularly nasty electrical dangers: the non-isolated line power supply and the CRT high voltage.

Major parts of nearly all modern TVs and many computer monitors are directly connected to the AC line - there is no power transformer to provide the essential barrier for safety and to minimize the risk of equipment damage. In the majority of designs, the live parts of the TV or monitor are limited to the AC input and line filter, degauss circuit, bridge rectifier and main filter capacitor(s), low voltage (B+) regulator (if any), horizontal output transistor and primary side of the flyback (LOPT) transformer, and parts of the startup circuit and standby power supply. The flyback generates most of the other voltages used in the unit and provides an isolation barrier so that the signal circuits are not line connected and safer.

Since a bridge rectifier is generally used in the power supply, both directions of the polarized plug result in dangerous conditions and an isolation transformer really should be used - to protect you, your test equipment, and the TV, from serious damage. Some TVs do not have any isolation barrier whatsoever - the entire chassis is live. These are particularly nasty.

The high voltage to the CRT, while 200 times greater than the line input, is not nearly as dangerous for several reasons. First, it is present in a very limited area of the TV or monitor - from the output of the flyback to the CRT anode via the fat red wire and suction cup connector. If you don't need to remove the mainboard or replace the flyback or CRT, then leave it alone and it should not bite. Furthermore, while the shock from the HV can be quite painful due to the capacitance of the CRT envelope, it is not nearly as likely to be lethal since the current available from the line connected power supply is much greater.

Safe Discharging of Capacitors in TVs and Video Monitors

It is essential - for your safety and to prevent damage to the device under test as well as your test equipment - that large or high voltage capacitors be fully discharged before measurements are made, soldering is attempted, or the circuitry is touched in any way. Some of the large filter capacitors commonly found in line operated equipment store a potentially lethal charge.

This doesn't mean that every one of the 250 capacitors in your TV need to be discharged every time you power off and want to make a measurement. However, the large main filter capacitors and other capacitors in the power supplies should be checked and discharged if any significant voltage is found after powering off (or before any testing - some capacitors (like the high voltage of the CRT in a TV or video monitor) will retain a dangerous or at least painful charge for days or longer!)

The technique I recommend is to use a high wattage resistor of about 100 ohms/V of the working voltage of the capacitor. This will prevent the arc-welding associated with screwdriver discharge but will have a short enough time constant so that the capacitor will drop to a low voltage in at most a few seconds (dependent of course on the RC time constant and its original voltage).

Then check with a voltmeter to be double sure. Better yet, monitor while discharging (not needed for the CRT - discharge is nearly instantaneous even with multi-M ohm resistor).

Obviously, make sure that you are well insulated!

- For the main capacitors in a switching power supply which might be 100 uF at 350 V this would mean a

5K 10W resistor. RC=.5 second. 5RC=2.5 seconds. A lower wattage resistor can be used since the total energy in not that great. If you want to be more high tech, you can build the capacitor discharge circuit outlined in the companion document: Capacitor Testing, Safe Discharging, and Other Related Information. This provides a visible indication of remaining charge and polarity.

- For the CRT, use a high wattage (not for power but to hold off the high voltage which could jump across a tiny 1/4 watt job) resistor of a few M ohms discharged to the chassis ground connected to the outside of the CRT - NOT SIGNAL GROUND ON THE MAIN BOARD as you may damage sensitive circuitry. The time constant is very short - a ms or so. However, repeat a few times to be sure. (Using a shorting clip lead may not be a bad idea as well while working on the equipment - there have been too many stories of painful experiences from charge developing for whatever reasons ready to bite when the HV lead is reconnected.) Note that if you are touching the little board on the neck of the CRT, you may want to discharge the HV even if you are not disconnecting the fat red wire - the focus and screen (G2) voltages on that board are derived from the CRT HV.

  WARNING: Most common resistors - even 5 W jobs - are rated for only a few hundred volts and are not suitable for the 25kV or more found in modern TVs and monitors. Alternatives to a long string of regular resistors are a high voltage probe or a known good focus/screen divider network. However, note that the discharge time constant with these may be a few seconds. Also see the section: Additional Information on Discharging CRTs.

  If you are not going to be removing the CRT anode connection, replacing the flyback, or going near the components on the little board on the neck of the CRT, I would just stay away from the fat red wire and what it is connected to including the focus and screen wires. Repeatedly shoving a screwdriver under the anode cap risks scratching the CRT envelope which is something you really do not want to do.

Again, always double check with a reliable voltmeter!T

Reasons to use a resistor and not a screwdriver to discharge capacitors:

1. It will not destroy screwdrivers and capacitor terminals.

2. It will not damage the capacitor (due to the current pulse).

3. It will reduce your spouse's stress level in not having to hear those scary snaps and crackles.

Additional Information on Discharging CRTs

You may hear that it is only safe to discharge from the Ultor to the Dag. So, what the @#$% are they talking about? :-).

BTW, don't wash your CRTs even if the Maid complains about the filth until you have confirmed that your 'Dag isn't water soluble (maybe that's why it has 'aqua' in the name!). It may all come off! Wipe off the dirt and dust with a cloth (and stay away from the HV connector or make sure it is discharged first!).

(From: Asimov (mike.ross@juxta.mnet.pubnix.ten).)

'Dag' is short for Aquadag. It is a type of paint made of a graphite pigment which is conductive. It is painted onto the inside and outside of picture tubes to form the 2 plates of a high voltage filter capacitor using the glass in between as dielectric. This capacitor is between .005uF and .01uF in value. This seems like very little capacity but it can store a substantial charge with 25,000 volts applied.

The outside "dag" is always connected to the circuit chassis ground via a series of springs, clips, and wires around the picture tube. The high voltage or "Ultor" terminal must be discharged to chassis ground before working on the circuit especially with older TV's which didn't use a voltage divider to derive the focus potential or newer TV's with a defective open divider.

Warning about disconnecting CRT neck board

Some manufacturers warn against powering a TV or monitor CRT without the CRT neck board connected. Apparently, without something - anything - to drain the charge resulting from the current flow due to residual gas ions inside the CRT, the shortest path may be through the glass neck of the tube to the yoke or from the pins outside the CRT to whatever is nearby. There aren't many ions in a modern CRT but I suppose a few here, a few there, and eventually they add up to enough to cause a major disaster at least on some CRTs.

This is probably not a problem on small CRTs but for large ones with high high voltages and high deflection angles where the glass of the neck is very thin to allow for maximum deflection sensitivity, the potential does exist for arcing through the glass to the yoke to occur, destroying the CRT.

There is really no way to know which models will self destruct but it should be possible to avoid such a disaster by providing a temporary return path to the DAG ground of the CRT (NOT SIGNAL GROUND!!) via the focus or G2 pins preferably through a high value high voltage rated resistor just in case one of these is shorted.

This probably applies mostly to large direct-view TVs since they use high deflection angle CRTs but it won't hurt to take appropriate precautions with video and computer monitors as well.

CRT Implosion Risk?

Also see the section: [Disposing of Dead TVs or Monitors (CRTs and Charged HV Capacitors)].

(From: Jeroen Stessen (Jeroen.Stessen@philips.com).)

I have checked with our CRT expert and he thinks that any 'normal' type of scratch does not pose any danger. Usual disclaimer applies ... (what is 'normal'?)

The front of the tube is much thicker and stronger than the rear. It has to be, to withstand the air pressure, because the curvature radius is so much larger. You won't break it by throwing a slipper at it. The neck is in fact very easy to break, usually without causing injuries to anyone.

Normally, if the tube should implode, the rimband (the tensioned steel band around the rim of all modern CRTs of any size) prevents the glass from flying outward too far. Every tube type has to pass tests in which it is deliberately imploded and it is checked whether any large shrapnel flies too far out.

What *is* very dangerous is a CRT with its rimband missing, or a CRT which never had a decent rimband in the first place (like some dubious Russian-made samples we once saw). Such a tube should not be handled at all. NEVER ever attempt to remove the rimband for and reason!

I just saw a picture tube that was broken due to dropping the (entire) TV on one corner. In the cone (the backside) there are open cracks of some 3 feet length in total. Nevertheless all the glass is still in its original place and it looks as if no glass has flown outward. The faceplate is still intact. So in this case nobody would have got hurt. I remember reading about Americans (who else?) who tried to shoot CRT's with smaller rifles, with little or no success.

Does this comfort you? Get out the shotgun and have a go at it!

Or, perhaps, the following:

(From: Ren Tescher (ren@rap.ucar.edu).)

Our 6 month old 20" SGI color monitor (model GDM-20D11) lost a fight with a fork lift. The case is intact, the CRT probably still has a vacuum, but the outer layer of glass on the screen is shattered.

Picture Tube Implosion IS Possible - But You Really Need To Work at It!

As noted elsewhere in this document, picture tube implosion is a hazard but under normal conditions, quite unlikely. Someone wrote:

> "I heard somewhere that in the early days of TV, the tubes had a tendency to implode at the drop of a hat. (Due to poor design?) In order to prevent flying glass, the sets had a plastic sheet in front of the screen. Obviously, modern sets no longer have this. How safe are modern CRT screens in terms of impact damage etc?"

Well, it isn't quite as simple as that..... However, even if CRT implosion is one of those highly unlikely events, the downside is that should it occur in just the wrong way, the consequences can be disastrous. So, I wouldn't depend on the experiences below to guide you! Treat a CRT about the same way you would an armed nuclear bomb. OK, well maybe just 10 sticks of dynamite. :-)

(From: Dan Evens (dan.evens@hydro.on.ca).)

In high school, our electronics teacher did a demo for each class. He saved out an old black-and-white tube for each class and set up a place to break it. Put the tube on the ground by a brick wall, with a hammer suspended on a wire from the top of the wall. Did it on the driveway so that the glass would be easier to pick up. The tube was placed image-side down.

First he pulled the hammer back about 20 feet and just let it go. It bounced off the tube. This was to show that such tubes are pretty tough. Then he pulled the hammer back and gave it a pretty good shove, turning his back to the tube and moving quickly away from it. (Let's face it, the guy could probably have found a safer way to do this.)

Palm sized chunks of glass flew 50 feet. The noise was quite impressive. The thickness of the image plate of the tube was also quite impressive. Kind of looked like a porthole on a submarine. This was from the tube of a small black-and-white TV, about 14 inches or so. One of the larger colour models might be a LOT more violent.

If I was handling these things in such a way as to have the possibility of dropping one, I'd insist on body armor and face protection. And if it involves a picture tube, I insist on competent trained professionals for service.

(From: Matthias Meerwein (Matthias.Meerwein@rt.bosch.de).)

They ARE quite safe. I've got several TVs and computer monitors in for repair that had been dropped. None of them had an imploded CRT. The damage encountered ranged from:

- Broken circuit boards, often around the flyback transformer (the most heavy weight part on the board) - This is quite easily repairable.

- Shadow mask inside the tube knocked out of position (mostly in trinitron tubes due to their heavy aperture grille construction) - this renders the tube (and thus usually the set) a dumpster candidate.

- Neck of tube broken of (usually when the set hit the floor back end first) - obviously junk.

Furthermore, I did some experimentation with junk sets:

- 26 inch color TV with back panel removed placed face-down under a bridge. Dropped a ~10 pound brick from top of the bride (about 10 ft high) into the glass funnel of the tube. Result: Funnel of tube shattered, faceplate intact. All glass shards (most of them rather large) were lying inside the set's cabinet - no flying glass.

- 14 inch B/W computer monitor tube dropped from the second story onto concrete floor, hitting the ground faceplate-first. Result: tube shattered into thousands of small glass particles (the largest ones were about one inch in size), but all debris was located on one heap - none of them traveled farther than about three feet.

Conclusion: According to my experience, spectacular picture tube implosions are something like cars in movies that explode upon roll-over, hitting a tree or driving down the cliffs: an urban legend.

(From: Clifton T. Sharp Jr. (agent150@spambusters.ml.org).)

With today's tubes, that's more or less true (although walking through a picture tube plant can be instructive as you hear the exploding tubes). With older tubes it was a hazard. With pre-1960 tubes it was a big one. My old boss in the TV service, who I trusted not to exaggerate about such things, told me stories of setting a picture tube near a second-floor window, having them fall to the sidewalk and literally blow a hole in the sidewalk. I can tell you factually and first-person that although he took few precautions with other things, when he had to "pop" a picture tube in the dumpster he never ever ever did it without safety glasses, a shield and a six-foot piece of heavy pipe. (I stopped working there around 1973.)

Risks from CRT Scratches?

A really deep long scratch or gouge on the CRT face should be considered a serious safety hazard as it may reduce the structural integrity and increase the risk of implosion. However, you would likely need a hammer and chissel or diamond tipped tool to make scratches that deep. It is very unlikely that such scratches could come from any reasonable normal use. Dropping it from a cliff, deliberate use of a glass cutter, the use of a really really BIG hammer, or 12 gauge shotgun, might perhaps be sufficient.

This is more of a concern for modern CRTs that usually have 'integral implosion protection' - that steel rimband around the outside near the front. Older CRTs used either (1) a separate safety shield - that laminated glass plate in front of your grandmom's TV - or (2) a second contoured glass panel bonded to the actual tube face. In both of these cases, the second panel is protective and cosmetic but is not part of the structure of the CRT. Therefore, any damage to it does not significantly compromise the tube. In the case of modern CRTs, the steel band in conjunction with the basic tube envelope is used to maintain the integrity of the overall CRT. In addition should implosion occur as a result of catastrophic damage, the rimband will reduce the range and velocity of flying debris.

Also see the section: CRT Implosion Risk?.

BTW, scratches in the CRT have absolutely no effect on X-ray emission. X-rays are blocked long before they come anywhere near the surface and glass has very little effect on their direction. Any scratch deep enough to have any detectable effect on X-ray emission (actually, it would need to be an inch deep gouge) would have caused the tube to implode.

Disposing of Dead TVs or Monitors (CRTs and Charged HV Capacitors)

I don't know what the law says, but for safety, here is my recommendation:

Treat the CRT with respect - the implosion hazard should not be minimized. A large CRT will have over 10 tons of air pressure attempting to crush it. Wear eye protection whenever dealing with the CRT. Handle the CRT by the front - not the neck or thin funnel shaped envelope. Don't just toss it in the garbage - it is a significant hazard. The vacuum can be safely released (Let out? Sucked in? What does one do with an unwanted vacuum?) without spectacular effects by breaking the glass seal in the center of the CRT socket (may be hidden by the indexing plastic of the socket). Cover the entire CRT with a heavy blanket when doing this for additional protection. Once the vacuum is gone, it is just a big glass bottle though there may be some moderately hazardous materials in the phosphor coatings and of course, the glass and shadow mask will have many sharp edges if it is broken.

In addition, there could be a nice surprise awaiting anyone disconnecting the high voltage wire - that CRT capacitance can hold a charge for quite a while. Since it is being scrapped, a screwdriver under the suction cap HV connector should suffice.

The main power supply filter caps should have discharged on their own after any reasonable length of time (measured in terms of minutes, not days or years).

Of course around here, TVs and monitors (well, wishful thinking as I have yet to see a decent monitor on the curb) are just tossed intact which is fortunate for scavengers like me who would not be happy at all with pre-safed equipment of this type!

(From: Jeroen Stessen (Jeroen.Stessen@philips.com).)

We have a procedure for disposing of used CRT's. The vacuum must be broken to avoid future implosion, like when it will be crushed by the dumpster truck press. That's NOT funny! One method is to punch or drill a small hole in the anode contact, which is made of a soft metal. But take care of the electrical discharge of the aquadag capacitance first!!!

The other method is to break the stem in the centre of the socket pins. This is the stem through which the tube was pumped empty during manufacturing. It breaks off easily (after you have removed the plastic part around the pins).

You want to avoid making too large holes, like for example from chopping off the entire neck in one blow with a hammer.

- Back to CRT FAQ Table of Contents.

General CRT Construction and Characteristics

Why is the CRT Still Dominant?

Currently, most TVs and computer monitors are still based on the Cathode Ray Tube (CRT) as the display device. However, many hand-held TVs, portable equipment, laptop computers, and the screens inside video projectors now use flat panel technology, mostly Liquid Crystal Displays - LCDs. These are a lot less bulky than CRTs, use less power, and have better geometry - but suffer from certain flaws.

First, the picture quality in terms of gray scale, color, and brightness is generally inferior to a decent analog monitor. The number of distinct shades of gray or distinct colors is a lot more limited. They are generally not as responsive as CRTs when it comes to real-time video which is becoming increasingly important with multimedia computers. Brightness is generally not as good as a decent CRT display. And last but not least, the cost is still much much higher due both to the increased complexity of flat panel technology and lower production volumes (though this is certainly increasing dramatically). It is really hard to beat the simplicity of the shadow mask CRT. For example, a decent quality active matrix color LCD panel may add $1000 to the cost of a notebook computer compared to $200 for a VGA monitor. More of these panels go into the dumpster than make it to product do to manufacturing imperfections.

A variety of technologies are currently competing for use in the flat panel displays of the future. Among these are advanced LCD, plasma discharge, and field emission displays. Only time will tell which, if any survives to become **the** picture-on-the-wall or notepad display - at reasonable cost.

At least one company is about to introduce a 42 inch diagonal HDTV format flat plasma panel multisystem color TV/monitor which will accept input from almost any video or computer source. Its price at introduction will be more than that of a typical new automobile - about $15,000! :-) Thus, at first, such sets will find their way into business conference rooms and mansions rather than your home theater but prices will drop over time.

Projection - large screen - TVs and monitors, on the other hand, may be able to take advantage of a novel development in integrated micromachining - the Texas Instruments Inc. Digital Micromirror Device (DMD). This is basically an integrated circuit with a tiltable micromirror for each pixel fabricated on top of a static memory - RAM - cell. This technology would permit nearly any size projection display to be produced and would therefore be applicable to high resolution computer monitors as well as HDTV. Since a reflective medium is used in this device, the light source can be as bright as needed. Commercial products based on the DMD are beginning to appear.

Comparison of CRT Types

> "Could someone please help to elucidate the comparative advantages of each technology? I know how they work but do not know which is advantageous and why."

(From: Jeroen Stessen (Jeroen.Stessen@philips.com).)

Trinitron is Sony technology. The shadow mask (called the aperture grille) consists of vertical wires under tension. The mask is always straight in the vertical direction and curved in the horizontal direction, thus the shape is a cylinder. The tube surface is also cylindrical, which causes some strange effects, particularly funny mirror reflections of yourself. Because the wires are under a lot of tension, the internal tube structure must be very strong and thus relatively heavy. Because the glass surface is cylindrical instead of spherical, the glass must be thicker and heavier too, to withstand atmospheric pressure.

Heavier always equates to more expensive!

The electron gun construction is also different: there are still 3 guns (not one as some may thing but the 3 guns share one main lens. (The assembly of focusing grids is called a lens, in analogy to the optical principle.) There are still 3 cathodes and 3 G1s, as usual. The large diameter lens has the advantage of less spherical aberration (and thus a sharper spot) but the disadvantage of large physical length which means a deeper cabinet.

In the deflection coil design another compromise is found between spot quality, purity and convergence. As a result horizontal convergence must be helped by an auxiliary dynamic convergence waveform (on an extra convergence coil?). This adds to cost and can occasionally give an interesting failure of the horizontal convergence.

The best non-Trinitron (or clone) CRTs use a conventional shadow mask made of Invar - originally Matsushita technology; Philips uses it too. The shadow mask is of the standard shape (spherical metal plate with holes in it) but it is made of a special alloy with a 7 times lower coefficient of thermal expansion than regular iron. This allows a brighter picture with less purity errors.

The problem with regular shadow masks is 'doming'. Due to the inherent principle of shadow masks, 2/3 or more of all beam energy is dissipated in the mask. Where static bright objects are displayed, it heats up several hundred degrees. This causes thermal expansion, with local warping of the mask. The holes in the mask move to a different place and the projections of the electron beams will land on the wrong colours: purity errors. The use of invar allows about 3 times more beam current for the same purity errors. See the section: What is Doming?.

Combating purity errors is a necessity due to 2 trends:

- Flatter picture tubes: flatter shadow masks are more sensitive to doming
- Darker (glass) picture tubes: this gives more contrast but more beam current is needed for enough brightness

The trinitron aperture grill shadow mask is inherently insensitive to doming as long as the tension in the wires remains positive. If the wires become too long then they become more sensitive to microphony (try tap the cabinet...). The vertical wires are connected in several places by thin horizontal wires. Some people complain about seeing faint shadows of these wires.

To summarize: Trinitron monitors are probably heavier, larger, more expensive, maybe better on purity, and maybe better on focus than other monitors, with or without invar shadow masks. There are excellent monitors other than Trinitron too... I suppose the Coke-Pepsi comparison is true.

Color CRT Construction

For a couple introductory on-line articles about (mostly) CRTs, see:

- High Tech Tubes, Popular Mechanics, April 1997.
- Display.

All the color CRTs found in TVs and computer and video monitors utilize a shadow mask or aperture grill a fraction of an inch (1/2" typical) behind the phosphor screen to direct the electron beams for the red, green, and blue video signals to the proper phosphor dots. Since the electron beams for the R, G, and B phosphors originate from slightly different positions (individual electron guns for each) and thus arrive at slightly different angles, only the proper phosphors are excited when the purity is properly adjusted and the necessary magnetic field free region is maintained inside the CRT. Note that purity determines that the correct video signal excites the proper color while convergence determines the geometric alignment of the 3 colors. Both are affected by magnetic fields. Bad purity results in mottled or incorrect colors. Bad convergence results in color fringing at edges of characters or graphics.

The shadow mask consists of a thin steel or InVar (a ferrous alloy) with a fine array of holes - one for each trio of phosphor dots - positioned about 1/2 inch behind the surface of the phosphor screen. With some CRTs, the phosphors are arranged in triangular formations called triads with each of the color dots at the apex of the triangle. With many TVs and some monitors, they are arranged as vertical slots with the phosphors for the 3 colors next to one another.

An aperture grille, used exclusively in Sony Trinitrons (and now their clones as well), replaces the shadow mask with an array of finely tensioned vertical wires. Along with other characteristics of the aperture grille approach, this permits a somewhat higher possible brightness to be achieved and is more immune to other problems like line induced moire and purity changes due to local heating causing distortion (doming) of the shadow mask.

However, there are some disadvantages of the aperture grille design:

- Weight - a heavy support structure must be provided for the tensioned wires (like a piano frame).

- Price (proportional to weight).

- Always a cylindrical screen (this may be considered an advantage depending on your preference.

- Visible stabilizing wires which may be objectionable or unacceptable for certain applications.

Apparently, there is no known way around the need to keep the fine wires from vibrating or changing position due to mechanical shock in high resolution tubes and thus all Trinitron monitors require 1, 2, or 3 stabilizing wires (depending on tube size) across the screen which can be see as very fine lines on bright images. Some people find these wires to be objectionable and for some critical applications, they may be unacceptable (e.g., medical diagnosis).

Assembly of Color CRTs

(Portions from: Jeroen H. Stessen (Jeroen.Stessen@philips.com).)

The following is a greatly simplified description of the general process of color (shadow or slot mask) CRT construction. Trinitrons should be basically similar.

The screen and envelope glass pieces are molded separately and then glued (Epoxied?) together as one of the last steps of assembly prior the baking and evacuation. (You will note this seam if you examine the envelope of a color CRT near the front.)

The shadow mask is manufactured through a photo etching process. No, there are no workers responsible for punching all those holes! Since a position error of even a tiny fraction of a mm would result in purity errors, each shadow mask is unique for its faceplate. They are not interchangeable. To facilitate the following steps, it can easily be mounted and removed (essentially clicked in place) during tube production. Registration pins assure precise alignment.

- For each of the phosphor colours (and optional black matrix) one phosphor layer is deposited followed by one photoresist layer.

  At least one manufacturer adds some steps for the Superbright tubes. They put 3 different colour filters between the glass and the phosphor. In terms of contrast that tube is a definite killer.

- The shadow mask for that CRT (unique) is then mounted - clicked in place.

- An intense point source of light is mounted at the location of the effective center of deflection for the electron gun associated with that phosphor.

- The photoresist is exposed to light.
- The shadow mask is removed and the excess resist (not exposed to light) and phosphor is washed away.

These steps are repeated for the red, green, and blue phosphors, and the optional (but very common) black matrix surround.

Using the shadow mask repeatedly in this manner guarantees close registration. How else would you lay down a million individual dots in exactly the right place - paint by numbers? :-).

Then, an aluminum overcoat is deposited over the phosphor/black matrix. This has several functions:

- Provide the return path for the electron beam - connected to the EHT 2nd anode.

- Reduces backscattering or secondary emission. Electrons that bounce back from either the shadow mask or the screen may hit a phosphor elsewhere and thus cause unwanted white light. That reduces contrast and colour purity.

- A side benefit is that it blocks negative ions from residual air molecules from hitting the phosphors. These might result in an unsightly blemish in the center of the screen since they are much heavier (many thousands of times the mass) than electrons and are not deflected very much. (This was a problem in the early days of CRT production but apparently not with present high vacuums and getters to clean up whatever is left.)

The shadow mask is then mounted for a final time and the faceplate, envelope (with its electron gun assembly already fused to it) are mated. At this point, it is ready for the final baking and evacuation.

The tube is evacuated through the thin stem that is located in the middle of the socket. That takes several hours at the vacuum pumps. The stem is then sealed by heating and melting.

The getter - part of the electron gun assembly - is then 'activated' via induction heating from a coil external to the next of the CRT. This vaporizes and deposits a highly active metal on the interior of the glass of the neck. The getter material adsorbs much of any remaining gas molecules left over from the evacuation of the tube. The getter material is normally silvery - if it changes to red or milky white, the tube is probably gassy or up to air.

When the tube is ready it is matched with a deflection coil that provides optimum purity. It takes some ingenuity to get a good match between using a light for exposure which matches the behaviour of the future electron optical system, in order to get good purity.

Amazingly, this basic process has not changed in any fundamental way since the invention of the shadow mask CRT!

However, Computer Aided Design (CAD) has had a major impact on the design of the electron optics. The working of the electron gun and deflection system is now much more predictable thanks to advanced computer simulation. This has reduced the number of active correction circuits for focus, geometry and convergence to almost zero.

CRT Fine Tuning

Once the CRT is sealed, baked, evacuated, etc., the job is not yet done!

(From: Jeroen H. Stessen (Jeroen.Stessen@philips.com).)

They still need to match the finished tube with a deflection coil that will give adequate purity performance and then they need to fiddle with magnets (multipole rings around the neck and sometimes other magnets all over the cone) to improve it further. And even then many tubes need active correction for convergence and/or geometry.

Only after all that correction can you call the yield high. (But you should see their scrap yard, good thing that glass recycles well...)

Northern/Southern Hemisphere Corrections and Adjustments

The vertical component of the earth's magnetic field varies in intensity and polarity (N/S) as one moves from the North pole over the equator and to the South pole. It is maximum at the poles and decreases to zero at the equator. The total strength is not large - after all it is less than the total magnitude of the earth's magnetic field of about .5 Gauss (.00005 Tesla). However, it is enough to affect the trajectory of the electron beam(s) slightly.

For monochrome monitors and B/W TVs, this will result only in a slight shift in position or rotation of the picture depending on the orientation of the CRT with respect to the earth's magnetic field. For the most part such effects will not be significant enough to be objectionable.

However, for high resolution color monitors and even some color TVs, the result of transporting the unit from the hemisphere from which it was manufactured or set up to a location in the opposite hemisphere may be uncorrectable purity problems or excessive sensitivity to local magnetic fields.

Note that is it quite possible that you will never encounter any of these problems. The extent to which your particular monitor or TV is affected depends on many factors - many of which you have no control over.

(From: Bob Myers (myers@fc.hp.com).)

For many monitors - especially the larger sizes, such as 21" - there is a subtle difference in the CRT itself which may mean that a unit with the wrong tube could NOT be adjusted to be within specifications when used in the 'wrong' hemisphere.

(From: Jeroen Stessen (Jeroen.Stessen@philips.com).)

There are two types of adjustments:

- The passive ones that are done in the picture tube factory and
- The active ones that are done by the setmaker a/o the customer.

In the factory inside the neck of every (Philips) tube a metal ring is permanently magnetized to create a multipole correction field. Then each tube is matched with a deflection yoke to achieve optimum colour purity. It is possible that a couple of yokes must be tried in succession. This matching is done under specific ambient magnetic field conditions. On oriental tubes you will often see little permanent magnets added to achieve further fine correction of landing and/or convergence. When the tube is within landing specification it is shipped to the setmaker.

Depending on the sophistication of the circuitry in the (television or monitor) set, the setmaker can adjust geometry and sometimes convergence (if there is a set of convergence coils present). If there is a rotation coil present then this may also improve the landing a bit.

In the 'digital monitors' there are flexible waveform generators to adjust the corrections. There may be further adjustments possible for the uniformity of the colour point and brightness. This gives a place-dependent modulation of the 3 beam currents, it does nothing to improve the landing.

The most expensive monitors (large screen, fine phosphor pitch, very critical on landing) may have active magnetic field compensation in all 3 directions with electronic magnetic field sensors for automatic adjustment. These monitors should be mostly insensitive to the earth magnetic field. (This technology was originally invented for the use of CRT displays on board of jet fighter planes, which tend to turn relative to the earth...)

All other monitors will degrade picture quality when the degaussing is not able to completely compensate for the earth magnetic field. With a tube built for the wrong hemisphere it is possible that the effect of the vertical component of the earth magnetic field will give a residual landing error. This can not be corrected by turning any of the available adjustments, digital or not. Re-alignment might become a very costly job.

Tubes for All Nations

(From: Jeroen Stessen (Jeroen.Stessen@philips.com).)

CRT Manufacturers actually make different versions of their tubes for TV's for the northern and southern hemisphere, and sometimes a 3rd neutral type. These are so-to-say precorrected for the uncompensated field. (Note that the term 'tube' here includes much of the convergence hardware as well - not just what is inside the glass.)

I remember when we exported projection televisions from Belgium to Australia, a couple of years ago. They all had to be opened on arrival to re-adjust the rotation settings on the convergence panel, due to the different magnetic field in Australia. Projection TV's don't have degaussing (there is nothing to degauss), and the customer can only adjust red and blue shift, not rotation.

Our CRT application group has a "magnetic cage". This is a wooden cube (approx. 2 meter long sides) with copper coils around each of the 6 surfaces. With this they can simulate the earth magnetic field for every place on earth (as indicated on a map on the wall).

During production and adjustment of the tube, the beam landing is optimized for the field condition in which it will be used later. There may be different tube specifications for north, south and equator ("neutral"). If you choose to use it in different conditions then the landing reserve will be diminished and you will suffer sooner from colour purity errors. I'm not so sure if the convergence would be a primary problem, maybe yes.

With a dotted shadow mask, also the horizontal component of the field matters, which is bad because it also depends on which direction you orient the display. This too will eat away from your landing reserve. How critical it all is depends on tube size (bigger is worse) and on dot pitch (smaller is worse). Workstation monitors are most critical.

Using a Helmholtz cage you can test or optimize for a particular place on earth. The most expensive monitors come with their own built-in Helmholtz cage and magnetic sensors to always create a field-free space.

Another interesting bit of trivia:

B&O (Bang & Olufsen of Danmark) use Philips picture tubes in their beautifully designed cabinets. In order to facilitate a more narrow styling they decided to mount the tube upside-down, so they don't need safety clearance for the EHT on top. As a consequence they needed a southern-hemisphere tube for the northern hemisphere! So here is a hint for a solution to you all...

(From the editor).

In light of the above discussion, the following makes perfect sense:

(From: Nigel Morgan (nigel@wycombe.demon.co.uk).

When I was in the TV trade some 20 years ago, I was introduced to a model with a PYE badge on which differed in one significant detail: on all TV sets I'd seen to that date the tube had the blue gun uppermost and the EHT connector at the top of the tube. Thorn TV sets mounted the tube upside-down for some reason so that the EHT connector was at the bottom along with the blue gun, but these PYE sets had the blue gun at the bottom, but the EHT connector was at the top! When I asked about this, I was told that the tubes used in the PYE sets were 'Southern Hemisphere tubes. I never could decide whether this was genuine or BS!

(From: Terry DeWick (dewickt@esper.com).)

The magnetic field for South America is about 0 to -100 mG while the U.S. runs 400 to 500 mG (milli Gauss). For a CRT to set up correctly the gun is offset 1 to 1.5 mm left of center for the 500mG field and 1 mm to the right for 0 mG this way the purity will be centered and the yoke tilt will be centered making setup easy during production. A North American CRT can be set up in South America but there is a chance that it will not set up well with excessive purity correction and or wedging set to the extremes.

So What Does It Mean to Have a Trinitron CRT?

Trinitron is a CRT technology developed by Sony. The patent has recently expired and therefore other manufacturers are free to offer similar CRTs. The CRT uses a set of fine vertical wires called an aperture grill instead of a steel shadow mask to separate the R, G, and B electron beams and force them to strike only the appropriate colored phosphors. This in conjunction with an in-line set of electron guns is supposed to provide a brighter image with simpler convergence and purity adjustments. It should be brighter because the percentage of open space of the aperture grill is higher then that of a shadow mask. Other adjustments should be less critical in the vertical direction. In addition, since there is no imposed structure in the vertical direction, undesirable moire patterns caused by scan line pitch compared with the shadow mask dot pitch should be eliminated.

You can recognize a Trinitron tube by the fact that the picture is made up of fine vertical stripes of red, green, and blue rather than dots or slots. The shadow mask in all other kinds of common CRTs are made up of either dots (nearly all good non-Trinitron computer monitors) or slots (many television sets). The Trinitron equivalent is called an aperture grill and is made of around a thousand vertical wires under tension a fraction of an inch behind the glass faceplate with its phosphor stripes.

Several photos of a disemboweled Trinitron aperture grille can be found at James Sweet's Sony/Trinitron Directory along with some screen shots showing the symptoms resulting from a monitor falling on its face. :(

Since the aperture grill wires run the full height of the tube, there are 1 or 2 stabilizing wires to minimize vibration and distortion of the aperture grill. These may be seen by looking closely 1/3 and/or 2/3 of the way down the tube. The larger size tubes will have 2 while those under 17 inch (I think) will only have a single wire. Many have complained about these or asked if they are defects - no they are apparently needed. You can be sure that Sony would have eliminated them if it were possible.

Another noticeable characteristic of Trinitrons is the nearly cylindrical faceplate. The radius in the vertical direction is very large compared to the horizontal. This is both a requirement and a feature. Since the aperture grill wires are under tension, they cannot follow the curve of the glass as a normal shadow mask may. Therefore, the glass must be flat or nearly flat in the vertical direction. As a selling point, this is also an attractive shape.

In the final analysis, the ultimate image quality on a monitor depends as much on other factors as on the CRT. There are many fine monitors that do not use Trinitrons as well as many not-so-great monitors which do use Trinitron tubes.

Why are There Fine Lines Across My Trinitron Monitor or TV?

These are not a defect - they are a 'feature'. :-)

All Trinitron (or clone) CRTs - tubes that use an aperture grille - require 1, 2, or 3 very fine wires across the screen to stabilize the array of vertical wires in the aperture grille. Without these, the display would be very sensitive to any shock or vibration and result in visible shimmering or rippling. (In fact, even with these stabilizing wires, you can usually see this shimmering if you whack a Trinitron monitor.) The lines you see are the shadows cast by these fine wires.

The number of wires depends on the size of the screen. Below 15" there is usually a single wire; between 15" and 21" there are usually 2 wires; above 21" there may be 3 wires.

Only you can decide if this deficiency is serious enough to avoid the use of a Trinitron based monitor. Some people never get used to the fine lines but many really like the generally high quality of Trinitron based displays and eventually totally ignore them.

Differences between Trinitron and Diamondtron CRTs

(From: Bill Nott (BNott@Bangate.compaq.com).)

Mitsubishi makes the Diamondtron under license from Sony - the subtle differences (according to Mitsubishi) are improvements in the electron gun design for spot uniformity over the CRT face. Also, for the time being, Mitsubishi has tried to introduce Diamondtron tubes in sizes which are not available as Trinitrons - to keep from directly competing, and (ostensibly) to address niches which other sizes can't address.

In order to properly evaluate a monitor, one must consider more than the tube alone - as many readers know, Trinitrons are finding their way into various manufacturer's sets, but they don't all perform the same. In todays market, it's quite possible to find a dot mask design which performs as well as (or better in some cases) the aperture grill design - IMHO every critical monitor purchase should be made by personally examining the monitor to be bought, under the intended application(s).

(BTW, all color tubes use 3 guns, including the Trinitron. Sony used to talk about a "unitized gun", but that only refers to the cathode structure. It's classical use of a misleading term to gain market awareness (looks like it works).)

(From: Someone who wishes to remain anonymous.)

I have found other differences between the Trinitron and Diamondtron tubes. Most noticeable is the grill pitch. The 21" Sony GDM-F520 is 0.22 mm. The 22" Mitsubishi (Cornerstone P1750) is 0.25 mm. For high resolution screens, this makes a difference.

I have also noticed that in a room full of Dell Trinitron monitors, no two monitors have the same color. This is not just a setup issue, the actual tubes have different colors when they are off. The darkness of the black changes.

My gut feeling is that the Dells use a Mitsubishi tube, and that the quality control is not up to Sony's. It is just a feeling, I have not done any research on this.

From what little I know, if you want the very best, you will have to pay for it, (or you get what you pay for).

Some History of In-Line Gun CRTs

(From: Thomas Maggio (staccato@gate.net).)

GE's first set was a 10 or 11 inch " "PortaColor" TV which, to the best of my memory, was introduced in the mid-60s. It was a tube chassis that made use of space saving Compactron multifunction tubes. A solid state version followed some years later I believe. If I remember correctly, the color circuit used a novel method to generate the local 3.58 MHz color signal: it used the recovered color burst to 'ring' a series crystal to produce a continuous carrier. I remember reading about all this in one of the late great "Radio-Electronics" Annual Color TV issues that I looked forward to each year back then as color TVs were dynamically evolving from many US companies.

The GE CRT did indeed use 3 in-line guns aimed at a conventional shadow mask triad phosphor screen. This simplified convergence and the CRT neck components needed. Sony uses one gun with a large common cathode to emit 3 electron beams which focus through a single large electrostatic 'lens' instead of 3 smaller ones like the GE and others used.

One last stroll down memory lane: Does anyone remember the forerunner of the Sony Trinitron? It began as the "Lawrence Tube" (named after its U.S. inventor Dr. Lawrence) then was demonstrated as the "Chromatron" (I think Paramount had some stake in it then). I don't know how the concept became Sony's property so if anyone can corroborate or correct any of my recollections, I would enjoy hearing about it. Thanks.

(From: Andy Cuffe (baltimora@psu.edu).)

I read about Sony's development of the Trinitron. Apparently Sony actually manufactured a 17" TV with a Chromatron CRT in the early 60's. It was only sold in Japan and used a very unreliable tube chassis. According to the book they all ended up being returned and Sony lost a lot of money on it. Later Sony took ideas from the GE in-line tube and the Cromatron to invent the Trinitron. They used the 3 in-line cathodes of the GE tube with the vertical phosphor stripe screen of the chromatron. The common focusing lens was a way to stay as close as possible to the single electron gun design of the chromatron. The tone of the book suggested that Sony bet the whole company on the success of the Trinitron. Apparently they were very close to licensing the shadow mask design from RCA because of the amount of money they were losing by developing their own color CRT. If anyone is interested I think the title of the book was "Sony Vision". It also had chapters on the Betamax and the development of the first solid state TV.

How Far is the Shadow Mask from the Phosphor Screen?

(Portions from: Jeroen H. Stessen (Jeroen.Stessen@philips.com).)

This is simple geometry - similar triangles (at least for a good approximation).

It is easy to do the calculations based on the distance between the electron guns and the horizontal stripe pitch of the CRT (assuming slot mask or Trinitron - just a little more trouble for dot mask to convert the dot pitch).

```
    Dot pitch: 0.3 mm
      | |
 ___________________________________ Phosphor screen
  G B R G B R G B R G B R G B    ^
       \|/                     15 mm
 - ----- ----- ----- ----- --------- Shadow mask
       /|\                       ^
      / | \                      |
     /  |  \                   350 mm
    /   |   \                    |
   /    |    \                   v
  B-gun G-gun R-gun ---------------- Electron guns (center of deflection)
        |     |
        |     |
       Gun pitch: 7 mm
```

(Cool diagram based on efforts of Jeroem Stessen.)

Be aware that both face-plate and shadow-mask are curved and that the radius of curvature is much larger than the distance to the guns. The screen is relatively flat. This too has consequences for the calculation. Oh, heck.

At the center of the screen, we have:

```
          Distance between E-guns (R-G)           Slot pitch (R-G)
     -----------------------------------------  = -----------------
      Distance from deflection center to mask      Mask to screen
```

For a typical 25 inch TV CRT with a .9 mm slot pitch (.3 mm between adjacent stripes) and 7 mm between adjacent guns we have a ratio of about 23:1.

For a distance of 350 mm between the center of deflection and mask, this gives us about 15 mm (~.6 inches) between the mask and the screen.

How is the Shadow Mask Mounted Inside the CRT?

(Portions from: Jeroen H. Stessen (Jeroen.Stessen@philips.com).)

The shadow mask is mounted in a diaphragm. The diaphragm is mounted to the inside of the tube with 4 metal springs. In the old days these were bimetal springs. They have an important role for colour purity: they allow the mask to move forward as it expands due to self-heating.

Remember: it must dissipate a lot of power and there is no cool air in there...

During production the mask is mounted and removed many times to allow for etching of the phosphors. A point light source is precisely positioned at the deflection center of each gun in-turn to expose the photoresist used in laying down the phosphor dots. (I know, you thought they were painted on one spot at a time! :-)

The mask is never fastened permanently, only clicked in to place just prior to having the envelope glued to the front assembly.

As no two masks are identical, each tube is always paired with its own mask.

(From: David Moisan (dmoisan@shore.net).)

From pictures I've seen, the best way to describe the shadow mask is that it is like a picture inside its frame: The glass face is the frame and the mask is the picture it holds, so to speak. The mask is carefully designed in a frame of its own, with spring clips around the edges, so that it won't distort under the heating it gets from the electron beams (not to mention during manufacturing). There's also a magnetic shield around the inside of the bell in some tubes.

Why is the Shadow Mask or Aperture Grill Made of a Magnetic Material?

(From: Jeroen Stessen (Jeroen.Stessen@philips.com).)

The question often arises: Well, if magnetization and the need for degauss is a problem, why not make the shadow mask or aperture grille from something that is non-magnetic?

The shadow mask *must* be made of magnetic material! This may seem to be undesirable or counterintuitive but read on:

Together with the internal shielding hood it forms sort of a closed space in which it is attempted to achieve a field-free space. The purpose of degaussing is *not* to demagnetize the metal, but to create a magnetization that compensates for the earth's magnetic field. The *sum* of the two fields must be near zero! Degaussing coils create a strong alternating magnetic field that gradually decays to zero. The effect is that the present earth magnetic field is "frozen" into the magnetic shielding and the field inside the shielding will be (almost) zero. Non-zero field will cause colour purity errors.

Now you will understand why a CRT must be degaussed again after it has been moved relative to the earth's magnetic field. This will also explain why expensive computer monitors on a swivel pedestal have a manual degaussing button, you must press it every time after you have rotated the monitor.

The axial component of the magnetic field is harder to compensate by means of degaussing. Better compensation may be achieved by means of a "rotation coil" (around the neck or around the screen), this requires an adjustment that depends on local magnetic field. CRT's for moving vehicles (like military airplanes) may be equipped with 6 coils to achieve zero magnetic field in all directions. They use magnetic field sensors and active compensation, thus they don't need any degaussing function. This is too expensive for consumer equipment.

Why do CRTs Use Red, Green, and Blue rather than Red, Yellow, Blue?

So you were taught in grade school that any color could be made up of red, yellow, and blue paint. Why are these not used in CRTs?

Nearly any color that we can perceive can be made from some combination of primary colors. There are two types - additive and subtractive.

RGB are primary additive colors - anything that emits light will use these.

The three types of cone (color) recepters in the retina of the human eye have peaks (roughly) sensitive to these primary colors.

Those red, yellow, and blue primaries you used to create your works of art should actually not have been red, yellow, blue but rather magenta, yellow, cyan - close but no cigar. Red, yellow, and blue are approximations good enough for basic painting or printing but are not capable of reproducing the widest range of colors.

CMY (cyan, magenta, yellow) are subtractive colors. Printing processes and color photography use these because layers of ink or dye absorb light. Basically, each of CMY removes a single color from (RGB).

- Cyan = (green+blue) and is the complement of red.
- Magenta = (red+blue) and is the complement of green.
- Yellow = (red+green) and is the complement of blue.

The phosphors used in CRTs are not necessarily optimal - that is why some monitors or TVs may appear to have better color rendition than others.

Purpose of a Separate CRT Faceplate

The surface of the screen you see is most often part of the CRT envelope. In this case, there should be a tensioned steel band - a rimband - around the edge of the CRT near the front. The rimband is essential to assure the structural integrety of the CRT envelope against the emmense forces due to the air pressure attempting to crush it. In the event of a catastrophic event, the rimband will also reduce the range and velocity of any debrie. This is called 'integral implosion protection' by some manufacturers.

Warning: A CRT that is supposed to have a rimband but where it is missing or damaged is a serious hazard since the possibility of implosion is greatly increased and the effects of such an implosion will be more severe. However, such a situation is virtually impossible to occur on its own since the rimband is part of the mounting bracket assembly. Don't be tempted to remove the rimband for any reason unless the vacuum has been let out (in, whatever one does with a vacuum) of the CRT! Spontaneous implosion is even possible. See below for an example.

In some cases, there will be a separate faceplate. Older TVs usually had either a totally separate laminated glass plate in front of the CRT or a contoured glass panel bonded (glued) to the CRT itself. Part of its purpose is protective. It would prevent damage to the CRT in the event of a blow from a thrown object like an ashtray or shoe! In addition, it would contain the debrie in the unlikely event of an implosion resulting from some really catastrophic event.

However, the separate or bonded glass plate can also be used for cosmetic purposes to:

- Improve contrast in a bright light by using a tinted glass.
- Reduce reflection by using an anti-reflection coating.
- Iron out the bumps by using a glass plate smoother than the CRT.
- Give the impression of a flatter display by using a glass plate with a larger radius of curvature than the CRT itself.
- Give the impression of a Sony Trinitron by using a cylindrical (plastic) plate in front of a real-flat rear-projection screen.

(From: Joe (rimband@megsinet.net).)

I got my User ID from the metal band. :) Anyway, a friend of mine decided to cut the rimband off a picture tube. I wasn't there, he told me about it. This was a 25" RCA tube he wanted to fit into a Zenith TV (don't ask me why). What happened in the next few seconds after he cut the rimband, the picture tube imploded in his face, embedding the neck and yoke assembly in the ceiling, he came out with a cut about half an inch above his right eye that needed 6 stitches to close. Had that shard of glass been half an inch lower, he would be wearing an eye patch or have a glass eye for the rest of his life.

I told him what an idiot he was, he's lucky he didn't kill himself or blind himself, and also told him NEVER cut the rimband off a picture tube that has vacuum. I just wanted to add that!:)

Leaded Glass and CRT Coatings

> "Is it really true that they put lead in the CRT glass for X-ray shielding? What is the transparent conductive coating on the front of the CRT made of?"

(From: Bob Myers (myers@fc.hp.com).)

First - yes, the glass is leaded (or contains other "impurities") to reduce emissions. In short, it's not just straight sand. :-)

There are various proprietary formulas used to make the faceplate coating, which often acts both as a conductive layer to reduce low-frequency electric fields and as a glare-reduction layer, but one of the most popular materials for making a transparent conductive layer is indium-tin oxide, a.k.a. "ITO". Such transparent conductors are also used in LCDs and other flat-panel technologies - at least the top layer of electrodes (row or column lines) has to be transparent! As conductors go, these things aren't THAT conductive - the age of see-through power lines or Star Trek's "transparent aluminum" is not upon us (and for certain theoretical reasons CAN'T be) - but they get the job done.

Flat Versus Non-Flat CRTs

The long and the short of it is that people would like absolutely flat tubes but there are several electronics and manufacturing problems which make the production of a totally flat (or even almost totally flat) CRT a challenge:

- **Geometry correction:** As the electron beam scans across a flat faceplate, its velocity increased near the edges and corners. Without compensation, the pixels will be stretched significantly in these areas.

- **Brightness uniformity:** Likewise, this means less time on each phosphor dot and lower brightness. In addition, the electron beam hits the screen at an increasingly steep angle which further decreases the brightness for a fixed dot size.

- **Structural integrity:** A totally flat faceplate would have to be much thicker to withstand the force due to the atmosphere with respect to the vacuum inside. So, most "flat" CRTs will still have a slight spherical shape.

Compensation for the geometry and brightness problems becomes much more challenging and it's never perfect. Even a well adjusted CRT will often have a very detectable, if not obvious, variation in brightness from center to edges and corners. Scan linearity and pincushion correction require most complex and carefully adjusted circuits. The thicker faceplate means a heavier CRT and monitor.

The net effect is that for a given screen size, cost will be greater. At a normal viewing distance, the perceived advantages may be minimal. Some people may find (after having gotten used to a moderately spherical CRT) that they actually like a flat one *less* especially if the deficiencies are easily seen. Note that Sony Trinitron (and clone) CRTs are nearly flat in the vertical direction and curved in the horizontal direction. To get used to this geometry may take some time as well.

Resolution, Dot Pitche, and Other CRT Specifications

Color CRT Resolution - Focus and Dot/Slot/Line Pitch

The ability to display fine detail involves many factors including the resolution of the video source, video bandwidth, sharpness of the electron beam(s), and the dot/slot/line pitch (color only) of the CRT.

The CRT is primarily responsible for the latter two.

The focus or sharpness of the spot or spots that scan across the screen is a function of the design of the electron gun(s) in the CRT and the values of the various voltages which drive them. Focus may be adjustmented but excellent focus everywhere on the screen is generally not possible.

Sharp focus is a difficult objective - the negatively charged electrons repel each other and provide an inherent defocusing action. However, increasingly sharp focus would not be of value beyond a certain point as the ultimate resolution of a color CRT is limited by the spacing - the pitch - of the color phosphor elements. (For monochrome displays and black-and-white TVs, CRT resolution is limited primarily by the electron beam focus.)

One of three approaches are used to ensure that only the proper electron beam strikes each color phosphor. All perform the same function:

1. Dot mask - the phosphor screen consists of triads of R, G, and B, circular dots in a triangular arrangement. The shadow mask is a steel or InVar sheet filled with holes - one for triad. The dot mask has been used since the early days of color TV and is still popular today. The electron guns are also arrange in a triangular configuration.

2. Slot mask - the phosphor screen consists of triples of vertically elongated R, G, and B, stripes (actually, these are usually full vertical stripes interrupted by narrow gaps). The shadow mask is a steel or InVar sheet filled with slots - one for each triple. Ideally, the metal between the slots vertically is as thin as possible to maintain the structural stability of the slot mask sheet. This type of tube seems to be very popular in TVs but also shows up in some computer monitors. The electron guns are in line which makes some of the setup adjustments less critical compared to the dot mask CRT.

3. Aperture grille - the phosphor screen consists of triples of vertical R, G, and B, lines running the full height of the screen. The aperture grille is a series of tensioned steel wires running vertically behind the phosphor stripes - one for each triple. The aperture grille - until recently under patent protection and therefore only available in the Trinitron from Sony - is found in both TVs and monitors. The electron guns are also in line.

The pitch of a color CRT refers to the spacing of phosphor triads or triples. For dot mask CRTs, this parameter is relevant in both the horizontal and vertical direction. For slot mask and aperture grille CRTs, the pitch is only relevant in the horizontal direction.

Dot pitches as small as .22 mm are found in high resolution CRTs. Very inexpensive 14" monitors - often bundled with a 'low ball' PC system - may have a dot pitch as poor as .39 mm. This is useless for any resolution greater than VGA. Common SVGA monitors use a typical dot pitch of .28 mm. TVs due to their lower resolution have pitches (depending on screen size) as high as .75 mm - or more.

Obviously, with smaller screens and higher desired video source resolutions, CRT pitch becomes increasingly important. However, it isn't a simple relationship like the size of a pixel should be larger than the size of a dot triad or triple, for example. Focus is important. All other factors being equal, a smaller pitch is generally preferred and you will likely be disappointed if the pitch is larger than a pixel. As the pixel size approaches the phosphor triad or triple size, Moire becomes more likely. However, the only truly reliable way to determine whether Moire will be a problem with your monitor is to test it at the resolutions you intend to use.

A Discussion of Issues Relating to Monitor and CRT Resolution

Many factors influence the effective resolution of a monitor but the CRT dot or slot mask or aperture grill is the ultimate limit (though it may still be possible to use a monitor at a resolution which exceeds the that of the CRT). However, as the pixel spacing approaches that of the CRT, moire effects are likely to be more of a problem.

(From: Bob Niland (rjn@csn.net).)

Dot pitch is the major component in the actual resolution of the monitor. Most monitor vendors quote the highest resolution signal their monitor will sync to irrespective of whether or not the tube can resolve it. Indeed, it often cannot resolve the highest (and even second highest) claimed display resolution.

(From: Bob Myers (myers@fc.hp.com).)

Very true. On the other hand, things may not be quite as bad as what the numbers appear to say, sometimes.

(From: Bob Niland (rjn@csn.net).)

It's no accident that monitor size is specified in inches, and dot pitch in mm. The vendors don't want to make it easy for you to know what the geometry of their phosphor triads actually is, i.e. how many RGB dot triplets there are across and down the screen."

(From: Bob Myers (myers@fc.hp.com).)

Well, I wouldn't want to accuse the tube industry of deception. Expressing diagonal sizes in inches comes from long-standing tradition. Expressing pitch in millimeters is actually a relatively new practice in comparison, and isn't too unusual when you realize that most tube manufacturers - esp. those in the Far East - actually spec their tube diagonals in metric terms. For instance, Matsushita (Panasonic) has listed their "15 inch visual" color CRTs as "420xxxx" models, 420 being the overall diagonal in mm (16.54")

(From: Bob Niland (rjn@csn.net).)

Here's how to figure it out. You need first to know:

- The diagonal 'active picture" area (APD). If the vendor fails to specify this, subtract 1 inch from the advertised monitor size. I.e. a '21 inch' monitor will usually have about a 20-inch usable diagonal picture area. ('PC Inches' versus 'real inches' is a topic for another time. :-)

- You need the horizontal dot pitch (HDP). The vertical and horizontal are often different (with the vertical being a smaller number). If you have been given only one number, it's probably the diagonal, and is misleading, but it is all we have to work with.

(From: Bob Myers (myers@fc.hp.com).)

Trinitron (aperture grille) tubes will never have the pitch specified as a diagonal measurement, since they have vertical stripes of phosphor. Conventional (flat-square) models will, and probably the safest conversion between diagonal and horizontal for these is to mlutiply by the cosine of 30 degrees (0.866), unless you know for sure the angle to horizontal at which the diagonal measurement was made. (It varies for different tube designs.) See the section: How to Compute Effective Dot Pitch.

(From: Bob Niland (rjn@csn.net).)

- The monitor aspect ratio (AR). This is 4:3 (or 1.33:1) for any CRT you are likely to be using.

To calculate useful horizontal resolution:

- Multiply the APD by .80 (4:3 tube).

  This is the Active Picture Horizontal size (APH) in inches.

- Multiply APH by 25.4.

  This is the APH in mm (APHmm).

- Divide the APHmm by the HDP.

  This is the useful horizontal resolution of the monitor.

  Notice that this number probably does not precisely match any common (640, 800, 1024, 1152, 1280 or 1600) resolution in use, and that it is probably *less* than what the vendor claimed.

I use a Hitachi AccuVue UX4921D (aka HM-4921-D/A-HT01) 21-inch monitor. It is a claimed 1600x1200 monitor, and having a .22 horizontal dot pitch, actually has over 1800 phosphor triads across the screen. This is rare. Most large monitors usually have 1280 or fewer triads across the screen.

(From: Bob Myers (myers@fc.hp.com).)

Here is where some words of explanation are in order.

What many people fail to realize is that the phosphor triads of the screen *do not* correspond to pixels in the image; they are not kept in alignment with the image pixels/lines/whatever, nor is there are reason for them to be. The phosphor dot pitch IS a limiting factor in resolution, but we need to look a little further to determine whether or not a given tube will be usable for a given format (what most people mistakenly call a "resolution".)

The true resolution capabilities of a CRT are limited primarily by the dot pitch AND the spot size. For practically all CRTs and monitors in the PC market, the spot size is considerably larger than the dot pitch - up to 2X or so at the corners, if the tube is at or near its specification limits. This doesn't necessarily cause a problem with the image quality, however, since you aren't really resolving individual "pixels" in any case - what you need to resolve are the *differences* between adjacent pixels, or pixel/line pairs. And, oddly enough, it doesn't take a dot pitch of equal or greater size than a logical pixel to do this to most people's satisfaction. In fact, display types sometimes talk about a 'Resolution/Addressibility Ratio', or RAR, which is in effect the ratio of the actual size of a spot on the display to the size of a "logical" pixel in the image. And for best perceived appearance, this is generally going to be GREATER than 1:1 - say, 1.5:1 or even 2:1. (Too high, and the image is blurred; but too low, and the image takes on a grainy appearance that most people find objectionable.)

Bob is absolutely correct in stating that most displays, when run at the highest support addressibility or format (or, if you insist, "resolution") wind up with the "pixel size" being smaller than the dot pitch. But what is also correct, if somewhat counterintuitive, is that this is OK, and can still result in an image that will be acceptable (and even perceived as 'sharp') to the user.

You can certainly exceed the resolution capabilities of a tube and/or monitor (monitors differ from simple tubes by also having a video amp to worry about!). For instance, you probably won't be really happy with 1600 x 1200 on a 17" 0.28 mm CRT. But 1280 x 1024 on an 0.31 mm 20-21" tube can look very good, even though the numbers don't appear to work out.

(From: Bob Niland (rjn@csn.net).)

While not stated above, I would speculate that this is due to various human visual system factors, particularly that humans have more visual acuity in luminance (B&W) than in chrominance (color). If a CRT can actually illuminate less than a full phosphor triad, its luminance resolution can exceed the dot pitch. There will be some color fringing, but the eye may not notice.

(From: Bob Myers (myers@fc.hp.com).)

That's a good bit of it. Whether or not you're going to be satisfied with a given dot pitch versus addressibility ("resolution") basically has to do with what you think "resolve" means.

The fact that we don't generally have the same spatial acuity for color - in other words, you won't really see small details based on differences in color alone, there has to be a difference in brightness - is a big part of this. And you will be able to see such variations acceptably even when the size of the logical pixel is somewhat under the dot pitch size. When this occurs, you don't get constant color pixels - you don't even get constant *luminance* pixels - but you do perceive acceptable levels of detail to call the image 'sharp'.

About the Quality of Monitor Focus

> "I have 2 identical monitors. One is razor sharp from edge to edge. The other is blurred at the corners- not from convergence problems, but just plain out of focus. In this monitor, the focus adjustment on the flyback can improve the focus at the edges, but then the center of the screen becomes worse..My question is : Is this a problem in the electronics and presumably a fixable flaw or is it caused by variance in the picture tube itself and not correctable ? Or is it some other issue?"

(From: Bob Myers (myers@fc.hp.com).)

The adjustment on the flyback sets the "static" focus voltage, which is a DC voltage applied to the focus electrode in the CRT. However, a single fixed focus voltage will not give you the best focus across the whole CRT screen, for the simple reason that the distance from the gun to the screen is different at the screen center than it is in the corners. (The beam SHAPE is basically different in the corners, too, since the beam strikes the screen at an angle there, but that's another story.) To compensate for this, most monitors include at least some form of "dynamic" focus, which varies the focus voltage as the image is scanned. The controls for the dynamic focus adjustment will be located elsewhere in the monitor, and will probably have at LEAST three adjustments which may to some degree interact with one another. Your best bet, short of having a service tech adjust it for you, would be to get the service manual for the unit in question.

It is also possible that the dynamic focus circuitry has failed, leaving only the static focus adjust.

As always, DO NOT attempt any servicing of a CRT display unless you are familiar with the correct procedures for SAFELY working on high-voltage equipment. The voltages in even the smallest CRT monitor can be lethal.

How to Compute Effective Dot Pitch

We always see CRTs specififed in terms of dot pitch but what does this mean with respect to actual useful horizontal and vertical dot pitch?

The usual arrangement of phoshpor dots on the screen of a dot mask type CRT is shown below:

```
      B R G B R G B R G B R G B R                         R --- G --- B --- R
     R G B R G B R G B R G B R G B   Magnified ->             / |
      B R G B R G B R G B R G B R                         /     |
     R G B R G B R G B R G B R G B                     G --- B -+- R --- G --- B
```

(Portions from: Jac Jamar (jamar@comp.snads.philips.nl).)

For a dot mask type CRT, normally the nominal pitch (also called the Hexagonal Pitch or HexP) is defined as the distance between one phosphor dot to the next same colored one in the 'hexagonal' direction (i.e. in the direction 30 degrees above the horizontal).

The calculations below follow from simple geometry:

- The Vertical Dot Pitch (VDP) will be equal to: HexP * 1/2.

- The Same Color Horizontal Dot Pitch (SCHDP) will be:

  ```
          SCHDP = HexP * sqrt(3) (sqrt(3) = 1.732 or 2 * cos(30 degrees))
  ```

  This is the distance between one phosphor dot and the next dot of the same color on the same horizontal line.

- The Horizontal Dot Pitch (HDP) is the distance between adjacent columns of same color dots. This is equal to: SCHDP * 1/2.

- The distance between adjacent dots of different colors or Closest Dot Spacing (CDS) is equal to: SCHDP * 1/3. A landing error of this magnitude (due to improper manufacture, adjustment, inadequate degauss, external fields, or doming) may completely shift the color from what it is supposed to be to one of the other primary colors.

So, for a 0.28 mm dot pitch CRT, VDP = .14 mm, SCHDP = .485 mm, HDP = .242 mm, and CDS = .16 mm.

Dot Pitch of TV CRTs

Computer monitor specifications always include the dot pitch of the CRT. However, this information is rarely available for TVs. Why? The quick answer is that since TVs are always used at the same scan rate (except for multisystem international TVs), this information is not nearly as important for TVs as for high resolution multiscan computer monitors.

In general, the dot/slot/line pitch of TV CRTs is very large compared to even mediocre computer monitors. Here are some typical values which I measured very precisely (!!) by putting a machinest's scale against the screen. These are all slot mask type CRTs:

- 13 inch GE - .60 mm.
- 19 inch Samsung - .75 mm.
- 25 inch RCA - .9 mm.

Therefore, you can forget about trying to use one of these CRTs for your 1280x1024 high resolution PC or workstation. The dot/stripe pitch needed for 1280 pixels on a 25" tube would be about .3-.4 mm maximum. The pixels are about .35 mm. Typical high resolution CRTs for high resolution computer monitors have a dot/stripe pitch of .25 to .28 mm (I have heard of numbers as low as .22 mm in commercially available monitors).

CRT Aspect Ratio

Nearly all modern CRTs have a 4:3 aspect ratio (H:V). Of course, with HDTV, 16:9 will probably become standard but CRTs may be obsolete by then!

(From: Bob Myers (myers@fc.hp.com).)

The physical shape of the tubes themselves came through this evolution, but the aspect ratio assumed for the original transmission format specs WAS 4:3, as driven by Hollywood. Where did you think the shape of the masks came from?

The desired 4:3 aspect ratio standard was known right from the start, and the early TV designers DID realize that the use of round tubes to display this was a literal case of a "square peg in a round hole". Rectangular CRTs for TV use had been developed as early as 1939, with the first American rectangular tube to enter production in late 1949.

(See Peter Keller's very excellent "The Cathode Ray Tube: Technology, History, and Applications" for all the details.)

CRT Deflection Angle

What does this mean? What is the difference between a 110 degree tube and a 90 degree tube?

This is the maximum angle the beam makes with respect to the gun axis to fill the screen.

- All other factors being equal, a 110 degree tube is shorter than a 90 degree tube. This is the principle advantage of higher deflection angle CRTs.

- High deflection angles means higher deflection power for a given accelerating (2nd anode) voltage.

- Higher deflection angle CRTs are more difficult to converge and maintain focus, purity, and uniform brightness across the screen. Reducing geometric errors is more challenging. Yoke design is also trickier.

In the early days, 60 degrees was considered high tech. 110 degrees is about the practical limit for TV CRTs now. Give me a 90 degree CRT any day. Monitor tubes are usually 90 degrees.

CRT Contrast Ratio

(From: Don Stauffer (stauffer@htc.honeywell.com).)

Apparently CRTs have made quite an increase lately. Years ago when I looked into it, CRTs were not much better than about 20:1. Now, folks are claiming well over 40:1.

One thing to watch, though. The phosphor has two decay curves, a rapid one followed by a slow one. A change in scene can lower contrast ratio of a bar chart that appears in a region that was a large white area.

(From: Steve Eckhardt (skeckhardt@mmm.com).)

This comment makes me curious about the claims made by manufacturers of video projectors. Visually, their images have lots of resolution but mediocre contrast at large scale. A video monitor looks a lot better in contrast. The manufacturers, however, claim contrast ratios of 100:1 or better.

Are the numbers simply marketing hyperbole or have I missed something interesting?

There are several methods for arriving at the advertised numbers for contrast. One is to simply advertise the number for the imager and ignore the degradation due to the rest of the system. Another is to measure the illuminance of a white screen compared to a black screen. The best way is to use the ANSI method and advertise ANSI contrast, which is the practice at 3M. We really do sell projectors that achieve 100:1 contrast when measured by the ANSI standard. This is, however, a relatively recent achievement. LCD projectors are improving at a rapid rate.

CRT projectors are an alternate technology that I know little about, but they have characteristics that allow them to produce very high localized contrast. This can make displays and projectors based on CRT's look superior to anything an LCD can produce.

(From: Don Stauffer (stauffer@htc.honeywell.com).)

One big problem with LCD displays, projection or otherwise, is view angle. In order to cut off the light completely, polarization needs to be controlled to a couple of degrees. The LCD works by affecting the rotation, so many degrees per unit distance through the crystal. But the total path through the crystal depends on view angle. So max contrast may be only over a small field angle. Now, games can be played with this in projection optics, but it is hard.

Effects of External Magnetic Fields on CRTs

Magnetic Interference and Shielding

When color CRTs must be operated in areas where the magnetic field causes unacceptable purity errors or distortion (either static or dynamic depending on whether the source is constant (as with the magnet in an MRI scanner or MegaBase(tm) loudspeaker) or changing (as with nearby motors, transformers, or even other monitors), there are several options (besides relocating):

- Passive shielding - soft magnetic materials (those that are easily magnetized and don't retain their magnetism) can effectively block modest strength magnetic fields. The best known of these for shielding purposes is called 'Mu-metal', an alloy of 76% nickel, 17% iron, 5% copper, and 2% chromium. (from Nelson and Parker, A.L.Physics).

  Advantages: simple (at least in priniple), doesn't care if conditions change (within specified field strength limits). Mu-metal can be very effective if used properly - but see below.

  Disadvantages: expensive and often ugly. The cost of a complete functional but not aesthetic enclosure for use of a color monitor near an MRI scanner was about $2,000 a couple of years ago when we needed to provide this for one of our customers. Check out MuShield specifically under "Monitor Enclosures" if you're curious. Less EMF, Inc. sells Mu-metal foil by the foot but what they have listed is rather thin - I don't know how well it would work for CRT shielding.

- Active compensation - a set of coils is energized with exactly the correct currents to cancel the effects of the interfering fields.

  Advantages: can be built inside the monitor using small coils in some cases.

  Disadvantages: must be engineered for each situation. Change almsot anything and it will no longer be effective even if feedback is used. Complex in practice since interfering field geometry is often not well behaved.

- Shielding can also sometimes be introduced at the source. See the section: Comments on Speaker Shielding.

  Advantages: will reduce interference for all monitors in the vicinity.

  Disadvantages: shielding location may not be readily accessible. Geometry offending device may not lend itself to a reasonable size or shape shield.

(From: Tony Williams (tonyw@ledelec.demon.co.uk).)

You can buy commercial Mu-metal screening cans and yes they are a complete enclosure, with small holes for the I/O wires.

Mu-metal is very expensive and not easy to work but will solder, especially with acid flux.

I suggest you try a dummy run first with some mild steel to get the design sorted and to test if it looks worth it.

You never know your luck, mild steel may do the job anyway and you may not want to deal with mu-metal (--- sam):

> "Just got my 10' sheet of mu-metal delivered today. It came very well packaged sandwiched between two pieces of wood so that it would not bend during shipment."

(From: James P. Meyer (jimbob@acpub.duke.edu).)

One of the reasons it came so well packaged was the fact that the magnetic properties are degraded if the material is bent or stressed in any way. Once you fabricate anything out of the mu-metal, you have to go through a high temperature annealing process to remove the stress and restore its full magnetic properties. If you don't do that, you are no better off with Mu-metal than you would be with tin-can stock.

Comments on Speaker Shielding

When loudspeakers - even those little speakers that came with your PC - are near TVs or monitors, there may be problems with the fringe fields of the powerful magnets affecting color purity, convergence, or geometry. Speakers designed to be used with PCs in close proximity to their monitor will likely include some internal shielding. This may even be effective. However, the large powerful loudspeakers used with high performance stereo systems will likely not have such shielding. The best solution where display problems have been traced to the loudspeakers is to move them further away from the TV or monitor (and then degauss the CRT to remove the residual magnetism). Where this is not possible, consider the special speakers designed to be used in closer proximity to CRTs. These have (or should have) specially shielded magnet structures or an additional magnet with its field set up to cancel the main magnet's fringe field which will minimize these effects.

Shielding of conventional speakers may also be possible:

(From: Lionel Wagner (ck508@freenet.carleton.ca).)

Put a Tin can over the magnet. This will reduce the external field by about 50%. If more shielding is desired, put additional cans over the first, in layers, like Russian dolls. (Note: a Tin can is actually made nearly entirely of steel - the term 'Tin' is historical. --- sam)

(From: Nicholas Bodley (nbodley@tiac.net).)

While both electrostatic and electromagnetic (E/M) fields can affect the paths of the electron beams in a CRT, only E/M fields are likely to be strong enough to be a problem.

Magnetic shields have existed for about a century at least. Some decades ago, a tradenamed alloy called Mu-Metal became famous, but it lost its effectiveness when bent or otherwise stressed. Restoring it to usefulness required hydrogen annealing, something rarely done in a home shop (maybe one or two in the USA).

More-recent alloys are much less fussy; tradenames are Netic and Co-Netic.

Magnetic shields don't block lines of force; they have high permeability, vastly more than air, and they guide the magnetism around what they are shielding; they make it bypass the protected items.

I have been around some shielded speakers recently, but never saw any disassembled. They looked conventional, must have had the "giant thick washer" (my term) magnet, and seemed to have a larger front polepiece than usual.

They had a shielding can around the magnet; there was a gap between the front edge of the can and the polepiece. I suspect that a second internal magnet was placed between the rear of the main magnet and the rear (bottom) of the can, so there would be minimal flux at the gap between the can and the front polepiece. Holding pieces of steel close to the gap between the can and the polepiece showed very little flux there.

Modern magnets are not easy to demagnetize, in general.

(From: Dave Roberts (dave@aasl.demon.co.uk).)

The *good* so-called magnetically screened speakers rely on two means of controlling stray flux. The static field from the magnet on the speaker (which would cause colour purity problems) is minimized by the design of the magnet. This is often at the expense of gap field linearity, leading to greater distortion - not that most users seem to worry about that...

The mains varying field is minimized by use of a toroidal mains transformer, but the more recent mains powered speakers seem to be coming with *plug top* PSUs, which take the problem further away.

Why Magnetic Fields May Cause the Picture to Rotate

One might think that the result of the Earth's or stray magnetic fields would only be for the picture to shift position slightly. Why isn't this the case?

Magnetic fields don't really 'pull' on charged particles, they result in a force at right angles to the field lines with a direction dependent on the charge (negative for electrons, positive for protons) and field (North or South). The magnitude of the effect also depends on the energy/speed of the particles and their mass. For the case of a CRT:

- If the field is horizontal with respect to the screen, the picture will mostly shift up or down.

- If the field is vertical with respect to the screen, the picture will mostly shift left or right.

- If the field is in the direction of the tube axis, electrons going toward the right will experience a shift in the opposite direction as those going toward the left (as the beam is deflected). Presto: The picture will rotate.

The actual direction of the Earth's magnetic field experienced by the CRT depends on the latitude and includes both horizontal and vertical components - horizontal at the equator and becoming progressively angled toward the poles (with opposite polarities - N or S - depending on which hemisphere it is in). This is the main reason that TVs and monitors really need to be set up slightly differently depending on location (hemisphere and latitude). And, of course, local magnetic conditions also affect this including geologic formations and other equipment and wiring which produce magnetic fields.

The rotation knob or setting ion some TVs and monitors varies the current in a coil wrapped around the CRT bell just beyond the neck which has its axis parallel to the CRT's axis and adds a magnetic field to counteract the component of the ambient field along that direction.

Best Direction to Face a Monitor?

One would think that the magnetic field of the earth is inconsequential compared to what is used to drive a CRT. While the reasons this is not true should be obvious from other sections of this document, some would still call worrying about such issues as the direction of the monitor nonsense.

(From: Bob Myers (myers@fc.hp.com).)

No, it's not nonsense. The fields generated by the deflection coils, etc., ARE much greater in magnitude than the Earth's field, but they're AC fields. The DC offset of these fields is relatively small, and the Earth's field (also DC) IS sufficient to cause a visible shift in the position of the raster and affect the beam landing, etc.. This is why, for instance, there ARE often problems when trying to use a "Northern hemisphere" monitor in the Southern hemisphere.

Having said that, however, this isn't really something the average user needs to worry about. In the detailed specs for any monitor, there generally ARE a set of specific ambient conditions under which certain performance specs are intended to be checked. These usually include the ambient magnetic fields (which also tells you what magnetic environment was used at the factory for adjustment), and the orientation of the monitor within those fields. For the vast majority of monitors, the specified ambient conditions simulate average magnetic fields in the U.S. or Europe (which are very similar), and the monitor is specified as facing east or west within those fields. Strictly speaking, one has to establish those conditions (and so match the factory adjustment environment) in order to evaluate the monitor for compliance with these specifications.

Monitors are aligned in whatever field the manufacturer (or large OEM customer) SPECIFIES. This USUALLY involves an east or west alignment, as this results in no field component in the CRT's Z-axis (the axis "down the throat" of the CRT, perpendicular to the center of the screen).

However, this doesn't necessarily mean that optimum performance at YOUR location will be obtained with the unit facing east or west, as local fields can vary considerably from the specified nominal field. The field identified in the specs is just that - it is part of the conditions under which those specifications are to be checked.

But the *specific* conditions for a given installation can vary considerably from the nominal, and so the only advice I can give the individual user is that if you're happy with the performance, don't worry about it. If you DO think that a local DC field (the Earth's field or any other) is causing a problem, THEN try to move or rotate the unit to see if you can find a better orientation or location. Of course, *AC* fields, such as those from a nearby power line or electrical equipment, are something else entirely.

Ways Around North/South or Other Sensitivity to Magnetic Fields?

(From: Jeroen Stessen (Jeroen.Stessen@philips.com).)

They use magnetic field compensation for the professional types. This is too expensive for us mortals, so we get a CRT that has been optimized for one field condition only: North, South or Neutral. Not all displays are CRTs. LCDs for instance are not sensitive to the earth magnetic field. And not all CRTs use a shadow mask for colour selection. For instance, in Tektronix colour oscilloscope they use a white CRT with a colour LCD shutter in front of it. That too would not be affected too much by the earth magnetic field.

You see, plenty of ways out for aircraft, ships, and the Space Shuttle.

Additional Comments/Summary on Northern/Southern Hemisphere Issues

(From: Jeroen Stessen (Jeroen.Stessen@philips.com).)

- The vertical component of the earth magnetic field varies as a function of latitude, particularly between hemispheres a vertical magnetic field will influence the color purity of a CRT.
- The magnetic shielding of a CRT will, after degaussing, not provide complete compensation for the vertical field, especially for the space between shadow mask and screen.
- That's why manufacturers produce different displays for different hemispheres: northern, southern and neutral. They do this by adjusting for optimum purity in a simulated magnetic field.

Where you have a TV or monitor that was manufactured for a different location, your options (apart from tossing it) are:

- Re-adjust the purity, this involves moving the deflection coil, adjustment magnets, adding more magnets, etcetera. This is a big job and success would not be guaranteed.
- Simulate a southern hemisphere location by creating a vertical magnetic field around the TV, put two big multi-turn wire loops (Helmholtz coils) above and below the TV and run a DC current through them. Might be expensive and certainly would provide a 'different' look!
- Replace the picture tube with a northern hemishpere type, this is very expensive.
- Mount the picture tube upside-down inside the TV cabinet. Then reverse the wires for the line (H) and field (V) deflection to put the picture correct side up again.

  For this case, you might have some problems with:

  - The mounting nuts for the tube are hard to reach and may have left thread (look carefully before turning!
  - The wires to the inverted picture tube panel being too short, they can probably be easily extended.
  - The distance between high-voltage anode connection and the chassis (circuits) being too short (safety!)
  - Condensation dripping into the anode contact.

  Bang & Olufsen once made a compact style television where they wanted the anode contact to be away from the top of the cabinet, so the back cover could fit tighter. So they mounted the tube upside-down.

> Consequently they had to order southern hemisphere tubes for a northern hemisphere TV set. That works, of course.

Orientation Considerations for Projection TVs

Projection TVs do have have CRTs with shadow masks or aperture grills but nonetheless can be affected by magnetic fields. In fact, it is possible that degaussing could even be needed if a strong magnet were somehow placed near the set - but how would THAT happen? :-)

> "Any truth to the rumor that how you position a projection TV in a room (N,E,S,W) can affect the image quality? Does the Earth's magnetic field truly have that much of an effect."

(From: Jeroen Stessen (Jeroen.Stessen@philips.com).)

Yes, it is true.

It makes a difference whether you talk about a front or rear projector. Front projectors are expensive and critical enough that they will be converged after installation, so that takes care of any convergence errors. Purity errors are of course no issue with 3 separate CRTs...

Rear projectors are converged in the factory, the customer does only the static convergence (4 pots) after he has decided which direction the set will face. This takes care of problems due to the horizontal component of the earth agnetic field.

In a rear projector the CRTs are mounted almost vertically. The vertical component of the earth magnetic field causes a rotation error. Normally this is not an issue because that component does not depend on the orientation of the set and it is more or less constant over the entire continent.

It makes a biiiig difference though if you manufacture PTVs in Belgium and then export them to Australia... That means opening the cabinet and re-adjusting for rotation.

A front projector has its tubes mounted horizontally. The rotation error will depend on the direction the set is facing. This is easily adjusted through the convergence.

Picture Quality and Appearance Issues

Why Does the Intensity Appear So Non-Uniform in Bright Areas?

Actually, the intensity variation is likely to be even worse than you might think - possibly as much as 2:1 from the center to the corners. In most cases you do not notice it. With large deflection angle tubes, fewer electrons make it to phosphor dots near the edge of the screen. It is simple geometry.

(From: Bob Myers (myers@fc.hp.com).)

It is extremely difficult for any CRT display to maintain perfect brightness and color uniformity across the entire image. Just the geometry of the thing - the change distance from the gun to the screen as the beam is scanned, the changing spot size and shape, etc. - makes this nearly impossible, and there can also be variations in the phosphor screen, the thickness of the faceplate, etc.. Typical brightness-uniformity specs are that the brightness won't drop to less than 70% or so of the center value (usually the brightest spot on the screen).

On color tubes, the lack of perfect brightness uniformity is aggravated by the lack of perfect *color* uniformity and purity. What appear to be "dark spots" on a solid gray image may actually be beam mislanding (color purity) problems, which may to some degree be remedied by degaussing the monitor.

Again, *some* variation is normal; if you think you're seeing too much, you can try degaussing the thing and seeing if that helps. If it doesn't, then the question is whether or not the product meets its published specs, and that is something you'll have to discuss with the manufacturer or distributor.

Comments On Color Purity, Set Orientation, and Doming

> "The problem with my TV is that bright parts of the picture change color. For example, white areas may shift towards yellow or blue depending on the orientation of the set.
>
> What are the possible causes of doming? I have noticed that the magnitude of the doming effect varies with TV orientation even after degaussing several times at the new orientation. Does this help identify the cause of the doming in my case?"

(Portions from: Jeroen Stessen (Jeroen.Stessen@philips.com).)

The problem with regular shadow masks is 'doming'. Due to the inherent principle of shadow masks, 2/3 or more of all beam energy is dissipated in the mask. Where static bright objects are displayed, it heats up several hundred degrees. This causes thermal expansion, with local warping of the mask. The holes in the mask move to a different place and the projections of the electron beams will land on the wrong colours: purity errors. The use of invar allows about 3 times more beam current for the same purity errors.

Both local doming and magnetic fields compete for the remaining landing reserve. Due to improper degaussing, the doming problem may be more visible. And applying a tube designed for the wrong hemisphere may very well increase the doming complaints. It is possible to deliberately offset the nominal landing in order to get more doming reserve (the shift due to doming is always to the outside of the tube). You would do this using spoiler magnets put in the right places.

Permanently setting the contrast lower is not a real cure because the customer might not like such a dark picture. A better picture tube (Invar shadow mask) *is* a good cure (in most cases) but there is the cost price increase. (This is mainly due to the fact that Invar metal is harder to etch.)

Also see the section: What is Doming?.

Difference in Color Rendition Between CRTs

(From: Jeroen H. Stessen (Jeroen.Stessen@philips.com).)

There can be several reasons why primary colours (especially red) may look different between picture tube brands:

1. Different phosphor composition. In the beginning everybody was looking for the phosphors with the highest luminous efficiency. Nowadays with the trend to avoid heavy metals, particularly cadmium, in consumer products the composition had to be changed. This shifts the colour point.

2. Back scattering. Not all electrons that hit the shadow mask are absorbed. In fact, a quite high percentage is scattered back into the empty space between gun and mask. If they bounce back again from internal metal parts, then they may find their way to the screen and activate an arbitrary phosphor element. This increases the black level and reduces saturation of the primary colours. Red turns a bit towards orange. Even with good phosphors, large area colours will be less than perfect. Triple-CRT projection TVs do not have this problem, fantastic red!

3. Colour filters. Toshiba has developed a process where they put individual colour filters between glass and phosphor. This makes the black much better and also improves the colour points when unwanted spectral lines are suppressed.

4. There can also be differences with respect to the NTSC system, like wrong matrix from YUV to RGB. The definition in the Japanese NTSC system differs from the USA NTSC system and the signal processing should take that into account.

Contour Lines on High Resolution Monitors - Moire

These fall into the category of wavey lines, contour lines, or light and dark bands even in areas of constant brightness. (Some people may refer to this phenomenon as "focus or Newton's rings".) These may be almost as fine as the dot pitch on the CRT or 1 or 2 cm or larger and changing across the screen. If they are more or less fixed on the screen and stable, then they are not likely to be outside interference or internal power supply problems. (However, if the patterns are locked to the image, then there could be a problem with the video board.)

One cause of these lines is moire (interference patterns) between the raster and the dot structure of the CRT. Ironically, the better the focus on the tube, the worse this is likely to be. Trinitrons, which do not have a vertical dot structure should be immune to interference of this sort from the raster lines (but not from the horizontal pixel structure).

You can test for moire by slowly adjusting the vertical size. If it is moire, you should see the pattern change in location and spatial frequency as slight changes are made to size. Changes to vertical position will move the patterns without altering their structure - but they will not remain locked to the moving image.

If they are due to the raster line structure - your focus is too good - the patterns will remain essentially fixed in position on the face of the CRT for horizontal size and position adjustments - the patterns will remain fixed under the changing image.

How to eliminate it? If moire is your problem, then there may be no easy answer. For a given resolution and size, it will either be a problem or not. You can try changing size and resolution - moire is a function of geometry.

Ironically, I have a monitor which is nicer in this respect at 1024x768 interlaced than at 800x600 non-interlaced.

Some monitors have a 'Moire Reduction Mode' switch, control, or mode. This may or may not be of help. One way to do this is - you guessed it - reduce the sharpness of the beam spot and make the picture fuzzier! You might find the cure worse than the disease.

Another cause of similar problems is bad video cable termination creating reflections and ghosting which under certain conditions can be so severe as to mimic Moire effects. This is unlikely to occur in all colors with a VGA display since the termination is internal to the monitor and individual resistors are used for each color (RGB).

I think it is ironic that some people will end up returning otherwise superb monitors because of moire - when in many cases this is an indication of most excellent focus - something many people strive for! You can always get rid of it - the converse is not necessarily true!

Moire and Shadow Mask Dot Pitch

(From: myers@fc.hp.com (Bob Myers).)

The density of the holes in the shadow mask set an upper limit on the resolution supported by that monitor. Lower resolutions work just fine; there is no need to have the logical pixels in the image line up with the physical holes in the mask (nor is there any mechanism to make this happen), and so you can think of this as the "larger pixels" of the lower-res image simply covering more than one hole or slot in the mask.

As the effective size of the pixels in the image approach the spacing of the mask holes, individual pixels are no longer guaranteed to cover enough phosphor dots on the screen to ensure that they are constant color or constant luminance, but an image will still be displayed which ON AVERAGE (over a reasonably large area) looks OK. Actually, the specified "top end" format ("resolution") for most monitors usually is at or slightly beyond this point - the effective pixel size is somewhat UNDER the dot pitch.

Isolated Spots on Display

These could be a problem with the video source - bad pixels in the video card's frame buffer or bad spots on a camcorder's CCD, for example. Or, they could be dirt or dead phosphor areas in the CRT. Except for problems with the on-screen character generator, it is unlikely that the monitor's circuitry would be generating isolated spots.

You can easily distinguish between video problems and CRT problems - missing pixels due to the video source will move on the screen as you change raster position. CRT defects will remain stationary relative to the screen and will generally be much more sharply delineated as well.

There is a specification for the number and size of acceptable CRT blemishes so you may have to whine a bit to convince the vendor to provide a replacement monitor under warranty.

Purple Blob - or Worse

Have you tried demagnetizing it? Try powering it off for a half hour, then on. Repeat a couple of times. This should activate the internal degausser. See the section: Degaussing (Demagnetizing) a CRT.

Is there any chance that someone waved a magnet hear the tube? Remove it and/or move any items like monster speakers away from the set.

Was your kid experimenting with nuclear explosives - an EMP would magnetize the CRT. Nearby lightning strikes may have a similar effect.

If demagnetizing does not help, then it is possible that something shifted on the CRT - there are a variety of little magnets that are stuck on at the time of manufacture to adjust purity. There are also service adjustments but it is unlikely (though not impossible) that these would have shifted suddenly. This may be a task for a service shop but you can try your hand at it if you get the Sams' Photofact or service manual - don't attempt purity adjustments without one.

If the monitor or TV was dropped, then the internal shadow mask of the CRT may have become distorted or popped loose and you now have a hundred pound paper weight. If the discoloration is slight, some carefully placed 'refrigerator' magnets around the periphery of the tube might help. See the section: Magnet Fix for Purity Problems - If Duct Tape Works, Use It!.

It is even possible that this is a 'feature' complements of the manufacturer. If certain components like transformers and loudspeakers are of inferior design and/or are located too close to the CRT, they could have an effect on purity. Even if you did not notice the problem when the set was new, it might always have been marginal and now a discoloration is visible due to slight changes or movement of components over time.

Magnet Fix for Purity Problems - If Duct Tape Works, Use It!

The approach below will work for slight discoloration that cannot be eliminated through degaussing. However, performing the standard purity adjustments would be the preferred solution. On the other hand, the magnets may be quick and easy. And, where CRT has suffered internal distortion or dislocation of the shadow mask, adjustments may not be enough.

In any case, first, relocate those megablaster loudspeakers and that MRI scanner with the superconducting magnets.

The addition of some moderate strength magnets carefully placed to reduce or eliminate purity problems due to a distorted or dislocated shadow mask may be enough to make the TV usable - if not perfect. The type of magnets you want are sold as 'refrigerator magnets' and the like for sticking up notes on steel surfaces. These will be made of ferrite material (without any steel) and will be disks or rectangles. Experiment with placement using masking tape to hold them in place temporarily. Degauss periodically to evaluate the status of your efforts. Then, make the 'repair' permanent using duct tape or silicone sealer or other household adhesive.

Depending on the severity of the purity problem, you may need quite a few magnets! However, don't get carried away and use BIG speaker or magnetron magnets - you will make the problems worse.

Also note that unless the magnets are placed near the front of the CRT, very significant geometric distortion of the picture will occur - which may be a cure worse than the disease.

WARNING: Don't get carried away while positioning the magnets - you will be near some pretty nasty voltages!

(From: Mr. Caldwell (jcaldwel@iquest.net).)

I ended up with the old 'stuck on a desert island trick':

I duck taped 2 Radio Shack magnets on the case, in such a way as to pull the beam back.!!!!

A $2 solution to a $200 problem. My friend is happy as heck.

RCA sells magnets to correct corner convergence, they are shaped like chevrons and you stick them in the 'right' spot on the rear of the CRT.

How Much Tilt is Acceptable?

This was in reply to a concern that a 1 degree tilt on a 27" TV was a problem. Yes, you may not like it, but unless there is a user tilt adjustment, the laws of physics prevail!

(From: David Kuhajda (dkuhajda@mail.locl.net).)

A 1 degree tilt given the effect of the earth's magnetic field is well within tolerance for a 27" TV set. The larger the picture tube, the more the tilt effect of the earth's magnetic field is noticeable. Even a shielded speaker may have just enough magnetic field to cause some slight tilt. 1 degree, however, is anything but a serious problem. Probably you would notice it you turned the TV 180 degrees on its axis that the tilt would then be going the other was. Factory standard is to have the picture straight when the back of the TV set is facing magnetic north. The actual measured tilt we have seen is as much as 3 degrees on a 36" tv set. This is why the higher-end larger TV sets have an adjustment for picture tilt.

What is Doming?

The shadow or slot mask inside the CRT is a thin sheet of steel or InVar positioned a half an inch or so behind the phosphor screen. The flatter the screen, the more susceptible it will be to thermal expansion effects: With individual phosphor dots spaced as as little as .13 mm apart (for a .22 mm dot pitch CRT), it doesn't take much inaccuracy in their position to result in a noticeable effect. (See the section: How to Compute Effective Dot Pitch.) As a result, high resolution CRTs tend to be more susceptible to doming problems.

(Portions from: Jac Jamar (jamar@comp.snads.philips.com).)

1. Doming is a deformation of the shadow mask or its support structure caused by heating and subsequent expansion in bright (high beam current) areas of the picture. This causes a shift in position of the finely spaced holes or slots in the mask. The result will be color purity problems - discoloration and brightness variations. For a .28 mm dot pitch CRT, a change of only .14 mm in the position of a hole or slot can totally shift the display from one of the primary colors to another.

2. InVar shadow masks can sustain a significantly higher current density than steel shadow masks (by as much as 3:1) without noticeable problems.

Trinitrons are more resistant to local doming effects as long as the wires are under enough tension. However, expansion of the suspension components can still result in doming with an overall bright picture.

3. The onset and disappearance of color purity problems will generally lag the cause due to the thermal mass of the affected components. For local heating resulting from picture highlights, this will be only a few seconds since the thermal mass of a small area of the mask is not that great. However, for effects having to do with expeansion of the suspension or support structure, it may take up to 30 minutes to reach equilibrium.

4. The orientation of the TV or monitor with respect to the earth's magnetic field and even whether the CRT was set up for the Northern or Southern hemispheres may affect the resulting color shift. Thus, the picture may tend toward yellow while the monitor is facing one way and blue when rotated 180 degrees on its base (even if degaussed at each position).

5. Reducing the brightness/contrast or setting the brightness limiter will prevent doming but may result in an unacceptably dark picture.

6. Shadow mask doming in itself is not something that becomes defective and has to be repaired. It is a characteristic of the CRT assembly. However, shifts in the position of purity adjustments can results in increased sensitivity to slight doming.

Purity problems resulting in discolouration and/or brightness variations are due to mislanding of the microscopic electron beams (the electron beams after the mask) on the red/green/blue phosphor stripes or dots. The mislanding is in general caused by:

- Influences of ambient magnetic fields (such as the earth magnetic field).
- Shadow mask doming.
- Tolerances occurring in the production of CRTs.
- Less than optimal setup of the purity adjustments (yoke position, rings on CRT neck, etc.

Only when the sum of these influences exceeds the 'guardband' provided in the CRT design, discolouration (or brightness variations) becomes visible.

If discolouration complaints arise, this will normally not be due to changes in doming behaviour, but to changes in shielding against magnetic fields.

The ambient magnetic fields are shielded by means of iron components inside (or sometimes outside) the tube, which have to be 'degaussed' to give good shielding. For this in a set degaussing coils and circuits are provided. A discolouration complaint will thus often be due to insufficient degaussing.

- TV sets and monitors which are kept in 'stand-by' mode for a long time may never be degaussed adequately because the degaussing circuit may only operate for a short time after the unit is switched on from cold - whether this is so with your unit depends on the design). In this case, they can pick up magnetic fields from magnets moved nearby or other equipment.

The solution in this case is to switch the TV or monitor completely off or pull the plug if in doubt, let it cool down for half an hour or longer and switch it on again. If necessary this procedure can be repeated a few times (I had to do this at home once when my children had been playing with magnets). For monitors with degauss buttons, you can usually hear a hum when the degauss is activated.

- Similarly, if the orientation of a unit with respect to the earth's magnetic field is changed, it requires degaussing. So if you put your TV in another corner of the room or rotate your computer monitor on its tilt-swivel base, you have to activate its degauss circuitry (by letting it cool down or in the case of a high-end monitor, using its degauss button) or degauss it manually (see the section: Degaussing (Demagnetizing) a CRT).

- The PTC resistor (thermistor or posistor) in the degaussing circuit can become defective. This prevents proper degaussing after switch-on.

Since lower resolution CRTs are used for most TVs compared to similar size computer monitors, doming would not be nearly as much of a problem if they were both run at similar brightness (energy density) levels. However, TVs are very often used at higher brightness levels resulting in more of a thermal load on the mask which offsets the lower resolution.

Afterglow - Phantom Patterns on CRT After Shutoff

Why is there a splotch of colored light at the center of the CRT after I kill power to my TV? Why does this not happen if the plug is pulled instead? It seems to last for hours (well maybe minutes at least).

(Portions of the following from a video engineer at Philips.)

A broad diffused glow (not a distinct spot in the middle of the screen) that lasts for a few seconds to minutes is called 'afterglow' and may be considered 'normal' for your model. The warm CRT cathodes continue to emit electrons due to the high voltage that is still present even though the signal circuits may have ceased to operate.

For more sharply defined spots there are two phenomena:

1. Thermal emission from a cathode that has not yet cooled off (and this could take several minutes) gives a more or less circular spot near the centre. It is actually 3 spots from the 3 cathodes, we at Philips call them 'Christmas balls'.
2. Field emission from sharp whiskers on any electron gun part gives a much sharper spot, sometimes with a moon-shaped halo around it. Even with the filament off, there may be some electron emission from these sharp points on the cold cathode(s) due to the strong high voltage (HV) electric fields in the electron gun. I do not know how likely this is or why this is so.

The shape of the spot is an inverted image of the shape of the emitting area(s) on the electron guns cathodes.

The visibility of both effects depends in the same way on the decay time of the high voltage (HV/EHT) on the anode.

When turned off with the remote or front panel button, you are not actually killing AC power but are probably switching off the deflection and signal circuits. This leaves the HV to decay over a few minutes or longer as it is drained by the current needed to feed the phantom spot or blob.

When you pull the plug, however, you are killing AC input and all the voltages decay together and in particular, the video signal may be present for long enough to keep the brightness (and beam current) up and drain the HV quickly. Whether this actually happens depends on many factors - often not dealt with by the designers of the set.

A proper design (who knows, yours may simply have been broken from day 1 or simply be typical of your model) would ensure that the HV is drained quickly or that the other bias voltages on the CRT are clamped to values that would blank the CRT once the set is off. If the problem developed suddenly, then this circuitry may have failed. On the other hand, if it has been gradually getting more pronounced, then the characteristics of the CRT or other circuitry may have changed with age.

In most sets it is left to chance whether the picture tube capacitance will be discharged by beam current at switch-off. It may simply be due to the behaviour of the video control IC when its supply voltage drops that causes the cathodes to be driven to white and this may not be formally specified by the manufacturer of the IC. Some of of the latest sets have an explicit circuit to discharge the EHT at shutdown.

As noted in the section: "Safety guidelines" the HV charge on the CRT capacitance can be present for a long time. A service technician should be very aware of that before touching HV parts!

Interestingly, most sets for the Asian Pacific market have a bleeder resistor built in that will discharge the EHT without the need for a white flash at switch-off. These will in fact drive the beam to black at switch-off via a negative voltage to the CRT G1 electrode. The AP market is very sensitive to proper set behaviour, they don't like a white flash.

In short, it all depends on the demands of the particular market, the chance of the picture tube producing a spot/blob, and the mood of the designer.

So, it may not be worth doing anything to 'fix' this unless the splotch is so bright (more so than normal video and for an extended time) that CRT phosphor damage could result. This is usually not a problem with direct view TVs but would definitely be a concern with high intensity projection tubes.

On the other hand, your phantom blob may provide for some interesting conversation at your next party!

Discussion on the causes of color flare

On the right side of high intensity colors, some CRTs will exhibit a flare - the color will appear to be stuck at its highest level. This often occurs with older CRTs even at modest drive but can usually be forced to happen with any CRT if the drive level is turned up very high.

(From: Andy Cuffe (baltimora@psu.edu).)

I think it's due to the electron gun clipping when it's overdriven. Even a new CRT will bleed if it's driven hard enough, but most TVs are designed so you can't turn up the contrast that much. Once the CRT goes into clipping, it must take a short time to start working normally again after the drive level falls below clipping. The same thing happens when certain problems develop in the video amp.

All CRTs do it when they get weak enough. Samsung seem to be worse than most. In general, all CRT manufacturers have been cutting costs. A larger percentage or 8 year old or newer TVs that I see have bad CRTs than ones that are more than about 16 years old. I just picked up a heavily used 1982 Zenith from the side of the road and it has a better looking CRT than most new TVs.

(From: Michael Shell (mikes1987@yahoo.com).)

I suspect that you may be right. I used to work a lot on older tube color televisions and I don't recall the bleeding problem. The first time I remember seeing it was on a 1978 Sampo. I have seen it EVERYWHERE since then. Has anybody seen the problem on a, say 1970, tube type set with good video drivers and correct CRT voltages (so you know it to be the CRT).

(From: Andy.)

My theory is that a weak CRT (or a good one with reduced G2) represents a higher impedance load to the video output transistor. The biasing of the video outputs would have to be designed for the load created by a good CRT. When the output load impedance goes high enough, the voltage can go high enough to saturate the transistor (the CRT isn't pulling enough current to keep the C-E voltage from going close to 0).

tubes, being like FETs (in that they are majority carrier devices) which are used in high speed digital circuits because don't have any delay in getting out of saturation.

(From: Michael.)

I think we may have a winner. A scope on the cathode should be able to confirm it.

(From: JURB6006 (jurb6006@aol.com).)

Hmm, that's one of most technical questions I've heard in a while.

First of all, realize that most sets do this with a lowered G2 voltage. While on the surface, lowering the G2 seems to mimic a weak CRT, this is not the case. Only in some ways it does, apparently.

Some sets have an unusual resistance, and others seem to have an unusual propensity to "bleed" (we call it flaring at my shop).

I was around before ICs, and have had an opportunity to study the design of the video output circuit(s) of TVs without ICs. I do understand circuit design, and have reached the following conclusion (this completely excludes sets with AKB):

It depends on how the video output transistors are driven. It seems that if there is a path for current feedback, the set will flare. This is the worst in sets that drive the emitters of the outputs.

Other sets, which could be designated as "voltage drive sets" either have such solid drive to the emitters that CRT load doesn't affect it or they just drive the base(s) of the outputs.

Engineering-wise, I think it basically boils down to the output impedance of the video output stage, and on a single ended stage, as most are and were, this impedance is different for negative and positive going slopes in the waveform.

There are other theories, this is only one. I speak of this because the flaring effect was almost always noticed on some chassis, back when all the CRTs were interchangeable. It followed the set, not the CRT.

(From: Michael.)

OK, I agree with what you are getting at here. Consider what happens when a transistor is overdriven. There are so many excess carriers in the device that it takes a long time for recombination to occur. This delay will result in the transistor taking a longer than normal time to switch off.

As noted above, often bad video driver circuitry/designs can cause bleeding (flaring) too. These cases could be caused by overdriven transistors (see above), feedback loops, or some type of ringing effect. I am interested in this as well, but my real fascination is when the CRT is the trouble maker.

Unlike a semiconductor, a CRT is a pure majority carrier device - no holes, just electrons flying around in there.

What bothers me is this: Say we have a test pattern consisting of a solid red square in the middle of an otherwise black screen. We turn up the saturation/contrast (and have a weak CRT), we will see bleeding to the right of the square. Instinctively, we FEEL we know what is going on. But think about it. The instant the electron beam leaves the square, the voltages on the CRT grid/cathodes are such (or should be) that the red gun should be shut off. (It is only like a nanosecond from the gun to the screen.) If the CRT cathode is weak, or the G2 voltage is too low, then I would expect the beam to cutoff even faster! Yet, the phosphors in the bleed DO see electrons exciting them! So, what is happening here? Did charge somehow build up somewhere in the tube? OR has the tube changed properties in such a way to cause trouble for the video output stages in a manner which would cause problems like Jurb6006 suggested? In the later case, it should be possible to design or modify the output stages to be resistant or immune to this problem. (I am not suggesting it would be worth it though).

The thing I really despise is that it seems to happen on CRTs that still have perfectly acceptable brightness.

(From: JURB6006.)

When they flare, yet the CRT isn't weak, it is usually due to a low collector Supply voltage to the vid outs. Unfortunately there is no way to tell on a normal scope whether the effect is being driven to the CRT or if the effect is IN the CRT.

Actually on what I call "voltage driven" units, you CAN see some type of clipping when either the CRT is weak or the G2 is low, but let's say on an older Sony, it seems like the clipping is omnidirectional.

Yet when this happens, the purity is not extremely affected.

On the sets that flare profusely, is it possible that the designers stumbled on a rudimentary form of AKB?

(From: Asimov (warpcastgate@dynip.com.)

It's analogous to how speakers and amps distort when the clip. When the clipping occurs in the CRT it's bandwidth falls to zero and you see then a type of ringing or smear. It's like the beam gets cutoff then saturates repeatedly very fast at a video rate. Also the electrostatic voltages which set the convergence get all thrown out of whack when this happens. This last is why a CRT with weak emission will also show poor purity, bad convergence, and a loss of tracking.

(From: Andy.)

I wonder if it would be possible to modify the video output circuit to eliminate the bleeding in a TV with a weak CRT that's not too far gone to be usable?

(From: Michael.)

I plan to try this in the next month or so. If I have any luck, I will post the results. In order to do this, voltages are gonna have to climb to keep that transistor out of saturation. This is going to result in more heat. Could it be possible that energy conservation mandates from the government resulted in flaring? If so, the same thing that causes my CRTs to flare also causes my toilet and shower to lose power.

From the point of view of the cathode, the CRT is a current controlled device like a BJT. From the point of view of the grid, it is a voltage controlled device, like a MOSFET. I can't remember why the video drive is applied to the cathodes rather than the grids, but I know there was/is a good reason.

So, barring a radical change, such as CRT grid drive, I think we want to use BJTs, but we need total control over Ik, regardless of how Mr. CRT feels. So, we would drive the CRT cathode with the NPN BJT collector, and have a fairly large Vce - which implies a bigger transistor with more heat sinking. I had thought of an alternative - using a transistor that comes out of saturation faster, but as you mentioned before, we lose detail in saturation and thus would still not like the resulting picture. Another simple solution would be to "tweak a few V's".

Instinctively, I feel we can do this. Then why haven't the OEMs?

I thought up some humorous explanations for flaring during the course of this discussion. Maybe somebody will get a laugh:

1. A crust spot on the cathode, which only emits at high drive levels, causes the electrons that pass through it to have a reduced velocity - by a factor of a 10000. These delayed electrons form the flare.

2. The front of the cathode starts to wear out. Under high drive levels, electrons are emitted from the BACK of the cathode. The G2 voltage then pulls them around, but the result is a corkscrew spiral path to the screen whose total linear length is on the order of a 1000 feet. Hence the delay. Purity is not affected due to "circular symmetry".

3. A crust forms on the cathode. Under high drive levels, electrons are trapped within the layers of this crust. Even when the video drive cuts off current to the cathode, the trapped electrons continue to leak to the surface resulting in a flare. This is known as the "cathode becomes a capacitor" theory.

4. The phosphor of old CRTs become "flaky". When hit by electrons, ionic radiation is emitted radially outward. This radiation makes other adjacent phosphors super sensitive to future electron exposure.

Hence, we are able to see a nearly zero electron beam which results in the flare.

And finally:

5. It's all in your head. Buying a new TV raises endorphens in the human brain, fixing the problem for a couple years. This also explains why more expensive, feature rich TVs have the problem less often. The CRT restorer should be applied to the USER not the TV. In skillful hands, it can also cure one of "color vision" allowing the use of much more inexpensive B/W sets.

Magnetic Fields and Degaussing

Degaussing (Demagnetizing) a CRT

Degaussing may be required if there are color purity problems with the display. On rare occasions, there may be geometric distortion caused by magnetic fields as well without color problems. The CRT can get magnetized:

- if the TV or monitor is moved or even just rotated.
- if there has been a lightning strike nearby. A friend of mine had a lightning strike near his house which produced all of the effects of the EMP from a nuclear bomb.
- If a permanent magnet was brought near the screen (e.g., kid's magnet or megawatt stereo speakers).
- If some piece of electrical or electronic equipment with unshielded magnetic fields is in the vicinity of the TV or monitor.

Degaussing should be the first thing attempted whenever color purity problems are detected. As noted below, first try the internal degauss circuits of the TV or monitor by power cycling a few times (on for a minute, off for at least 20 minutes, on for a minute, etc.) If this does not help or does not completely cure the problem, then you can try manually degaussing.

Note: Some monitors have a degauss button, and monitors and TVs that are microprocessor controlled may degauss automatically upon power-on (but may require pulling the plug to do a hard reset) regardless of the amount of off time. However, repeated use of these 'features' in rapid succession may result in overheating of the degauss coil or other components. The 20 minutes off/1 minute on precedure is guaranteed to be safe. (Some others may degauss upon power-on as long as the previous degauss was not done within some predetermined amount of time - they keep track with an internal timer.)

Commercial CRT Degaussers are available from parts distributors like MCM Electronics and consist of a hundred or so turns of magnet wire in a 6-12 inch coil. They include a line cord and momentary switch. You flip on the switch, and bring the coil to within several inches of the screen face. Then you slowly draw the center of the coil toward one edge of the screen and trace the perimeter of the screen face. Then return to the original position of the coil being flat against the center of the screen. Next, slowly decrease the field to zero by backing straight up across the room as you hold the coil. When you are farther than 5 feet away you can release the line switch.

The key word here is ** slow **. Go too fast and you will freeze the instantaneous intensity of the 50/60 Hz AC magnetic field variation into the ferrous components of the CRT and may make the problem worse.

WARNING: Don't attempt to degauss inside or in the back of the set (near the CRT neck. This can demagnetize the relatively weak purity and convergence magnets which may turn a simple repair into a feature length extravaganza!

It looks really cool to do this while the CRT is powered. The kids will love the color effects.

Bulk tape erasers, tape head degaussers, open frame transformers, and the "butt-end" of a weller soldering gun can be used as CRT demagnetizers but it just takes a little longer. (Be careful not to scratch the screen face with anything sharp. For the Weller, the tip needs to be in place to get enough magnetic field.) It is imperative to have the CRT running when using these whimpier approaches, so that you can see where there are still impurities. Never release the power switch until you're 4 or 5 feet away from the screen or you'll have to start over.

I've never known of anything being damaged by excess manual degaussing as long as you don't attempt to degauss *inside* or the back of the TV or monitor - it is possible to demagnetize geometry correction, purity, and static converence magnets in the process! However, I would recommend keeping really powerful bulk tape erasers-turned-degaussers a couple of inches from the CRT.

If an AC degaussing coil or substitute is unavailable, I have even done degaussed with a permanent magnet but this is not recommended since it is more likely to make the problem worse than better. However, if the display is unusable as is, then using a small magnet can do no harm. (Don't use a 20 pound speaker or magnetron magnet as you may rip the shadow mask right out of the CRT - well at least distort it beyond repair. What I have in mind is something about as powerful as a refrigerator magnet.) Also see the juggler's technique, below. :-)

Keep degaussing fields away from magnetic media. It is a good idea to avoid degaussing in a room with floppies or back-up tapes. When removing media from a room remember to check desk drawers and manuals for stray floppies, too.

It is unlikely that you could actually affect magnetic media but better safe than sorry. Of the devices mentioned above, only a bulk eraser or strong permanent magnet are likely to have any effect - and then only when at extremely close range (direct contact with media container).

All color CRTs include a built-in degaussing coil wrapped around the perimeter of the CRT face. These are activated each time the CRT is powered up cold by a 3 terminal thermister device or other control circuitry. This is why it is often suggested that color purity problems may go away "in a few days". It isn't a matter of time; it's the number of cold power ups that causes it. It takes about 15 minutes of the power being off for each cool down cycle. These built-in coils with thermal control are never as effective as external coils.

Note that while the monochrome CRTs used in B/W and projection TVs and mono monitors don't have anything inside to get magnetized, the chassis or other cabinet parts of the equipment may still need degaussing. While this isn't likely from normal use or even after being moved or reoriented, a powerful magnet (like that from a large speaker) could leave iron, steel, or other ferrous parts with enough residual magnetism to cause a noticeable problem.

If you try the 'technique' below, make sure you don't smash the TV or your spouse!

(From: Mike Champion (mchampfl@gdi.net).)

I replaced the magnetron in my microwave and ripped apart the old one with my kids to 'see how it works'. Boy, there are some mother magnets in there! The kids and I had fun with them. You know - push me pull you; the paper clip boat; which Easter egg has the metal and which has the wood; etc. Dnough with this kid stuff - 'wanna see something really cool?', says I. Having been around monitors for a long time in the computer business, i showed them what what a REALLY powerful magnet will do to an electron beam in a cathode ray tube - my sharp 19" color TV. "Wow, dad!", "psychodelic!" "it looks like all the colors are flushing down the toilet!" Boy, was I DAD or what? The problem was that my experience with magnets and monitors were in the monochrome days! so the price I paid for such esteem in the eyes of my children were purple faces and green legs on my sharp 19" color TV! Uh-oh! well, maybe it will be allright by tomorrow. Well it wasn't. Now I'm getting worried! I used to do computer support at a television station so I called an old engineer friend there for help. He just hee-hawed! As he was drying his eyes, he suggested that I had probably just magnetized the mask and he'd loan me a degausser. I offered to buy him lunch for the favor. This was Friday and because of my friend's diagnosis T was able to relax about the problem enough to think about it. Hmmmm. degausser = alternating magnetic field... Strong magnetron magnet... Alternating... So I got this great idea! I took the ring magnet I used to mess it up, tied a string to it, suspended it on the string and spun it as fast as i could. I put it up to the CRT and brought it away slowly! Eureka! On Monday I called my smart-alek friend and cancelled the lunch!

How Often to Degauss

Some monitor manufacturers specifically warn about excessive use of degauss, most likely as a result of overstressing components in the degauss circuitry which are designed (cheaply) for only infrequent use. In particular, there is often a thermister that dissipates significant power for the second or two that the degauss is active. Also, the large coil around the CRT is not rated for continuous operation and may overheat.

If one or two activations of the degauss button do not clear up the color problems, manual degaussing using an external coil may be needed or the monitor may need internal purity/color adjustments. Or, you may have just installed your megawatt stereo speakers next to the monitor!

You should only need to degauss if you see color purity problems on your CRT. Otherwise it is unnecessary. The reasons it only works the first time is that the degauss timing is controlled by a termister which heats up and cuts off the current. If you push the button twice in a row, that thermister is still hot and so little happens.

One word of clarification: In order for the degauss operation to be effective, the AC current in the coil must approach zero before the circuit cuts out. The circuit to accomplish this often involves a thermister to gradually decrease the current (over a matter of several seconds), and in better monitors, a relay to totally cut off the current after a certain delay. If the current was turned off suddenly, you would likely be left with a more magnetized CRT. There are time delay elements involved which prevent multiple degauss operations in succession. Whether this is by design or accident, it does prevent the degauss coil - which is usually grossly undersized for continuous operation - to cool.

Ultra Cheap Degaussing Coil

Pack Rat Trick #457384:

Next time you scrap a computer monitor (or tv), save the degaussing coil (coil of wire, usually wrapped in black tap or plastic) mounted around the front of the tube. To adapt it for degaussing sets, wrap it into a smaller coil, maybe 4"-6". To limit the current to something reasonable, put it in series with a light bulb (60 to 100 W, maybe as high as 200 W but keep a finger on the temperature of the coil!). You need AC current to degauss, so just put the bulb in series with the coil and use the your local 120 VAC outlet. BE VERY CAREFUL that you actually wired it in series, and that everything is properly insulated before you plug it in (A fuse would be a real good idea too!!)

A few circles over the affected area will usually do it. Note that it will also make your screen go crazy for a little bit, but this will fade out within a minute or so.

Just a couple of points for emphasis:

1. The coil as removed from the TV is not designed for continuous operation across the line as indicated above. In fact, it will go up in a mass of smoke without the light bulb to limit the current. The poor TV from which this organ was salvaged included additional circuitry to ramp the current to 0 in a few seconds after power is turned on.

2. Reducing the coil size by a factor of 2 or 3 will increase the intensity of the magnetic field which is important since we are limiting the current with the light bulb to a value lower than the TV used. You don't need to unwind all the magnet wire, just bend the entire assembly into a smaller coil. Just make sure that the current is always flowing in the same direction (clockwise or counterclockwise) around the coil.

3. Insulate everything very thoroughly with electrical tape. A pushbutton momentary switch rated for 2 amps at 115 volts AC would be useful so that you do not need to depend on the wall plug to turn it on and off.

(From: Larry Sabo (sabo@storm.ca).)

I've been using a couple of degaussing coils from "parts" monitors, connected n series. The combined resistance is about 27 ohms, for a current of around 4 to 5 amps. Sorry, I don't know the wire size, but it's very substantial, not like some of the thin, flimsy stuff I see. Works great!

Bob Myers' Notes on Degaussing

A couple of comments: first of all, it makes no difference whatsoever if the display is on while it's being degaussed. (Oh, some people DO like to watch the psychodelic light show, but it really doesn't help anything for it to be on.) Actually, there is a very minor case to be made for degaussing while OFF, at least for the Trinitron and similar tubes. (The field of an external degauss coil CAN cause the grille wires to move slightly, and they're a bit more flexible when hot - so it is conceivable, although certainly unlikely, that you're running a higher risk of causing the grille wires to touch or cross and become damaged.)

Secondly, a good practice for degaussing is to slowly back away from the monitor after giving the screen a good going over. Once you're about 5-6' away, turn the coil so it's a right angles to the CRT faceplate (which minimizes the field the monitor is seeing), and THEN turn to coil off. This is to reduce the possibility of the field transient caused by switching the coil off from leaving you once again with a magnetized monitor.

The last point is to make sure that you DON'T leave the coil on too long. These things are basically just big coils of wire with a line cord attached, and are not designed to be left on for extended periods of time - they can overheat. (I like the kind with the pushbutton "on" switch, which turns off as soon as I release the button. That way, I can never go off and leave the coil energized.)

Oh, one more thing - make sure your wallet is in a safe place. You know all those credit cards and things with the nice magnetic stripe on them? :-)

(Actually, I've got a good story about that last. I was teaching a group of field service engineers how to do this once, and being the "Big Deal Out of Town Expert", made VERY sure to place my wallet on a shelf far away from the action. Unfortunately, Mr. Big Deal Out of Town Expert was staying in a hotel which used those neat little magnetic-card gadgets instead of a "real" key. Ever try to explain to a desk clerk how it was that, not only would your keycard NOT let you into your room, it was no longer anything that their system would even recognize as a key? :-))

Degaussing after lightning strike

Sometimes a nearby lightning strike may produce effects which mimic those of a nuclear explosion, at least in terms of EMP induced magnetization. This may be take the form rainbow patterns or purity blotches that the internal degaussing coil or even an typical external degauss won't cure.

(From: JURB6006 (jurb6006@aol.com).)

A lightning strike produces a VERY high magnetic field, something the degausser can't handle. Somehow connect a good, like 10 amp Variac straight to the degaussing coil(s) and turn it all the way up and down, fairly quickly. You might do better to get ready, flip the switch on and turn it down from the top, but DON'T blow the fuse, that might make things worse. Turn it down quick, but it is the top end that gets the job done. Thing is those coils can only stand it for a second or two, but that is way longer than it takes. You can also do this with it running, but you risk damaging the vertical circuit. However you can try different levels and see if less than max is enough to do it. At extremely high levels you risk damaging the shadow mask, that is if it is not already damaged.

I almost scrapped a 36" Sony for this, same thing, near a lightning strike. The colors were seriously FUBARed. The coil to the variac trick did it. What happens is I think the purity shield itself gets magnetized, despite it's low coercivity. It takes a bit more than the standard degausser in the set to do the trick.

Degaussing Humor - If it Works, Use It!

Note: If you are forced to use this stunt, sorry, approach, make sure you don't end up smashing something important! :)

(From: Mike Champion (mchampfl@gdi.net).)

I replaced the magnetron in my microwave and ripped apart the old one with my kids to 'see how it works'. Boy, there are some mother magnets in there! me and the kids had fun with them. you know - push me pull you; the paper clip boat; which easter egg has the metal and which has the wood; etc. enough with this kid stuff - 'wanna see something really cool?' Says I. Having been around monitors for a long time in the computer business, I showed them what what a REALLY powerful magnet will do to an electron beam in a cathode ray tube - my sharp 19" color TV. "Wow, dad! psychodelic! It looks like all the colors are flushing down the toilet!" Boy, was I DAD or what? The problem was that my experience with magnets and monitors were in the monochrome days! So the price I paid for such esteem in the eyes of my children were purple faces and green legs on my sharp 19" color TV! Uh-oh! Well, maybe it will be all right by tomorrow. Well it wasn't.

Now I'm getting worried! I used to do computer support at a television station so I called an old engineer friend there for help. He just hee- hawed! This was Friday and because of my friend's diagnosis I was able to relax about the problem enough to think about it. Hmmmm... Degausser = alternating magnetic field. Strong magnetron magnet. Hmmmm... Alternating... So I got this great idea! I took the ring magnet I used to mess it up, tied a string to it, suspended it on the string and spun it as fast as I could. I put it up to the CRT and brought it away slowly! Eureka! On Monday, I called my smart-aleck friend and cancelled the lunch! :)

Can a Really Strong Magnet Permanently Damage the CRT?

Even a magnet that can suspend your weight may still not have much range as they usually have metal pole pieces that concentrate the flux and work well only with a matching flat steel plate.

The only thing in the guts of a TV or monitor (that is accessible from outside the cabinet) that can be damaged permanently is the shadow or slot mask of the CRT. If the magnet is strong enough to distort it, the CRT will be ruined. Even manual degaussing with a similarly powerful degaussing coil will then not totally clear up color purity problems. The shadow or slot mask is a very thin perforated steel or InVar sheet about 1/2 inch behind the glass of the CRT screen - which is itself about 1 inch thick or more. So, even up against the screen, your magnet is still at least 1-1/2 inches from the shadow mask. It would take a mighty powerful magnet to distort it.

For Trinitron (or clone) CRTs with aperture grilles - tensioned fine wires in place of a shadow or slot mask, the force required would be even greater.

No way to know without trying it :-(.

(From: Jeff Mangas (jeff@edldisplays.com).)

I work in a small monitor factory and some time ago we were using some very strong degaussing wands to remove magnetism from some of our chassis. We found that this caused a weakening of the shadow mask and it would take only a small shock/vibration to break the mask loose. We are not 100% sure that it was the degaussing that caused the problem but we only used these strong wands for a short time (lost several tubes while using them) and have not had any problems before or since.

WARNING about degaussing late model Sony Trinitron CRTs

The following has been confirmed by others.

(From: David Kuhajda (dkuhajda@locl.net).)

You should NEVER use a big degauss coil on ANY SONY WEGA tube, or ANY SONY 27" or larger CRT made after 1997. Sony deliberately put a small amount of magnetic field into the strapping and aperture grill to compensate and improve the convergence. A BIG degauss will remove this and make the tube look very bad.

A BIG manual degauss coil from about 3 feet away should have a low enough field to be safe. (Note: should) I NEVER use the large degauss coils on the Sony tubes after seeing the Sony video of how CRTs have been damaged. I USE a smaller degauss coil and work it on a Variac at a lowered AC voltage, and bring the voltage up each successive pass to degauss the CRT until it is cleared up.

If the internal degauss is not taking care of the problem, you have other things to look at. Has the yoke or yoke purity rings been moved? Have the TV or monitor been dropped? Are all the connections good on the degauss thermister? If it is a three leg thermister it still may be bad as those leave a small current flowing on the older Sony coils. Have any of the extra purity magnets fallen off the yoke or CRT?

Note that Sony tubes do NOT have shadow masks, but they have aperture grills which are an array of incredibly fine wires under tension. A BIG degauss coil can also rip the aperture grill away from the stabilization wires.

- Back to CRT FAQ Table of Contents.

CRT Related Adjustments

Principles of Purity and Convergence Adjustment

Purity involves bending all 3 of the beams so that they cross the space between shadow mask and screen at the proper angle and will land at a different place on the phosphors. Convergence involves adjusting the aim of 1 or 2 of the beams at a different angle so that they all land at the same place on the screen.

Dynamic convergence circuitry is now virtually non-existent, except in high resolution monitor tubes and in Sony Trinitron tubes (they require a very basic horizontal convergence). All other tubes have the convergence correction built into the design of the tube and the coil. Sony has chosen a different trade-off between price and performance (which includes also sharpness).

Most CRTs have a series - usually 3 pairs - of ring magnets mounted on the neck near the socket end. These are used for part of the purity adjustment and static convergence. (Coarse purity is set by the position of the yoke and dynamic convergence is set by the tilt of the yoke.) These rings consist of multi-pole magnets which due to their field configuration are able to affect the electron beams from the 3 guns in different ways.

(Some CRTs employ internal structures that are premagnetized at the factory and cannot be adjusted in the field - though perhaps auxiliary magnet rings could be added if the original magnetization were lost for reasons we won't go into :-). This type of CRT will be obvious as there will be no adjustable rings to mess screw up!)

The relative orientation of the rings in a pair affect the strength of the effect.

In a nutshell, the electron guns in most modern CRTs are arranged in-line. For example: GRB. Some of the ring adjustments are designed to affect them all while others pretty much leave the center gun's beam alone and only affect the outer ones. Various options then exist depending on the magnetic field configuration.

The three sets of ring magnets are shown below along with the position of the red (R), green (G), and blue (B) electron beams passing through them. Each is actually a pair of rings which may be moved relative to one-another to control the strength of the magnetic field. When the tabs are adjacent, the fields from the two rings nearly cancel and the rings then have no effect. Two typical orientations are shown (N and S are the poles of the ring magnets):

Orientation 1:

```
                          S             S   N

  N  R G B  S       N  R G B  N     N  R G B  S

                          S             S   N

    2-pole            4-pole            6-pole
   (purity)         (red-blue)    (red/blue-green)
   0 Degrees        0 Degrees         0 Degrees
```

Orientation 2:

```
       N             N       S            S
                                      N       N
     R G B             R G B            R G B
                                      S       S
       S             S       N            N

    2-pole            4-pole            6-pole
   (purity)         (red-blue)    (red/blue-green)
  90 Degrees        45 Degrees        30 Degrees
```

(My apologies if I have the direction of deflection reversed - I can never remember the right hand rule for electrons moving in magnetic fields!)

- The 2-pole purity rings move the set of RGB beams more or less together to fine tune the position of the center of deflection.

  The field lines go generally across (at the orientation shown) between the N and S poles.

  Orientation 1, the RGB beams will be raised.

  Orientation 2, the RGB beams will be moved to the right.

- The 4-pole red-blue rings move the R and B beams relative to the G beam but leave the G beam alone.

  The field lines go generally between adjacent N and S poles. On opposite sides of the rings, the polarity/direction of the lines oppose and thus tend to move the R and B beams in opposite directions. The G beam in the center does not experience any deflection from the 4-pole ring magnets since all the fields tend to cancel.

Orientation 1: The R beam will move up and the B beam will move down relative to G.

Orientation 2: The R beam will move up and to the right and the B beam will move down and to the left relative to G.

- The 6-pole red/blue-green rings move the RB beams with relative to the G beam but leave the G beam alone.

  The field lines go generally between adjacent N and S poles. On opposite sides of the rings, the polarity/direction of the lines are the same and thus tend to affect the R and B beams in the same direction. The G beam in the center does not experience any deflection from the 6-pole ring magnets since all the fields tend to cancel.

  Orientation 1: The R and B beams will move up relative to G.

  Orientation 2: The R and B beams will move up and to the right relative to G.

For purity to be perfect (or as good as possible), the electron beams must originate from the same effective center of deflection as used in originally laying down the phosphors. Moving the yoke forward and backward on the neck of the CRT can precisely set the deflection center along the axis of the neck. However, slight transverse errors may still exist due to imperfections in the yoke windings or positions of the electron guns. This is affected slightly by the earth's magnetic field as well. The purity magnet rings are those closest to the yoke and provide the means for moving the electron beams very slightly to compensate.

The adjustment procedures generally use the red gun for the setting purity. Intuitively, one would think this should be the center (green) gun. However, since the red beam current is the highest (red phosphor is least sensitive), problems are likely to show up first with the red purity so it is used for the adjustment. In any case, it is a good idea to check all three guns for proper purity and tweak if needed before moving on to convergence.

In an in-line gun, the green gun is always in the middle. The only reason for adjusting purity with the red beam is because it gives the greatest sensitivity:

(From: Jeroen H. Stessen (Jeroen.Stessen@philips.com).)

- The red beam current usually has the largest amplitude.
- A landing error of the red beam gives the best visible discoloration (much better than green, better than blue).
- This makes the landing of the red beam the most critical.

Detailed Purity and Static Convergence Adjustment Procedure

Also see the adjustment information in the documents: Notes on the Troubleshooting and Repair of Computer and Video Monitors or Notes on the Troubleshooting and Repair of Television Sets.

(From: Alan McKinnon (alan.mck@pixie.co.za).)

The rearmost pair of magnets (seem from the service position behind the set in other words furthest from you nearest the front of the tube) affects purity. More on this later. The middle and front magnets are for convergence and work on pairs of colours. The effects can most easily be seen on a cross hatch test pattern (10 or so horizotal lines, 15 or so vertical lines).

But first, purity:

Without getting into the details of what happens inside the guns, I assume you need to know how to do the adjustments. You need some means of generating an evenly red screen. An (expensive) pattern generator is the preferred method. Fiddle the rear purity rings to distort the screen by bringing green and blue blobs into it. You will note that the magnets can be adjusted by moving both together, and moving them aart relative to each other. The best advice here is: adjust slowly and observe what happens. Once you have the screen evenly red, move on to convergence, which is the trick of getting the red green and blue beams to coincide on the screen to produce white, with the minimum of colour shadowing.

With a cross hatch pattern on screen, you can see easily how convergence works, and how the magnets affect the picture. Each tube type is different in exactly how this is done, but the general idea is that one set of magnets affects two specific colours only, moving them apart and bringing them nearer, while leaving the third colour alone. The other set of magnets takes the colours affected by the other set, and moves them together relative to the third colour. Also, moving a pair of magnets together adjusts the colours in one direction (vert or horiz) while moving the magents apart adjusts the other direction. With all things in life, there is some overlap, so you need to look carefully and see what happens mostly - the adjustments are not cut and dried. Oh, and they are interactive to some degree. Keep checking purity after you do convergence. All of this is best shown with a picture, the colours are arbitrary, you may well find the details do not apply to your tv, but the basic principles will. These initial converence adjustments apply only to the centre of the screen by the way, the edges are done elsewhere:

Rotating one set of magnets together might move red and blue together till they coincide vertically:

```
         | |  |           | | |           |  |
         | |  | ----->    | | |  ----->   |  |
         | |  |           | | |           |  |
         R G  B           G R B           G R&B
```

And moving them apart relative to each other might move red and blue together horizontally:

```
         R -----
                             R --------       R&B---------
         G -----  -----> G --------  -----> G ---------
                             B --------
         B -----
```

Moving the other set of magnets together might take the red and blue pair and move them to coincide with the green, vertically:

```
      |  |         | |          |
      |  | -----> | | ------> |
      |  |         | |          |
      G  R&B       G R&B      R&G&B (=white)
```

And moving them apart relative to each other might move the red and blue pair and move them to coincide with green horizontally:

```
    R&B -------
                         R&B -------
              ----->                ----> ------- R&G&B
                           G -------               (=white)
      G -------
```

Once the convergence is perfect in the centre of the screen (called static convergence) it's time to handle the edges and corners (called dynamic convergence for historical reasons). This is done by physically moving the entire yoke that is clamped around the tube neck with the deflection coild on it. It is anchored in place by a collar on the tube neck, loosen this slightly, butnot enough so that the yoke can move backwards. It is also held in place by rubber wedges glued or taped down. Take the wedges out. By gripping the yoke and levering it up and down, left and right, you will change he convergence in the corners. The effects don't work as you might at first suppose - moving the yoke left affects the lower right corner, this type of thing. Get the dynamic convergence right and stuff the wedges back under the yoke to hold it precisely in place and glue them back down. The recheck purity.

There you have it. Easy as pie. Some folk would have you believe no-one in their right minds adjusts these things. Well, balls. Someone did it at the factory, and they did it the way I just described. All you need is the right tools (pattern generator), patience, and time.

Tony's Notes on Setting Convergence on Older Delta Gun CRTs

(From: ard12@eng.cam.ac.uk (A.R. Duell))

The older delta-gun tubes (3 guns in a triangle, not in a line) can give **excellent** pictures, with very good convergence, provided:

1. You've set those 20-or-so presets correctly - a right pain as they interact to some extent.

2. The CRT is set up in the final position - this type of tube is more sensitive to external fields than the PIL type.

Both my delta-gun sets (a B&O 3200 chassis and a Barco CDCT2/51) have very clearly set out and labeled convergence panels, and you don't need a service manual to do them. The instructions in the Barco manual are something like:

"Apply crosshatch, and adjust the controls on the convergence board in the numbered order to converge the picture. The diagrams by each control show the effect".

Here's a very quick guide to delta gun convergence where the settings are done using various adjustments on the neck of the CRT (if you don't have a service manual but do know what each control does, and where they all are - otherwise, follow the instructions in the service manual --- sam):

1. Apply a white crosshatch or dot pattern to the set. Don't try and converge on anything else - you'll go insane. It's useful to be able to switch between those 2 patterns.

2. Before you start, set the height, width, linearity, pincushion, etc. They will interact with the convergence. Also check PSU voltages, and the EHT voltage if it's adjustable. That's where you do need a service manual, I guess.

3. Turn off the blue gun using the A1 switch, and use the red and green static radial controls to get a yellow croshatch in the middle of the screen. These controls may be electrical presets, or may be movable magnets on the radial convergence yoke (the Y-shaped think behind the deflection yoke).

4. Turn on the blue gun and use the 2 blue static controls (radial and lateral) to align the blue and yellow crosshatches at the center of the screen. Some manufacturers recommend turning off the green gun when doing this, and aligning red with blue (using *only* the blue controls, of course), but I prefer to align blue with yellow, as it gives a check on the overall convergence of the tube.

5. Turn off the blue gun again. Now the fun starts - dynamic convergence. The first adjustments align the red and green crosshatches near the edges - I normally do the top and bottom first. There will be 2 controls for this, either a top and a bottom, or a shift and a linearity. The second type is a *pain* to do, as it's not uncommon for it to affect the static convergence.

6. Getting the red and green verticals aligned near the edges is a similar process.

7. You now have (hopefully) a yellow crosshatch over the entire screen.

8. Now to align the blue. This is a lot worse, although the principle is the same. Turn on the blue gun again, and check the static (center) convergence

9. To align the blue lines with the yellow ones, you'll find not only shift controls, but also slope controls. Use the shift controls to align the centers of the lines and the slope controls to get the endpoints right. These interact to some extent. You'll need to fiddle with the controls for a bit to work out what they do, even if you have the manual.

The convergence over the entire screen should now be good....

A word of warning here... The purity is set by ring magnets on almost all colour CRTs, but on PIL tubes, there are other ring magnets as well - like static convergence. Make sure you know what you are adjusting.

Jerry's Comments on Convergence and Other Advanced Adjustments

(From: Jerry G. (jerryg@total.net).)

Convergence alignment is not something you can do yourself unless you have the proper calibration instruments and skills. It takes lots of experience and time. There are published specs for most of the good monitors. Most of the time they are as follows:

There is the 'A area', 'B area', and 'C area'. On a 15 inch monitor the A area would be a diameter of about 4 inches. The B area would be about 7.5 inches. The C area would be the outside areas including the corners. These numbers are approximate. There are actually standard specs for these areas. They are expressed in percentage of screen viewing area. Therefore the inches would vary with the CRT size.

The higher the price (quality) of the monitor CRT, yoke, and scanning control circuits, the tighter the convergence can be aligned by the technician. For the A area on a good monitor, the maximum error should not exceed 0.1 mm. For the B area it should not exceed more than about 0.25 mm. And for the C area, it can be allowed up to about 0.3 mm. Most of the monitors that I have repaired, seen, and used did not meet these specs unless they were rather expensive. With these specs there would not be any real visible misconvergence unless you put your nose very close to the screen... A lot of the ones in the medium price range they were about 0.15 mm error in the A area, about 0.4 in the B and greater than in the C area. This also annoys me because I am very critical.

If one has the skills and test gear he or she can do a better job on most monitors. It is a question of the time involved. To see the convergence errors a grating or crosshatch pattern is used. A full raster color generator is required for the purity adjustments as well. This is necessary to align the landing points of the CRT guns. The exact center reference and purity adjustments are done with the ring magnets on the CRT neck. The yoke position angle adjustments are also done for the side and top-bottom skewing as well. Everything interacts!

The corners are done with various sorts of slip or edge magnets. As for corner convergence skewing, button magnets are used. The color purity will be effected as you go, and must be also corrected. These adjustments interact on one another, and the processes continues until the convergence and purity are good at the same time...!

I don't recommend the amateur or hobbiest, or even the do-it-yourselfer to attempt this alignment procedure. The test gear would exceed the cost of a really good monitor anyways...!!! And without the proper skills required, he or she would only make it worse anyways...

As for purity specs, the color change from any corner to any corner must not exceed an error of more than 200 degrees Kelvin. The error in the B area should not exceed 300 degrees kelvin. This applies to a white raster. Most of the monitors I see don't get better than about 300 degrees Kelvin. And some are even 1000 out! The purity errors are best checked with a full Red raster using 100 % saturation. Then the other color vector angles are checked with cyan, and then magenta. The color temperature stability should be the same in all aspects.

A color spectrometer should be used to judge this error factor. As far as the eye is concerned, it will see a purity error of more than about 500 degrees Kelvin if the person knows what to look for...

When changing the CRT, this alignment must be done completely. Most shops do not even employ people who are skilled to a proper alignment, or don't even own the instruments to do it right, and the poor customer get back a monitor that is not in specs...!

CRTs with No Purity or Static Convergence Rings

I have a late model TV with a 13 inch tube with no static purity or convergence rings. I don't get to see that many modern tubes so this was a bit of a surprise or maybe I just hadn't noticed before on small CRTs if they didn't have purity/convergence problems. I do see it has wrapping of a rubber-ferrite-permalloy type material where the ring assembly would go. I assume that this is magnetized selectively at the factory to adjust purity/convergence? The yoke has the usual position and tilt adjustments. This one was an RCA/GE CRT.

What this means is that if you were to accidentally bring a strong permanent magnet near the base of the CRT or a strong degaussing coil, there is a slight possibility of totally messing up this compensation requiring replacement of the CRT. I don't know how possible this is without really working at it!

(From: Jeroen H. Stessen (Jeroen.Stessen@philips.com).)

Since eternity, Philips CRTs have not had external multipole magnet rings around the neck. There is an iron ring inside the neck, at the end of the electron gun assembly. This ring is permanently magnetized in the factory by a strong outside magnetic field at a later stage of the production. Further responsibility for purity, convergence and geometry is in the design of the coil windings distribution and some metal parts. Final purity adjustment is achieved by matching a tube with a coil and then shifting and tilting the coil slightly. This explains why Philips CRTs are always sold as a matched combination of tube and coil, contrary to some other brands.

Projection Set Convergence Adjustment Principles

(From: Jeroen H. Stessen (Jeroen.Stessen@philips.com).)

CRT projection displays require much convergence correction, especially since the 3 tubes aim at the screen under different angles. Generally the green Horizontal convergence coil is not driven because that is a geometry correction which is taken care of by the horizontal deflection circuit. The 3 vertical convergence coils usually also take care of vertical geometry correction (N-S corrrection) because the vertical deflection circuit is generally a standard direct-view type. Add to that a severe keystone correction for the Red and Blue tubes.

The convergence waveforms used to be generated from an analog polynomial generator. The components are then weighted and summed to form a Taylor polynomial. Consider the adjustment of horizontal convergence, then typical polynomial components are:

> 1 (shift),
> x (amplitude),
> x^2 (linearity),
> y (rotation or tilt),
> y^2 (bow),
> x*y (keystone),
> x^2*y (dunno if it's used).
> x*y^2 (pin-cushion),
> x^3 (side linearity).
> x*y^4 (corner pin-cushion)

Adjusting convergence is a highly iterative (read: costly) process because each potentiometer tends to influence the whole screen. Also, this method is not easily extendible to higher order adjustments for more accuracy. That's why better waveform generators have been designed, like digital look-up tables with D/A converters (which are quite expensive) and spline-like waveform generators (which are cheap and easy to adjust, the Philips design is called Convergence Spline Processor, it's digital too).

Monitor Tune-Up?

(The following from: Bob Myers (myers@fc.hp.com).)

Most manufacturers will quote an MTBF (Mean Time Before Failure) of somewhere in the 30,000 to 60,000 hour range, EXCLUSIVE OF the CRT. The typical CRT, without an extended-life cathode, is usually good for 10,000 to 15,000 hours before it reaches half of its initial brightness. Note that, if you leave your monitor on all the time, a year is just about 8,000 hours.

The only "tuneup" that a monitor should need, exclusive of adjustments needed following replacement of a failed component, would be video amplifier and/or CRT biasing adjustments to compensate for the aging of the tube. These are usually done only if you're using the thing in an application where exact color/brightness matching is important. Regular degaussing of the unit may be needed, of course, but I'm not considering that a "tuneup" or adjustment.

A Discussion on Correction Magnets

(From Ludwig (eastcomp@gmx.de).)

When repairing and recalibrating color monitors of different brands, one experiences those "dirty little tricks" called correction magnets, which have different forms, sizes and magnet strength, and which are attached at different locations somewhere near the electronic beams at the neck of the tube. These magnets are used to correct bad edge geometry/convergence and problems with color convergence at various locations on the screen.

Depending on the quality (i.e., magnetic geometry) of the tube and the deflection coils/fields there are monitors, which have only few (or even none) of these correction magnet, while others (some brands are "famous" for this) are really clustered with these magnets.

The magnets can have different forms and sizes:

1. Most often there are used small and thin, weak magnets, which are glued to the end of a plastic stripe. These stripes are inserted into the small gap between the tube and the deflection coils (ferrite coil) and the fixed by glue, silicon or plaster. This magnets are weak and therefore have to be positioned very near to the electron beam at the neck of the tube. They usually are intended to correct bad convergence at the corners and edges of the picture.

2. Plastisized magnets (e.g., 4x4x1 mm, 3x10x1 mm, or 10x10x0.2mm), which have a much bigger magnetic strength, are either glued to the the edges of the plastic case of the deflection coils or - if the magnet is not so strong - to the tube itself. These types of magnets often are used to correct larger deficiencies in geometry - and to a lesser extent - in convergence.

Those are my observations, but what I'd like to know is this:

- Why aren't such magnets demagnetized during the power-on degaussing?
- Aren't such magnets demagnetized, if one uses an extra demagnetizing coil for removing undesired magnetic fields at the tube? Are those demagnetizing coils harmful to the different correction magnets on/at the neck of the coil?

  What type of magnets are used for those correction magnets ? (barium titanate, other types of ferrites?).

(From: Sam.)

The answers to both (1) and (2) is that if using the internal degauss coil and/or properly positioned (front of CRT only) external coil, the strength of the field is (hopefully) insufficient to affect the correction magnets. That is why one should NEVER attempt to degauss in the rear of the TV or monitor or inside the case!

I don't believe the magnets are made of anything special - they appear to be similar to your typical refrigerator (note holding) magnets in composition and strength.

(From: Ludwig.)

By the way: Almost any monitor, which is older than 1-2 years has developed deficiencies in convergence, geometry and sharpness, and has to be recalibrated, if you'd prefer an optimal picture (and being careful with one's eyes). It's not quite easy to do fine recalibration of convergence and geometry (even modern monitors allow only to correct coarse via OSD menus), because during recalibration the monitor has to be at power-on state, i.e. high voltages are at every edge of the monitor. I successfully used household rubber/plastics gloves to do the recalibration by repositioning the above mentioned magnets while the monitor is powered on. Using household rubber/plastics gloves is also a valuable means to prevent beginners from electric shock, and therefore should be recommended for every job to do with the monitor case open and power on (even just for monitoring electronic signals with an oscilloscope).

CRT and CRT Related Maintenance and Repair

Preventive Maintenance - Care and Cleaning

Preventive maintenance for a TV or monitor is pretty simple - just keep the case clean and free of obstructions. Clean the CRT screen with a soft cloth just dampened with water and mild detergent or isopropyl alcohol. This will avoid damage to normal as well as antireflection coated glass. DO NOT use anything so wet that liquid may seep inside of the monitor around the edge of the CRT. You could end up with a very expensive repair bill when the liquid decides to short out the main circuit board lurking just below. Then dry thoroughly. Use the CRT sprays sold in computer stores if you like but again, make sure none can seep inside. If you have not cleaned the screen for quite a while, you will be amazed at the amount of black grime that collects due to the static buildup from the CRT high voltage supply.

There is some dispute as to what cleaners are safe for CRTs with antireflective coatings (not the etched or frosted variety). Water, mild detergent, and isopropyl alcohol should be safe. Definitely avoid the use of anything with abrasives for any type of monitor screen. And some warn against products with ammonia (which may include Windex, Top-Job, and other popular cleaners, as this may damage/remove some types of antireflective coatings. To be doubly sure, test a small spot in corner of the screen.

In really dusty situations, periodically vacuuming inside the case and the use of contact cleaner for the controls might be a good idea but realistically, you will not do this so don't worry about it.

(From: Bob Myers (myers@fc.hp.com).)

Windex is perfectly fine for the OCLI HEA coating or equivalents; OCLI's coating is pretty tough and chemical-resistant stuff. There may be alternative (er..cheaper) coatings in use which could be damaged by various commercial cleaners, (For what it's worth, OCLI also sells their own brand of glass cleaner under the name "TFC", for "Thin Film Cleaner".)

I have cleaned monitors of various brands with both Windex and the OCLI-brand cleaner, with no ill results. But then, I'm usually pretty sure what sort of coating I'm dealing with...:-)

Monitor coatings are always changing; besides the basic "OCLI type" quarter-wave coatings and their conductive versions developed to address E-field issues, just about every tube manufacturer has their own brew or three of antiglare/antistatic coatings. There are also still SOME tubes that aren't really coated at all, but instead are using mechanically or chemically etched faceplates as a cheap "anti-glare" (actually, glare-diffusing) treatment.

In general, look in the user guide/owner's manual and see what your monitor's manufacturer recommends in the way of cleaning supplies.

Shorts in a CRT

Occasionally, small conductive flakes or whiskers present since the day of manufacture manage to make their way into a location where they short out adjacent elements in the CRT electron guns. Symptoms may be intermittent or only show up when the TV or monitor is cold or warm or in-between. Some possible locations are listed below:

- Heater to cathode (H-K). The cathode for the affected gun will be pulled to the heater (filament) bias voltage - most often 0 V (signal ground). In this case, one color will be full on with retrace lines. Where the heater is biased at some other voltage, other symptoms are possible like reduced brightness and/or contrast for that color. This is probably the most common location for a short to occur.

- Cathode to control grid (K-G1). Since the G1 electrodes for all the guns are connected together, this will affect not only the color of the guilty cathode but the others as well. The result may be a very bright overloaded *negative* picture with little, none, or messed up colors.

- Control grid to screen (G1-G2). Depending on circuitry can result in any degree of washed out or dark picture.

- Screen to focus (G2-F). Screen (G2) and focus voltage will be the same and the controls on the flyback will interact. Result will be a fuzzy white raster with retrace lines and little or very low contrast picture.

Symptoms will be similar to those of a flyback with breakdown in the focus/screen divider network.

- Focus to high voltage (F-HV). High voltage will be pulled down - probably arcing at the focus spark gaps/other protective devices. Line fuse and/or HOT may blow.

- Other locations between electron gun elements as feed wires.

Replacing the CRT may be required but there are a variety of 'techniques' that can often be used to salvage a TV that would otherwise end up in the dump since replacing a CRT is rarely cost effective:

1. Isolation - this will usually work for H-K shorts as long as only one gun is involved.

2. Blowing out the short with a capacitor - depending on what is causing the short, this may be successful but will require some experimentation.

3. Placing the CRT (TV or monitor) face down on a soft blanket and gently tapping the neck to dislodge the contamination. Depending on the location of the short, one side or the other might be better as well.

A combination of (2) and (3) may be required for intermittent shorts which don't appear until under power. See the sections below for additional details. However, for shorts involving the focus and high voltage elements, even a sharp edge can result in arcing even if there is no actual short. There is no remedy for these types of faults.

Providing Isolation for a CRT H-K Short

This procedure will substitute a winding of your own for the one that is built in to the flyback to isolate the shorted filament from the ground or voltage reference. Note that if you have a schematic and can determine where to disconnect the ground or voltage reference connection to the filament winding, try this instead.

The flyback is the thing with the fat red wire coming out of it (and perhaps a couple of others going to the CRT board or it is near this component if your set has a separate tripler) and may have a couple of controls for focus and screen. It should have some exposed parts with a ferrite core about 1/2-3/4" diameter.

The filament of the CRT is the internal heater for each gun - it is what glows orange when the set is on. What has happened is that a part of the fine wire of the bad color's filament (assuming this is indeed your problem) has shorted to the cathode - the part that actually emits the electrons. Normally, the heater circuit is grounded or tied to a reference voltage so when it shorts to the cathode, the cathode voltage level is pulled to ground or this reference.

You will need some well insulated wire, fairly thick (say #18-22). Find a spot on the flyback where you can stick this around the core. Wrap two turns around the core and solder to the CRT filament pins after cutting the connections to the original filament source (scribe the traces on the board to break them). Make sure you do not accidentally disconnect anything else.

This winding should cause the filaments to glow about the same brightness as before but now isolated from ground. If they are too dim, put another turn on the flyback to boost the voltage. (Don't go overboard as you may blow the filament totally if you put too many turns on the core - you then toss the TV or monitor.)

Route the wires so that there is no chance of them getting near the high voltage or any sharp metal edges etc. Your picture quality may be a tad lower than it was before because of the added stray capacitance of the filament wiring being attached to the the (formerly bad) video signal, but hey, something is better than nothing.

Rescuing a Shorted CRT

If the short is filament-cathode (H-K), you don't want to use the following approach since you may blow out the filament in the process. If this is the case, you may be able to float the filament and live with the short (see the document: Notes on the Troubleshooting and Repair of Television Sets.

Shorts in the CRT that are between directly accessible electrodes can be dealt with in a more direct way than for H-K shorts. At this point you have nothing to loose. A shorted CRT is not terribly useful.

If the short is between two directly accessible electrodes like cathode-grid, then as a last resort, you might try zapping it with a charged capacitor (see below for K-G1 short).

Unplug the CRT socket!

Start with a relatively small capacitor - say a few uF at a couple hundred volts. Check to see if the short is blown after each zap - few may be needed. Increase the capacitance if you feel lucky but have had little success with the small capacitor.

If the fault is intermittent, you will, of course, need to catch the CRT with the socket disconnected and the short still present. Try some gentle tapping if necessary. If you do this with the charged capacitor across the suspect electrode, you **will** know when the short occurs!

(From: Terry DeWick (dewickt@esper.com).)

I have seen this problem many times, shorted CRT red cathode, tap neck of CRT (not hard enough to brake, but close) or hit with a Tesla coil, we use one in shop, remove CRT board, run coil around pins for about 10 seconds, would you believe there is a service bulletin from Philips on this and focus shorts - I do not have a copy - I just helped write it - demonstrated use of coil to the service engineer and fixed 2 bad tubes in process.

(From: JURB6006 (jurb6006@aol.com).)

If it takes more than about 400 mA to clear the short the cathode is usually toast. The big cap makes it a big thing, but only for a certain time, this is based on thermal mass.

Recently after I had tried everything I decided to use external power to remove a G1 short. This was the most solid short I've ever seen, I used an old AT PC power supply and all I got was to make the internal "wires" to the elements RED HOT!!!

The best way to remove a G1 short is (I don't do it this way all the time it is too much trouble).

1. Completely disconnect the cathode of the offending gun.

2. Connect the cathode to a clip lead.

3. Connect the G1 to ground, not DAG on an NAP and if it's an NAP you must isolate it and connect it to ground, if not an NAP 99% of the time you don't have to do it. You still need to tie G1 to ground, but in most sets you can just do it.

4. As the short starts to manifest itself, touch the clip lead from the cathode to the video output 220 VDC source.

Determining if Your CRT is up to Air

> "I have a Compuadd monitor that's completely blank.The high voltage is very low and there's flashing inside the neck of the picture tube. I believe there may be a small hairline crack in the neck of the picture tube. I suspect that a crack has compromised the vacuum in the tube and that's what is causing the flashing and the low voltage. Is that possible, and if so, is there anything that can be done other than junking it?"

If there is a crack, then everything else is possible. However, these rarely develop on their own.

Look around the neck of the CRT for a coating - the getter. If it has turned white or red, your CRT is history. If it is still silver, the vacuum is intact and your arcing may be due to a bad flyback putting excessive voltage on the screen or focus electrode or a CRT that is bad in other ways. There are supposed to be external protection spark gaps, etc. for this but may not always work.

Sorry, junking it is probably the only realistic solution. Unless you find a cheap used CRT, the expense is not worth it. Even then, adjustments may be quite involved.

Scratches or Other Damage to the CRT Face

It is generally difficult to accidentally scratch the face of the screen but accidents do happen. The way the manufacturer would repair it is to replace the CRT. If the scratch is the result of shipping damage, file a claim with the shipping company. If it is a factory defect, get it repaired or replaced under warranty.

Barely visible scratches can be removed with jeweler's rouge or similar ultra-fine abrasive unless the CRT has an antireflective or textured surface.

Jeweler's rouge is the same stuff that is used in the final polishing of lenses and mirrors so it makes for a fine finish. However, any kind of scratch deep enough to be felt will not yield to this approach.

For larger scratches, one would normally start out with a coarser abrasive like 300 grit and work toward successively finer sizes - 600, 1200, etc. - with the final polishing being done with the rouge. However, realistically, this isn't really a viable approach for a CRT faceplate. It takes a lot of grinding to remove enough material to smooth out a scratch and you are more likely to mess things up than to improve matters.

If the CRT has an antireflective coating or textured surface, it will almost certainly be best to leave the scratch alone. Any type of polishing *will* remove affect the appearance in the vicinity and leave you with a big unsightly blob. This will be much more objectionable than a slight scratch.

The types of fillers sold in auto parts stores for repairing auto windshields may reduce the visibility of any scratches but DO NOT restore the integrity of the glass.

I don't quite know whether this is better or worse than the disease but it might be worth trying:

(From: Cooper@Hub.ofthe.NET).

> "I may have come across an easy fix for those who have scratched glass on the monitor face. I am currently using window film as an adhering material to cover and conceal the scratches. This looks much better and enables me to continue usage of the monitor without the aggravating distortion."

- Back to CRT FAQ Table of Contents.

CRT Degradation

CRT Aging - Effects on Electrical Characteristics and Performance

(From: Jeroen H. Stessen (Jeroen.Stessen@philips.com).)

Specifications for Philips CRTs can be found in the regular series of data books from Philips Components. Companies and universities usually have them. Usually the data sheets show typical Ik/Vk characteristics. They also list the spread on cutoff voltage and cathode gain, and this spread is quite large even on new CRTs. They also list phosphor sensitivity (Lum/Ik), this too has a large spread. But they almost never list anything about the aging process.

Here are some of the effects:

- Phosphor ages due to burn-in, particularly on static pictures, this is immediately obvious on visual inspection. If the aging is even (no pattern) then at least the efficiency is reduced.
- Cathodes age due to loss of emission material, particularly for oxide cathodes. The central part of the cathode surface has carried the most current density and will wear out first. The surrounding area takes over, this will lead to an unsharp picture. Adjusting the focus voltage will not really improve it. The tube is worn out.
- Also poisoning of cathode surface may occur. This can be cured temporarily by short-time overheating ("re-conditioning").
- The cathode that wears out first (often the red one) also loses gain, so the white point of the image will shift (to cyan). The white point can be re-adjusted with the gain potentiometers and the contrast, but peak brightness will not be as high as new.
- The cutoff voltages of all cathodes will drift. Common drift is adjusted by the user by controlling the

brightness. Different drift leads to a coloration of the black background level. In extreme cases vertical flyback lines will appear. Cutoff voltage can be adjusted with potentiometers, or there is automatic stabilisation. Still, the VG2 (screen) may need periodic adjustment too.

- Leakage currents may disturb VG2 and focus voltage, re-adjustment has only a temporary effect.

- VG2 and focus potentiometers may wear out due to electromigration etc. A hole may form under the wiper, re-adjustment is then impossible.

- Some types of cathode wear (according to a friend in Philips Semiconductors) can cause the Ik/Vk transfer characteristic to divert so much from an ideal gamma function that no adjustment can compensate for it. Then the tube is really worn out.

I hope that this helps you to distinguish between a really worn out tube and one that still has some life in it after re-adjustment.

CRT Age Resulting in Dark Picture

Where circuit problems have been ruled out:

(From: Jeroen Stessen (Jeroen.Stessen@philips.com).)

Most probably the cathodes have worn out. The emission material on the surface slowly becomes inactive. Usually you see one colour go first, then the others. At the same time you will observe a loss in sharpness, because a larger cathode area is being used, giving a bigger spot.

Rejuvenating is done by applying a (too) high filament voltage, in order to bring new emission material to the surface. It will not work for long and there is the risk of burning the filament wire for good. It may be worth a try, though.

Other wear mechanisms are:

- Glass browning (generally only for projection tubes).
- Phosphor aging (life time is defined by efficiency < 50%).
- Vacuum leaks (generally cause EHT flashover, audible).

Then again, it may also be that for some mysterious reason your VG2 voltage has dropped below spec. A too high VG2 voltage will cause a smaller cathode area to be used, leading to a sharper picture but accelerated cathode wear.

Brightening an Old CRT

If performing adjustments of the internal background and/or screen controls still results in a dark picture even after a long warmup period (and the controls are having an effect - they are not faulty), the CRT may simply be near the end of its useful life. In the old days of TVs with short lived CRTs, the CRT brightener was a common item (sold in every corner drugstore, it seemed!).

First confirm that the filaments are running at the correct voltage - there could be a marginal connection or bad resistor or capacitor in the filament power supply. Since this is usually derived from the flyback, it may not be possible to measure the (pulsed high frequency) voltage with a DMM but a service manual will probably have a waveform or other test. A visual examination is not a bad way to determine if the filaments are hot enough. They should be a fairly bright orange to yellow color. A dim red or almost dark filament is probably not getting its quota of electrons. It is not be the CRT since all three filaments are wired in parallel and for all three to be defective is very unlikely.

If possible, confirm that the video output levels are correct. For cathode driven CRTs, too high a bias voltage will result in a darker than normal picture.

CRT brighteners are available from parts suppliers like MCM Electronics. Some of these are designed as isolation transformers as well to deal with heater-to-cathode shorts.

You can try a making a brightener. Caution: this may shorten the life of the CRT - possibly quite dramatically (like it will blow in a couple of seconds or minutes). However, if the monitor or TV is otherwise destined for the scrap heap, it is worth a try.

The approach is simple: you are going to increase the voltage to the filaments of the electron guns making them run hotter. Hopefully, just hotter enough to increase the brightness without blowing them out.

Voltage for the CRT filament is usually obtained from a couple of turns on the flyback transformer. Adding an extra turn will increase the voltage and thus the current making the filaments run hotter. This will also shorten the CRT life - perhaps rather drastically. However, if the monitor was headed for the dumpster anyhow, you have nothing to lose. You can just add a turn to an existing winding or make your own separate filament winding as outlined in the section: Providing Isolation for a CRT H-K short.

In some monitors, there is a separate filament supply on the mainboard - this should be obvious once you trace the filament wires from the video driver board). In this case, it still may be possible to increase this output or substitute another supply but a schematic will be required.

There are also commercial CRT rejuvenators that supposedly zap the cathodes of the electron guns. A TV or monitor service center may be able to provide this service, though it is, at best, a short term fix.

Checking the Age of the CRT

So you have this great deal on a used TV or monitor. How can you tell if the picture tube is about to die on you?

(From: Andy Cuffe (baltimora@psu.edu).)

The best way to tell is to look at the picture quality. There is no way to tell the exact number of hours. Also, the life of CRTs varies quite a bit. some will go down hill much faster than others.

- It should be sharply focused over the entire screen and all 3 colors should be equally sharp.
- Set the picture brightness and color to maximum. If you see any bleeding or smearing to the right of bright objects don't buy it.

- When you first turn it on the picture should look normal in well under a minute. If it is dim, tinted, or blurry for more than a minute or two the CRT is getting weak.

- A B/W picture should not be tinted.

- The picture should have decent brightness with the picture at about mid range.

Apart form that, if the overall picture is good the CRT is fine. CRTs usually fail very slowly. Even if it's starting to show it's age it probably has several years left.

(Portions from: Jerry G. (jerryg50@hotmail.com).)

You cannot tell the hours used by just looking or even measuring a tube. A tube can go at any time. There are no hour counters!

Turn on the unit and see if there is any unusual bleeding of the image in the picture at high contrast levels. When turning the brightness up and down, the color temperature should not change, only the brightness. When turning the contrast up and down, the focus at the center should also be very stable. It may change only a little bit. When turning on the set, the color temperature should be stable within about 3 to 5 minutes.

Look at the colors in the corners to see if the purity is good. Bad purity can be attributed to a miss-adjusted yoke assembly, to a bad shadow mask.

To know the manufacture date of the unit, it us usually on the back with the model and serial number. Most TV sets are on about 5 to 8 hours a day if it is a family TV. If it is a bedroom TV the hours may be 1/2 that amount. Monitors may be on 24 hours a day - or much less.

A good way to know if the emission of the CRT is up to specs is to get a CRT analyzer and measure the gun emission. Some service centers own one.

- Back to CRT FAQ Table of Contents.

CRT Rejuvenation

What is CRT Rejuvenation?

Where one or more electron guns in the CRT have deteriorated due to wear and tear, it is sometimes possible to give them a new, but possibly, temporary lease on life through rejuvenation using a special piece of CRT service equipment.

There may be some schematics for commercial CRT rejuvenators accessible from the Sencore Service Page.

(From: Gary Klechowitz (klechowi@execpc.com).)

When I rejuvenate a tube I inform the customer that there is no warranty on the job. Rejuvenating a CRT is like when Clatuu was brought back to life by Gort in "The Day The Earth Stood Still". When asked "How long will you live"? he replied: "no one knows".

I use a Sencore Beam Builder. If your tube is just moderately dim and blurry but still shows good cut off threshold, I would just use the auto restore mode on the beam builder rather than using the restore button. If the tube is really bad with little or no cutoff threshold, then the rejuvenator is needed but that has less than a 50% chance of fixing the tube and in many cases the tube gets worse to trashed in the process.

CRT Degradation and Rejuvenation

> "As I understand it, when a CRT ages, its filament looses material. It ejects fewer electrons, and this accounts for the need to crank up the cutoff. Is the focusing problem caused by the high cutoff voltage accelerating the electrons too fast for the focusing assembly to work? And what would explain the shadowing problem?"

Replies from: Jeroen H. Stessen (Jeroen.Stessen@philips.com) and another engineer at Philips who we shall call Tom.

Tom:

Yes, the cathode surface is losing the Barium/Strontium oxide slowly and hence the working voltage to free the electrons is rising. In itself, this will not change the cut-off voltage needed for proper operation. This stays the same, only there are fewer electrons left that can be drawn towards the screen at a certain drive voltage. The focusing problem occurs at the moment that the TV-set tries to establish a certain beam current and finds out that a higher driver voltage is needed to give this current. Consequently, a larger cathode area is used to get enough electrons out of it. This larger cathode area will be imaged onto the screen and give a larger spot size.

Another point is the drift of leakage current, leading in a practical TV-set with high impedance focus circuit (this allows voltage drop) to a focus voltage at the CRT focus pin that is lower than it should be and this again leads to a bad focus performance.

Jeroen:

Readjustment of the focus voltage will be only a temporary solution.

Addressing each of the effects and CRT rejuvenation:

1. Why is poor focus sometimes a symptom of a failing CRT?

Tom:

Normally only the emission from the centre of the cathode adds to the electron beam. If the emission material in the centre is exhausted then the outer area comes in. This is a larger surface, the electron lens projects this into a larger spot. It is not that the focus is bad, the lens works OK. It is that a larger object is projected onto a larger image.

Jeroen:

This applies mainly to oxide cathodes. Impregnated cathodes are much more robust. They can be applied at a higher cutoff voltage and thus deliver a smaller spot without premature wear. They are more sensitive to a too high heater temperature, however, because they are operated at a higher temperature to begin with. They do evaporate more metal during their lifetime. At one time there was fear that they would deposit too much metal on the glass around the electrodes, leading to leakage currents. These can cause drift of focus and screen voltages and can disturb the cutoff current measurement. Those can influence the picture too.

Tom:

Impregnated cathodes contain a lot of emission material that moves more easily towards the cathode surface as time passes. Oxide cathodes have the problem that the Ba/Sr-oxide is positioned too deep to be very effective. Hence, the life time of an I-cathode should be longer than that of an oxide cathode but indeed the sensitivity to correct heater voltage is higher. Second, an impregnated cathode, being highly conductive compared to an oxide cathode which is a semi-conductor, can handle a much higher peak current since the cathode material is not locally heated up by this peak current. An oxide cathode can be destroyed by a too high peak beam current !

Jeroen:

Oxide cathodes are typically operated at cutoff voltages between 100 and 130 V. Impregnated cathodes are typically operated at cutoff voltages between 130 V and 200 V. Hence they can provide a much sharper spot, but it is also much more difficult to design a video output amplifier with sufficient bandwidth at the required large drive voltage (like 120 V peak-peak).

2. Why is horizontal streaking sometimes another symptom?

Jeroen:

Two symptoms, both related to the cutoff voltage being higher than what the video output amplifier(s) can deliver. The cutoff voltage is proportional to the VG2 (second grid voltage). The higher VG2 is the higher the cutoff voltage VK - VG1 must be to blank the beam. The video amplifier delivers VK. VG1 is fixed. Remember: cathode drive is negative, e.g. +130V = black, +30V = white.

If the video amplifier clips before cutoff is reached then the beam will not be blanked completely and you will see a lighted background with slanted retrace lines. Some class-B video amps will also show a bad recovery time from clipping to black, this may lead to black streaks after black images. Class-A amps should not have this problem. (In my experience this is more common with clipping to white, usually leading to red or yellow streaks.)

If the cutoff voltage rises (due to some unexplained wear) or because VG2 rises (due to drift or due to owner intervention: turning the Screen potmeter) then the user may compensate for the increased (background) brightness by lowering the brightness control of the set. Some televisions automatically lower the brightness of each channel because they have automatic cutoff control. Either way, the cathode voltages rise and clipping may occur with retrace lines as a result.

Tom:

Well, as said earlier, in principle the cut-off doesn't change due to cathode wear-out. The fewer electrons still need the same voltage to prevent them from reaching the accellerating lens. I have heard of cut- off drift due to distance drift between G1 and G2 for which it is very sensitive. However, this is not something that gets worse over time.

> 3. And finally, what is the real story on CRT restorers/rejuvenators?

Jeroen:

Some of the possible 'remedies' include:

- Excess heater temperature may bring some new emission material to the surface of the cathode. This is done by putting 9-10 V (?) on a 6.3 V heater. There is not emission material much left, so this will be a temporary solution at best. I don't think it is needed or recommended with I-cathodes (impregnated).

  Tom:

  This also helps for poisoned cathodes. Cathodes that have been operated too long on a too low heater voltage get poisoned, meaning that the Ba/Sr-oxide gets chemically binded, leading to a higher working voltage. Indeed, only oxide cathodes can be rejuvenated this way. Impregnated cathodes have a more sudden death mechanism and can not be regenerated in this way.

  There is also the risk of burning out a heater filament for good.

- Some type of electrode shorts may be removed by high currents.

- The vacuum may be improved by activating the getter electrode using an induction heater or RF source to heat the ring shaped getter electrode to red/orange temperature. (This probably only applies and then only in a limited way if the getter spot has faded - turned red or milky from its normal silvery appearance --- sam.)

  Tom:

- Further: burning metal whiskers off the electrodes can help reducing a leakage current problem.

  Jeroen:

  This is done by running high (flash) currents between electrodes. A similar procedure is performed on new picture tubes in the factory.

Also see the sections starting with: "Brightening an old CRT".

More Comments on CRT Rejuvenation

(From: Ren Tescher (ren@rap.ucar.edu).)

Reduced emission (dim picture) can occur when the cathode/filament has used up most of the electrons it can emit to the screen. Or, a 'crust' may have formed on the thoriated emitter material that can be 'boiled off' to expose more electrons.

A rejuvenator or restorer generally hits the cathode/filament with a higher than normal current to accomplish this.

But, while a rejuvenator gives the cathode/filament a 'blast' of power, a restorer can slowly increase the temperature while monitoring beam current on one of the grids.

So generally a rejuvenator was a 'do or die' unit and a restorer could give only what was needed to accomplish increased emission. But these definitions have always been blurred by advertising hype.

The early restorers, such as my REM, had the operator watch the grid current on a meter(s) to determine when emission was sufficient. I suppose newer units have a PIC chip or some other logic to do the job.

(From: Terry DeWick (dewickt@esper.com).)

I use a hand held Tesla coil to all pins for about 5 seconds. Then, follow up with rejuvenator for a quick check and cleanup if needed. Tesla coil is type the neon sign people use for testing. 95% or better luck - saved a lot of out of warranty Zeniths from big repair bills or junk pile.

Home-Made CRT Rejuvenator 1

(From: Tony Duell (ard@p850ug1.demon.co.uk).)

I've read some articles in 'Television' which describe home-brew CRT rejuvenators. I've not tried any of the circuits yet...

It appears that you overrun the heater by up to 50% (for a 6V heater, try 7.5V and 9V, say). Don't blame me if it burns out ;-)

You then apply about 300V, current limited to say 50 or 60mA between cathode and 1st grid. One of the older designs used the UK 240V mains, a single diode as a half-wave rectifier, and a 15W light bulb in series for this PSU. I don't like unisolated equipment, so I'm not going to try it.

Some designs apply that voltage continuously, and you watch the emission current rising (or the bulb getting brighter...). With others you apply it for a few seconds, and then check the emission using, e.g. a 12V supply and a microammeter between cathode and grid.

One old article suggested that if you get no improvement, switch off the heater supply with the 300V still connected. As the cathode cools down, you get quite violent stripping of the cathode - observable as sparks from the electron gun area of the CRT. On the other hand, it is claimed that this can completely ruin the cathode, or even cause short-circuits to occur in the CRT.

Home-Made CRT Rejuvenator 2

I have no comments one way or another with respect to this device. Please contact the author for further information.

(From: Mario Di Stefano (mario.distefano@siemens.it).)

Here is the 'gadget' I use to rejuvenate 'tired' CRT's:

```
                T1
o---+--------+    +-------------------------------->
    |         )||(
M   |         )||(
A   |         )||( 6.3 or 12 Vac                    To Filament
I   |         )||( Secondary                        CRT Tube
N   |         )||(                                  (no Polarity)
S   |         )||(
    |         )||(
o---|-----+--+    +-------------------------------->
    |     |
    |     --------------------------------------> CRT Cathode
    |
    |                  +-----+     _|_
    ------------------| LP1 |-----o o------------> CRT 1st Grid
                       +-----+     P1
```

Where:

- T1 is a standard mains AC transformer.
- LP1 is a standard FILAMENT LAMP (60 - 100 W) working voltage according to mains.
- P1 Hand Pushbutton.

Other things needed (not shown):

- Mains switch (best if with overload protection or with fuse)
- 4 ISOLATED clips like the ones used in electronics to make contacts with the pins of ICs. These isolated clips ARE IMPORTANT. You don't have to touch any connection during the cleaning.

I think this circuit works better if the mains voltage is 220 Vac.

How to use it:

First we have an tired CRT (BW or colour is the same). We have poor image contrast, 'strange' brightness, also strange colours. Next we have to remove (if present) the CRT socket to its circuitry (beware to disconnect mains voltage FIRST!!!!!). At this point could be useful to discharge the HV using an isolated wire FIRST connected to CRT grey body and then to the make the contact UNDER the suction gummy which carries EHT. to the tube. It is not a dangerous voltage, but could be better not to discharge it over the body!

Now we have to identify the filament pins. Usually on the schematic circuitry of the Monitor/TV it is clearly written. If the schematic is not available, using an ohmmeter we should find the two contacts which gives a few ohms. These contacts usually are put aside each other) have to be connected to the transformer secondary of the circuit above. The Cathode and 1st grids can be found looking very closely into the tube glass (use lens and good light if necessary). Keep in mind the way the CRT electron sources are built. These usually follows this:

```
                    Cathode
                    |                  (B/W CRT tube)
                    V
          O------+  |  |
                 +  |  | <- 1st Grid
       Filament  +  |  |
                 +  |**| <-Spark (read text below)
          O------+  |  |
                    |  |
                    |  |
 Cathode  O---------+  |
 Connection            |
                       |
 1st Grid O------------+                  (Damn'd ASCII graphics!)
 Connection
```

Try to connect and turn on the transformer. The Filament in the CRT should turn on in a not-so-bright red (if it is a colour tube, we have 3 filaments on).

Now turn off the transformer again. Connect the Cathode wire to the cathode pin of the CRT Tube. Connect the 1st grid accordingly.

Turn on the transformer. FIRE button P1. If there is dust (due to aging) between the cathode and 1st grid, the circuit will blow-up it. If this happens, you could (but not always) even see the LP1 turn on and off randomly (a good cleaning gives a lamp OFF) and some sparks inside the tube. The tube collar glass now becomes hot: it is normal. You can even 'force' better sparks if you 'ting' your finger against the CRT glass (not so strong, of course). If it is a Colour CRT, you have 3 Cathodes, 3 1st grids a anyway 1 filament. Useless to say that the procedure have to be carried out for all these electrodes. A good cleaning, gives a LP1 steady OFF. If it is a steady bright or dim, means that a 'bridge' has been formed between the electrodes and there is no way to recover the tube. Turn off the mains, remove the connections, and re-apply the original socket. That's all. I'm not tired to say: BEWARE OF THE MAINS VOLTAGE: IT CAN KILL!! If you are not so skilled, don't try to do this procedure. I used this circuit lots of times. It worked almost anyway. I recovered lot of thrown away PC monitors, and now are working well....

Home-Made CRT Rejuvenator 3

Here's another circuit found on the Web:

- CRT Rejuvenator Description
- CRT Rejuvenator Schematic

And, some comments:

(From: Chris F. I recently built a homemade CRT tester & rejuvenator from plans I got these plans. The test mode works quite well, providing a good indication of the CRT emissions and showing the presence of H-K or K-G shorts. But the restore mode often doesn't help very much, though it has done a half-decent job on at least a few old CRTs. Anyway, I've been told that Sencores "Beam Builder" applies 450 Volts cathode to grid for a short time to restore the emissions. Now I have some old 450-volt transformers from really old TVs and I wondered if I could modify this design to use 450 VAC between cathode and grid (during restoration only). How long would the restoration process take at this voltage, would this work, and how dangerous would it be? I've heard horror stories of all kinds about CRTs during handling, rejuvenation, and so on, and I don't like taking chances with these things.

But I'd rather give this a try than spend the $2000 Cdn it would cost me for a Sencore unit.

Items of Interest

Lifespans of Monitors

(From: Bob Myers (myers@fc.hp.com).)

Most manufacturers will quote an MTBF (Mean Time Before Failure) of somewhere in the 30,000 to 60,000 hour range, EXCLUSIVE OF the CRT. The typical CRT, without an extended-life cathode, is usually good for 10,000 to 15,000 hours before it reaches half of its initial brightness. Note that, if you leave your monitor on all the time, a year is just about 8,000 hours.

The only 'tune-up that a monitor should need, exclusive of adjustments needed following replacement of a failed component, would be video amplifier and/or CRT biasing adjustments to compensate for the aging of the tube. These are usually done only if you're using the thing in an application where exact color/brightness matching is important. Regular degaussing of the unit may be needed, of course, but I'm not considering that a tune-up or adjustment.

Monitor Life, Energy Conservation, and Laziness

A common misconception about the care and feeding of computer monitors is that they should be left on all the time. While there are some advantages to this, there are many more disadvantages:

1. CRT Life: The life of a monitor is determined by the life of the CRT. The CRT is by far the most expensive single part and it is usually not worth repairing a monitor in which the CRT requires replacement. The brightness half-life of a CRT is usually about 10-15 K hours of on time independent of what is being displayed on the screen. 10 K hours is only a little more than a year. By not turning the monitor off at night, you are reducing the life of the monitor by a factor of 2-3. Screen savers do not make any substantial difference especially with modern displays using X-Windows or MS Windows where the

screen layout is not fixed. With video display terminals, the text always came up in the same position and eventually burned impressions into the screen phosphor. With modern CRTs, the filaments can be left on to minimize the time needed for a picture to appear since this doesn't affect CRT life very much.

2. Component life: The heat generated inside a monitor tends to dry out parts like electrolytic capacitors thus shortening their life. These effects are particularly severe at night during the summer when the air conditioning may be off but it is still a consideration year around.

3. Safety: While electronic equipment designed and manufactured in accordance with the National Electrical Codes is very safe, there is always a small risk of catastrophic failure resulting in a fire. With no one around, even with sprinklers and smoke alarms, such an failure could be much more disastrous.

4. Energy use: While modern monitors use a lot less energy than their older cousins, the aggregate energy usage is not something to be ignored. A typical monitor uses between 60 and 200 Watts. Thus at a $.10 per kWH electric rate such a monitor will cost between $48 and $160 a year for electricity. During the night, 1/2 to 2/3 of this is wasted for every monitor that is left on. If air conditioning is on during the night, then there is the additional energy usage needed to remove this heat as well - probably about half the cost of the electricity to run the monitor.

The popular rationalization for what is most often just laziness is that power-on is a stressful time for any electronic device and reducing the number of power cycles will prolong the life of the monitor. With a properly designed monitor, this is rarely an issue. Can you recall the last time a monitor blew up when it was turned on? The other argument, which has more basis in reality is that the thermal cycling resulting from turning a monitor on and off will shorten its life. It is true that such thermal stress can contribute to various kinds of failures due to bad solder connections. However, these can be easily repaired and do not effect the monitor's heart - the CRT. You wouldn't leave your TV on 24 hours a day, would you? Full power saving where virtually everything including the CRT filaments is turned off is really best but the delay before a picture appears may be 20 seconds or more.

Also see the section: Thernal Cycling and Component Life.

Some of the newest ('green') monitors have energy conserving capabilities. However, it is necessary for the software to trigger these power reduction or power down modes. Few monitors in actual use and fewer workstations or PCs are set up to support these features. If you have such a monitor and computer to support it, by all means set up the necessary power off/power down timers. However, using the power saving modes of a 'green' PC with an older monitor can potentially cause damage since some of the modes disable the sync signals. A 'green' monitor which can detect a blank screen and and use this as a trigger can easily be used with a screen saver which can be set to display a blank screen - on any PC or workstation.

Even if the monitor does not support power saving modes, a blank screen or dark picture will reduce stress on the CRT and power supply. Electronic components will run cooler and last longer.

Please make it a habit to turn your monitors off at night. This will extend the life of the monitor (and your investment) and is good for the environment as well. For workstations, there are good reasons to leave the system unit on all the time. However, the monitor should be turned off using its power switch. For PCs, my recommendation is that the entire unit be turned off at night since the boot process is very quick and PCs are generally not required to be accessible over a network 24 hours a day.

(From: Jerry Greenberg (jerryg50@hotmail.com).)

This can be a complicated issue.

There is more to the CRT than just the heater. When there is cathode current, the ware is higher. There is a minimum cathode current when there is no brightness on the screen. The tube has to be biased slightly on all the time when working, even though it is in black. When there is some brightness on the screen, there is a greater amount of cathode wear in the electron-gun.

Having a black screen saver will in fact save some amount of cathode wear. If you have a small image on the screen that is moving around, this would introduce a bit more cathode current, but it would not be the same amount as having a full screen of white.

The best solution is if the screen is not being used for about a 2 to 3 hour period, turn it off, or have the Windows power savings utility turn it off. Cycling the monitor power on and off, can introduce a greater stress on the support components, and the tube, rather than simply leaving it on. This gets in to duty cycle statistics on the wear of the electronics, and tube. This can get very complicated in many cases.

The standard CRT should last about 30,000 hours. At this time factor, the brightness output should be about 50% of the nominal. This figure is with the brightness set to normal, and the contrast at about 50 to 70% of its maximum rage. If the monitor is used at about 10 hours per day, it should last about 8 years.

In reality these monitors will last about 5 to 6 years. There are many support components that can go wrong before the tube does. Cycling the power off and on will also cause the monitor to fail quicker. After about 6 years of normal use, many of the capacitors start to go bad in monitors and TV sets. Then there are many other types of components that can fail. Since most monitors, unless they are very expensive and high end models, they are designed to not be serviced. In the low to medium end monitors, many of the manufactures don't sell the parts for out of warranty servicing.

Enjoy the monitor. The way things are going obsolete these days, in a few years, your monitor will be useless, and may have to be changed anyways.

Thernal Cycling and Component Life

(From: Bob Myers (myers@fc.hp.com).)

In a CRT monitor, the shortest-lived component BY FAR is the CRT itself, and it ages (more properly, the cathode is aging) as long as the heater is on and the tube is under bias. Most monitors don't get around to turning the heater down or off until they enter the DPMS "suspend" or "off" modes. (And no, screen-savers do NOT help here - the tube is still on and the cathode is aging.)

Other factors - simply having the circuits hot and powered up in general means that they're aging. Clearly, they're NOT aging when they're off. This needs to be balanced against the thermal-cycling sort of stresses that you mention which happen during power cycling, and this is why I recommend shutting off only when you're going to be away for an extended period, such as overnight. This is, of course, most important for those components which have clear heat-related aging, but most do to some extent. Esp. vulnerable are things like electrolytic caps, for obvious reasons.

The bottom line is that nothing is ever going to last forever, and trying to maximize the life of the product is an exercise in making tradeoffs between various aging/failure mechanisms.

Expected Life of TV CRTs

(From: David (dakuhajda@aol.com).)

The "unofficial" designed life is 10,000 hours on the guns used in most Thomson manufactured sets. I got this from a Thomson engineer. They are no longer plating the guns but dipping them.

Given the number of hours most people watch TV these days, take 6 hours a day on average 365 days a year and you get 4.5 years. Also note that the 10,000 hours is at the preset way too high brightness and contrast settings that the set comes with from the factory. Since most people never adjust from these expect 5 years. We do the contract repair service for all the hospitals and hotels in our area. The sets bought in 1993 in one hospital are now coming in with complaint of green picture or bad focus at edges. All due to the picture tubes being worn out.

Zenith on the other hand has a company expected life of 3 years on new sets. Plus the hard short failures they have been having on all "L" and "M" line sets.

Thomson does have a "better" line of picture tubes for the higher end sets. They are actually plating the guns the way they use to.

Final note: we see 7 and 8 year old sets come in all the time with crappy picture tubes, and a few with really good looking pictures.

Why are Prices of Video Monitors So High Compared to Similarly Size TVs?

How come I can buy a 32" Sony Trinitron TV set for $800, but when it comes to buying a monitor for my PC, $1400 only gets me a no-name 20" tube?

Why can't a giant like Sony produce a PC monitor anywhere close in cost to an equivalently sized TV set?

(Some of this from: Mike Stewart (mstewart@whale.st.usm.edu).)

There are several significant factors being overlooked here:

1. Economy of scale. There are still *many* more TV sets being sold than computer monitors. Manufacturers order TV chipsets in much larger quantities. This drives down the price.

2. Resolution. NTSC TV signals aren't even VGA resolution. Try getting that 32" Sony Trinitron XBR to give you 1280x1024. A computer monitor has a CRT with a resolution about 2 to 3 times that of a TV of similar size in both horizontal and vertical directions. The beam is also more sharply focused.

3. Refresh rates. NTSC TV signals come at one refresh rate, period. You either watch broadcast NTSC at 59.94Hz (interlaced), or you don't watch it at all. No nice, clean 72Hz NI display on there. (NOTE: This

only refers to the 99+% of TV playback equipment that contains no line- doubling circuitry. That's fair, as you'll pay a good bit more for a non-interlaced, line-doubled NTSC picture than the previous poster was complaining about, anyway.)

Therefore, a auto-scan monitor needs more sophisticated deflection and power supply circuitry. It must run at much higher scan rates and this complicates the circuitry as well.

4. Geometry. The precision of a good computer monitor is much greater then any TV. The sides will be parallel and square. Adjustments are provided to eliminate pincushion, keystone, and trapizoid distortions.

5. Stability. The image on a high quality computer monitor is rock solid and does not shift position or change size as components warm up, or the power line voltage fluctuates, etc.

Problems with Designing a Combination TV and Computer Monitor

(The following is from: Bob Myers (myers@fc.hp.com).)

It's possible, and has been done (for instance, Toshiba has one product and offerings from other companies are available or are on the way). But such designs ARE compromises, and won't give the best performance possible in either application.

There is a fundamental difference between CRTs designed for TV use, and those used in computer monitors. It's a brightness/resolution tradeoff - TV tubes are run about 3X or so the brightness of a typical computer monitor, but sacrifice the ability to use small spot sizes and fine dot pitches to do this. You don't see very many color tubes running at 100 - 150 fL brightness and still using an 0.28 mm pitch!

Picture Tube Disassembly for Demonstration Purposes

Here are several questions from a budding exhibit constructor:

> "1. I am interested in using a dead CRT for a display at our science center on how things work and know about the safety issues. Also, I would really like to cut one (or parts of one) open, so it would be great to know what other things to worry about or what tools to use."

(Portions from: Jeroen H. Stessen (Jeroen.Stessen@philips.com).)

Back in the TV-lab we have an unassembled picture tube for that purpose. Most convenient!

- First, make sure that the electrical capacitance of the CRT is properly discharged. Pull the mains plug. Connect a wire to the outer aquadag. Then push it under the anode cap and make a good short-circuit. Remove the anode cap and EHT wire.

- Next you want to break the vacuum. This is my preferred method:

    - Use a sharp object or a drill to punch a small hole in the anode contact. It's made of really soft metal, probably copper. It takes several minutes for the air to fill the entire tube. In the mean time you can have some fun putting your finger over the hole. No, that's not harmful.

    - The other way to break the vacuum is via the thin tube that was used to pump the air out of the tube. That is located in the middle of the socket at the end of the neck. Remove the plastic part around the pins and break the little tube by hitting it with e.g. the tip of a screwdriver (+hammer). If you score it with a fine triangular file, it will crack off cleanly.

  I like this method less, for fear of breaking too much glass.

- You might also want to cut off the neck for easier manipulation and study of the electron gun parts. Use a glass cutting saw if one is available. Else, score totally around the neck with a fine triangular file or glass cutter and then it should snap fairly cleanly.

  Don't just chop off the neck - especially if you have not released the vacuum. Aside from the danger of flying bits of glass, you get a very characteristic dirty spot on the front of the screen, it looks as if the phosphor layer has been blown away from the faceplate by the strong inrush of air. Or maybe it was the shadow mask being blown against the faceplate. Very tell-tale and spoils your nice display.

- The deflection coils (and purity/convergence magnet assembly, if used) are also easily removed. Loosen the clamps and twist and slide them off of the neck. It's best to find an old tube where the coils have not been potted (against the noise they tend to make). Then you can see them very well.

- The difficult part will be to cut the connection between faceplate and funnel. Normally the two parts are glued together. I think it will require a glass cutting saw to get the tube open again.

  You want to separate it just behind the faceplate or else there will not be enough space to grab and remove the shadow mask. That's just clicked into place, very easy to unclick.

And one more question:

> "2. I would assume the phosphors are a problem... Any things I need to know about chemical hazards?"

Old tubes had environmentally unfriendly phosphors, containing heavy metals such as cadmium and some rare earths. Nothing immediately toxic but the long-term effects are not healthy either. Modern tubes should at least have cadmium-free phosphor. But the phosphor is covered with a metal layer, so normally it would not even be exposed. Just don't touch it.

> "3. Or that we would need to bond a cover over the exposed interior components both for safety and to keep them intact?"

Obviously, you will want to prevent the curious from being injured by sharp metal parts but nothing will fall apart (assuming your original disassembly was not overly violent). The internal magnetic screen is attached to the shadow mask, which is clicked into metal parts at the face plate. The whole assembly removes easily.

Have fun, this is going to be a wonderful demonstration of a very practical application of some heavy *physics*.

Turning a Large CRT Faceplate into the Side of a Fish Tank

So, you want to turn your 1950's vintage console TV into the ultimate fish tank experience.

WARNING: Make sure the CRT capacitance had been discharged and the vacuum let out first! See the section: Disposing of Dead TVs or Monitors (CRTs and Charged HV Capacitors).

Cutting the CRT apart would be a tricky business. If it is a typical color TV, the front is over an inch thick so you have to slice it around the edge behind the main faceplate. I wouldn't recommend even trying a glass cutter except as a last resort. If you can gain access to a diamond saw to cut around the edge, that is possible - a masonry dealer or industrial glass company might be talked into doing this. With the proper tools, it is a 10 minute job. The problem then becomes whether the inside surface is frosted or not. The phosphors may be at least somewhat toxic (to fish at least) so every trace of them need to be removed. Once this is done, the resulting finish (if the glass itself is frosted) may interfere with your fish viewing pleasure. :-)

Why do TVs Overscan?

(The following includes material from: Jeroen Stessen (Jeroen.Stessen@philips.com).)

TVs are always set up to generate a picture which is 10-15 percent large than the visible face of the CRT. Why?

In the early days of TV, this was probably done to make the design easier. Component tolerances and power line voltage fluctuations would be masked even if they caused changes in picture size.

There certainly is almost no reason today to have any more than a couple of percent overscan. Most modern TVs have very well regulated power supplies and component values do not really drift much.

Computer monitors, for example, are usually set up for no overscan at all so that the entire image is visible.

We are constantly reminded of that, now that we are building TV's with VGA inputs (PD5029C1 in the USA, US$ 2000). This mixed application has overscan in TV mode and underscan in VGA mode. Geometry adjustment is quite critical if you see border-on-border.

Unfortunately, TV's may be good but VCR's certainly are not. If you have too little overscan and then put the VCR in any feature mode (like picture search) then one (black) picture edge may become visible. Bad form. Viewers do not like this.

While design considerations may have been the original reason for overscan, now it has become accepted as a de facto standard, and broadcasters are counting on the overscan being a certain percentage. One wonders whether it will ever change or whether this really matters.

I suppose when we have true flat panel digitally addressed displays, we might have 0% overscan.

At the Japan Electronics Show all the signs are pointed toward flat panel displays so maybe I will not have to hold your breath for much longer.

Physically, as with an LCD display on a laptop computer, there will be 0% overscan (no need to build the extra pixels) but that doesn't mean that all 480 lines will be visible.

What is Aquadag?

You may see the term 'Aquadag' referring the the black paint covering the outside of most of the funnel section of the CRT.

(From: Nicholas Bodley (nbodley@tiac.net).)

Aquadag used to be a trademark of Acheson Colloids [Corp.?], I think around Niagara Falls or Buffalo, NY. It was one of many "-dag" colloidal graphites; they also made Oildag, Gredag (grease), and Alcoholdag, as I recall. Unfortunately, it's probably sold in 55-gallon drums minimum. I hope you can find smaller quantities. Are there any CRT rebuild shops around the USA? See the Thomas Catalog (ThomCat) in a library to find Acheson.

I am pretty sure there's nothing magic about the graphite. If you can find some reasonably-priced nickel-flake or copper-flake paint (be sure it's conductive!), you might have an affordable (?) coating. How about plain metal foil, maybe even ordinary aluminum foil? You surely don't need current-carrying capacity; you would need a decent adhesive, though. How to make sure you have continuity between pieces, I'm not so sure; shoot for really tight crimps that deform the metal and are gas-tight. (This might, however, be quite unnecessary.)

Why are Indirectly Heated Cathodes Used in CRTs

Here are three reasons:

1. The cathode can be made of and/or coated with a material optimal for emitting electrons without regard to its performance as a heater.
2. The separate cathode and filament can be electrically isolated so that the filament voltage and cathode drive signal, if any, do not interfere.
3. The cathode can have an optimal shape for the application. This would be particularly significant for CRTs. The spot on the screen is a reduced focused image of the effective shape of the emitting portion of the cathode.

Frequency Response of CRTs

(From: Jeroen Stessen (Jeroen.Stessen@philips.com).)

The impedance of a gun is fairly high, with 50 to 100 V p-p swing and 1 to 5 mA p-p beam current it is in the order of 10 to 100 K Ohm. Consequently, series inductance plays no important role but parallel capacitance does! In fact, the video amplifiers supply more parasitic capacitive current than beam current!

For a TV tube the total parasitic capacitance (CRT + socket + PCB + amplifier output devices) is at least 10 pF. Assuming a beam current of 5 mA p-p at 100 V p-p swing then above 800 kHz there will be more peak-peak capacitive current than beam current !

The pull-up resistor in the typical class-A video amplifier also consumes current, about 12 mA p-p for an 8.2 K

Ohm resistor. Together with the beam current this shifts the dominant pole up to 2.7 MHz. Obviously there is a dominant pole well within the range of interest, even for TV.

Better tubes may or may not have lower C but it is not very important. The dominant pole is first shifted to a higher frequency by using lower-value pull-up resistors in the video amplifier. Of course this will increase dissipation losses.

Then the dominant pole is compensated by a zero in the emitter circuit of the output transistor. There may be other compensation networks too, often with inductors. This is what allows a better monitor chassis to achieve a higher bandwidth.

Frequency compensation alone is not enough. Without a sufficiently low value for the pull-up resistor the NPN transistor will simply switch off during a rising edge and the edge will be limited by the R*C of the dominant pole alone. The compensation network is effectively decoupled from the output by the switched-off transistor. Remember that, boys and girls!

Of course, class-B designs with active pull-up will improve much. But good wide-band high-voltage PNP transistors are still a bit hard to get.

Of course, spot size (sharpness of focus) is critical to allow a better CRT to achieve a sharper picture! A better monitor needs both a better CRT (sharper beam) and better video amplifiers (higher bandwidth).

CRT Service Information

How to Read CRT Part Numbers

More than you ever wanted to know (but still not that useful)!

(From: Jeff Roberts (jroberts@axionet.com).)

The following information comes from the Sencore CR7000 Manual

The tube number is broken down in to 5 parts:

Example: M / 36 / KME / 20 / XX

Part 1: Tube Type:

A or W = TV picture tube.
M = Monitor tubes (differ in the size and pitch of the phosphor dots).
P = Projection tube.
D = Electrostatic deflection.

Part 2: Minimum viewable diagonal. Measurement is in cm. (1 inch = 2.54 cm).

Part 3: Family Number - Tubes Within a particular family have specific mechanical and electrical characteristics.

> These letters are assigned alphabetically beginning with "AAA", followed by "AAB", "AAC", etc.
>
> Tubes with the same sequence of letters are identical as far as their setup for the Sencore CR7000.
>
> The letter sequences are grouped according to the country they are manufactured in.

Part 4: Member of Family - This one or two digit number specifies a particular member within a family.

> A different number is assigned to tubes within the same family that have different neck diameters, for example. Single digit member #s = monochrome, double digit members = Color tubes.

Part 5: Phosphor Type.

Typical Color CRT Pinout

It is usually possible - with a little effort - to determine the pinout of a CRT from the markings and circuit configuration on the CRT neck board and by visually following the base lead wires inside the neck of the tube.

Here is one pinout common in color TVs. Note that this tube socket includes integral spark gaps and pin 12 doesn't actually go into the CRT.

> Pin 1: Focus
> Pin 2: NC
> Pin 3: NC
> Pin 4: NC
> Pin 5: G1
> Pin 6: Green Cathode
> Pin 7: G2
> Pin 8: Red Cathode
> Pin 9: Filament
> Pin 10: Filament
> Pin 11: Blue Cathode
> Pin 12: Sparkgap Ground

Here is another without sparkgaps in the socket:

> Pin 1: Focus
> Pin 2: NC
> Pin 3: Blue Cathode
> Pin 4: Filament
> Pin 5: Filament

Pin 6: G1
Pin 7: Red Cahtode
Pin 8: G2
Pin 9: Green Cathode

(There may actually be no pins present for those marked "NC" as well as a gap between the highest numbered pin and pin 1.)

CRT Substitution

> "I have an RCA TV model # f20700dg that has a bad crt #A51ABU14X what I would like to know is can I replace it with a #A51AGC14X."

(From: Tech 7 (gscivi@aol.com).)

Perhaps you need to know why the #'s are different?

The A is for the grade of the tube (AA is all new, B is rebuilt etc), the 51 is size in cm, the ABU is gun type, the 14 is # of elements used (pins), and the X is for phosphor type. Since the gun type is different in your two tubes, I would not spend the time to sub the tube without first check the voltages on the old one, get a schematic of set for new one, compare the parameters and then decide.

CRT Replacement Worth It?

The sad fact is that even if you can obtain a new CRT you won't have the proper set up for getting proper alignment and convergence. They generally use various permanent magnet glued to the perimeter of the yoke to set the geometry of the raster. It takes a special factory jig to do this step or really great persistence and patience. However, if you have the time and will resist punching a hole in the new CRT before you finish, by all means.

Also, consider the cost of a new CRT may be more than half the cost of the monitor when it was new.

Replacing a monochrome CRT is a snap in comparison.

A better (or at least less stressful) approach is to locate a monitor that died due to a circuit problem and salvage the CRT including the yoke and all the other magical magnets and coils.

(From: Andy Cuffe (baltimora@psu.edu).)

I have found that most 15" monitors use compatible CRTs. I just put the CRT from an old Gateway2000 with analog controls into a nice 2 year old monitor. As long as the yokes and CRT sockets are similar it should work fine. Don't try to swap the yokes or you will never get it converged.

Rebuilt CRTs

(From: B. K. Richardson (rchvid7@flash.net).)

Try Hawkeye. They have been giving us good service for at least 15 years. Their rebuilds are covered by warranty.

- Hawk-Eye Picture Tube Mfg., Inc.
  724 Scott Avenue, Des Moines, IA. 50309-5052
  Phone: 515-288-8567
  Fax: 515-288-8568

Suppliers of standard & high resolution color and monochrome picture tubes.

What Does It Take to be a Picture Tube Rebuilder, Really?

(From: Charles Godard (cgodard@iamerica.net).)

Back in the late 50's A Tech friend of mine built a picture tube rebuilding plant from scratch. He made a living with it for a few years selling rebuilt b&w tubes. Everybody around said he sold the best rebuilt tubes that you could get. He said the secret was in the good vacuum pump and that he used and the amount of time that he pumped down the tube.

He always said that a tube could be made to last practically forever if you could get a high enough vacuum on it. The only real money he put into his plant was in the pump.

A few years ago he retired and brought the whole thing down to my shop for storage. It was a marvel to behold. The cooker was an old upright deep freeze with a pyrex pie plate for a window. The lathe where he welded the tube necks onto the tube was built of scraps of angle iron with a washing machine motor. The device that he used to cut the necks off of the tube was a model railroad controller with a homemade foot pedal and a couple of whittled down broomsticks with metal tips shaped so that you could easily fold the nichrome wire around the tube neck. He said it was the only transformer he could find, at the time, that would hold up to heat the wire hot enough to cut the neck off of the tube. It was very low voltage but would supply hi current.

He said he had the most trouble when designing the inductance heater but finally got it built with the help of a local genius who had built one of our local TV station's nearly from scratch back in the 50's.

In addition to the tube plant, he also designed and got a patent on a cotton picker. I've got a copy of his patent on display in my shop. Some of us only half believed him for years, when he said he had the patent, but when he died, we searched the shop and found his patent papers hidden away in a file cabinet of old Sams Photofacts.

We found the contract where he sold the rights to build and market the picker for a $500 per picker royalty. The guy he sold it to took the patent and went to a nearby state, borrowed $200,000 from the bank with the Patent as collateral then skipped the country. My friend never got anything from his invention, and some of his design ideas were later stolen and incorporated into some one of the big name picker manufacture's products.

Those old guys were something else. They could start with a few old scraps and build something worthwhile and useful.

Speaking of patent's, I've also seen the original patent for the hinges RCA used to hold up the tops on the old console stereo's. I made a service call a few years ago, and the guy's widow showed me the patent and his original prototype hinges. The only thing is, they took the idea from the patent and redesigned it so they wouldn't have to pay our local guy for the hinges. RCA's redesign didn't work as well as his original, but was recognizable as his original with only a couple of changes. RCA 'did him' about the same way they 'did' Philo Farnsworth.

When I get a slack spell, I'll try the inductance heater to see if it still works. If it does, I try it on the tubes and let you know. I believe you called it a Tesla coil?

Shipping Damage: Why Monitors are Like Basketballs

(From: Stephen Swann (swann@panix.com).)

Monitors are more prone to shipping damage than most other computer components, and it doesn't help that they typically pass through several people's hands (several stages of shipping) before they get to you: factory -> distribution center -> vendor -> you.

And from what I've seen first hand of shipping practices (I put in a couple of months working in a distribution warehouse during college), you can safely assume that each stage of shipping is roughly the equivalent of your monitor being dropped down a flight of stairs.

You wouldn't *believe* the abuse that UPS and FedEx can subject packages to. In fact, putting a *FRAGILE* sign on the side of the box is about the equivalent of writing "KICK ME" on it. I remember receiving packages marked "FRAGILE" where the (originally cubical) cardboard boxes had been smashed into shapeless cardboard "bags", and it took us 20 minutes to figure out what the contents of the box had originally been. ("What are all these shards?" "I think it was some kind of vase" "No, it was some kind of lamp." "Where's the bulb socket, then?" "How about this squashed piece of aluminum?" "Yeah, you're right, but where's the cord then?" etc). :-) Shipping guys would think nothing of dropping "fragile" boxes from waist-high onto a concrete floor - safe in the knowledge that the package had passed through so many hands that the damage could never possibly be traced back to them. "Blameless is Guiltless" should be the motto of these folks.

Basically, what I'm saying is that if 1 monitor in 3 arrives arrives in workable condition, you should be surprised that even that one monitor survived.

DISCLAIMER

Working inside a CRT-based computer or video monitor, or television set can be lethal from line-connected and high voltage power supplies as well as CRT implosion. Read and follow ALL of the safety guidelines found in Safety Guidelines for High Voltage and/or Line Powered Equipment and the section "SAFETY", below. If in doubt about your abilities or experience, leave repair and internal adjustments to a professional.

We will not be responsible for damage to equipment, your ego, county wide power outages, spontaneously generated mini (or larger) black holes, planetary disruptions, or personal injury or worse that may result from the use of this material.

- Back to Monitor Repair FAQ Table of Contents.

Introduction

Monitors, monitors, and more monitors

In the early days of small computers, a 110 baud teletype with a personal paper tape reader was the 'preferred' input-output device (meaning that this was a great improvement over punched cards and having to deal with the bozos in the computer room. Small here, also meant something that would comfortably fit into a couple of 6 foot electronics racks!)

The earliest personal computers didn't come with a display - you connected them to the family TV. You and your kids shared the single TV and the Flintstones often won out. The Commodore 64 would never have been as successful as it was if an expensive monitor were required rather than an option.

However, as computer performance improved, it quickly became clear that a dedicated display was essential. Even for simple text, a TV can only display 40 characters across the screen with any degree of clarity.

When the IBM PC was introduced, it came with a nice 80x25 green monochrome text display. It was bright, crisp, and stable. Mono graphics (MGA or MDA) was added at 720x350, CGA at a range of resolutions from 160x200 to 640x200 at 2 to 16 colors, and EGA extended this up to a spectacular resolution of 640x350. This was really fine until the introduction of Windows (well, at least once Windows stayed up long enough for you to care).

All of these displays used digital video - TTL signals which coded for a specific discrete number of possible colors and intensities. Both the video adapter and the monitor were limited to 2, 4, 16, or a whopping 64 colors depending on the graphics standard. The video signals were logic bits - 0s and 1s.

With the introduction of the VGA standard, personal computer graphics became 'real'. VGA and its successors - PGA, XGA, and all of the SVGA (non) standards use analog video - each of the R, G, and B signals is a continuous voltage which can represent a continuous range of intensities for each color. In principle, an analog monitor is capable of an unlimited number of possible colors and intensities. (In practice, unavoidable noise and limitations of the CRT restricts the actual number to order of 64-256 distinguishable intensities for each channel.)

Note that analog video was only new to the PC world. TVs and other video equipment, workstations, and image analysis systems had utilized analog signals for many years prior to the PC's 'discovery' of this approach. In all fairness, both the display adapter and monitor are more expensive so it is not surprising that early PCs did not use analog video.

Most of the information in this document applies to color computer video monitors and TV studio monitors as well as the display portions of television sets. Black and white, gray scale, and monochrome monitors use a subset of the circuitry (and generally at lower power levels) in color monitors so much of it applies to these as well.

For most descriptions of symptoms, testing, diagnosis, and repair, an auto-scan PC SVGA monitor is assumed. For a fixed frequency workstation monitor, studio video monitor, or closed circuit TV monitor, only a subset of the possible faults and procedures will apply.

Note: we use the term 'auto-scan' to describe a monitor which accepts a wide (and possibly continuous) range of scan rates. Usually, this refers mostly to the horizontal frequency as the vertical refresh rate is quite flexible on many monitors of all types. Fixed scan or fixed frequency monitors are designed to work with a single scan rate (though a 5% or so variation may actually be accepted). Multi-scan monitors sync at two or more distinct scan rates. While not very common anymore, multi-scan monitors may still be found in some specific applications.

Related Information

See the documentss: Troubleshooting and Repair of Small Switchmode Power Supplies and Troubleshooting and Repair of Television Sets for additional useful pointers. Since a monitor must perform a subset of the functions of a TV, many of the problems and solutions are similar. For power related problems the info on SMPSs may be useful as well. If you are considering purchasing a monitor or have one that you would like to evaluate, see the companion document: Performance Testing of Computer and Video Monitors.

Monitor fundamentals

Note: throughout this document, we use the term 'raster' to refer to the entire extent of the scanned portion of the screen and the terms 'picture', 'image'. or 'display', to refer to the actual presentation content.

Monitors designed for PCs, workstations, and studio video have many characteristics in common. Modern computer monitors share many similarities with TVs but the auto-scan and high scan rate deflection circuitry and more sophisticated power supplies complicates their servicing.

Currently, most inexpensive computer monitors are still based on the Cathode Ray Tube (CRT) as the display device. However, handheld equipment, laptop computers, and the screens inside video projectors now use flat panel technology, mostly Liquid Crystal Displays - LCDs. These are a lot less bulky than CRTs, use less power, and have better geometry - but suffer from certain flaws. As the price of LCD (and other technology) flat screen technology decreases, such monitors will become dominant for desktop computers as well and CRT based monitors will eventually go the way of dinosaurs, core memory, and long playing records that dominated their respective industries for decades but eventually yielded to fundamentally new technology. :)

However, there are still problems with (low cost, at least) LCD monitors. First, the picture quality in terms of gray scale and color is generally inferior to a decent analog monitor. The number of distinct shades of gray or distinct colors is a lot more limited. They are generally not as responsive as CRTs when it comes to real-time video which is becoming increasingly important with multimedia computers. This is partly due to the response of the LCD material itself but also a result of the scan conversion that's needed for non-native resolution formats. Brightness is generally not as good as a decent CRT display. And last but not least, the cost is still somewhat higher due both to the increased complexity of flat panel technology and lower production volumes (though this is certainly increasing dramatically). It is really hard to beat the simplicity of the shadow mask CRT.

Also a note to those with less than perfect vision: If you tend to view your monitor from less than 10 to 15 inches, you may be disappointed, or at least have a hard time getting used to LCD monitors. The appearance of a CRT display is nearly independent of viewing angle. But for an LCD display, this is not the case. Only the central part of your field of vision will have the proper brightness, contrast, and color rendition. If the curser isn't within this central area, it will be harder to locate than on a CRT. In short, don't just depend on the hype. An LCD with a slightly lower contrast ratio and lower price may have a sbustantially wider viewing angle and better match to your needs than a top-of-the-line model. Test drive multiple LCD monitors before committing to one!

Nonetheless, a variety of technologies are currently competing for use in the flat panel displays of the future. Among these are advanced LCD, plasma discharge, and field emission displays. Only time will tell which, if any survives to become **the** picture-on-the-wall or notepad display - at reasonable cost.

Projection displays, on the other hand, can take advantage of a novel development in integrated micromachining - the Texas Instruments Inc. Digital Micromirror Device (DMD). This is basically an integrated circuit with a tiltable micromirror for each pixel fabricated on top of a static memory - RAM - cell. DMD technology would permit nearly any size projection display to be produced and would therefore be applicable to HDTV as well as PCs. Since it is a reflective device, the light source can be as bright as needed. This technology is already appearing in commercial high performance computer projectors and is competing for use in totally digital movie theaters to replace the film projector, but to my knowledge is not in any consumer TV sets - yet.

As noted, the plasma panel flat screen display has been around for several years in high-end TVs, typically in the 42 inch diagonal range. But they are very expensive ($5,000 to $15,000 as of Winter, 2003), and their life expectancy may be limited due to the gradual degradation of the active pixel cells - which occurs faster than for a CRT. The physical resolution is also probably still too low to really justify the large screen size for computer displays. However, there is little doubt that this or a similar technology will eventually replace the direct view CRT and 3-tube projection TVs in the mid to large screen sizes in the not too distant future. But to what extent it is used for computer monitors is still unclear.

The remainder of this document concentrates on CRT based computer and video monitors since these still dominate the market and realistically, they are the only type where there is a good chance of repair without access to specialized test equipment and parts. I wouldn't recommend any sort of attempt at repair of flat screen TVs or monitors - no matter what the size - beyond checking for bad connections, dead power supplies, or other obvious problems. The chance of success is vanishingly small and it's very likely that even with great care, damage could occur to the panels or circuitry.

Monitor characteristics

The following describe the capabilities which characterize a display:

1. Resolution - the number of resolvable pixels on each line and the number of scanning lines. Bandwidth of the video source, cable, and monitor video amplifiers as well as CRT focus spot size are all critical. However, maximum resolution on a color CRT is limited by the dot/slot/line pitch of the CRT shadow/slot mask or aperture grille.

2. Refresh rate - the number of complete images 'painted' on the screen each second. Non-interlaced or progressive scanning posts the entire frame during each sweep from top to bottom. Interlaced scanning posts 1/2 of the frame called a field - first the even field and then the odd field. This interleaving reduces the apparent flicker for a given display bandwidth when displaying smooth imagery such as for TV. It is usually not acceptable for computer graphics, however, as thin horizontal lines tend to flicker at 1/2 the vertical scan rate. Refresh rate is the predominant factor that affects the flicker of the display though the persistence of the CRT phosphors are also a consideration. Long persistence phosphors decrease flicker at the expense of smearing when the picture changes or moves. Vertical scan rate is equal to the refresh rate for non-interlaced monitors but is the twice the refresh rate for interlaced monitors (1 frame equals 2 fields). Non-interlaced vertical refresh rates of 70-75 Hz are considered desirable for computer displays. Television uses 25 or 30 Hz (frame rate) interlaced scanning in most countries.

3. Horizontal scan rate - the frequency at which the electron beam(s) move across the screen. The horizontal scan rate is often the limiting factor in supporting high refresh rate high resolution displays. It is what may cause failure if scan rate speed limits are exceeded due to the component stress levels in high performance deflection systems.

4. Color or monochrome - a color monitor has a CRT with three electron guns each associated with a primary color - red, green, or blue. Nearly all visible colors can be created from a mix of primaries with suitable spectral characteristics using this additive color system.

   A monochrome monitor has a CRT with a single electron gun. However, the actual color of the display may be white, amber, green, or whatever single color is desired as determined by the phosphor of the CRT selected.

5. Digital or analog signal - a digital input can only assume a discrete number of states depending on how many bits are provided. A single bit input can only produce two levels - usually black or white (or amber, green, etc.). Four bit EGA can display up to 16 colors (with a color monitor) or 16 shades of gray (with a monochrome monitor).

   Analog inputs allow for a theoretically unlimited number of possible gray levels or colors. However, the actual storage and digital-to-analog convertors in any display adapter or frame store and/or unavoidable noise and other characteristics of the CRT - and ultimately, limitations in the psychovisual eye-brain system will limit this to a practical maximum of 64-256 discernible levels for a gray scale display or for each color channel.

   However, very high performance digital video sources may have RAMDACs (D/A convertors with video lookup tables) of up to 10 or more bits of intensity resolution. While it is not possible to perceive this many distinct gray levels or colors (per color channel), this does permit more accurate tone scale ('gamma') correction to be applied (via a lookup table in the RAMDAC) to compensate for the unavoidable non-linearity of the CRT phosphor response curve or to match specific photometric requirements.

Types of monitors

Monitors can be classified into three general categories:

1. Studio video monitors - Fixed scanning rate for the TV standards in the country in which they are used. High quality, often high cost, utilitarian case (read: ugly), underscan option. Small closed circuit TV monitors fall into the class. Input is usually composite (i.e., NTSC or PAL) although RGB types are available.

2. Fixed frequency RGB - High resolution, fixed scan rate. High quality, high cost, very stable display. Inputs are analog RGB using either separate BNC connectors or a 13W3 (Sun) connector. These often have multiple sync options. The BNC variety permit multiple monitors to be driven off of the same source by daisychaining. Generally used underscanned for computer workstation (e.g., X-windows) applications so that entire frame buffer is visible. There are also fixed frequency monochrome monitors which may be digital or analog input using a BNC, 13W3, or special connector.

3. Multi-scan or auto-scan - Support multiple resolutions and scan rates or multiple ranges of resolutions and scan rates. The quality and cost of these monitors ranges all over the map. While cost is not a strict measure of picture quality and reliability, there is a strong correlation. Input is most often analog RGB but some older monitors of this type (e.g., Mitsubishi AUM1381) support a variety of digital (TTL) modes as well. A full complement of user controls permits adjustment of brightness, contrast, position, size, etc. to taste. Circuitry in the monitor identifies the video scan rate automatically and sets up the appropriate circuitry. With more sophisticated (and expensive) designs, the monitor automatically sets the appropriate parameters for user preferences from memory as well. The DB15 high density VGA connector is most common though BNCs may be used or may be present as an auxiliary (and better quality) input.

Why auto-scan?

Thank IBM. Since the PC has evolved over a period of 15 years, display adapters have changed and improved a number of times. With an open system, vendors with more vision (and willing to take more risks) than IBM were continuously coming up with improved higher resolution display adapters. With workstations and the Apple MacIntosh, the primary vendor can control most aspects of the hardware and software of the computer system. Not so with PCs. New improved hardware adapters were being introduced regularly which were not following any standards for the high resolution modes (but attempted to be backward compatible with the original VGA as well as EGA and CGA (at least in terms of software).) Vast numbers of programs were written that were designed to directly control the CGA, EGA, and VGA hardware. Adapter cards could be designed to emulate these older modes on a fixed frequency high resolution monitor (and these exist to permit high quality fixed scan rate workstation monitors to be used on PCs) However, these would be (and are) much more expensive than basic display adapters that simply switch scan rates based on mode. Thus, auto-scan monitors evolved to accommodate the multiple resolutions that different programs required.

Note: The generic term 'auto-scan' is used to refer to a monitor which automatically senses the input video scan rate and selects the appropriate horizontal and vertical deflection circuitry and power supply voltages to display this video. Multi-scan monitors, while simpler than true auto-scan monitors, will still have much of the same scan rate detection and selection circuitry. Manufacturers use various buzz words to describe their versions of these monitors including 'multisync', 'autosync','panasync', 'omnisync', as well as 'autoscan' and 'multiscan'.

Ultimately, the fixed scan rate monitor may reappear for PCs. Consider one simple fact: it is becoming cheaper to design and manufacture complex digital processing hardware than to produce the reliable high quality analog and power electronics needed for an auto-scan monitor. This is being done in the specialty market now. Eventually, the development of accelerated chipsets for graphics mode emulation may be forced by the increasing popularity of flat panel displays - which are basically similar to fixed scan rate monitors in terms of their interfacing requirements.

Analog versus digital monitors

There are two aspects of monitor design that can be described in terms of analog or digital characteristics:

1. The video inputs. Early PC monitors, video display terminal monitors, and mono workstation monitors use digital input signals which are usually TTL but some very high resolution monitors may use ECL instead.

2. The monitor control and user interface. Originally, monitors all used knobs - sometimes quite a number of them - to

control all functions like brightness, contrast, position, size, linearity, pincushion, convergence, etc. However, as the costs of digital circuitry came down - and the need to remember settings for multiple scan rates and resolutions arose, digital - microprocessor control - became an attractive alternative in terms of design, manufacturing costs, and user convenience. Now, most better quality monitors use digital controls - buttons and menus - for almost all adjustments except possibly brightness and contrast where knobs are still more convenient.

Since monitors with digital signal inputs are almost extinct today except for specialized applications, it is usually safe to assume that 'digital' monitor refers to the user interface and microprocessor control. And, except perhaps for the very cheapest monitors, all now have digital controls.

Interlacing

Whether a monitor runs interlaced or non-interlaced is almost always strictly a function of the video source timing. The vertical sync pulse is offset an amount equal to 1/2 the line time on alternate fields (vertical scans - two fields make up a frame when interlaced scanning is used).

- Generally, a monitor that runs at a given resolution non-interlaced can run interlaced at a resolution with the same number of pixels per line but twice the number of lines vertically at roughly the same horizontal and vertical scan rates and video bandwidth (but half the frame rate).

- Alternatively, it may be possible to increase the resolution in both directions while keeping the horizontal scan rate the same thus permitting a monitor to display the next larger size format. However, in this case, the video bandwidth will increase.

Here are a couple of examples:

- A monitor that will run 640x240 at 60 frames per second non-interlaced will run 640x480 at 30 frames per second interlaced. This would permit a monitor with a horizontal scan rate of 15.7 kHz (NTSC TV compatible) to display VGA resolution images - though they will likely flicker since the 30 Hz is way too low for most graphics.

- A resolution of 1024x768 at 50 frames per second interlaced requires roughly the same horizontal scan rate (about 42 kHz) as 800x600 at 66 frames per second non-interlaced. The flicker may be acceptable in this case being at 50 Hz for the worst case of single horizontal lines as the high 100 Hz vertical scan rate will reduce flicker otherwise.

Whether the image is usable at the higher resolution of course depends on many other factors (in addition to flicker) including the dot pitch of the CRT and video bandwidth of the video card and monitor video amplifiers, as well as cable quality and termination.

Monitor performance

The ultimate perceived quality of your display is influenced by many aspects of the total video source/computer-cable-monitor system. Among them are:

1. Resolution of the video source. For a computer display, this is determined by the number of pixels on each visible scan line and the number of visible scan lines on the entire picture.

2. The pitch of the shadow mask or aperture grille of the CRT. The smallest color element on the face of the CRT is determined by the spacing of the groups of R, G, and B colors phosphors. The actual conversion from dot or line pitch to resolution differs slightly among dot or slot mask and aperture grille CRTs but in general, the finer, the better - and more expensive.

   Typical television CRTs are rather coarse - .75 mm might be a reasonable specification for a 20 inch set. High resolution computer monitors may have dot pitches as small as .22 mm for a similar size screen.

A rough indication of the maximum possible resolution of the CRT can be found by determining how many complete phosphor dot groups can fit across the visible part of the screen.

Running at too high a resolution for a given CRT may result in Moire - an interference pattern that will manifest itself as contour lines in smooth bright areas of the picture. However, many factors influence to what extent this may be a problem. See the section: Contour lines on high resolution monitors - Moire.

3. Bandwidth of the video source or display card - use of high performance video amplifiers or digital to analog convertors.

4. Signal quality of the video source or display card - properly designed circuitry with adequate power supply filtering and high quality components.

5. High quality cables with correct termination and of minimal acceptable length without extensions or switch boxes unless designed specifically for high bandwidth video.

6. Sharpness of focus - even if the CRT dot pitch is very fine, a fuzzy scanning beam will result in a poor quality picture.

7. Stability of the monitor electronics - well regulated power supplies and low noise shielded electronics contribute to a rock solid image.

The following are only partly dependent on the monitor's design:

8. Anti-glare treatment of screen and ambient lighting conditions - No matter how good are the monitor's electronics, the display can still be washed out and difficult or tiring to view if there is annoying glare or reflections. The lighting and location are probably more important than how the screen itself is designed to minimize glare.

9. Electromagnetic interference - Proximity to sources of magnetic fields and power line noise can degrade the performance of any monitor, no matter how well shielded it might be.

Performance testing of monitors

WARNING: No monitor is perfect. Running comprehensive tests on your monitor or one you are considering may make you aware of deficiencies you never realized were even possible. You may never be happy with any monitor for the rest of your life!

Note: The intent of these tests is **not** to evaluate or calibrate a monitor for photometric accuracy. Rather they are for functional testing of the monitor's performance.

Obviously, the ideal situation is to be able to perform these sorts of tests before purchase. With a small customer oriented store, this may be possible. However, the best that can be done when ordering by mail is to examine a similar model in a store for gross characteristics and then do a thorough test when your monitor arrives. The following should be evaluated:

- Screen size and general appearance.
- Brightness and screen uniformity, purity and color saturation.
- Stability.
- Convergence.
- Edge geometry.
- Linearity.
- Tilt.

- Size and position control range.
- Ghosting or trailing streaks.
- Sharpness.
- Moire.
- Scan rate switching.
- Acoustic noise.

The companion document: Performance Testing of Computer and Video Monitors provides detailed procedures for the evaluation of each of these criteria.

CAUTION: Since there is no risk free way of evaluating the actual scan rate limits of a monitor, this is not an objective of these tests. It is assumed that the specifications of both the video source/card and the monitor are known and that supported scan rates are not exceeded. Some monitors will operate perfectly happily at well beyond the specified range, will shut down without damage, or will display an error message. Others will simply blow up instantly and require expensive repairs.

Monitor repair

Unlike PC system boards where any disasters are likely to only affect your pocketbook, monitors can be very dangerous. Read, understand, and follow the set of safety guidelines provided later in this document whenever working on TVs, monitors, or other similar high voltage equipment.

If you do go inside, beware: line voltage (on large caps) and high voltage (on CRT) for long after the plug is pulled. There is the added danger of CRT implosion for carelessly dropped tools and often sharp sheetmetal shields which can injure if you should have a reflex reaction upon touching something you should not touch. In inside of a TV or monitor is no place for the careless or naive.

Having said that, a basic knowledge of how a monitor works and what can go wrong can be of great value even if you do not attempt the repair yourself. It will enable you to intelligently deal with the service technician. You will be more likely to be able to recognize if you are being taken for a ride by a dishonest or just plain incompetent repair center. For example, a faulty picture tube CANNOT be the cause of a color monitor only displaying in black-and-white (this is probably a software or compatibility problem). The majority of consumers - and computer professionals - may not know even this simple fact.

This document will provide you with the knowledge to deal with a large percentage of the problems you are likely to encounter with your monitors. It will enable you to diagnose problems and in many cases, correct them as well. With minor exceptions, specific manufacturers and models will not be covered as there are so many variations that such a treatment would require a huge and very detailed text. Rather, the most common problems will be addressed and enough basic principles of operation will be provided to enable you to narrow the problem down and likely determine a course of action for repair. In many cases, you will be able to do what is required for a fraction of the cost that would be charged by a repair center.

Should you still not be able to find a solution, you will have learned a great deal and be able to ask appropriate questions and supply relevant information if you decide to post to sci.electronics.repair. It will also be easier to do further research using a repair text such as the ones listed at the end of this document. In any case, you will have the satisfaction of knowing you did as much as you could before taking it in for professional repair. With your new-found knowledge, you will have the upper hand and will not easily be snowed by a dishonest or incompetent technician.

Most Common Problems

The following probably account for 95% or more of the common monitor ailments:

- Intermittent changes in color, brightness, size, or position - bad connections inside the monitor or at the cable connection to the computer or or video source.

- Ghosts, shadows, or streaks adjacent to vertical edges in the picture - problems with input signal termination including use of cable extensions, excessively long cables, cheap or improperly made video cables, improper daisychaining of monitors, or problems in the video source or monitor circuitry.

- Magnetization of CRT causing color blotches or other color or distortion problems - locate and eliminate sources of magnetic fields if relevant and degauss the CRT.

- Electromagnetic Interference (EMI) - nearby equipment (including and especially other monitors), power lines, or electrical wiring behind walls, may produce electromagnetic fields strong enough to cause noticeable wiggling, rippling, or other effects. Relocate the monitor or offending equipment. Shielding is difficult and expensive.

- Wiring transmitted interference - noisy AC power possibly due to other equipment using electric motors (e.g., vacuum cleaners), lamp dimmers or motor speed controls (shop tools), fluorescent lamps, and other high power devices, may result in a variety of effects. The source is likely local - in your house - but could be several miles away. Symptoms might include bars of noise moving up or down the screen or diagonally. The effects may be barely visible as a couple of jiggling scan lines or be broad bars of salt and pepper noise, snow, or distorted video. Plugging the monitor into another outlet or the use of a line filter may help. If possible, replace or repair the offending device.

- Monitor not locking on one or more video scan ranges - settings of video adapter are incorrect. Use software setup program to set these. This could also be a fault in the video source or monitor dealing with the sync signals.

- Adjustments needed for background brightness or focus - aging CRT reduces brightness. Other components may affect focus. These are often easy internal (or sometimes external) adjustments but some manufacturers have gone to digital setup requiring expensive an adapter (serial cable) to a PC and their own (expensive and/or unavailable) software.

- Dead monitor due to power supply problems - very often the causes are simple such as bad connections, blown fuse or other component.

Repair or replace

If you need to send or take the monitor to a service center, the repair could easily exceed half the cost of a new monitor. Service centers may charge up to $50 or more for providing an initial estimate of repair costs but this will usually be credited toward the total cost of the repair (of course, they may just jack this up to compensate for their bench time). With new monitors going for under $200, the costs of any significant repair are no longer justifiable unless there is something unique about your monitor.

Some places offer attractive flat rates for repairs involving anything but the CRT, yoke, and flyback. Such offers are attractive if the repair center is reputable. However, if by mail, you will be stuck with a tough decision if they find that one of these expensive components is actually bad.

Monitors become obsolete at a somewhat slower rate than most other electronic equipment. Therefore, unless you need the higher resolution and scan rates that newer monitors provide, repairing an older one may make sense as long as the CRT is in good condition (adequate brightness, no burn marks, good focus). However, it may just be a good excuse to upgrade.

If you can do the repairs yourself, the equation changes dramatically as your parts costs will be 1/2 to 1/4 of what a professional will charge and of course your time is free. The educational aspects may also be appealing. You will learn a lot in the process. Thus, it may make sense to repair that old clunker for your 2nd PC (or your 3rd or your 4th or....).

Monitors 101

Subsystems of a monitor

Please refer to Typical SVGA Monitor Block Diagram while reading the following description.

A computer or video monitor includes the following functional blocks:

1. Low voltage power supply (some may also be part of (2).) Most of the lower voltages used in the monitor may be derived from the horizontal deflection circuits, a separate switchmode power supply (SMPS), or a combination of the two. Rectifier/filter capacitor/regulator from AC line provides the B+ to the SMPS or horizontal deflection system. Auto-scan monitors may have multiple outputs from the low voltage power supply which are selectively switched or enabled depending on the scan rate, or an power supply with programmable output voltage for the deflection system. A common configuration is a pair of SMPSs where one provides all the fixed voltages and the other is programmable based on scan rate.

   Degauss operates off of the line whenever power is turned on (after having been off for a few minutes) to demagnetize the CRT. Better monitors will have a degauss button which activates this circuitry as well since even rotating the monitor on its tilt-swivel base can require degauss.

2. Horizontal deflection. These circuits provide the waveforms needed to sweep the electron beam in the CRT across and back at anywhere from 15 kHz to over 100 kHz depending on scan rate and resolution. The horizontal sync pulse from the sync separator or the horizontal sync input locks the horizontal deflection to the video signal. Auto-scan monitors have sophisticated circuitry to permit scanning range of horizontal deflection to be automatically varied over a wide range.

3. Vertical deflection. These circuits provide the waveforms needed to sweep the electron beam in the CRT from top to bottom and back at anywhere from 50 - 120 or more times per second. The vertical sync pulse from the sync separator or vertical sync input locks the vertical deflection to the video signal. Auto-scan monitors have additional circuitry to lock to a wide range of vertical scan rates.

4. CRT high voltage 'flyback' power supply (also part of (2).) A modern color CRT requires up to 30 kV for a crisp bright picture. Rather than having a totally separate power supply, most monitors derive the high voltage (as well as many other voltages) from the horizontal deflection using a special transformer called a 'flyback' or 'Line OutPut Transformer (LOPT) for those of you on the other side of the lake. Some high performance monitors use a separate high voltage board or module which is a self contained high frequency inverter.

5. Video amplifiers. These buffer the low level inputs from the computer or video source. On monitors with TTL inputs (MGA, CGA, EGA), a resistor network also combines the intensity and color signals in a kind of poor man's D/A. Analog video amplifiers will usually also include DC restore (black level retention, back porch clamping) circuitry stabilize the black level on AC coupled video systems.

6. Video drivers (RGB). These are almost always located on a little circuit board plugged directly onto the neck of the CRT. They boost the output of the video amplifiers to the hundred volts or so needed to drive the cathodes (usually) of the CRT.

7. Sync processor. This accepts separate, composite, or 'sync-on-green' signals to control the timing of the horizontal and vertical deflection systems. Where input is composite rather than separate H and V syncs (as is used with VGA/SVGA), this circuit extracts the individual sync signals. For workstation monitors which often have the sync combined with the green video signals, it needs to separate this as well. The output of the sync processor is horizontal and vertical sync pulses to control the deflection circuits.

8. System control. Most higher quality monitors use a microcontroller to perform all user interface and control functions from the front panel (and sometimes even from a remote control). So called 'digital monitors' meaning digital controls not digital inputs, use buttons for everything except possibly user brightness and contrast. Settings for horizontal and vertical size and position, pincushion, and color balance for each scan rate may be stored in non-volatile memory. It may communicate with the video card over the serial VESA bus to inform if of its capabilities. The microprocessor also analyzes the input video timing and selects the appropriate scan range and components for the detected resolution. While these circuits rarely fail, if they do, debugging can be quite a treat.

Most problems occur in the horizontal deflection and power supply sections. These run at relatively high power levels and some components run hot. This results in both wear and tear on the components as well as increased likelihood of bad connections developing from repeated thermal cycles. The high voltage section is prone to breakdown and arcing as a result of hairline cracks, humidity, dirt, etc.

The video circuitry is generally quite reliable. However, it seems that even after 15+ years, manufacturers still cannot reliably turn out circuit boards that are free of bad solder connections or that do not develop them with time and use.

For more information on monitor technology

The books listed in the section: Suggested references include additional information on the theory and implementation of the technology of monitors and TV sets.

Philips/Magnavox used to have a very nice on-line introduction to a variety of consumer electronics technologies. Although their site has disappeared - and even people who work for them have no clue - I have now recovered several of the articles including those on TVs, VCRs, camcorders, satellite reception, and connections. See the Introductory Consumer Electronics Technology Series.

On-line tech-tips databases

A number of organizations have compiled databases covering thousands of common problems with VCRs, TVs, computer monitors, and other electronic equipment. Most charge for their information but a few, accessible via the Internet, are either free or have a very minimal monthly or per-case fee. In other cases, a limited but still useful subset of the for-fee database is freely available.

A tech-tips database is a collection of problems and solutions accumulated by the organization providing the information or other sources based on actual repair experiences and case histories. Since the identical failures often occur at some point in a large percentage of a given model or product line, checking out a tech-tips database may quickly identify your problem and solution.

In that case, you can greatly simplify your troubleshooting or at least confirm a diagnosis before ordering parts. My only reservation with respect to tech-tips databases in general - this has nothing to do with any one in particular - is that symptoms can sometimes be deceiving and a solution that works in one instance may not apply to your specific problem. Therefore, an understanding of the hows and whys of the equipment along with some good old fashioned testing is highly desirable to minimize the risk of replacing parts that turn out not to be bad.

The other disadvantage - at least from one point of view - is that you do not learn much by just following a procedure developed by others. There is no explanation of how the original diagnosis was determined or what may have caused the failure in the first place. Nor is there likely to be any list of other components that may have been affected by overstress and may fail in the future. Replacing Q701 and C725 may get your equipment going again but this will not help you to repair a different model in the future.

Please see the document: On-Line Tech-Tips Databases for the most up to date compilation of these resources for TVs, VCRs, computer monitors, and other consumer electronic equipment.

- Back to Monitor Repair FAQ Table of Contents.

CRT Basics

Note: Most of the information on TV and monitor CRT construction, operation, interference and other problems. has been moved to the document: TV and Monitor CRT (Picture Tube) Information. The following is just a brief introduction with instructions on degaussing.

Color CRTs - shadow masks and aperture grills

All color CRTs utilize a shadow mask or aperture grill a fraction of an inch (1/2" typical) behind the phosphor screen to direct the electron beams for the red, green, and blue video signals to the proper phosphor dots. Since the electron beams for the R, G, and B phosphors originate from slightly different positions (individual electron guns for each) and thus arrive at slightly different angles, only the proper phosphors are excited when the purity is properly adjusted and the necessary magnetic field free region is maintained inside the CRT. Note that purity determines that the correct video signal excites the proper color while convergence determines the geometric alignment of the 3 colors. Both are affected by magnetic fields. Bad purity results in mottled or incorrect colors. Bad convergence results in color fringing at edges of characters or graphics.

The shadow mask consists of a thin steel or InVar (a ferrous alloy) with a fine array of holes - one for each trio of phosphor dots - positioned about 1/2 inch behind the surface of the phosphor screen. With some CRTs, the phosphors are arranged in triangular formations called triads with each of the color dots at the apex of the triangle. With many TVs and some monitors, they are arranged as vertical slots with the phosphors for the 3 colors next to one another.

An aperture grille, used exclusively in Sony Trinitrons (and now their clones as well), replaces the shadow mask with an array of finely tensioned vertical wires. Along with other characteristics of the aperture grille approach, this permits a somewhat higher possible brightness to be achieved and is more immune to other problems like line induced moire and purity changes due to local heating causing distortion of the shadow mask.

However, there are some disadvantages of the aperture grille design:

- Weight - a heavy support structure must be provided for the tensioned wires (like a piano frame).
- Price (proportional to weight).
- Always a cylindrical screen (this may be considered an advantage depending on your preference.
- Visible stabilizing wires which may be objectionable or unacceptable for certain applications. (Definitely on 15" and larger sizes, possibly on smaller ones as well.)

Apparently, there is no known way around the need to keep the fine wires from vibrating or changing position due to mechanical shock in high resolution tubes and thus all Trinitron monitors require 1, 2, or 3 stabilizing wires (depending on tube size) across the screen which can be see as very fine lines on bright images. Some people find these wires to be objectionable and for some critical applications, they may be unacceptable (e.g., medical diagnosis).

Degaussing (demagnetizing) a CRT

Degaussing may be required if there are color purity problems with the display. On rare occasions, there may be geometric distortion caused by magnetic fields as well without color problems. The CRT can get magnetized:

- if the TV or monitor is moved or even just rotated.
- if there has been a lightning strike nearby. A friend of mine had a lightning strike near his house which produced all of the effects of the EMP from a nuclear bomb.
- If a permanent magnet was brought near the screen (e.g., kid's magnet or megawatt stereo speakers).
- If some piece of electrical or electronic equipment with unshielded magnetic fields is in the vicinity of the TV or monitor.

Degaussing should be the first thing attempted whenever color purity problems are detected. As noted below, first try the internal degauss circuits of the TV or monitor by power cycling a few times (on for a minute, off for at least 20 minutes, on for a minute, etc.) If this does not help or does not completely cure the problem, then you can try manually degaussing.

Note: Some monitors have a degauss button, and monitors and TVs that are microprocessor controlled may degauss automatically upon power-on (but may require pulling the plug to do a hard reset) regardless of the amount of off time. However, repeated use of these 'features' in rapid succession may result in overheating of the degauss coil or other components. The 20 minutes off/1 minute on precedure is guaranteed to be safe. (Some others may degauss upon power-on as long as the previous degauss was not done within some predetermined amount of time - they keep track with an internal timer.)

Commercial CRT Degaussers are available from parts distributors like MCM Electronics and consist of a hundred or so turns of magnet wire in a 6-12 inch coil. They include a line cord and momentary switch. You flip on the switch, and bring the coil to within several inches of the screen face. Then you slowly draw the center of the coil toward one edge of the screen and trace the perimeter of the screen face. Then return to the original position of the coil being flat against the center of the screen. Next, slowly decrease the field to zero by backing straight up across the room as you hold the coil. When you are farther than 5 feet away you can release the line switch.

The key word here is ** slow **. Go too fast and you will freeze the instantaneous intensity of the 50/60 Hz AC magnetic field variation into the ferrous components of the CRT and may make the problem worse.

WARNING: Don't attempt to degauss inside or in the back of the set (near the CRT neck. This can demagnetize the relatively weak purity and convergence magnets which may turn a simple repair into a feature length extravaganza!

It looks really cool to do this while the CRT is powered. The kids will love the color effects (but then lock your degaussing coil safely away so they don't try it on every TV and monitor in the house!).

Bulk tape erasers, tape head degaussers, open frame transformers, and the "butt-end" of a weller soldering gun can be used as CRT demagnetizers but it just takes a little longer. (Be careful not to scratch the screen face with anything sharp. For the Weller, the tip needs to be in place to get enough magnetic field.) It is imperative to have the CRT running when using these whimpier approaches, so that you can see where there are still impurities. Never release the power switch until you're 4 or 5 feet away from the screen or you'll have to start over.

I've never known of anything being damaged by excess manual degaussing as long as you don't attempt to degauss *inside* or the back of the monitor - it is possible to demagnetize geometry correction, purity, and static converence magnets in the process! However, I would recommend keeping really powerful bulk tape erasers-turned-degaussers a couple of inches from the CRT.

If an AC degaussing coil or substitute is unavailable, I have even done degaussed with a permanent magnet but this is not recommended since it is more likely to make the problem worse than better. However, if the display is unusable as is, then using a small magnet can do no harm. (Don't use a 20 pound speaker or magnetron magnet as you may rip the shadow mask right out of the CRT - well at least distort it beyond repair. What I have in mind is something about as powerful as a refrigerator magnet.)

Keep degaussing fields away from magnetic media. It is a good idea to avoid degaussing in a room with floppies or back-up tapes. When removing media from a room remember to check desk drawers and manuals for stray floppies, too.

It is unlikely that you could actually affect magnetic media but better safe than sorry. Of the devices mentioned above, only a bulk eraser or strong permanent magnet are likely to have any effect - and then only when at extremely close range (direct contact with media container).

All color CRTs include a built-in degaussing coil wrapped around the perimeter of the CRT face. These are activated each time the CRT is powered up cold by a 3 terminal thermistor device or other control circuitry. This is why it is often suggested that color purity problems may go away "in a few days". It isn't a matter of time; it's the number of cold power ups that causes it. It takes about 15 minutes of the power being off for each cool down cycle. These built-in coils with thermal control are never as effective as external coils.

Note that while the monochrome CRTs used in B/W and projection TVs and mono monitors don't have anything inside to get magnetized, the chassis or other cabinet parts of the equipment may still need degaussing. While this isn't likely from normal use or even after being moved or reoriented, a powerful magnet (like that from a large speaker) could leave iron, steel, or other ferrous parts with enough residual magnetism to cause a noticeable problem.

See the document: TV and Monitor CRT (Picture Tube) Information for some additional discussion of degaussing tools, techniques, treatments for severe magnetization from lightning strikes, and cautions.

How often to degauss

Some monitor manufacturers specifically warn about excessive use of degauss, most likely as a result of overstressing components in the degauss circuitry which are designed (cheaply) for only infrequent use. In particular, there is often a thermistor that dissipates significant power for the second or two that the degauss is active. Also, the large coil around the CRT is not rated for continuous operation and may overheat.

If one or two activations of the degauss button do not clear up the color problems, manual degaussing using an external coil may be needed or the monitor may need internal purity/color adjustments. Or, you may have just installed your megawatt stereo speakers next to the monitor!

You should only need to degauss if you see color purity problems on your CRT. Otherwise it is unnecessary. The reasons it only works the first time is that the degauss timing is controlled by a thermistor which heats up and cuts off the current. If you push the button twice in a row, that thermistor is still hot and so little happens.

One word of clarification: In order for the degauss operation to be effective, the AC current in the coil must approach zero before the circuit cuts out. The circuit to accomplish this often involves a thermistor to gradually decrease the current (over a matter of several seconds), and in better monitors, a relay to totally cut off the current after a certain delay. If the current was turned off suddenly, you would likely be left with a more magnetized CRT. There are time delay elements involved which prevent multiple degauss operations in succession. Whether this is by design or accident, it does prevent the degauss coil - which is usually grossly undersized for continuous operation - to cool.

Why are there fine lines across my Trinitron monitor or TV?

These are not a defect - they are a 'feature'.

All Trinitron (or clone) CRTs - tubes that use an aperture grille - require 1, 2, or 3 very fine wires across the screen to stabilize the array of vertical wires in the aperture grille. Without these, the display would be very sensitive to any shock or vibration and result in visible shimmering or rippling. (In fact, even with these stabilizing wires, you can usually see this shimmering if you whack a Trinitron monitor.) The lines you see are the shadows cast by these fine wires.

The number of wires depends on the size of the screen. Below 15" there is usually a single wire; between 15" and 21" there are usually 2 wires; above 21" there may be 3 wires. (Some very small Trinitron CRTs may not need these but they will be present on most of the sizes of interest here.)

Only you can decide if this deficiency is serious enough to avoid the use of a Trinitron based monitor. Some people never get used to the fine lines but many really like the generally high quality of Trinitron based displays and eventually totally ignore them.

Monitor Placement and Preventive Maintenance

General monitor placement considerations

Proper care of a monitor does not require much. Following the recommendations below will assure long life and minimize repairs:

- Subdued lighting is preferred for best viewing conditions. Avoid direct overhead light falling on the screen or coming from behind the monitor if possible.

- Locate the monitor away from extremes of hot and cold. Avoid damp or dusty locations if possible. (Right you say, keep dreaming!) This will help keep your PC happy as well.

- Allow adequate ventilation - monitors use a fair amount of power - from 60 watts for a 12 inch monochrome monitor to over 200 W for a 21 inch high resolution color monitor. Heat is one major enemy of electronics.

- Do not put anything on top of the monitor that might block the ventilation grill in the rear or top of the cover. This is the major avenue for the convection needed to cool internal components.

- Do not place two monitors close to one another. The magnetic fields may cause either or both to suffer from wiggling or shimmering images. Likewise, do not place a monitor next to a TV if possible.

- Locate loudspeakers and other sources of magnetic fields at least a couple of feet from the monitor. This will minimize the possibility of color purity or geometry problems. The exception is with respect to good quality shielded multimedia speakers which are designed to avoid magnetic interference problems.

  Other devices which may cause interference include anything with power transformers including audio equipment, AC or DC wall adapters, and laptop power supplies; fluorescent lamps with magnetic ballasts; and motorized or heavy duty appliances.

- Situate monitors away from power lines - even electric wiring behind or on the other side of walls - and heavy equipment which may cause noticeable interference like rippling, wiggling, or swimming of the picture. Shielding is difficult and expensive.

- Make sure all video connections are secure (tighten the thumbscrews) to minimize the possibility of intermittent or noisy colors. Keep the cables as short as possible. Do not add extension cables if at all possible as these almost always result in a reduction in image crispness and introduce ghosting, smearing, and other termination problems. If you must add an extension, use proper high quality cable only long enough to make connections conveniently. Follow the termination recommendations elsewhere in this document.

- Finally, store magnetic media well away from all electronic equipment including and especially monitors and loudspeakers. Heat and magnetic fields will rapidly turn your diskettes and tapes into so much trash. The operation of the monitor depends on magnetic fields for beam deflection. Enough said.

Non-standard monitor mounting considerations

Monitors normally are positioned horizontally or via the limits of their tilt swivel bases out in the open on a table or desktop. However, for use in exhibits or for custom installations, it may be desirable to mount a monitor in a non-standard position and/or inside an enclosure.

(From: Bob Myers (myers@fc.hp.com).)

Your mileage may vary, but (and please take the following for what it is, a very general answer)...

There are basically two potential problems here; one is cooling, and the other is the fact that the monitor has no doubt been set up by the factory assuming standard magnetic conditions, which probably DIDN'T involve the monitor tilting at much of an angle. If you're happy with the image quality when it's installed in the cabinet, that leaves just the first concern. THAT one can be addressed by simply making sure the cabinet provides adequate ventilation (and preferably adding a fan for a bit of forced-air cooling), and making sure that the whole installation isn't going to be exposed to high ambient temperatures. (Most monitors are speced to a 40 deg. C ambient in their normal orientation; adding forced-air cooling will usually let you keep that rating in positions somewhat beyond the normal.) Under no circumstances should you block the cabinet's vents, and - depending on the installation - it may be preferable to remove the rear case parts of the monitor (but NOT the metal covers beneath the plastic skin) in order to improve air circulation.

Your best bet is to simply contact the service/support people of the monitor manufacturer, and get their input on the installation. Failing to get the manufacturer's blessing on something like this most often voids the warranty, and can probably lead to some liability problems. (Note - I'm not a lawyer, and I'm not about to start playing one on the net.)

Preventive maintenance - care and cleaning

Preventive maintenance for a monitor is pretty simple - just keep the case clean and free of obstructions. Clean the CRT screen with a soft cloth just dampened with water and mild detergent or isopropyl alcohol. This will avoid damage to normal as well as antireflection coated glass. DO NOT use anything so wet that liquid may seep inside of the monitor around the edge of the CRT. You could end up with a very expensive repair bill when the liquid decides to short out the main circuit board lurking just below. Then dry thoroughly. Use the CRT sprays sold in computer stores if you like but again, make sure none can seep inside. If you have not cleaned the screen for quite a while, you will be amazed at the amount of black grime that collects due to the static buildup from the CRT high voltage supply.

There is some dispute as to what cleaners are safe for CRTs with antireflective coatings (not the etched or frosted variety). Water, mild detergent, and isopropyl alcohol should be safe. Definitely avoid the use of anything with abrasives for any type of monitor screen. And some warn against products with ammonia (which may include Windex, Top-Job, and other popular cleaners), as this may damage/remove some types of antireflective coatings. To be doubly sure, test a small spot in a corner of the screen.

In really dusty situations, periodically vacuuming inside the case and the use of contact cleaner for the controls might be a good idea but realistically, you will not do this so don't worry about it.

Note that a drop of oil or other contamination might appear like a defect (hole) in the AR coating. Before getting upset, try cleaning the screen.

(From: Bob Myers (myers@fc.hp.com).)

Windex is perfectly fine for the OCLI HEA coating or equivalents; OCLI's coating is pretty tough and chemical-resistant stuff. There may be alternative (er..cheaper) coatings in use which could be damaged by various commercial cleaners, (For what it's worth, OCLI also sells their own brand of glass cleaner under the name "TFC", for "Thin Film Cleaner".)

I have cleaned monitors of various brands with both Windex and the OCLI-brand cleaner, with no ill results. But then, I'm usually pretty sure what sort of coating I'm dealing with... :-)

Monitor coatings are always changing; besides the basic "OCLI type" quarter-wave coatings and their conductive versions developed to address E-field issues, just about every tube manufacturer has their own brew or three of antiglare/antistatic coatings. There are also still SOME tubes that aren't really coated at all, but instead are using mechanically or chemically etched faceplates as a cheap "anti-glare" (actually, glare-diffusing) treatment.

In general, look in the user guide/owner's manual and see what your monitor's manufacturer recommends in the way of cleaning supplies.

(From: Tom Watson (tsw@johana.com).)

If you are maintaining a site, consider periodic cleaning of the monitors. Depending on the location, they can accumulate quite a bit of dust. In normal operation there is a electrostatic charge on the face of the crt (larger screens have bigger charges) which act as 'dust magnets'. If the operator smokes (thankfully decreasing), it is even worse. At one site I helped out with, most of the operators smoked, and the screens slowly got covered with a film of both dust and smoke particles. A little bit of glass cleaner applied with reasonable caution and the decree of "adjustments" to make the screen better (these were character monochrome terminals), and lo and behold, "what an improvement!". Yes, even in my dusty house, the TVs get a coating of film/goo which needs to be cleaned, and the picture quality (BayWatch viewers beware) improves quite a bit. Try this on your home TV to see what comes off, then show everyone else. You will be surprised what a little bit of cleaning does.

(From: Bob Myers (myers@fc.hp.com).)

1. Don't block the vents; make sure the monitor has adequate ventilation, and don't operate it more than necessary at high ambient temperatures.

2. If the monitor is used in particularly dusty environments, it's probably a good idea to have a qualified service tech open it up every so often (perhaps once a year, or more often depending on just how dirty it gets) and clean out the dust.

3. The usual sorts of common-sense things - don't subject the monitor to mechanical shock and vibration, clean up spills, etc., promptly, and so forth. And if you're having repeated power-supply problems with your equipment, it may be time to get suspicious of the quality of your AC power (are you getting noise on the line, sags, surges, spikes, brownouts, that sort of thing?).

And most importantly:

4. Turn the monitor OFF when it's not going to be used for an extended period (such as overnight, or if you'll be away from your desk for the afternoon, etc.). Heat is the enemy of all electronic components, and screen-savers do NOTHING in this regard. Many screen-savers don't even do a particularly good job of going easy on the CRT. With modern power-management software, there's really no reason to be leaving a monitor up and running all the time.

These won't guarantee long life, of course - nothing can do that, as there will always be the possibility of the random component failure. But these are the best that the user can do to make sure the monitor goes as long as it can.

Monitor tuneup?

(From: Bob Myers (myers@fc.hp.com).)

Most manufacturers will quote an MTBF (Mean Time Before Failure) of somewhere in the 30,000 to 60,000 hour range, EXCLUSIVE OF the CRT. The typical CRT, without an extended-life cathode, is usually good for 10,000 to 15,000 hours before it reaches half of its initial brightness. Note that, if you leave your monitor on all the time, a year is just about 8,000 hours.

The only "tuneup" that a monitor should need, exclusive of adjustments needed following replacement of a failed component, would be video amplifier and/or CRT biasing adjustments to compensate for the aging of the tube. These are usually done only if you're using the thing in an application where exact color/brightness matching is important. Regular degaussing of the unit may be needed, of course, but I'm not considering that a "tuneup" or adjustment.

- Back to Monitor Repair FAQ Table of Contents.

Monitor Troubleshooting

SAFETY

TVs and computer or video monitors are among the more dangerous of consumer electronic equipment when it comes to servicing. (Microwave ovens are probably the most hazardous due to high voltage at flesh frying and cardiac arresting high power.)

There are two areas which have particularly nasty electrical dangers: the non-isolated line power supply and the CRT high voltage.

Major parts of nearly all modern TVs and many computer monitors are directly connected to the AC line - there is no power transformer to provide the essential barrier for safety and to minimize the risk of equipment damage. In the majority of designs, the live parts of the TV or monitor are limited to the AC input and line filter, degauss circuit, bridge rectifier and main filter capacitor(s), low voltage (B+) regulator (if any), horizontal output transistor and primary side of the flyback (LOPT) transformer, and parts of the startup circuit and standby power supply. The flyback generates most of the other voltages used in the unit and provides an isolation barrier so that the signal circuits are not line connected and safer.

Since a bridge rectifier is generally used in the power supply, both directions of the polarized plug result in dangerous conditions and an isolation transformer really should be used - to protect you, your test equipment, and the TV, from serious damage. Some TVs do not have any isolation barrier whatsoever - the entire chassis is live. These are particularly nasty.

The high voltage to the CRT, while 200 times greater than the line input, is not nearly as dangerous for several reasons. First, it is present in a very limited area of the TV or monitor - from the output of the flyback to the CRT anode via the fat HV wire and suction cup connector. If you don't need to remove the mainboard or replace the flyback or CRT, then leave it alone and it should not bite. Furthermore, while the shock from the HV can be quite painful due to the capacitance of the CRT envelope, it is not nearly as likely to be lethal since the current available from the line connected power supply is much greater.

Of particular note in: Major Parts of Typical SVGA Monitor with Cover Removed are the CRT HV cable and connector, flyback or LOPT, and the horizontal output transistor and its heat sink. With many TVs and some monitors, this may be line-connected and electrically hot. However, this monitor uses a separate switchmode power supply and in any case, there is likely an insulator between the transistor and heat sink.

Safety Guidelines: These guidelines are to protect you from potentially deadly electrical shock hazards as well as the equipment from accidental damage.

Note that the danger to you is not only in your body providing a conducting path, particularly through your heart. Any involuntary muscle contractions caused by a shock, while perhaps harmless in themselves, may cause collateral damage - there are many sharp edges inside this type of equipment as well as other electrically live parts you may contact accidentally.

The purpose of this set of guidelines is not to frighten you but rather to make you aware of the appropriate precautions. Repair of TVs, monitors, microwave ovens, and other consumer and industrial equipment can be both rewarding and economical. Just be sure that it is also safe!

- Don't work alone - in the event of an emergency another person's presence may be essential.

- Always keep one hand in your pocket when anywhere around a powered line-connected or high voltage system.

- Wear rubber bottom shoes or sneakers.

- Don't wear any jewelry or other articles that could accidentally contact circuitry and conduct current, or get caught in moving parts.

- Set up your work area away from possible grounds that you may accidentally contact.

- Know your equipment: TVs and monitors may use parts of the metal chassis as ground return yet the chassis may be electrically live with respect to the earth ground of the AC line. Microwave ovens use the chassis as ground return for the high voltage. In addition, do not assume that the chassis is a suitable ground for your test equipment!

- If circuit boards need to be removed from their mountings, put insulating material between the boards and anything they may short to. Hold them in place with string or electrical tape. Prop them up with insulation sticks - plastic or wood.

- If you need to probe, solder, or otherwise touch circuits with power off, discharge (across) large power supply filter capacitors with a 2 W or greater resistor of 100 to 500 ohms/V approximate value (e.g., for a 200 V capacitor, use a 20K to 100K ohm resistor). Monitor while discharging and verify that there is no residual charge with a suitable voltmeter. In a TV or monitor, if you are removing the high voltage connection to the CRT (to replace the flyback transformer for example) first discharge the CRT contact (under the suction cup at the end of the fat HV wire). Use a 1M to 10M ohm 5 W or greater wattage (for its voltage holdoff capability, not power dissipation) resistor on the end of an insulating stick or the probe of a high voltage meter. Discharge to the metal frame which is connected to the outside of the CRT.

- For TVs and monitors in particular, there is the additional danger of CRT implosion - take care not to bang the CRT envelope with your tools. An implosion will scatter shards of glass at high velocity in every direction. There are several tons of force attempting to crush the typical CRT. While implosion is not really likely even with modest abuse, why take chances? However, the CRT neck is relatively thin and fragile and breaking it would be very embarrassing and costly. Always wear eye protection when working around the back side of a CRT.

- Connect/disconnect any test leads with the equipment unpowered and unplugged. Use clip leads or solder temporary wires to reach cramped locations or difficult to access locations.

- If you must probe live, put electrical tape over all but the last 1/16" of the test probes to avoid the possibility of an accidental short which could cause damage to various components. Clip the reference end of the meter or scope to the appropriate ground return so that you need to only probe with one hand.

- Perform as many tests as possible with power off and the equipment unplugged. For example, the semiconductors in the power supply section of a TV or monitor can be tested for short circuits with an ohmmeter.

- Use an isolation transformer if there is any chance of contacting line connected circuits. A Variac(tm) is not an isolation transformer! The use of a GFCI (Ground Fault Circuit Interrupter) protected outlet is a good idea but will not protect you from shock from many points in a line connected TV or monitor, or the high voltage side of a microwave oven, for example. (Note however, that, a GFCI may nuisanse trip at power-on or at other random times due to leakage paths (like your scope probe ground) or the highly capacitive or inductive input characteristics of line powered equipment.) A fuse or circuit breaker is too slow and insensitive to provide any protection for you or in many cases, your equipment. However, these devices may save your scope probe ground wire should you accidentally connect it to a live chassis.

- Don't attempt repair work when you are tired. Not only will you be more careless, but your primary diagnostic tool - deductive reasoning - will not be operating at full capacity.

- Finally, never assume anything without checking it out for yourself! Don't take shortcuts!

Warning about disconnecting CRT neck board

Some manufacturers warn against powering a TV or monitor CRT without the CRT neck board connected. Apparently, without something - anything - to drain the charge resulting from the current flow due to residual gas ions inside the CRT, the shortest path may be through the glass neck of the tube to the yoke or from the pins outside the CRT to whatever is nearby. There aren't many ions in a modern CRT but I suppose a few here, a few there, and eventually they add up to enough to cause a major disaster at least on some CRTs.

This is probably not a problem on small CRTs but for large ones with high high voltages and high deflection angles where the glass of the neck is very thin to allow for maximum deflection sensitivity, the potential does exist for arcing through the glass to the yoke to occur, destroying the CRT.

There is really no way to know which models will self destruct but it should be possible to avoid such a disaster by providing a temporary return path to the DAG ground of the CRT (NOT SIGNAL GROUND!!) via the focus or G2 pins preferably through a high value high voltage rated resistor just in case one of these is shorted.

This probably applies mostly to large direct-view TVs since they use high deflection angle CRTs but it won't hurt to take appropriate precautions with video and computer monitors as well.

Troubleshooting tips

Many problems have simple solutions. Don't immediately assume that your problem is some combination of esoteric complex convoluted failures. For a monitor, it may just be a bad connection or blown fuse. Remember that the problems with the most catastrophic impact on operation like a dead monitor usually have the simplest solutions. The kind of problems we would like to avoid at all costs are the ones that are intermittent or difficult to reproduce: the occasional jitter or a monitor that blows its horizontal output transistor every six months.

If you get stuck, sleep on it. Sometimes, just letting the problem bounce around in your head will lead to a different more successful approach or solution. Don't work when you are really tired - it is both dangerous (especially with respect to monitors) and mostly non-productive (or possibly destructive).

Whenever working on complex equipment, make copious notes and diagrams. You will be eternally grateful when the time comes to reassemble the unit. Most connectors are keyed against incorrect insertion or interchange of cables, but not always. Apparently identical screws may be of differing lengths or have slightly different thread types. Little parts may fit in more than one place or orientation. Etc. Etc.

Pill bottles, film canisters, and plastic ice cube trays come in handy for sorting and storing screws and other small parts after disassembly. This is particularly true if you have repairs on multiple pieces of equipment under way simultaneously.

Select a work area which is wide open, well lighted, and where dropped parts can be located - not on a deep pile shag rug. The best location will also be relatively dust free and allow you to suspend your troubleshooting to eat or sleep or think without having to pile everything into a cardboard box for storage.

Another consideration is ESD - Electro-Static Discharge. Some components (like ICs) in a TV are vulnerable to ESD. There is no need to go overboard but taking reasonable precautions such as getting into the habit of touching a **safe** ground point first.

WARNING: even with an isolation transformer, a live chassis should **not** be considered a safe ground point. When the monitor is unplugged, the shields or other signal ground points should be safe and effective.

A basic set of precision hand tools will be all you need to disassemble a monitor and perform most adjustments. These do not need to be really expensive but poor quality tools are worse than useless and can cause damage. Needed tools include a selection of Philips and straight blade screwdrivers, socket drivers, needlenose pliers, wire cutters, tweezers, and dental picks. For adjustments, a miniature (1/16" blade) screwdriver with a non-metallic tip is desirable both to prevent the presence of metal from altering the electrical properties of the circuit and to minimize the possibility of shorting something from accidental contact with the circuitry. A set of plastic alignment tools will be useful for making adjustments to coils (though you can forgo these until the (rare) need arises.

A low power (e.g., 25 W) fine tip soldering iron and fine rosin core solder will be needed if you should need to disconnect any soldered wires (on purpose or by accident) or replace soldered components. A higher power iron or small soldering gun will be needed for dealing with larger components. Never use acid core solder or the type used for sweating copper pipes!

CAUTION: You can easily turn a simple repair (e.g., bad solder connections) into an expensive mess if you use inappropriate soldering equipment and/or lack the soldering skills to go along with it. If in doubt, find someone else to do the soldering or at least practice, practice, practice, soldering and desoldering on a junk circuit board first! See the document: Troubleshooting and Repair of Consumer Electronic Equipment for additional info on soldering and rework techniques.

For thermal or warmup problems, a can of 'cold spray' or 'circuit chiller' (they are the same) and a heat gun or blow dryer come in handy to identify components whose characteristics may be drifting with temperature. Using the extension tube of the spray can or making a cardboard nozzle for the heat gun can provide very precise control of which components you are affecting.

For info on useful chemicals, adhesives, and lubricants, see "Repair Briefs, an Introduction" as well as other documents available at this site.

Test equipment

Don't start with the electronic test equipment, start with some analytical thinking. Your powers of observation (and a little experience) will make a good start. Your built in senses and that stuff between your ears represents the most important test equipment you have.

However, some test equipment will be needed:

- Multimeter (DMM or VOM) - This is essential for checking of power supply voltages and voltages on the pins of ICs or other components - service literature like the SAMs Photofacts described elsewhere in this document include voltage measurements at nearly every circuit tie point for properly functioning equipment. The multimeter will also be used to check components like transistors, resistors, and capacitors for correct value and for shorts or opens. You do not need a fancy instrument. A basic DMM - as long as it is reliable - will suffice for most troubleshooting. If you want one that will last for many years, go with a Fluke. However, even the mid range DMMs from Radio Shack have proven to be reliable and of acceptable accuracy. For some kinds of measurements - to deduce trends for example - an analog VOM is preferred (though some DMMs have a bar graph scale which almost as good).

- Oscilloscope - While many problems can be dealt with using just a multimeter, a 'scope will be essential as you get more into advanced troubleshooting. Basic requirements are: dual trace, 10-20 MHz minimum vertical bandwidth, delayed sweep desirable but not essential. A good set of proper 10X/1X probes. Higher vertical bandwidth is desirable but most consumer electronics work can be done with a 10 MHz scope. A storage scope or digital scope might be desirable for certain tasks but is by no means essential for basic troubleshooting.

  I would recommend a good used Tektronix (Tek) or Hewlett Packard (HP) scope over a new scope of almost any other brand. You will usually get more scope for your money and these things last almost forever. Until recently, my 'good' scope was the militarized version (AN/USM-281A) of the HP180 lab scope. It has a dual channel 50 MHz vertical plugin and a delayed sweep horizontal plugin. I have seen these going for under $300 from surplus outfits. For a little more money, you can get a Tek 465 or 465B (newer version but similar specifications) 100 Mhz scope ($200 to $600, sometimes cheaper on eBay or elsewhere but there is more risk than buying from a reputable dealer). I have now acquired a Tek 465B and that's what I use mostly these days. The HP-180 is still fine but I couldn't pass up a really good deal. :) The Tek 465/B or other similar model will suffice for all but the most demanding (read: RF or high speed digital) repairs.

- A video signal source - depending on what type of monitor you are repairing, you may need both computer and television signals.

  Computer Monitors - a test PC is useful as a video source. Of course, it will need to support whatever scan rates and video types the monitor is designed to accept. Software programs are available to display purity, convergence, focus, color, and other test patterns. Or create your own test patterns using a program like Windows Paint. See the section: Using a PC as a monitor test pattern generator.

  Studio monitors - a baseband video source like a VCR or camcorder is useful in lieu of a test pattern generator. These will allow you to you to control the program material. In fact, making some test tapes using a camcorder or video camera to record static test patterns will allow you full control of what is being displayed and for how long.

- Color bar/dot/crosshatch signal generator. This is a useful piece of equipment if you are doing a lot of TV or studio monitor repair and need to perform CRT convergence and chroma adjustments. However, there are alternatives that are almost as good: a VHS recording of these test patterns will work for TVs. A PC programmed to output a suitable set of test patterns will be fine for monitors (and TVs if you can set up the video card to produce an NTSC/PAL signal. This can be put through a VCR to generate the RF (Channel 3/4) input to your TV if it does not have direct video inputs (RCA jacks).

  Sophisticated (and expensive) universal test pattern generators are available that will handle any possible monitor scan rate.

Incredibly handy widgets

These are the little gadgets and homemade testers that are useful for many repair situations. Here are just a few of the most basic:

- Series light bulb for current limiting during the testing of TVs, monitors, switching power supplies, audio power amplifiers, etc. I built a dual outlet box with the outlets wired in series so that a lamp can be plugged into one outlet and the device under test into the other. For added versatility, add a regular outlet and 'kill' switch using a quad box instead. The use of a series load will prevent your expensive replacement part like a horizontal output transistor from blowing if there is still some fault in the circuit you have failed to locate.

- A Variac. It doesn't need to be large - a 2 A Variac mounted with a switch, outlet and fuse will suffice for most tasks. However, a 5 amp or larger Variac is desirable. If you will be troubleshooting 220 VAC equipment in the US, there are Variacs that will output 0-240 VAC from a 115 VAC line (just make sure you don't forget that this can easily fry your 115 VAC equipment.) By varying the line voltage, not only can you bring up a newly repaired monitor gradually to make sure there are no problems; you can also evaluate behavior at low and high line voltage. This can greatly aid in troubleshooting power supply problems. Warning: a Variac is not an isolation transformer and does not help with respect to safety. You need an isolation transformer as well.

- Isolation transformer. This is very important for safely working on live chassis equipment. Since nearly all modern monitors utilize line connected switchmode power supply or line connected deflection circuits, it is essential. You can build one from a pair of similar power transformers back-to-back (with their highest rated secondaries connected together. I built mine from a couple of similar old tube type TV power transformers mounted on a board with an outlet box including a fuse. Their high voltage windings were connected together. The unused low voltage windings can be put in series with the primary or output windings to adjust voltage. Alternatively, commercial line isolation transformers suitable for TV troubleshooting are available for less than $100 - well worth every penny.

- Variable isolation transformer. You don't need to buy a fancy combination unit. A Variac can be followed by a normal isolation transformer. (The opposite order also works. There may be some subtle differences in load capacity.).

CAUTION: Keep any large transformer of this type well away from your monitor or TV. The magnetic field it produces may cause the picture to wiggle or the colors to become messed up - and you to think there is an additional problem!

- Degaussing coil. Make or buy. The internal degaussing coil salvaged from a defunct color TV or monitor doubled over to half it original diameter to increase its strength in series with a 200 W light bulb for current limiting will work just fine. Or, buy one from a place like MCM Electronics for about $15-$30 that will be suitable for all but the largest TVs and monitors. Also, see the section: Degaussing (demagnetizing) a CRT.

Safe discharging of capacitors in TVs and video monitors

It is essential - for your safety and to prevent damage to the device under test as well as your test equipment - that large or high voltage capacitors be fully discharged before measurements are made, soldering is attempted, or the circuitry is touched in any way. Some of the large filter capacitors commonly found in line operated equipment store a potentially lethal charge.

This doesn't mean that every one of the 250 capacitors in your TV need to be discharged every time you power off and want to make a measurement. However, the large main filter capacitors and other capacitors in the power supplies should be checked and discharged if any significant voltage is found after powering off (or before any testing - the CRT capacitance in a TV or video monitor, for example, can retain a dangerous or at least painful charge for days or longer!)

The technique I recommend is to use a high wattage resistor of about 100 ohms/V of the working voltage of the capacitor. This will prevent the arc-welding associated with screwdriver discharge but will have a short enough time constant so that the capacitor will drop to a low voltage in at most a few seconds (dependent of course on the RC time constant and its original voltage).

Then check with a voltmeter to be double sure. Better yet, monitor while discharging (not needed for the CRT - discharge is nearly instantaneous even with multi-M ohm resistor).

Obviously, make sure that you are well insulated!

- For the main capacitors in a TV or monitor power supply which might be 400 uF at 200 V, this would mean a 5K, 10W resistor. RC = 2 seconds. 5RC = 10 seconds. A lower wattage resistor can be used since the total energy in not that great. If you want to be more high tech, you can build the capacitor discharge circuit outlined in the companion document: Capacitor Testing, Safe Discharging, and Other Related Information. This provides a visible indication of remaining charge and polarity.

- For the CRT, use a several M ohm resistor good for 30 kV or more (or a string of lower value resistors to obtain this voltage rating). A 1/4 watt job will just arc over! Discharge to the chassis ground connected to the outside of the CRT - NOT SIGNAL GROUND ON THE MAIN BOARD as you may damage sensitive circuitry. The time constant is very short - a ms or so. However, repeat a few times to be sure, then use a shorting clip as these capacitors have a way of recovering a painful charge if left alone - there have been too many stories of painful experiences from charge developing for whatever reasons ready to bite when the HV lead is reconnected.

  Note that if you are touching the little board on the neck of the CRT, you may want to discharge the HV even if you are not disconnecting the fat red wire - the focus and screen (G2) voltages on that board are derived from the CRT HV.

  WARNING: Most common resistors - even 5 W jobs - are rated for only a few hundred volts and are not suitable for the 25 kV or more found in modern TVs and monitors. Alternatives to a long string of regular resistors are a high voltage probe or a known good focus/screen divider network. However, note that the discharge time constant with these may be a few seconds. Also see the section: Additional information on discharging CRTs.

  If you are not going to be removing the CRT anode connection, replacing the flyback, or going near the components on the little board on the neck of the CRT, I would just stay away from the fat red wire and what it is connected to including the focus and screen wires. Repeatedly shoving a screwdriver under the anode cap risks scratching the CRT envelope which is something you really do not want to do.

Again, always double check with a reliable voltmeter!

Reasons to use a resistor and not a screwdriver to discharge capacitors:

1. It will not destroy screwdrivers and capacitor terminals.

2. It will not damage the capacitor (due to the current pulse).

3. It will reduce your spouse's stress level in not having to hear those scary snaps and crackles.

Additional information on discharging CRTs

You may hear that it is only safe to discharge from the Ultor to the Dag. So, what the @#$% are they talking about? :-).

(From: Asimov (mike.ross@juxta.mnet.pubnix.ten).)

'Dag' is short for Aquadag. It is a type of paint made of a graphite pigment which is conductive. It is painted onto the inside and outside of picture tubes to form the 2 plates of a high voltage filter capacitor using the glass in between as dielectric. This capacitor is between .005uF and .01uF in value. This seems like very little capacity but it can store a substantial charge with 25,000 volts applied.

The outside "Dag" is always connected to the circuit chassis ground via a series of springs, clips, and wires around the picture tube. The high voltage or "Ultor" terminal must be discharged to chassis ground before working on the circuit especially with older TV's which didn't use a voltage divider to derive the focus potential or newer TV's with a defective open divider.

(From: Sam)

CAUTION: The Dag coating/springs/clips/etc. may not be the same as signal ground on the mainboard. Discharging to that instead could result in all sorts of expensive blown components. Discharging between the CRT anode cap and Dag should be low risk though it is best to use a HV probe or properly rated high value resistor.

For more details, see the document: TV and Monitor CRT (Picture Tube) Information.

Removing the CRT HV connector

WARNING: Make sure the CRT has been discharged FIRST!

The rubber part is usually not glued down so it can be lifted rather easily. However, there may be some silicone type grease between the rubber boot (that looks like a suction cup) and the CRT glass to seal out dust.

A metal clip with a spring keeping it spread out attaches inside the button.

While there are a variety of types of clips actually used, pushing the connector to one side and/or squeezing it in the appropriate direction (peel up one side of the rubber to inspect) while gently lifting up should free it. Probably :-).

The clip (when removed) and CRT button look sort of like this:

```
                       ||======= HV Cable
                       /\
               Clip   |  |
          (Removed)  _|  |_
                                (No DAG coating in vicinity of HV connector)
        ____________.-    -.___________
   CRT  ____________|______|___________ Glass
                  Metal Button
```

Replacement is done in reverse order!

This isn't rocket science and excessive force should not be needed! :-)

The series light bulb trick

When powering up a monitor (or any other modern electronic devices with expensive power semiconductors) that has had work done on any power circuits, it is desirable to minimize the chance of blowing your newly installed parts should there still be a fault. There are two ways of doing this: use of a Variac to bring up the AC line voltage gradually and the use of a series load to limit current to power semiconductors.

Actually using a series load - a light bulb is just a readily available cheap load - is better than a Variac (well both might be better still) since it will limit current to (hopefully) non-destructive levels.

What you want to do is limit current to the critical parts - usually the horizontal output transistor (HOT). Most of the time you will get away with putting it in series with the AC line. However, sometimes, putting a light bulb directly in the B+

circuit will be needed to provide adequate protection. In that location, it will limit the current to the HOT from the main filter capacitors of line connected power supplies. This may also be required with some switchmode power supplies as they can still supply bursts of full (or excessive) current even if there is a light bulb in series with the AC line.

Actually, an actual power resistor is probably better as its resistance is constant as opposed to a light bulb which will vary by 1:10 from cold to hot. The light bulb, however, provides a nice visual indication of the current drawn by the circuit under test. For example:

- Full brightness: short circuit or extremely heavy load - a fault probably is still present.

- Initially bright but then settles at reduced brightness: filter capacitors charge, then lower current to rest of circuit. This is what is expected when the equipment is operating normally. There could still be a problem with the power circuits but it will probably not result in an immediate catastrophic failure.

- Pulsating: power supply is trying to come up but shutting down due to overcurrent or overvoltage condition. This could be due to a continuing fault or the light bulb may be too small for the equipment.

Note: for a TV or monitor, it may be necessary (and desirable) to unplug the degauss coil as this represents a heavy initial load which may prevent the unit from starting up with the light bulb in the circuit.

The following are suggested starting wattages:

- 40 W bulb for VCR or laptop computer switching power supplies.
- 100 W bulb for small (i.e., B/W or 13 inch color) monitors or TVs.
- 150-200 W bulb for large color monitors or projection TVs.

A 50/100/150 W (or similar) 3-way bulb in an appropriate socket comes in handy for this but mark the switch so that you know which setting is which!

Depending on the power rating of the equipment, these wattages may need to be increased. I have had to go to a 300 W light bulb for some computer monitors. However, start low. If the bulb lights at full brightness, you know there is still a major fault. If it flickers or the TV (or other device) does not quite come fully up, then it should be safe to go to a larger bulb. Resist the temptation to immediately remove the bulb at this point - I have been screwed by doing this. Try a larger one first. The behavior should improve. If it does not, there is still a fault present.

Note that some TVs and monitors simply will not power up at all with any kind of series load - at least not with one small enough (in terms of wattage) to provide any real protection. The microcontroller apparently senses the drop in voltage and shuts the unit down or continuously cycles power. Fortunately, these seem to be the exceptions.

Getting inside a monitor

You will void the warranty - at least in principle. There are usually no warranty seals on a monitor so unless you cause visible damage or mangle the screws or plastic, it is unlikely that this would be detected. You need to decide. A monitor still under warranty should probably be returned for warranty service for any covered problems except those with the most obvious and easy solutions. Another advantage of using warranty service is that should your problem actually be covered by a design change, this will be performed free of charge. And, you cannot generally fix a problem which is due to poor design!

Getting into a monitor is usually quite simple requiring the removal of 2-10 Philips or 1/4" hex head screws - most around the edge of the cabinet or underneath, a couple perhaps in the rear. Disconnect the input and power cables first as it they stay with catch on the rear cover you are detaching. Reconnect whatever is needed for testing after the cover is removed. Set the screws aside and make notes if they are not all of the same length and thread type - putting a too long screw in the wrong place can short out a circuit board or break something else, for example. A screw that is too short may not be secure.

Once all visible screws are out, try to remove the cover. There still may be hidden catches or snaps around the edges or seam or hidden beneath little plastic or rubber cosmetic covers. Sometimes, the tilt-swivel base will need to be removed first. If no snaps or catches are in evidence, the cover may just need a bit of persuasion in the form of a carefully placed screwdriver blade (but be careful not to damage the soft plastic). A 'splitting' tool is actually sold for this purpose.

As you pull the cover straight back (usually) and off, make sure that no other wires are still attached. Often, the main circuit board rests on the bottom of the cover in some slots. Go slow as this circuit board may try to come along with the back. Once the back is off, you may need to prop the circuit board up with a block of wood to prevent stress damage and contact with the work surface.

Most - but not all - monitors can be safely and stably positioned either still on the tilt-swivel base or on the bottom of the frame. However, some will require care as the circuit board will be vulnerable.

Larger monitors are quite heavy and bulky. Get someone to help and take precautions if yours is one of the unstable variety. If need be, the monitor can usually safely be positioned on the CRT face if it is supported by foam or a folded blanket.

Once the cover is off, you will find anywhere from none to a frustratingly large number of sheetmetal (perforated or solid) shields. Depending on which circuit boards need to be accessed, one or more of these shields may need to be removed. Make notes of which screws go where and store in a safe place. However, manufacturers often place holes at strategic locations in order to access adjustments - check for these before going to a lot of unnecessary bother. Note: sheetmetal usually has sharp edges. Take care.

See Major Parts of Typical SVGA Monitor with Cover Removed for what will greet you. This particular sample has a shield only covering the video driver board on the neck of the CRT.

Reassemble in reverse order. Getting the circuit board to slide smoothly into its slots may take a couple of attempts but otherwise there should be no surprises.

Specific considerations before poking around inside a TV or monitor

Both electrical and mechanical dangers lurk:

- Main filter capacitor(s). This is the most dangerous (not the HV as you would expect). Fortunately, these capacitors will normally discharge in a few minutes or less especially if the unit is basically working as the load will normally discharge the capacitors nearly fully as power is turned off. With TVs, the main filter capacitor is nearly always on the mainboard. Monitors are more likely to have a separate power supply module.

  However, you should check across this capacitor - usually only one and by far the largest in the unit - with a voltmeter and discharge as suggested in the section: Safe discharging of capacitors in TVs and video monitors if it holds more than a few volts (or wait longer) before touching anything.

  Some of these are as large as 1,000 uF charged to 160 V - about 13 w-s or a similar amount of energy as that stored in an electronic flash. This is enough to be potentially lethal under the wrong circumstances.

- High Voltage capacitor formed by the envelope of the CRT. It is connected to the flyback transformer by the fat (usually red) wire at the suction cup (well, it looks like one anyhow) attached to the CRT. This capacitor can hold a charge for quite a while - weeks in the case of an old tube type TV!

  If you want to be doubly sure, discharge this also. However, unless you are going to be removing the HV connector/flyback, it should not bother you.

The energy stored is about 1 w-s but if you touch it or come near to an exposed terminal, due to the high voltage, you will likely be handed *all* the energy and you *will* feel it. The danger is probably more in the collateral damage when you jump ripping flesh and smashing your head against the ceiling.

Some people calibrate their jump based on voltage - about 1 inch/V. :-).

There will be some HV on the back of the circuit board on the neck of the CRT but although you might receive a tingle but accidentally touching the focus or screen (G2) pins, it is not likely to be dangerous.

- CRT implosion risk. Don't hammer on it. However, it is more likely that you will break the neck off the tube since the neck is relatively weak. This will ruin your whole day and the TV or monitor but will likely not result in flying glass everywhere. Just, don't go out of your way to find out.

- Sharp sheet metal and so forth. This is not in itself dangerous but a reflex reaction can send your flesh into it with nasty consequences.

Dusting out the inside of a monitor

The first thing you will notice when you remove the cover is how super dusty everything is. Complements to the maid. You never dreamed there was that much dust, dirt, and grime, in the entire house or office building!

Use a soft brush (like a new paintbrush) and a vacuum cleaner to carefully remove the built up dust. Blowing off the dust will likely not hurt the unit unless it gets redeposited inside various controls or switches but will be bad for your lungs - and will spread dirt all over the room. Don't turn anything - many critical adjustments masquerade as screws that just beg to be tightened. Resist the impulse for being neat and tidy until you know exactly what you are doing. Be especially careful around the components on the neck of the CRT - picture tube - as some of these are easily shifted in position and control the most dreaded of adjustments - for color purity and convergence. In particular, there will be a series of adjustable ring magnets. It is a good idea to mark their position in any case with some white paint, 'white out', or a Magic Marker so that if they do get moved - or you move them deliberately, you will know where you started.

Troubleshooting a monitor with the mainboard disconnected

There are times when it is desirable to remove the chassis or mainboard and work on it in a convenient location without having to worry about the attachments to the CRT and cabinet circuitry.

My approach is usually to do as much work as possible without removing the main board and not attempt to power it up when disconnected since there are too many unknowns. Professionals will plug the chassis into a piece of equipment which will simulate the critical functions but this is rarely an option for the doit-yourselfer.

Note that if you have a failure of the power supply - blown fuse, startup, etc., then it should be fine to disconnect the CRT since these problems are usually totally unrelated. Tests should be valid.

However, if you really want to do live testing with the main board removed, here are some considerations. There are usually several connections to the CRT and cabinet:

- Deflection yoke - since the horizontal coils are part of the horizontal flyback circuit, there could be problems running without a yoke. This could be anything from it appearing totally dead to an overheating or blown horizontal output transistor. There may be no problems. Vertical and any convergence coils may or may not be problems as well.

- CRT video Driver board - pulling this should not usually affect anything except possibly video output and bias voltages.

* CRT 2nd anode - without the CRT, there will be no capacitor to filter the high voltage and you would certaily want to insulate the HV connector **real** well. I do not know whether there are cases where damage to flyback could result from running in thie manner, however.

* Front panel controls - disconnecting these may result in inability to even turn the unit on, erratic operation, and other unexpected behavior.

* Degauss - you just won't have this function when disconnected. But who cares - you are not going to be looking at the screen anyhow.

* Remote sensor - no remote control but I doubt that the floating signals will cause problems.

* Speakers - there will be no audio but this should not cause damage.

  If you do disconnect everything, make sure to label any connectors whose location or orientation may be ambiguous. Most of the time, these will only fit one way but not always.

Comments on repairing modern computer monitors

(From: Wild Bill (kwag98@tcis.net).)

Without even taking into consideration all of the other features of most late model (15" or larger) monitors, such as the multisync and multi-resolution circuitry, many of these units are very complex. They combine almost every example of present circuit design technology. A vacuum display tube, digital data, HF switching, all types of regulators and sense circuits and linear power devices. Funny too, that the end result is just dots of light.

A good (perhaps the best) first action is to search the USENET newsgroup sci.electronics.repair via an archive like Deja.com for previous postings of questions on the same model with related symptoms and replies. Solder in the replacement part, and BINGO, it's repaired. Rest assured that it's always something simple. Yeah, right. :) Time to check some archive repair sites with tech-tips databases.

Typically, for a dead unit, I get a DMM, pencil and paper....

After a fairly thorough overall inspection, i generally resort to a section-by-section investigation for shorted/open power devices, followed by PN junction checks, then an overall ESR check SxS. In circuit ESR checking will nearly always convince me to replace at least a couple of caps. But if ya don't replace 'em, ya just never know. Hehehe.

By now, I'm at least an hour into this potential research project, if the unit's operation hasn't yet been restored. The next phase is usually determined by whatever i feel like doing next.. i might get a couple of datasheets, try a series lamp technique, or test the major parts.. flyback/IHVT, CRT or yokes. If one of these are faulty, it will help determine the cost effectiveness of proceeding. If it's not my monitor, i contact the owner.

Barring any major parts failure, there are several more options for a direction to proceed in.. making sense of any of the available voltages or waveforms, checking the HV semis for leakage, or as a last (but maybe not final) resort.. making circuit diagrams of specific sections. If there hasn't been any sign of progress by this point, the unit usually finds it's way to a shelf until more inspiration arrives.. that reminds me, when did i place that order?

---

Monitor Adjustments

These include both controls accessible to the user (and often not understood) as well as internal adjustments that may need to be touched up due to the aging of components or following a repair.

Note that monitor (software) drivers often have the capability to provide some control of picture size, position, color balance, and other parameters via the video card. There is also third-party software for this purpose. So, before blaming the monitor, make sure your software settings (and monitor user controls) have been reset to their defaults. Then see if the monitor controls and/or the driver adjustments have enough range with the procedures described below. However, where a sudden change in behavior occurred without anything being done in either hardware or software (e.g., a new video card or OS/revision), trying to adjust out such a fault is like putting a Band-Aid on a broken bone. There is likely to be a hardware fault in the monitor which will need to be identified and repaired.

User picture adjustment

For general viewing, subdued lighting is preferred. Avoid backlighting and direct overhead lighting if possible.

Display an image with a variety of colors and the full range of brightness from deep shadows to strong highlights. For PCs, a Windows desktop is generally satisfactory. An outdoor scene on a sunny day is excellent for studio monitors. Alternatively, use a test pattern specially designed for this purpose.

Turn the BRIGHTNESS and CONTRAST controls (or use the buttons) all the way down.

Increase the BRIGHTNESS until a raster is just visible in the darkest (shadow) areas of the picture and then back off until it **just** disappears.

Increase the CONTRAST until the desired intensity of highlights is obtained.

Since BRIGHTNESS and CONTRAST are not always independent, go back and forth until you get the best picture.

On monitors with a color balance adjustment, you may want to set this but unless you are doing photorealistic work, using the manufacturer's defaults will be fine unless you need to match the characteristics of multiple monitors located side-by-side.

Focus adjustment

One of the most common complaints is that the monitor is not as crisp as it used to be - or just not as sharp as expected.

Assuming that the focus has just been gradually getting worse over time, tweaking the internal focus control may be all that is needed.

Some monitors have the focus adjustment accessible through a (possibly unmarked) hole in the side or rear of the case. If there is a single hole, it is almost certainly for overall focus. If there are two holes, one may be the screen (G2 - master brightness) or the two adjustments may be for different aspects of focus (e.g., horizontal and vertical). Just carefully observe what happens when each adjustment is moved a little so that you can return it to its original setting if you turned the wrong one. Use a thin insulated screwdriver - preferably with a plastic blade. As a extra precaution, determine of the screwdriver will mate easily with the adjustment with the monitor **off** (don't turn anything, however).

Where there are two adjustment knobs on the flyback transformer, the top one is generally for focus and the bottom one is for G2.

Most inexpensive monitors have only what is known as static focus - a constant voltage derived from the HV power supply is applied to the focus grid of the CRT. This does not allow for optimal focus across the screen and any setting is just a compromise between central and edge sharpness.

Better monitors will have separate H and V focus controls as well as dynamic focus circuitry which generates focus correction signals that are a function of screen position to compensate for changing distance to electron guns at the edges and corners of the screen. There may be some interaction between the static and dynamic adjustments. If either of these controls has no effect or insufficient range, then there may be a fault in the circuitry for that particular adjustment - a fault with the driver, waveform source, power supply, etc.

The most sophisticated schemes use a microprocessor (or at least digital logic) to specify the waveform for each section of the screen with a map of correction values stored in non-volatile memory. It would be virtually impossible to troubleshoot these systems without detailed service information and an oscilloscope - and even then you might need a custom adapter cable and PC software to adjust values!

Also see the section: About the quality of monitor focus.

If you need to go inside to tweak focus pots:

SAFETY: as long as you do not go near anything else inside the monitor while it is on AND keep one hand in you pocket, you should be able to do this without a shocking experience.

Plug it in, turn it on and let it warm up for a half hour or so. Set your PC (or other video source) to display in the resolution you use most often. First turn the user brightness and contrast fully counterclockwise. Turn brightness up until the raster lines in a totally black area appear, then back a hair until they disappear. Then, turn the contrast control up until you get a fairly bright picture. Fullly clockwise is probably ok. Adjust FOCUS for generally best focus. You will not be able to get it razor sharp all over the screen - start at the center and then try to get the edges and corners as good as you can without messing up the center too much. Double check that the focus is OK at your normal settings of brightness and contrast and at other resolutions that you normally use.

The focus pot is usually located on the flyback transformer or on an auxiliary panel nearby. The focus wire usually comes from the flyback or the general area or from a terminal on a voltage the multiplier module (if used). It is usually a wire by itself going to the little board on the neck of the CRT.

The SCREEN control adjusts background brightness. If the two controls are not marked, you will not do any damage by turning the wrong one - it will be immediately obvious as the brightness will change rather than focus and you can then return it to its original position (or refer to the section on brightness adjustments to optimize its setting).

On a decent monitor, you should be able to make out the individual scanning lines at all resolutions though it will be toughest at the highest scan rates. If they lines are fuzzy, especially in bright areas, then focus may need to be adjusted or there may be an actual fault in the focus circuitry or a defective or just marginal CRT.

Brightness and color balance adjustment

A monitor which has a picture that is too dark or too bright and cannot be adequately set with the user brightness and contrast controls may need internal adjustment of the SCREEN (the term, screen, here refers to a particular electrode inside the CRT, not really the brightness of the screen you see, though it applies here), MASTER BRIGHTNESS, or BACKGROUND level controls. As components age, including the CRT, the brightness will change, usually decrease. The following procedure will not rejuvenate an old CRT but may get just enough brightness back to provide useful functionality for a few months or longer. If the problem is not with the age of the CRT, then it may return the monitor to full brightness. The assumption here is that there is a picture but the dark areas are totally black and the light areas are not bright enough even with the user brightness control turned all the way up.

Note that circuit problems can also cause similar symptoms. These are particularly likely if the brightness descresed suddenly - CRT emission problems will result in a gradual decrease in brightness over time.

In most cases, the cover will need to be removed. The controls we are looking for may be located in various places. Rarely, there will be access holes on the back or side. However, if there are unmarked holes, then the FOCUS and SCREEN controls are the most likely possibilities.

The controls may be located on the:

- Flyback (LOPT) transformer. Usually there is a master screen control along with a focus control on the flyback transformer.

- A little board on the neck of the CRT. There may be a master screen control. a master brightness control, a master background level control, or individual controls for red, green, and blue background level. Other variations are possible. There may also be individual gain/contrast controls.

- Main video board is less common, but the background level controls may be located here.

Display a black and white picture at the video resolution you consider most important. Select one that has both full blacks and full whites - an nice sunny outdoor scene that has been converted from a color image, for example.

Set the user brightness control to its midpoint and the user contrast control as low as it will go - counterclockwise.

Let the monitor warm up for at least 15 minutes so that components can stabilize.

If there is a MASTER BRIGHTNESS or BACKGROUND level control, use this to make the black areas of the picture just barely disappear. Them, increase it until the raster lines just appear. (They should be a neutral gray. If there is a color tint present, then the individual color background controls will need to be adjusted to obtain a neutral gray.) If there is no such control, use the master screen control on the flyback. If it is unmarked, then try both of the controls on the flyback - one will be the screen control and the other will be focus - the effects will be obvious. If you did touch focus, set it for best overall focus and then get back to the section on focus once you are done here.

If there are individual controls for each color, you may use these but be careful as you will be effecting the color balance. Adjust so that the raster lines in a black area are just visible and dark neutral gray.

If there is a 'service switch' you may prefer to make the adjustment with this in the service position. The raster will collapse to a single horizontal line and the video input will be disabled and forced to black. The BACKGROUND or SCREEN control can then be adjusted as above.

Now for the gain controls. On the little board on the neck of the CRT or on the video or main board there will be controls for R, G, and B DRIVE (also may be called GAIN, or CONTRAST - they are the same). The knobs or slots may even be color coded as to which primary (R,G,B) it affects.

If there are only two then the third color is fixed and if the color balance in the highlights of the picture was ok, then there is nothing more you can do here.

Set the user contrast control as high as it will go - clockwise.

Now adjust each internal color DRIVE control as high as you can without that particular color 'blooming' at very bright vertical edges. Blooming means that the focus deteriorates for that color and you get a big blotch of color trailing off to the right of the edge. You may need to go back and forth among the 3 DRIVE controls since the color that blooms first will limit the amount that you can increase the contrast settings. Set them so that you get the brightest neutral whites possible without any single color blooming.

Note that this is ignoring the effects of any beam current or brightness limiter circuitry. Any recommendations in the service manual should be followed to minimize the chance of excess X-ray emissions as well as to avoid burn-in of the phosphor screen.

Now check out the range of the user controls and adjust the appropriate internal controls where necessary. You may need to touch up the background levels or other settings. Check at the other resolutions and refresh rates that you normally use.

If none of this provides acceptable brightness, then either your CRT is in its twilight years or there is something actually broken in the monitor. If the decrease in brightness has been a gradual process over the course of years, then it is most likely the CRT. As a last resort you can try increasing the filament current to the CRT the way CRT boosters that used to be sold for TVs worked. See the section: Brightening an old CRT.

Optimal procedure for setting brightness/background and screen adjustments

For slight tweaks, the following is not necessary. However, if someone turned all the internal controls, if you are making significant changes that affect G2 (screen), or you are setting up a new or replacement CRT for the first time, then following the procedure below is desirable to achieve best performance and maximize life of the CRT.

The typical user controls - brightness and contrast can, of course, be set arbitrarily, depending on video content and ambient lighting conditions.

Set the user brightness and contrast controls in the middle for the following adjustments and let the monitor warm up for 20 minutes or so.

(From: Jeroen Stessen (Jeroen.Stessen@philips.com).)

Now the screen control, that's another matter. It sets the voltage on the second grid of the electron guns, typically between +500 and +1000 V. You will want to use a well-isolated screwdriver for that if it is a naked potentiometer. In the old days there used to be 3 separate potentiometers for 3 G2s, now there is generally only one.

Its purpose is to set the cutoff voltage for the guns, i.e. the voltage between K and G1 at which the beam is just off. The higher you set the VG2, the higher VK - VG1 must be to cut off the beam.

If you set VG2 too low then your picture will be dark. You can compensate for that with the brightness control, which in effect will lower the VKs. A disadvantage is that you will not get optimum sharpness and peak brightness from your picture tube.

If you set VG2 too high then your picture will be bright. You can compensate for that with the brightness control, which in effect will raise the VKs. You might even get retrace lines which can usually not be made to disappear with the brightness control. Another disadvantage is that you will not get optimum LIFETIME from your picture tube. With a too high cutoff voltage the cathode (electron emitting surface) will wear out too soon.

You will need to see the picture tube specifications (or possibly the service manual for the monitor --- sam) in order to find the correct setting for the cutoff voltage. This is measured as VK - VG1 (for each channel RGB) and is typically 130-160 V max. There will be spread between the 3 channels, typically the highest of the 3 measured values will be set against the upper limit.

The usual adjustment procedure is as follows:

- Use any low-level adjustments to set a black picture with all 3 cathode voltages at the specified level (e.g. 130 V) above the VG1 voltage (may be 0 V or 12 V or 20 V ?). (These are typically called RGB brightness, bias, or background level and are often on the little board on the neck of the CRT but not always --- sam).

- Adjust VG2 (screen) until one colour just starts too light up, turn it back down until the screen is just black again. (Occasionally, there are two G2 controls - one on the flyback and another on the CRT neck board or elsewhere. If so, they control are basically in series - leave the one on the flyback alone if the other one has enough range.)

- Now adjust 2 of the 3 low-level black controls until the other 2 colours just light up, and then back to black again.

- Select a white picture and use 2 low-level white (RGB drive or gain, also generally on the neck board --- sam) controls to set the proper colour temperature for white to your own taste.

- Check your black calibration again, may have to iterate a bit.

Position, size, and linearity adjustment

Position and size are usually user controls on computer and video monitors but not on TVs. On monitors with digital controls, they may usually be set for each resolution and (automatically) stored in non-volatile memory so they will be retained when the monitor is turned off. On cheaper monitors, there may be a knobs on the front or back panel and may need to readjusted whenever the scan rate/resolution is changed. Sometimes, there are located internally. There may be separate adjustments for each scan range and may or may not be accessible through holes in the back panel.

There may also be an adjustment called 'horizontal phase' which controls the relative timing of the horizontal sync pulse with respect to retrace. Its effect is subtly different than horizontal position which actually moves the raster. If possible, center the raster and then use H Phase to center the picture.

In monochrome monitors (mostly), position may be set via a pair of rings on the neck of the CRT.

Size can be set to your preference for each scan rate (if they are independent). For computer work, slight underscan is often preferred as all of the frame buffer is visible. However, any slight geometric problems with the raster will be all too visible when compared with the straight sides of the CRT bezel.

Note that resolutions like 640 x 480, 800 x 600, and 1024 x 768 all have a 4:3 aspect ratio. The edge of the image will line up with the bezel on most if not all monitors since CRTs are made to a 4:3 aspect ratio. However, resolutions like 1280 x 1024 and 1600 x 1280 have a 5:4 aspect ratio. With these, in order to get (highly desirable) square pixels, the horizontal size must be adjusted slightly smaller than that required to fill the screen.

For normal viewing of video (television) monitors, raster size should be set so that there is about 10-15 percent overscan all around. This will allow ample margin for power line voltage fluctuations, component aging, and the reduction in raster size that may occur with some VCR special effects (CUE and REV) modes. However, for studio use, underscan is often preferred or at least an option to permit the entire raster to be inspected.

Modern color monitors may not have any horizontal linearity control but you may find this on older models. There may be an internal vertical linearity adjustment. I am not aware of any that have user accessible linearity controls. If there are internal pots or coils, you will need to go back and forth between size and linearity as these adjustments are usually not independent.

Of course, parameters controlling your video card also affect position and size. There is no best approach to reconciling the effects of monitor and video card position adjustments. But, in general, start with the monitor controls centered within their range or use the memory defaults as appropriate. Then, use the video card setup program to optimize the settings. Only if these do not have enough range should you use the monitor controls.

Comments on linearity or lack thereof

(From: Jerry Greenberg (jerryg50@hotmail.com).)

If you can get a grating test generator this would be the proper way to test for non-linearity. Using a camera or device other than that would not be an acceptable reference if you call any engineer from the manufacture. If you mention a grating generator, he will certainly listen.

You would need the service manual for the model to know the specs. Some of these sets can have a non-linearity of up to about 2% near to the edges. Only professional broadcast monitors will be down to the 0.5% and less error factor near to the corners.

On a 27 inch screen 2% can mean an error of can give a visible non-linearity of 0.5 inches. Convergence errors can be as much as 0.25 or 1/4 inch at the corners. Generally they are more accurate than these figures. This is the worse case that is generally accepted on a consumer TV by the manufactures.

I have found that on flat screen consumer TV sets, the linearity sort of gets a bit stretched towards the ends of the scan. This is because of the beam angle. There is compensation for azimuth of beam focus (dynamic focus) and for the scans to a degree that keeps the price of the TV within consumer range.

The screens that are a bit more spherical or rounded will have less of this effect because it is lower in cost to compensate for these errors. A true accurate screen would be one that is spherical following exactly to the beam angle. But, for viewing this would not be very desirable.

Pincushion adjustments

Horizontal pincushion refers to any bowing in or out on the vertical sides of the raster. There is not usually any explicit vertical pincushion adjustment. Adjustment usually uses two controls - amplitude and phase. Pincushion amplitude as its name implies, controls the size of the correction. Pincushion phase affects where on the sides it is applied. Don't expect perfection.

If the controls have no effect, there is probably a fault in the pincushion correction circuitry.

It is best to make these adjustments with a crosshatch or dot test pattern

Geometry adjustment

This refers to imperfections in the shape of the picture not handled by the pincushion and size adjustments. These types of defects include a trapezoidal or keystone shaped raster and jogs or wiggles around the periphery of the raster. Unfortunately, one way these are handled at the factory is to glue little magnets to strategic locations on the CRT and/or rotate little magnets mounted on the yoke frame. Unless you really cannot live with the way it is (assuming there isn't something actually broken), leave these alone! You can end up with worse problems. In any case, carefully mark the position AND orientation of every magnet so that if this happens, you can get back to where you started. If the magnets are on little swivels, some experimenting with them one at a time may result in some improvement. Of course it is best to obtain a service manual and follow its instructions. However, this may not be possible at reasonable cost or at all for many computer monitors.

Why is the convergence on my monitor bad near the edges

Very simple - nothing is quite perfect. Perfect convergence is not even necessarily possible in theory with the set of adjustments available on a typical monitor. It is all a matter of compromises. Consider what you are trying to do: get three electron beams which originate from different electron guns to meet at a single point within a fraction of a mm everywhere on the screen. This while the beams are scanning at an typical effective writing rate of 50,000 mph across the face of a 17" CRT (assumed resolution: 1024x768 at 75 Hz) in a variable magnetic environment manufactured at a price you can afford without a second mortgage!

The specifications for misconvergence have two parts: a center error and a corner error. The acceptable center error is always the smaller of the two - possibly .1-.2 mm. compared to .3-.5 mm in the corners. Very often, you will find that what you are complaining about is well within this specification.

CRT purity and convergence

Purity assures that each of the beams for the 3 primary colors - R, G, B, - red, green, and blue - strikes only the proper phosphor for that color. A totally red scene will appear pure red and so forth. Symptoms of poor purity are blotches of discoloration on the screen. Objects will change shades of color when the move from one part of the screen to another. There may even be excess non-uniformity of pure white or gray images.

Convergence refers to the control of the instantaneous positions of the red, green, and blue spots as they scan across the face of the CRT so that they are as nearly coincident as possible. Symptoms of poor convergence are colored borders on solid objects or visible separate R, G, and B images of fine lines or images,

Note: It is probably best to face the monitor East-West (front-to-back) when performing any purity and convergence adjustments. Since you probably do not know what orientation will eventually be used, this is the best compromise as the earth's magnetic field will be aligned mostly across the CRT. This will minimize the possible rotation of the picture when the unit is moved to its final position but there may be a position shift. Neither of these is that significant so it probably doesn't really matter that much unless you are super fussy. Of course, if you know the final orientation of the monitor use that instead. Or, plan to do the final tilt and position adjustments after the monitor is in position - but this will probably require access to the inside!

First, make sure no sources of strong magnetic fields are in the vicinity of the monitor - loudspeakers, refrigerator magnets, MRI scanners, etc. A nearby lightning strike or EMP from a nuclear explosion can also affect purity so try to avoid these.

Cycle power a couple of times to degauss the CRT (1 minute on, 20 minutes off) - see the section: Degaussing (demagnetizing) a CRT. If the built in degaussing circuits have no effect, use an external manual degaussing coil to be sure that your problems are not simply due to residual magnetism.

Assuming this doesn't help, you will need to set the internal purity and/or convergence adjustments on the CRT.

First, mark the positions of all adjustments - use white paint, 'White out', or a Magic Marker on the ring magnets on the neck of the CRT, the position and tilt of the deflection yoke, and any other controls that you may touch deliberately or by accident.

Note: if your monitor is still of the type with a drawer or panel of knobs for these adjustments, don't even think about doing anything without a service manual and follow it to the letter unless the functions of all the knobs is clearly marked (some manufacturers actually do a pretty good job of this).

CRT purity adjustment

Purity on modern CRTs is usually set by a combination of a set of ring magnets just behind the deflection yoke on the neck of the CRT and the position of the yoke fore-aft. As always, mark the starting position of all the rings and make sure you are adjusting the correct set if rings!

Use the following purity adjustment procedure as a general guide only. Depending on the particular model monitor, your procedure may substitute green for red depending on the arrangement of guns in the CRT. The procedures for dot-mask, slot mask, and Trinitron (aperture grille) CRTs will vary slightly. See you service manual!

Obtain a white raster (sometimes there is a test point that can be grounded to force this). Then, turn down the bias controls for blue and green so that you have a pure red raster. Let the monitor warm up for a minimum of 15 minutes.

Loosen the deflection yoke clamp and move the yoke as far back as it will go,

Adjust the purity magnets to center the red vertical raster on the screen.

Now, move the yoke forward until you have the best overall red purity. Tighten the clamp securely and reinstall the rubber wedges (if your CRT has these) to stabilize the yoke position. Reset the video adjustments you touched to get a red raster.

CRT convergence adjustment

In the good old days when monitors were monitors (and not just a mass produced commodity item) there were literally drawers or panels full of knobs for setting convergence. One could spend hours and still end up with a less than satisfactory picture. As the technology progressed, the number of electronic adjustments went down drastically so that today there are very few if any. However, some high end monitors do have user accessible controls for minor adjustment of static (center) convergence.

Unless you want a lot of frustration, I would recommend not messing with convergence. You could end up a lot worse. I have no idea what is used for convergence on your set but convergence adjustments are never quite independent of one another. You could find an adjustment that fixes the problem you think you have only to discover some other area of the screen is totally screwed. In addition, there are adjustments for geometry and purity and maybe others that you may accidentally move without even knowing it until you have buttoned up the set.

Warning: Accurately mark the original positions - sometimes you will change something that will not have an obvious effect but will be noticeable later on. So it is extremely important to be able to get back to where you started. If only red/green vertical lines are offset, then it is likely that only a single ring needs to be moved - and by just a hair. But, you may accidentally move something else!

If you really cannot live with it, make sure you mark everything very carefully so you can get back to your current state. A service manual is essential!

Convergence is set using a white crosshatch or dot test pattern. For PCs (a similar approach applies to workstations) If you do not have a test pattern generator, use a program like Windows Paint to create a facsimile of a crosshatch pattern and use this for your convergence adjustments. For a studio video monitor, any static scene (from a camcorder or previously recorded tape, for example) with a lot of fine detail will suffice.

Static convergence sets the beams to be coincident in the exact center of the screen. This is done using a set of ring magnets behind the purity magnets on the CRT neck. (Set any user convergence controls to their center position).

Adjust the center set of magnets on the CRT neck to converge blue to green at the center of the screen. Adjust the rear set of magnets to converge red to green at the center of the screen." Your monitor may have a slightly different procedure.

Dynamic convergence adjusts for coincidence at the edges and corners.

On old tube, hybrid, and early solid state monitors, dynamic convergence was accomplished with electronic adjustments of which there may have been a dozen or more that were not independent. With modern monitors, convergence is done with magnet rings on the neck of the CRT, magnets glued to the CRT, and by tilting the deflection yoke. The clamp in conjunction with rubber wedges or set screws assures that the yoke remains in position.

Remove the rubber wedges.

Loosen the deflection yoke clamp just enough so that it can be tilted but will remain in the position you leave it. Rock the yoke up and down to converge the right and left sides of the screen. Rock the yoke from side to side to converge the top and bottom of the screen. The rubber wedges can be used as pivots to minimize the interaction between the two axes but you may need to go back and forth to optimize convergence on all sides. Reinstall the wedges firmly and tape them to the CRT securely. Tighten the yoke clamp enough to prevent accidental movement.

Some monitors may use a plastic frame and set screws instead of just a clamp and rubber wedges but the procedure is similar.

Refer to your service manual. (Is this beginning to sound repetitious?)

For additional comments on convergence adjustments, see the section: Tony's notes on setting convergence on older delta gun CRTs.

Tilted picture

You have just noticed that the picture on your fancy (or cheap) monitor is not quite horizontal - not aligned with the front bezel. Note that often there is some keystoning or other geometric distortion as well where the top and bottom or left and right edges of the picture are not quite parallel - which you may never have noticed until now. Since this may not be correctable (at least, not without a lot of hassle), adjusting tilt may represent a compromise at best between top/bottom or left/right alignment of the picture edges. You may never sleep again knowing that your monitor picture is not perfect! BTW, I can sympathize with your unhappiness. Few things are more annoying than a just noticeable imperfection such as this.

This is probably one reason why older monitors tended not to be able to expand the picture to totally fill the screen - it is easier to overlook imperfect picture geometry if there is black space between the edges of the picture and the bezel!

There are several possible causes for a tilted picture:

1. Monitor orientation. The horizontal component of the earth's magnetic field affects this slightly. Therefore, if you rotate the unit you may be able to correct the tilt. Of course, it will probably want to face the wall!

2. Other external magnetic fields can sometimes cause a rotation without any other obvious effects - have you changed the monitor's location? Did an MRI scanner move in next door?

3. Need for degaussing. Most of the time, magnetization of the CRT will result in color problems which will be far more obvious than a slight rotation. However, internal or external shields or other metal parts in the monitor could become magnetized resulting a tilt. More extensive treatment than provided by the built-in degaussing coil may be needed. Even, the normal manual degaussing procedure may not be enough to get close enough to all the affected parts.

4. You just became aware of it but nothing has changed. Don't dismiss this offhand. It is amazing how much we ignore unless it is brought to our attention. Are you a perfectionist? Did your friend just visit boasting about his P8-1000 screamer and point the tilt out to you?

5. There is an external tilt control which may be misadjusted. Newer Sony monitors have this (don't know about TVs) - a most wonderful addition. Too bad about the stabilizing wires on Trinitron CRTs. A digital control may have lost its memory accidentally. The circuitry could have a problem.

   For example, on the Sony CPD1730, you press the left arrow button and blue '+' button at the same time. Then adjust the tilt with the red buttons.

6. There is an internal tilt control that is misadjusted or not functioning. The existence of such a control is becoming

more common.

7. The deflection yoke on the CRT has gotten rotated or was not oriented correctly at the time of the set's manufacture. Sometimes, the entire yoke is glued in place in addition to being clamped adding another complication.

   If the monitor was recently bumped or handled roughly, the yoke may have been knocked out of position. But in most cases, the amount of abuse required to do this with the yoke firmly clamped and/or glued would have totally destroyed it in the process.

   There is a risk (in addition to the risk of frying yourself on the various voltages present inside an operating monitor) of messing up the convergence or purity when fiddling with the yoke or anything around it since the yoke position on the neck of the tube and its tilt may affect purity and convergence. Tape any rubber wedges under the yoke securely in place as these will maintain the proper position and tilt of the yoke while you are messing with it. (Don't assume the existing tape will hold - the adhesive is probably dry and brittle).

8. The CRT may have rotated slightly with respect to the front bezel. Irrespective of the cause of the tilt, sometimes it is possible to loosen the 4 (typical) CRT mounting screws and correct the tilt by slightly rotating the CRT. This may be easier than rotating the yoke. Just make sure to take proper safety precautions when reaching inside!

Monochrome monitor size, position, and geometry adjustments

These tend to be a lot simpler and less critical than for color monitors or TV sets.

On a monochrome (B/W) monitor you will probably see some of the following adjustments:

1. Position - a pair of rings with tabs on the neck of the CRT. There may be electronic position adjustements as well.

2. Width and height (possibly linearity as well) controls. There may be some interaction between size and linearity - a crosshatch test pattern is best for this. Vertical adjustments are almost always pots while horizontal (if they exist) may be pots and/or coils. Where desired, set sizes for 5-10% overscan to account for line voltage fluctuations and component drift. Confirm aspect ratio with test pattern which includes square boxes.

3. Geometry - some little magnets either on swivels around the yoke or glued to the CRT. If these shifted, the the edges may have gotten messed up - wiggles, dips, concave or convex shapes. There may be a doxen or more each mostly affecting a region around the edge of the raster. However, they will not be totally independent.

Check at extremes of brightness/contrast as there may be some slight changes in size and position due to imperfect HV regulation.

There may be others as well but without a service manual, there is no way of knowing for sure.

Just mark everything carefully before changing - then you will be able to get back where you started.

Low Voltage Power Supply Problems

Low voltage power supply fundamentals

Monitors require a variety of voltages (at various power levels) to function. The function of the low voltage power supply is to take the AC line input of either 115 VAC 60 Hz (220 to 240 VAC 50 Hz or other AC power in Europe and elsewhere) and produce some of these DC voltages.

- In all cases, the power to the horizontal output transistor (HOT) of the horizontal deflection system (B+) is obtained directly from the low voltage power supply.

  Note: we will often use the term 'B+' to denote the main DC voltage that powers the horizontal deflection system of most monitors.

- In some cases, some other DC voltages are also derived directly from the AC line by rectification, filtering, and possibly regulation.
- With small video monitors which operate at a fixed scan rate (e.g., TV monitors), many or most of the low voltages may be derived from secondary windings on the flyback (LOPT) transformer of the horizontal deflection system.
- The typical SVGA autoscan monitor will use one or more switchmode power supplies (SMPSs) to provide most or all of the low voltages - the flyback isn't used for this purpose. (High voltage is obtained from a flyback type supply or a separate HV module in which case there may be no flyback at all!)
- There are also various (and sometimes convoluted) designs using combinations of any or all of the above.

Typical Switchmode Power Supply for Small SVGA Color Monitor shows the complete schematic for the SMPS from a "I guarantee you never heard of the brand name" monitor.

The AC line input and degauss components are at the upper left, the SMPS chopper, its controller, and feedback opto-isolator are lower left/middle, and the secondaries - some with additional regulation components - occupy the entire right side of this diagram. Even for relatively basic application such as this, the circuitry is quite complex. There are more than a half dozen separate outputs regulated in at least 3 different ways!

For large high performance auto-scan monitors, it becomes even worse as highly stable voltages need to be programmed based on a wide range of scan rates. Several common design approaches are used to generate the required variable regulated B+ voltage:

1. A separate programmable SMPS generates the B+. This is done by selecting its reference voltage or the fraction of the output voltage that is fed back to the regulator.
2. A voltage from the main SMPS is fed through an additional series switchmode or linear regulator that drops it down to the required value.
3. One of several fixed post-regulators is selected based on scan rate.

Technique (2) is used by the power supply is the diagram, above. Can you locate the circuitry? Hint: Look in the upper right hand corner of the schematic.

The need for a variable B+ is one area where a typical PC monitor departs significantly in design compared to a TV or fixed scan rate studio or workstation monitor. Nearly everything is made more complex as a result of this requirement.

Components of the low voltage power supply

All monitor low voltage power supplies will have:

1. A power switch, relay, or triac to enable main power.

2. Various line filter, RFI, and surge suppression components (coupled inductors, LCL filter networks, MOVs, etc.).

3. A set of rectifiers - usually in a bridge or doubler configuration - to turn the AC into DC. Additional small ceramic capacitors are normally placed across the diodes to reduce RF interference. There may be an inrush current limiter in the form of an NTC (Negative Temperature Coefficient) resistor.

4. One or more large filter capacitors to smooth the unregulated DC. This voltage is either around 300 to 320 VDC (doubled from 115 VAC or bridge rectified from 230 VAC) for compatibility with U.S. and foreign power or 150 to 160 VDC bridge rectifier from the 115 VAC line.

   Many monitors permit the input voltage to be either 115 or 230 VAC depending on a switch or jumper, or automatically adapt to these or a range of input voltages - usually 100 to 240 VAC or DC. The latter are termed 'universal' power supplies.

5. A discrete, hybrid, IC, or switchmode regulator to provide B+ to the horizontal deflection.

6. Some means of generating the various other DC voltages required by the monitor's analog and logic circuitry.

Items (1) to (6) may be part of a separate low voltage power supply module or located on the mainboard.

7. Zero or more voltage dividers and/or regulators to produce additional voltages directly from the line power. This relatively rare except for startup circuits. THESE VOLTAGES WILL NOT BE ISOLATED FROM THE AC LINE!

8. A degauss control circuit usually including a thermistor or Posistor (a combination of a heater disk and Positive Temperature Coefficient (PTC) thermistor in a single package). Monitors having manual degauss buttons will include additional circuitry.

9. A startup circuit for booting the horizontal deflection if various voltages to run the monitor are derived from the flyback. This may be an IC, discrete multivibrator, or something else running off a non-isolated voltage or the standby power supply, or it may be derived from the video input. (Mostly small video monitors, not autoscan types.) However, the SMPS itself will have a startup circuit!

10. A standby power supply if the monitor doesn't use a latching power switch. Usually, this is a separate low voltage power supply using a small power transformer for line isolation.

What symptoms are likely the result of a low voltage power supply problem?

There are an almost unlimited number of possibilities but the following probably covers the most likely:

- Monitor is as dead as a concrete block - no picture or raster, no LEDs lit, no sounds of life (like degauss) of any kind.

  Most likely causes: No power at AC outlet or outlet strip, bad or loose line cord, bad power switch, blown fuse due to internal short or overload.

- No picture but unusual sounds like a whine, periodic clicks, tweets, or flubs, and/or possibly flickering or flashing front panel LEDs.

  Most likely causes: Excessive load or short on output of power supply (shutdown or cycling due to overcurrent) or loss of horizontal drive (cycling from overvoltage due to lack of load).

- Unusual aromas, smoke, or six foot flames coming from inside the case.

  Most likely causes: Failed parts in low voltage power supply, deflection, or high voltage sections.

  Actually, while burning smells and even smoke aren't that unusual when parts overheat as a result of a short circuit, actual fire is quite unlikely due to regulatory design requirements for materials and protection devices UNLESS safety systems have been tampered with or the monitor has been operated in an environment where there is lots of flammable dust.

- Jittering, vibrating, or unstable picture.

  Most likely causes: External magnetic interference or power line noise, hum in various power supply voltages resulting from dried up main filter capacitor(s) or other capacitors, resistors out of tolerance - all affecting power supply regulation.

- Loss of video, deflection, geometry or size problems, or some or all adjustments have no effect.

  Most likely causes: Failure of one or more power supply voltages, selection circuitry not selecting properly (autoscan monitors), bad connections.

- Monitor doesn't power up immediately.

  Most likely causes: Dried up electrolytic capacitors in power supply or bad connections.

- Interaction of adjustments. For example, turning up the brightness results in a loss of sync or a wavy raster.

  Most likely causes: Poor power supply regulation due to bad capacitor, resistor, regulator, or other component - or bad connections.

Note that the underlying cause may not be in the low voltage power supply itself but may actually be elsewhere - a shorted horizontal output transistor or deflection yoke, for example. This results in either the power supply shutting down, becoming extremely unhappy, blowing a fuse, or just plain dying. Thus, we cannot really limit our investigation to only the power supply! In fact, with so many interconnected systems in a monitor, particularly a high performance SVGA model - it can require the services of a master sleuth Sherlock Holmes type to identify the perpetrator!

However, before you break out the socket wrenches and DMM (or 10 pound hammer!) or call Scotland Yard, double check that:

- your AC outlet is live, the power cord is intact (not chewed by the dog), is firmly seated, and the monitor is switched on.

- that you have a valid video signal, the video cables are securely attached to the proper connectors (e.g., BNCs) and/or there are no bent over pins (e.g., VGA/SVGA HD15 or Mac DB15).

- the monitor isn't being commanded to go into a power savings mode because your computer thinks it is smarter than you!

- you have the front panel switches and controls set properly and the video source selection is correct. Reset it to factory defaults.

If possible, try the monitor with another known good video input that is compatible with its scan rates and signal levels or substitute a known good monitor for the suspect unit. In other words, try to rule out external problems and 'cockpit error'.

Monitor power supply problems

WARNING: Always use an isolation transformer when working on a monitor but this is especially important - for your safety - when dealing with the non-isolated line operated power supply section. Read and follow the safety guidelines presented last month and at my Web site.

The following can cause symptoms of a dead or mostly dead monitor:

1. Shorted Horizontal output transistor (HOT). This will usually blow a fuse or fusable resistor as well if fed directly from the AC line. However, when fed by a SMPS, the result may just be a soft audible whine or periodic tweet or flub possibly accompanied by flashing front panel LEDs. Here, the failure is not in the power supply itself but may result in damage to it or other components especially if it continues to run in this state.

2. Shorted output rectifier diodes can load down the outputs to the point of shutting down or resulting in the same audible symptoms as (1) above.

3. Flyback transformer can have shorted windings or shorts in the focus/screen divider network which load down the output.

   These (primary shorts in particular) may cause the horizontal output transistor to fail as well. This is a common problem with older MacIntosh computers and video terminals. Some secondary faults may not be instantly destructive but result in little or no high voltage and eventual overheating.

4. Some load or even the CRT could be shorted leading similar behavior or blowing fuses or fusable resistors which then result in no power to that circuitry.

5. Failure in horizontal drive chain - horizontal oscillator, driver, or driver transformer. Newer monitors may use an IC for the oscillator and this can fail. Without drive, there will be no deflection and this will either result in no high voltage directly (when it is derived from the horizontal deflection) or cause it to be shut down to prevent CRT screen burn (from a stationary spot or line). When powered by an SMPS, there may be an audible ticking from the SMPS cycling on overvoltage due to lack of load. This is also not a failure of the power supply itself.

6. Failure of an SMPS to start. There can be any number of causes though dried up electrolytic capacitors and open high value startup resistors are high on the list if the chopper transistor is not blown.

7. Cold solder joints or other bad connections - monitors tend to have these as a result of temperature cycling and with all too many - poor manufacturing quality control. It is possible that no parts have been damaged - at least not yet. Resoldering may be all that is needed.

If there is B+ (typically 60 to 150 VDC depending on the scan rate) at the output of the power supply but nothing on the HOT collector, an open fusable resistor, blown fuse, or bad connection, is likely.

If there is voltage on the HOT collector, there is probably a drive problem.

Troubleshooting the switchmode power supply

If the SMPS is a separate module, it may be possible to unplug its output connector and test it for proper operation independently of the monitor circuitry. However, a minimum load may be needed at least on the output that is used for regulation feedback and there could be other interlocks that will complicate your testing.

The most common failures in monitor SMPSs are:

- Main chopper transistor - in a monitor, this is often an expensive power MOSFET.
- Other shorted semiconductors - particularly high speed rectifiers on the secondary side of the high frequency transformer.
- Dried up electrolytic capacitors leading to startup and regulation problems.
- Open high value startup resistors resulting in no initial drive to chopper.
- Bad connections (is this sounding repetitive?).

See the document: Notes on the Troubleshooting and Repair of Small Switchmode Power Supplies for more information.

Common problems

Here are just a few of those that you may come across:

Power button on monitor is flakey

If the on/off (or other button) on the monitor itself behaves erratically then the most likely cause is the obvious - the button or switch is dirty or worn. Believe it or not, this isn't as unusual as you might think On a momentary pushbutton, if you can get at it, some contact cleaner may help. Replacement with a common pushbutton or toggle type switch (as appropriate) available at Radio Shack may be much easier than attempting to locate the original part!

Dead monitor

This means that there is absolutely no evidence of anything happening when the power switch is activated.

The most like causes are:

- Outlet isn't live, power cord is loose or defective. Try something else in the outlet, inspect/replace the power cord.
- Bad power switch. With plug pulled, check for continuity in the on or pressed position.
- Blown fuse or fusable resistor (probably from shorted parts in power supply or elsewhere like the HOT). It usually won't hurt to try a replacement fuse with exactly the same ratings but don't be surprised if it blows.
- Bad power supply (not starting up or just dead), bad connections. However, degauss would likely still operate in this case.

Monitor blows fuse

A blown fuse is a very common type of fault due to poor design very often triggered by power surges due to outages or lightning storms. However, the most likely parts to short are easily tested, usually in-circuit, with an ohmmeter and then easily removed to confirm.

Note that it *may be* useful to replace a fuse the *first* time it blows (though it would be better to do some basic checks for shorted components first as there is a small chance that having a fuse blow the second time could result in additional damage which would further complicate the troubleshooting process). However, if the new one blows, there is a real problem and the only use in feeding the TV fuses will be to keep the fuse manufacturer in business!

Sometimes, a fuse will just die of old age or be zapped by a power surge that caused no damage to the rest of the monitor. However, it must be an EXACT replacement (including slo-blow if that is what was there originally). Else, there could be safety issues (e.g., fire hazard or equipment damage from too large a current rating) or you could be chasing a non-existent problem (e.g., if the new fuse is not slo-blow and is blown by the degauss circuit inrush current but nothing is actually wrong).

If the fuse blows absolutely instantly with no indication that the circuits are functioning (no high pitched horizontal deflection whine (if your dog hides under the couch whenever the monitor is turned on, something is probably working).) then this points to a short somewhere quite near the AC power input. However, if there is indication of life - for a second or two, or longer, and then the fuse blows, the cause is likely an overload on the power supply. See the section: Dead monitor with audible whine, periodic tweet or flub, and low-low voltage since similar causes apply.

For the instantly blown fuse case, the most common places to look would be:

- Degauss Posistor. This is a combination of a heater and PTC thermistor which controls current to the degauss coil upon power-on. These tend to like to turn into short circuits.
- Shorted parts in the AC input line filter caps and MOVs.
- Diode(s) in main bridge.
- Main filter capacitor(s).
- SMPS chopper (usually a MOSFET) if there is a line operated SMPS or HOT (if a deflection derived power supply).

You should be able to eliminate these one by one using a multimeter to check for short circuits/low resistance. It is best to remove at least one side of each component while testing to avoid sneak paths which can fool your meter.

WARNING: Make sure to unplug the monitor and discharge the main filter capacitor(s) before attempting any of the following measuremente!

Unplug the degauss coil as this will show up as a low resistance.

- Measure across the input to the main power rectifiers - the resistance should not be that low (though it may start out at zero and climb as the main filter capacitors charge). A reading of only a few ohms may mean a shorted rectifier or two, a shorted Posistor, or a fried MOV.
- Test the posistor (if present). Trace back from the degauss connector - it will probably be nearby. The posistor is a little cubical component (about 1/2" x 3/4" x 1") with 3 legs. It includes a line operated heater disk (which often shorts out) and a PTC (Positive Temperature Coefficient) thermistor to control current to the degauss coil. The easiest thing to do it so remove the posistor and try power. If the monitor now works, obtain a replacement but in the meantime you just won't have the automatic degauss.
- Remove and test the HOT or chopper with an ohmmeter. A reading of less than 10 ohms between any combination of pins means the device is shorted.

For everything but the HOT or chopper, replacing the bad parts should be all that is needed - these rarely fail due to OTHER parts going bad.

However, if the HOT or chopper tests bad, it is possible (though not always the case) that something downstream is causing an excessive load which caused the part to fail. Therefore, don't put the cover back on just yet!

With the HOT or chopper removed, it should be possible to power the monitor with your series light bulb. Of course, not much will work - surprise, surprise. :-) With the deguass coil unplugged, the light should flash once as the main filter caps charge and then remain dark.

WARNING: Unplug the monitor and discharge the main filter caps after trying this experiment!

Install a new transistor and power the monitor using your series light bulb.

- If the bulb now flashes once and then settles down to a low brightness level, the monitor may be fine. See if there is an indication of deflection and HV - look for the glow of the CRT filaments and turn up the brightness to see if there is any indication of a raster. With the light bulb, not everything will be normal but some life would be a good sign. Even a pulsating light bulb may just mean that the light bulb is too small for the monitor power requirements. It may be safe to try a higher wattage bulb.

- However, if the bulb glows at close to full brightness, there is probably still some fault elsewhere. Don't be tempted to remove the light bulb just yet. There is still something wrong. Continue to search for shorted parts.

  See if you can locate any other large power transistors in metal (TO3) cans or large plastic (TOP3) cases. There may be a separate power transistor that does the low voltage regulation or a separate regulator IC or hybrid. As noted, some monitors have a switchmode power supply that runs off a different transistor than the HOT. There is a chance that one of these may be bad.

  If it is a simple transistor, the same ohmmeter check should be performed.

If none of this proves fruitful, it may be time to try to locate a schematic or a service center.

Internal fuse blew during lightning storm (or elephant hit power pole)

Power surges or nearby lightning strikes can destroy electronic equipment. However, most of the time, damage is minimal or at least easily repaired. With a direct hit, you may not recognize what is left of it!

Ideally, electronic equipment should be unplugged (both AC line and phone line!) during electrical storms if possible. Modern TVs, VCRs, microwave ovens, and even stereo equipment is particularly susceptible to lightning and surge damage because some parts of the circuitry are always alive and therefore have a connection to the AC line. Telephones, modems, and faxes are directly connected to the phone lines. Better designs include filtering and surge suppression components built in. With a near-miss, the only thing that may happen is for the internal fuse to blow or for the microcontroller to go bonkers and just require power cycling. There is no possible protection against a direct strike. However, devices with power switches that totally break the line connection are more robust since it takes much more voltage to jump the gap in the switch than to fry electronic parts. Monitors and TVs may also have their CRTs magnetized due to the electromagnetic fields associated with a lightning strike - similar but on a smaller scale to the EMP of a nuclear detonation.

Was the monitor operating or on standby at the time? If it was switched off using an actual power switch (not a logic pushbutton), then either a component in front of the switch has blown, the surge was enough to jump the gap between the switch contacts, or it was just a coincidence (yeh, right).

If it was operating or on standby or has no actual power switch, then a number of parts could be fried.

Monitors usually have their own internal surge protection devices like MOVs (Metal Oxide Varistors) after the fuse. So it is possible that all that is wrong is that the line fuse has blown. Remove the case (unplug it first!) and start at the line connector. If you find a blown fuse, remove it and measure across the in-board side of fuse holder and the other (should be the neutral) side of the line. The ohmmeter reading should be fairly high - more than 100 ohms in at least one direction. You may need to unplug the degaussing coil to get a reasonable reading as its resistance may be less than 30 ohms. If the reading is really low, there are other problems. If the resistance checks out, replace the fuse and try powering the monitor. There will be three possibilities:

1. It will work fine, problem solved.

2. It will immediately blow the fuse. This means there is at least one component shorted - possibilities include an MOV, line rectifiers, main filter cap, regulator transistor, horizontal output transistor, etc. You will need to check with your ohmmeter for shorted semiconductors. Remove any that are suspect and see of the fuse now survives (use the series light bulb to cut your losses - see the section: The series light bulb trick.

3. It will not work properly or appear dead. This could mean there are open fusable resistors other defective parts in the power supply or elsewhere. In this case further testing will be required and at some point you may need the schematic.

If the reading is very low or the fuse blows again, see the section: Monitor blows fuse.

Fuse replaced (doesn't blow) but monitor is still nearly dead

There may be a click indicating that the power relay is engaging (there could be bad contacts though this isn't that likely) and the degauss is probably working now.

Since the fuse doesn't blow now (you did replace it with one of the same ratings, right?), you need to check for:

- Other blown fuses. Occasionally there are more than one in a monitor.

- Open fusable resistors. These are usually low values (a few ohms or less) and are in big rectangular ceramic power resistor cases or smaller blue or gray colored cylindrical power resistors. They are supposed to protect expensive parts like the HOT but often blow at the same time - or the expensive HOT or SMPS chopper sacrifices itself to save the 25 cent resistor.

If any of these test open, they will need to be replaced with flameproof resistors of the same ratings. However, you can substitute an ordinary resistor for testing purposes ONLY as long as you don't leave the monitor unattended.

If you find one bad part, still check other power components for shorts or opens as more than one part may fail and just replacing that one may cause it to fail again. These include (depending on your monitor): Rectifier diodes, main filter capacitor(s), fuses and fusable resistors, horizontal output transistor, regulator pass or chopper transistor.

Assuming nothing tests faulty so far, clip a voltmeter set on its 500 V or higher scale across the horizontal output transistor and turn the power on. Warning - never measure this point if the horizontal deflection is operating. It is OK now since the monitor is dead. If the voltage here is 60 to 150 V, then there is a problem in the drive to the horizontal output circuit. If it is low or 0, then there are still problems in the power supply.

No picture but indications of power

The screen is blank with no raster at all. There are indications that the power is alive - the status LEDs are lit and you can hear the normal relay clicking sounds when you change video modes. This indicates that some of the low voltages are present but these may be derived from the standby supply.

Assuming there is no deflection and no HV, you either have a low voltage power supply problem, bad startup circuit, or bad horizontal output transistor (HOT)/bad parts in the horizontal deflection.

Check for bad fuses.

(If you have HV as indicated by static electricity on the front of the screen and you hear the high pitched whine of the horizontal deflection when it is turned on, then the following does not apply).

1. Use an ohmmeter to test the HOT for shorts. If it is bad, look for open fusable resistors or other fuses you did not catch.

2. Assuming it is good, measure the voltage on the collector-emitter of the HOT (this is safe if there is no deflection). You should see the B+ of between 60 and 150 V (typical) depending on mode (for a auto-scan monitor).

3. If there is no voltage, you have a low voltage power supply problem and/or you have not found all the bad/open parts. The flyback primary winding may be open as well.

4. If there is voltage and no deflection, you probably have a startup problem - all TVs and most monitors need some kind of circuit to kick start the horizontal deflection until the auxiliary power outputs of the flyback are available. Some designs use a simple multivibrator for this - a couple of transistors. Others power the horizontal oscillator IC from a special line-derived voltage.

   Look for pulses at the HOT base. If there are none, trace back to the driver and oscillator. Most likely: the power for startup is missing.

   Test the transistors if it is that type with an ohmmeter. If one is shorted, you have a problem. The usual way a TV service person would test for startup problems is to inject a signal to the base of the HOT of about 15.75 kHz. If the TV then starts and runs once this signal is removed, the diagnosis is confirmed. This is very risky for monitors and I would not recommend it - you can all too easily blow things up if not careful (including yourself).

If you hear the high pitched whine of the deflection (probably not for workstation or SVGA computer monitors unless you are a bat) and/or feel some static on the scree, confirm that the horizontal deflection and high voltage are working by adjusting the SCREEN control (probably on the flyback). If you can get a raster then your problem is probably in the video (or chroma) circuits, not the deflection or high voltage.

Monitor deflection derived power supply faults

This section applies to studio video monitors, small computer terminals, and most TVs, which derive many of their supply voltages from auxilary windings on the flyback transformer.

The following are common areas of failure:

- Horizontal output transistor (usually a TO3 metal or TOP3 plastic case shorts out. This will usually blow a fuse or fusable resistor as well.

- Horizontal drive chain - horizontal oscillator, driver, or driver transformer. Newer monitors may use an IC for the oscillator and this can fail.

- Startup - There may be some kind of startup circuit which gets the whole thing going until the auxiliary voltages are available. This could be as simple as a multivibrator or transistor regulator to provide initial voltage to the horizontal oscillator chip or circuit.

- Output rectifier diodes can fail shorted and load down the outputs to the point of shutting down.

- Some load could be shorted or a capacitor could be shorted leading to overload and shutdown.

- Flyback transformer can have shorted windings which load down the output. These (primary shorts in particular) may cause the horizontal output transistor to fail as well. Common problem with older MacIntosh computers and video terminals. Some secondary faults may not be instantly destructive but result in little or no high voltage and overheating.

- Cold solder joints or other bad connections - monitors tend to have these as a result of temperature cycling and bad manufacturing. (Is this sounding repetitive yet?)

- Sometimes there is a series regulator after the filter cap and this could be bad as well.

Without a schematic, I would attempt to trace the circuit from the main filter cap or output of the line operated switchmode power supply assuming that has the proper (approx. 60-120 VDC depending on scan range) voltage.

If you can locate the horizontal output transistor, see if there is voltage on its collector, should be the same. If there is, then there is probably a drive problem. If you have an ECG or similar semi cross reference, that will help you identify the ICs and transistors and locate the relevant portions of the circuitry.

If there is no voltage at the horizontal output transistor, then there is probably a blown fuse or bad connection somewhere or a fault in the line operated SMPS if there is one. However, the fuse may have blown due to a fault in the SMPS or horizontal deflection.

Power-on tick-tick-tick or click-click-click but no other action

A variety of problems can result in this or similar behavior. This applies to both monitors using SMPSs and flyback derived power supplies. Possibilities include:

- Lack of horizontal drive. The main regulator is cycling on overvoltage due to very little load.

- Excessive load or faulty power supply cycling on its overcurrent protection circuit. The sound in this case may be more like a tweet-tweet-tweet or flub-flub-flub, however - see the section: Dead monitor with audible whine, periodic tweet or flub, and low-low voltage.

- HV shutdown, or some other system detecting an out of regulation condition. However, in this case, there should be some indication that the deflection and HV is attempting to come up like momentary high pitched deflection whine, static on the screen, etc.

- A dried up main filter capacitor or other filter capacitor in the low voltage power supply that is producing an out-of-regulation condition

- A problem with the microcontroller, relay or its driver, or standby power supply.

If you have a Variac, vary the line voltage and observe the monitor's behavior. It may work fine at one extreme (usually low) or the other. This might give clues as to what is wrong.

Dead monitor with audible whine, periodic tweet or flub, and low-low voltage

A monitor which appears to be dead except for an audible whine or a once a second or so tweet or flub coming from the SMPS usually indicates an overload fault in the power supply itself or a short in one of its load circuits (usually the main B+). In most cases, the voltages (including B+) will be reduced to a fraction of their normal value (and/or be pulsing along with the animal sounds) as a result of the overload. The power (or other) LED may be weak or flashing as well. Flyback derived power supplies are less likely to exhibit these symptoms.

Note: using too small a series light bulb while testing for the size of the monitor may also result in this condition. If you have found and replaced a bad part, it increase the wattage of the light bulb and try again. If the frequency of the cycling decreases - i.e., it stays up longer, it may be safe to remove the light bulb entirely.

Summary of possible causes:

- Shorted rectifiers or capacitors on secondary side of SMPS.
- Other problems in the power supply or its controller like bad caps.
- Shorted HOT.
- Flyback with shorted turns or breakdown in focus/screen divider network.
- Short or excessive load on secondary supplies fed from flyback.
- Short in horizontal yoke windings.
- Bad solder connections.

Note that a whine may be perfectly normal for your monitor if there is no video input - confirm that there is a signal that is compatible with the monitor's scan rate(s) and type of sync (e.g., separate, composite, or sync-on-green).

However, where a confirmed good video input is present, this may indicate an overloaded low voltage switching power supply.

The whine is caused by the switching power supply's chopper frequency dropping down due to the overload. The periodic tweet or flub is caused by the SMPS attempting to come up, sensing the excessive load, and restarting.

Test the B+ input to the flyback.

If it is near zero, test the HOT for shorts and replace if defective, but continue testing with a series light bulb and/or Variac. There may be something causing the HOT to go bad like a shorted flyback or bad damper diode or snubber cap.

If the voltage is not zero but is low (e.g., it should be 120 V but is only 60 V) or fluctuating in time with the tweet or flub, there may be a problem with:

1. The SMPS. Test with a substitute load like a 40 W light bulb or power resistor. If the supply now outputs full voltage, it is probably fine. For a power resistor, select a value such that the load at the expected voltage will be about 1/2 to 2/3 of the nameplate power rating of the monitor.

   One common type of failure are shorted rectifiers in the switching supply or secondary supplies running off the flyback. The HFR854s (one popular type in monitors) or other high speed high efficiency rectifiers in the output side of the switching power supply or flyback seem to like to turn into short circuits. (I had a couple of DOA monitors where this was the problem. so much for quality control!)

   WARNING: Unplug the monitor and discharge the main filter caps before attempting the following tests!

   Use an ohmmeter to check the various diodes in the power supply. The higher power diodes appear commonly as black cylinders about 3/8" long by 1/4 diameter - kind of like 1N400Xs on steroids. The resistance of the diodes in at least one direction should be greater than 50 ohms in-circuit. If you find one that is much less (like 0 or 5 ohms), then it is probably bad. Unsolder and check again - it should test infinite (greater than 1M ohms) in one direction. If it now tests good, there may be something else that is shorted.

Replacements are available for about $0.25 from places like MCM Electronics.

2. Flyback (LOPT) transformer - shorted windings. See the document: Testing of Flyback (LOPT) Transformers.

3. Deflection yoke - shorted turns in the horizontal or geometry correction windings. See the section: Deflection yoke testing.

4. Excess load on one of the flyback's secondaries. Disconnect all secondary output pins from the flyback if possible and see if your B+ returns to normal.

5. Improper drive to HOT. Inspect with an oscilloscope. The drive should match the horizontal rate of the video input with a high time (at .7 to 1 V or so) typically 75 to 95% of the total line time.

Monitor power cycling on and off

The power light may be flashing or if you are runing with a series light bulb it may be cycling on and off continuously. There may be a chirping or clicking sound from inside the set. (Note: using too small a light bulb for the size of the monitor may also result in this condition.)

If there is a low voltage regulator or separate switching supply, it could be cycling on and off if the horizontal output, flyback, or one of its secondary loads were defective.

These symptoms are slightly different than those discussed in the section: Dead monitor with audible whine, periodic tweet or flub, and low-low voltage in that a picture may actually appear for an instant.

Verify that the main filter capacitor is doing its job. Excessive ripple on the rectified line voltage bus can cause various forms of shutdown behavior. An easy test is to jumper across the capacitor with one of at least equal voltage rating and similar capacitance (make connections with power off!).

Use a Variac, if possible, to bring up the input voltage slowly and see if the monitor works at any point without shutting down. If it does, this could be an indication of X-ray protection circuit kicking in, though this will usually latch and keep the set shut off if excessive HV were detected.

Something could be breaking down like a capacitor or the flyback as the voltage builds up to normal values

Startup problems - nothing happens, click, or tick-tick-tick sound

TVs and and small fixed scan rate monitors (e.g., CCTV or TV monitors, video display terminals) usually incorporate some kind of startup circuit to provide drive to the horizontal output transistor (HOT) until the flyback power supply is running. Yes, TVs and many monitors boot just like computers.

There are two typical kinds of symptoms: power on click but nothing else happens or a tick-tick-tick sound indicating cycling of the low voltage (line regulator) but lack of startup horizontal drive.

Check the voltage on the horizontal output transistor (HOT). If no voltage is present, there may be a blown fuse or open fusable resistor - and probably a shorted HOT.

However, if the voltage is normal (or high) - usually 60-150 V depending on scan rate (for an auto-scan monitor), then there is likely a problem with the startup circuit not providing initial base drive to the HOT.

The startup circuits may take several forms:

1. Discrete multivibrator or other simple transistor circuit to provide base drive to the HOT.

2. IC which is part of deflection chain powered off of a voltage divider or transformer.

3. Other type of circuit which operates off of the line which provides some kind of drive to the HOT.

The startup circuit may operate off of the standby power supply or voltage derived from non-isolated input. Be careful - of course, use an isolation transformer whenever working on TVs and especially for power supply problems.

Note that one common way of verifying that this is a startup problem is to inject a 15 kHz signal directly into the HOT base or driver circuit (just for a second or two). If the TV then starts up and continues to run, you know that it is a startup problem.

Caution: be careful if you do this. The HOT circuit may be line-connected and it is possible to destroy the HOT and related components if this is not done properly. I once managed to kill not only the HOT but the chopper transistor as well while working in this area. An expensive lesson.

I have also seen startup circuits that were designed to fail. Turning the TV on and off multiple times would exceed the power ratings of the components in the startup circuit. Some Zenith models have this 'feature'.

When this situation exists, it could be that the circuit is not providing the proper drive or that due to some other circuit condition, the drive is not always sufficient to get the secondary supplies going to the point that the normal circuits take over.

I would still check for bad connections - prod the circuit board with an insulated stick when the problem reoccurs.

Reduced width picture and/or hum bars in picture

The most likely cause is a dried up main filter capacitor. Once the effective capacitance drops low enough, 120 Hz (or 100 Hz in countries with 50 Hz power) ripple will make its way into the regulated DC supply (assuming full wave rectification).

Another likely cause of similar symptoms is a defective low voltage regulator allowing excessive ripple. The regulator IC could be bad or filter capacitor following the IC could be dried up.

Either of these faults may cause:

1. A pair of wiggles and/or hum bars in the picture which will float up the screen. For NTSC where the power line is 60 Hz but the frame rate is 59.94 Hz, it will take about 8 seconds for each bar to pass a given point on the screen. (On some sets, a half wave recitifier is used resulting in a single wiggle or hum bar).

   For high scan rate computer monitors, the this may result in horizontal hum bars, wiggles, or other distortions that will drift up or down the screen based on the difference frequency between the power line and video refresh rate being supplied by the PC or workstation. A confirmation can be obtained by varying the scan rate and seeing if the rate of drift changes predictably.

2. Possible regulation problems resulting in HV or total shutdown or power cycling on and off.

The best approach to testing the capacitors is to clip a good capacitor of approximately the same uF rating and at least the same voltage rating across the suspect capacitor (with the power off). A capacitor meter can also be used but the capacitor may need to be removed from the circuit.

Once the capacitors have been confirmed to be good, voltage measurements on the regulator should be able to narrow down the problem to a bad IC or other component.

Wiggling or jiggling picture

Depending on the frequency of the instability relative to the scan rate in use, the symptoms may be that the entire picture is vibrating, that ripples are moving up or down the screen, or something else. There may also be variatons in brightness - hum bars - in the picture.

- Very high frequency oscillations will result in multiple waves or scalloped edges on the sides of the raster possibly extending into the picture itself. These patterns may or may not remain stationary.

- Low or power line frequency oscillations will result in the entire raster moving back and forth, vibrating, or 1 or 2 wiggles along the sides of the raster that move up or down the screen. The actual behavior will depend on the relative frequencies of the oscilations and the vertical scan rate.

When the vertical scan rate is set close to the local power line frequency, effects resulting from power line interference or bad filter capacitors will produce 1 or 2 wiggles or bars, and these will remain almost stationary on the screen. Those caused by internal power supply stability problems may or may not do this.

First, eliminate the possibility of external magnetic interference, power line noise, or a video card/computer problem. Try the monitor in another location and on another computer if possible. Or, try another similar monitor in its place.

Once these causes have been ruled out, the most likely ones are:

- Dried up electrolytic capacitors in the power supply.

- A resistor or other component has changed value in the B+ (or other) regulator.

  For example, one very common monitor - the Gateway CS1572FS - uses a 91K, 1W resistor (R331) to set its 180 V B+ output. Invariably with use and age, its resistance increases in value leading to a vibrating raster and eventual failure of other parts.

- Bad connections.

Monitor doesn't power up immediately

The monitor may do nothing, cycle on and off for a while, power up and then shutdown in an endless cycle - or at least for a while. Then it comes on and operates normally until it is turned off.

A couple of possibilities:

1. The main filter capacitor or other filter capacitors in the low voltage power supply is dried up and this can cause all kinds of regulation problems. Other regulating components may be marginal. This may be allowing excessive voltage to reach the output of the power supply and then the X-ray protection circuitry shuts you down.

   Try powering the monitor on a Variac when cold. Bring up the voltage slowly and see if there is some point at which it would stay on. If there is, then a regulation problem is likely. If the picture has serious hum bars in it, check the main filter capacitor(s) first.

2. Bad connections may be preventing the power supply from operating normally until the mainboard or components heat up a bit.

   Inspect the solder side of the mainboard for cracked solder connections. Some gentle poking and prodding with a well insulated stick may reveal the location though a problem that goes away once the unit heats up can be tough to identify!. The use of 'cold spray' may help. Also, clean and reseat internal connectors.

   Also see the section: Old monitor requires warmup period.

Old monitor requires warmup period

So, what else is new? In the old days, a TV or monitor was expected to take a few minutes (at least) to warm up. We are all spoiled today. Of course, you usually maintained a full time technician or engineer to fiddle with the convergence adjustments!

If it just takes a while for the picture to become as bright as you like, this is probably just a result of an old tired CRT (see the section: Monitor Monitor life, energy conservation, and laziness and Brightening an old CRT. If, however, nothing happens for a few minutes, then some component needs to be powered for a while before it starts cooperatings. This is probably a dried up capacitor in the power supply since that is drifting with temperature and needs to be located with cold spray or a heat gun.

Adjustment or picture interactions

This describes problems such as turning up the brightness causes a loss of sync or adjusting height also affects width or produces a wavy raster. Or, a bright picture or opening a bright window results in a significant change in picture size or wiggly edges. Or, the monitor simply decides to shut down!

These may be caused by poor regulation in one or more low voltage power supplies or and interaction between the high voltage and low voltage power supplies - possibly a dried up capacitor if it is relatively old, bad connections, or another faulty component. Measure the B+ to the horizontal deflection (to the flyback, not the horizontal output transistor). If it is changing with the problem, then a regulation problem is confirmed. If this voltage is solid, you will need to check the others to see which one is actually changing.

Shorted Components

A failure of the horizontal output transistor or power supply switchmode transistor will blow a fuse or fusable resistor.

Look for blown fuses and test for open fusable resistors in the power circuits. If you find one, then test the HOT and/or switchmode transistor for shorts.

Other possibilities: rectifier diodes or main filter capacitor.

While you are at it, check for bad connections - prod the circuit board with an insulated stick when the problem reoccurs - as these can cause parts to fail.

Monitor turns off after warming up

If you can turn it back on with the s momentary key or power button:

When it shuts off, do you need to push the power button once or twice to get it back on? Also, does anything else about the picture or sound change as it warms up?

1. If once, then the controller is shutting the TV down either as a result of a (thermally induced) fault in the controller or it sensing some other problem. Monitoring the voltage on the relay coil (assuming these is one) could help determine what is happening. The controller thinks it is in charge.

2. If twice, then the power supply is shutting down as the controller still thinks it is on and you are resetting it. A couple of possibilities here would be low voltage or high voltage regulation error (excessive high voltage is sensed and causes shutdown to prevent dangerous X-ray emission). A partially dried up main filter capacitor could also cause a shutdown but there might be other symptoms like hum bars in the picture just before this happened. Clipping a good capacitor across the suspect (with power off!) would confirm or eliminate this possibility.

If it uses a hard on/off switch, then this may be like pulling the plug and would reset any abnormal condition.

Monitor shuts down with bright picture or when brightness is turned up

This is probably a protection circuit kicking in especially if turning power off or pulling the plug is required to restore operation.

The detection circuit could be in the power supply or horizontal deflection output circuit. It may be defective or the current may be too high for some other reason. A couple of tests can be performed to confirm that it is due to beam current:

- Determine if behavior is similar when adjusting the user brightness control and the screen (G2) pot (on the flyback) or master brightness control. If the monitor quits at about the same brightness level, overcurrent protection is likely.

- Disconnect the filaments to the CRT (unsolder a pin on the CRT socket) and see if it still shuts down under the same conditions. If it is overcurrent protection, shut down should now *not* take place since there is no beam current.

Relays in the Power Circuitry of monitors

What exactly is the purpose of such a relay? Why doesn't the power switch on the monitor just apply power directly instead of through a relay?

On a TV, the usual reason for a relay instead of a knob switch is to permit a remote control to turn power on and off. If your TV does not have a remote, then it is simply the same chassis minus 24 cents worth of circuitry to do the remote function. Isn't marketing wonderful?

On a monitor without any remote control, there can be two likely reasons:

1. Reduce the needed capacity of the on/off switch. High resolution monitors do consume a fair amount of power. A soft touch button may be more elegant or cheaper.

2. Allow for automatic power saving 'green' operation.

When replacing a relay, only unknown is the coil voltage. It is probably somewhere in the 6-12 volt range. You should be able to measure this on the coil terminals in operation. It will be a DC coil.

However, the relay controls the 125 VAC (or 220) which you should treat with respect - it is a lot more dangerous than the 25kV+ on the CRT!

Almost certainly, the relay will have 4 connections - 2 for power and 2 for the coil. If it is not marked then, it should be pretty easy to locate the power connection. One end will go to stuff near the AC line and the other end will go to the rectifier or maybe a fusable resistor or something like that. These will likely be beefier than the coil connections which will go between a transistor and GND or some low voltage, or maybe directly into a big microcontroller chip.

Of course, the best thing would be to get the schematic but with monitors this may not be easy.

Once you are sure of the AC connections - measure across them while it is off and also while it is on. While off, you should get 110-125 VAC. While on and working - 0. While on and not working either 110-125 VAC if the relay is not pulling in or 0 if it is and the problem is elsewhere. We can deal with the latter case if needed later on. Note the even if the relay contacts are not working, the problem could still be in the control circuitry not providing the correct coil voltage/current, though not likely.

It may be expensive and/or difficult to obtain an exact replacement, but these are pretty vanilla flavored as relays go. Any good electronics distributor should be able to supply a suitable electrical replacement though you may need to be creative in mounting it.

What is a posistor?

A posistor is a combination of a PTC (Positive Temperature Coefficient) resistor and another resistor-element to heat it up and keep it hot. Sometimes, these will go by the name posistor or thermistor. The heater is a disk shaped resistor across the power line and the themister is a disk shaped device in series with the degauss coil. They are in clamped together to be in close contact thermally. You can pry off the lid and see for yourself.

The most common failure mode is for the part to short across the line.

Its function is to control degauss, so the only thing you lose when you remove one of these is the degauss function on power-on. When you turn the TV or monitor on, the PTC resistor is cold and low resistance. When heated, it becomes very high resistance and turns off the degauss coil but gradually - the current ramps down to zero rather than being abruptly cut off..

Computer Component Source stocks a wide variety, I believe but it may be cheaper to go direct to the manufacturer if they will sell you one.

Flameproof Resistors

Flameproof Resistor or Fusable Resistor are often designated by the symbol 'FR'. They are basically the same. The designation "Flameproof" means that if they fail due to excessive current, there will be no chance of, well, them going up in flames. :) They will also have a power rating and thus can act as a protective device, though a specific circuit may not depend on a precise fuse rating, rather that the resistor will open with massively excessive current.

You may see these in the switchmode power supplies used in TVs and monitors. They will look like power resistors but will be colored blue or gray, or may be rectangular ceramic blocks. They should only be replaced with flameproof resistors with identical ratings. They serve a very important safety function.

These usually serve as fuses in addition to any other fuses that may be present (and in addition to their function as a resistor, though this isn't always needed). Since your FR has blown, you probably have shorted semiconductors that will need to be replaced as well. I would check all the transistors and diodes in the power supply with an ohmmeter. You may find that the main switch mode transistor has decided to turn into a blob of solder - dead short. Check everything out even if you find one bad part - many components can fail or cause other components to fail if you don't locate them all. Check resistors as well, even if they look ok.

Since they function as fuses, flameproof resistors should not be replaced with higher wattage types unless specifically allowed by the manufacturer. These would not blow at the same level of overload possibly resulting in damage to other parts of the circuitry and increasing the risk of fire.

Then, with a load on the output of the power supply use a Variac to bring up the voltage slowly and observe what happens. At 50 VAC or less, the switcher should kick in and produce some output though correct regulation may not occur until 80 VAC or more. The outputs voltages may even be greater than spec'd with a small load before regulation is correct.

---

3. Back to Monitor Repair FAQ Table of Contents.

Deflection Problems

Deflection fundamentals

Note: the following is just a brief introduction. For more detailed deflection system theory of operationo and sample circuits, see the document: TV and Monitor Deflection Systems.

The electron beams in the CRT need to be scanned horizontally and vertically in a very precise manner to produce a raster - and a picture.

For NTSC and PAL, the horizontal scan rates are 15,734 and 15,625 Hz respectively, the vertical scan rates are 60 and 50 Hz (approximately) respectively.

For PCs and workstation monitors, a wide range of scan rates are used.

For example:

```
   Standard      Horizontal, kHz  Vertical, Hz
 ------------------------------------------------
    MDA               18.43           50
    CGA               15.75           60
    EGA               15.75-21.85     60
    VGA               31.4            60-70
    SVGA (800x600)    35-40           50-75+
    SVGA (1024x768)   43-52+          43-75+
    SVGA (1280x1024)  64-72+          60-75+
    Workstations      64-102+         60-76+
```

Even in high resolution fixed frequency monitors, these high horizontal (in particular) scan rates necessitate some fancy circuit design. All components are running under stressful conditions and it is amazing that failures are not more common.

With auto-scan monitors, the complexity of the circuits increases dramatically to accommodate the wide range of horizontal scan rates. Relays or electronic switches are used to select power supply voltages, tuning components, and to make other alternations in the deflection circuits to handle DOS VGA one minute and Autocad 1280x1024 the next. It comes as no surprise that the most stressful time for a monitor may be when switching scan rates.

Unfortunately, successfully diagnosing problems dealing with the scan switching logic and circuitry is virtually impossible without a schematic.

The deflection yoke includes sets of coils for horizontal and vertical scanning oriented at 90 degrees with respect to each other. Additional coils are needed to correct for pincushion and other geometric defects.

The deflection circuits must be synchronized and phase locked to the incoming video signal.

Therefore, we have the following functions:

1. Sync separator to obtain horizontal and vertical synchronization pulses for monitors with composite video or sync inputs. Input sync detectors and auto polarity switching circuits as needed for separate horizontal and vertical sync inputs.

2. Horizontal oscillator which locks to horizontal sync pulses.

3. Horizontal drive followed by horizontal output which feeds deflection yoke (and flyback for HV and other voltages), Yoke requires a sawtooth current waveform for linear horizontal deflection. Horizontal output in all but the smaller TVs or monitors is a large discrete power transistor, most often an NPN bipolar type.

4. Vertical oscillator which locks to vertical sync pulses. Yoke requires sawtooth waveform for linear vertical deflection.

5. Vertical drive/output which feeds vertical deflection yoke. Newer TVs and monitors use ICs for vertical drive and output.

6. Various additional deflection signals to correct for the imperfections in the geometry of large angle deflection CRTs. These may be fed into the normal deflection coils and/or there may be separate coils mounted on the neck of the CRT.

7. Auto-scan deflection control and selection circuitry (auto-scan monitors only), probably controlled by a microprocessor which stores scan parameters for each scan rate and automatically detects the appropriate settings to use by analyzing the input video. For horizontal deflection, the usual way of size constant regardless of scan rate is to scale the B+ to the HOT with horizontal frequency. Thus, VGA resolution may us 60 V B+ while 1280x1024 at 75 Hz may require 150 V. Various other components may need to be selected based on scan rate. Relays are often used for this selection since they are easy to control and can handle the voltages and currents in the various deflection circuits reliably.

See Symptoms of Some Common Deflection Problems when referring to the specific descriptions below.

Monitor display is off-center

These sorts of problems usually relate to the picture shifting when switching between applications or between DOS and Windows. First, make sure you are using the correct monitor settings and video drivers. Note that a fraction of a mm offset may be normal and you are just too fussy!

If you have a setup program for your video card:

1. Make sure you are running well within the accepted scan rates for each resolution.

2. Toggle sync polarity and see if this makes any difference.

3. Adjust H position or phase and see what this does.

Also make sure your cables are secure. While a bad connection would likely messed things up worse, it won't hurt to check. Assuming none of this helps, your monitor may have a problem though it is not likely to be major (in a relative way). If you still like the monitor, repair may be worth the money.

Gross problems in size or position at certain scan rates

First, make sure you are not specifying incorrect scan rate for your monitor. Check your video card setup and/or monitor selection in Win95/98 as above.

Assuming you are not violating the scan rate specifications but have a picture that is twice the height of the screen and one half the width, for example, this could indicate a failure in the scan rate switching circuitry of an auto-scan monitor. Either the logic is faulty and ordering the wrong selections for power supply voltage and tuning components or the relays or the relevant parts are faulty. This could be due to bad connections as well - quite likely in fact. Also, try to reset the afflicted parameters using the digital controls (if relevant) and confirm that your video card is putting out the correct scan rate - try another monitor or examine the video signals with an oscilloscope.

Try prodding the circuit boards with an insulated stick - this may identify bad connections or unstick a sticky relay.

A schematics will likely be needed to proceed further with these sorts of problems.

Reduced width

Complaints about the picture not filling the screen with computer monitors are common but may not indicate problems (except with your expectations). Older monitors, in particular, often did not allow a full screen display at certain resolutions. There may be underscan modes/switches as well. Keep in mind that advertizing a large diagonal CRT does not necessarily imply that you can fill it!

However, if this problem just happened with no changes to your computer system (video card, scan rates, O/S), then the following are possibilities:

- The B+ to the horizontal output is lower than normal. The way width control functions is that as you increase the horizontal scan rate, the B+ to the HOT must increase to keep the width constant. It could be that yours is low to start with and not tracking scan rate changes either.

- A bad capacitor might also result in reduced width but I would expect non-linearity as well.

- As noted in the section: Gross problems in size or position at certain scan rates, there could be problems in the scan rate switching circuitry selecting incorrect components for certain scan rates.

- There might be a bad (low value or high ESR) decoupling capacitor. Scope the rail after the low-value decoupling R for H-rate stuff. There shouldn't be anything significant. If there is, the ESR of the decoupling capacitor is too high or its value is too low. Seen it often where it also cooks the decoupling R, because the efficiency of the H-out becomes poor. (gwoods@albany.net (Gary Woods).)

- A more unlikely possibility is a open yoke winding. The horizontal deflection yoke consists of multiple windings in parallel so it is theoretically possible for one or more of these to open up. I don't know what effects the associated detuning of the horizontal output circuit would have in this case.

Can incorrect or missing video damage my monitor?

The short answer is - quite possibly. Don't push your luck.

Mostly, there are problems at scan rates which exceed the monitor's specifications (low or high). However, some poorly designed monitors or just a particular combination of events can blow a monitor with too low a scan rate or an absent or corrupted signal input. There was one case where a very expensive high performance monitor would consistently blow its horizontal deflection circuits when driven by a particular ATI video card. It turned out that during the power-on self test of the ATI BIOS, just the wrong video timing was being generated for a fraction of a second - but that was enough.

As far as scan rate limits, there is no way of knowing - it really all depends on the quality of the design of your monitor. Some will happily run continuously at 25% above specifications. Other will blow out totally at the first excuse.

The specification that is likely to be more critical is the horizontal rate as it probably puts more stress on the components than the vertical rate. I have found that as you approach the upper limits, there is a good chance that the geometric accuracy of the raster near the top of the screen may start to deteriorate due to lock in problems as well. However, it would be foolhardy to depend on this sort of behavior as an indication of going over the edge.

It will be much too late when you find out. If the manual says 75 Hz V and 64 kHz H, stay below **both** of these. If you exceed the safe ratings and the design isn't really good, there is the possibility of blowing components in the horizontal deflection and high voltage sections which will result in expensive repair bills. You will likely get no warning of impending failure. In addition, even if the monitor does not immediately turn into a pile of smoking silicon and plastic, components may be under more stress and running at higher levels of power dissipation. Total failure may be just around the corner. More subtle degradation in performance may occur over time as well.

You won't see the difference anyhow beyond 75 Hz and your programs may run slightly faster at lower refresh rates since the video is not using as much bandwidth (however, the difference here may be very slight or non-existent depending on your board, computer, applications, etc.).

Picture squeezed in then died

You were happily playing 'Doom' when the sides of the picture squeezed in two inches or so when the entire monitor went dead - has remained like this since. There is no activity at all from the tube. Has it died? How much time, effort, and expense to fix?

No, it's not dead, at least it certainly is not the picture tube.

You probably shot the monitor instead of the bad guys!

Is there any indication of light on the screen? Any indication of the horizontal deflection running at all as evidenced by static on the screen?

In any case, there is a problem in the horizontal deflection and you probably have no high voltage as well assuming no light on the screen.

The fact that it squeezed in first indicates that a partial short or other fault may have developed in the horizontal deflection circuits - possibly the deflection yoke or flyback transformer. It could also have been a bad connection letting loose. Once it failed completely, the horizontal output transistor may have bought the farm or blown a fuse.

Horizontal deflection shutting down

Confirm that the horizontal deflection is shutting down along with the high voltage if it is derived from horizontal deflection: listen for the high pitched deflection whine (NTSC/PAL/CGA), test for static on the screen, see if the CRT filaments are lit, turn up the brightness and/or screen control to see if you can get a raster. Some possibilities:

- Power is failing to the horizontal output transistor - this could be due to a low voltage power supply problem, bad connection, etc.
- Base drive to the horizontal output transistor is failing - could be a fault in the horizontal oscillator or bad connection.
- Problem with the flyback transformer or its secondary loads (flyback may provide other power voltages).
- X-ray protection is activating - either due to excess HV or due to a fault in the X-ray protection circuitry.

If the problem comes and goes erratically it sounds like a bad connection, especially if whacking has an effect. If it comes and goes periodically, then a component could be heating up and failing, then cooling, etc.

Horizontal squashed

A very narrow picture may indicate problems with the power supply to the horizontal deflection circuits, incorrect scan rate selection or defective components, faulty deflection yoke, or bad connections.

If the size is erratic and/or gently whacking the monitor makes the width change, bad connections are likely. See the section: Monitor manufacturing quality and cold solder joints.

Confirm that your video card is running at the proper scan rate - particularly that it is not violating the monitor's specifications. An excessive horizontal scan rate is a common cause of a reduced width raster. Try its software setup adjustments as these may have been lost.

Beyond this, a schematic will probably be needed to isolate the fault.

Monitor non-linearity

Most modern monitors are nearly perfect with respect to linearity. There are almost never any user adjustments and there may not even be any internal adjustments. See the section: Position, size, and linearity adjustment.

A sudden change in linearity or a monitor that requires a warmup period before linearity becomes acceptable may have a bad component - probably a capacitor in the horizontal deflection circuits. For the latter, try some cold spray or a heatgun to see if you can locate the bad part.

(From: helio (mmccann@usa.pipeline.com).)

You should likely begin in the area immediately around the HOT, perhaps there might be a high frequency NP (non polarized) electrolytic just starting to go. Some larger monochrome monitors actually have working H-lin adjustment coils (believe it or not) especially if they are older ones. But most are glued/potted down or fixed value. If you locate it (the coil) the problem should be nearby.

Picture squeezed on both left and right side of screen

> "I'm trying to repair a Target DN-1564 monitor with a problem in the horizontal deflection: on both the left and right side of the screen the picture gets squeezed together, regardless of H-width and other settings. I've checked most semiconductors in this part, but I can't find anything wrong there."

This sounds like an S-correction capacitor may have too small a value or failed open. Check the capacitors in the vicinity of the deflection yoke connector and HOT. It could be due to bad connections as well.

S-correction is needed to linearize the horizontal scan (and vertical as well scan but that is a separate circuit). Without S-correction, the scan current would be nearly linear. This would result in greater coverage in a given time near the edges of high deflection angle CRTs. The picture would appear stretched near the edges In this case, the correction appears excessive.

(From: David Henniker (david.henniker@cableinet.co.uk).)

I had a similar problem with a monitor (here in Edinburgh Scotland). The S-correction cap was open-circuit altogether. Other caps in parallel allowed the distorted scan. If it had been a TV there wouldn't have been other caps in parallel and the result would have been no line scan, maybe a vertical line (line collapse) or nothing at all.

Vertical squashed

This means the vertical size is reduced with or without distortion.

Before attacking the circuitry, make sure your vertical scan rate is within the monitor's capabilities and that the user vertical size control is adjusted properly. If there is no distortion, this is likely as many (but not all) circuit problems would result in non-linearity or cutoff of the top or bottom portions of the picture. All you may need to do is change your computer's video settings! Swap the monitor or computer to be sure it is not a problem with the video card.

However, if failure happened suddenly and the vertical is squashed at all scan rates, this is likely a vertical deflection problem - possibly a bad capacitor, bad connection, bad flyback/pumpup diode, or other component. None of these should be very expensive (in a relative sort of way).

If the symptoms change - particularly if they become less severe - as the unit warms up, a dried up electrolytic capacitor is most likely. If they get worse, it could be a bad semiconductor. Freeze spray or a heat gun may be useful in identifying the defective component.

It is often easiest to substitute a good capacitor for each electrolytic in the vertical output circuit. Look for bad connections (particularly to the deflection yoke), then consider replacing the vertical output IC or transistor(s).

A defective deflection yoke is also possible or in rare cases, a bad yoke damping resistor (e.g., 500 ohms, may be mounted on the yoke assembly itself).

Where the entire top half or botton half of the picture is squashed into into the center (i.e., only half the picture shows), a missing power supply voltage, defective vertical output IC, or a component associated with it is likely bad. A bad connection or blown fusable resistor may be the cause of a missing power supply voltage.

The following are NOT possible: CRT or flyback (except possibly where it is the source for a missing power supply voltage but this is more likely just a bad solder connection at a flyback pin). I am just trying to think of really expensive parts that cannot possibly be at fault. :-)

Keystone shaped picture

This means that the size of the picture is not constant from top to bottom (width changes) or left to right (height changes). Note that some slight amount of this is probably just within the manufacturing tolerance of the deflection yoke and factory setup (geometry magnet placement, if any). With a monitor, such defects are more noticeable than with a TV since much of the display is of rectangular boxes - i.e., windows, lines of text, graphics, etc. Furthermore, the monitor is usually run just barely underscanned to maximize the viewing area without cutting anything off. Any deviations from perfection show up in relation to the CRT bezel.

However, a sudden increase may indicate a problem with the deflection yoke.

An open or short in a winding (or any associated components mounted on the yoke assembly) will result in the beam being deflected less strongly on the side where that winding is located. However, with a high scan rate monitor, there may be many individual windings connected in parallel in the yoke so the effect of only one opening up may not be as dramatic as with a TV where there may only be a single pair of windings for the horizontal and another for the vertical.

A simple test of the yoke in this case can be performed by simply swapping the connections to the yoke for the affected direction (i.e., if the width changes from top to bottom, interchange the connections to the vertical windings).

- If the keystone shape remains the same (but of course the picture flips), it is likely the yoke. The bad yoke winding is the one for the other axis (than what you swapped - if you just swapped the vertical, it is the horizontal yoke that has a short or open).

- If the keystone shape flips, it is a circuit problem (see below).

See the section: Deflection yoke testing.

If the monitor has been dropped off a 20 story building, the yoke may have shifted its position on the neck, of the CRT resulting in all sorts of geometry and convergence problems (at the very least).

(From: James Poore (aw133@lafn.org).)

I have seen the 'reverse keystoning' in several monitors and the fix is usually the same. In the horizontal leg of the pincushion transformer are 1 or more electrolytics to ground. The caps have + going to transformer and - to ground. Anyway when they start loosing capacitance and/or become leaky the reverse keystoning effects become more pronounced.

Picture size changing

If the picture area is expanding or contracting without any changes to your video card settings or other software. then there is a problem with the power supplies in the monitor. This would be confirmed if the change is (1) gradual over the course of say, an hour, and/or (2) gently whacking the monitor has some effect indicating bad internal connections. Software problems would not result in either of these characteristics.

Note that if the change is very small - say, less than 1 or 2%, then it may simply be normal for your monitor due to poor design or the use of inferior components - some parts associated with power supply regulation may be changing value as the monitors warms up.

A way to confirm that something is drifting due to thermal problems would be the monitor from another computer and see if the same thing happens. Just powering the monitor by itself (but not in any power saving mode) might also work for this test.

One possible cause could be that the high voltage is drifting gradually due to a faulty component - increasing and making the beam 'stiffer' or vice-versa. If this is the case there might also be a gradual change in brightness as well (decreasing image size -> increase in brightness). Alternatively, the HV may be stable but the power to both H and V deflection is gradually changing.

Excess high voltage can increase the X-ray emissions and any kind of power supply problems may ultimately result in total failure and an expensive repair. Therefore, these symptoms should not be ignored. See the sections on low voltage and high voltage power supply problems.

Monitor will not sync

For SVGA monitors, check that the sync pins in the video connector are not broken or bent. On the VGA HD15 connector, these are pin 13 (H) and 14 (V).

For monitors using BNC cables, first make sure that the cable connections are correct - interchange of H and V sync or G with one of the other video signals (sync-on-gree setups) can result in all kinds of weird sync problems.

There are a wide variety of causes for a monitor that will not display a stable or properly configured image. Among the symptoms are:

- Lack of sync horizontal - drifts smoothly horizontally. Depending on the difference between the video horizontal rate and the free-run frequency of the horizontal oscillator, the picture may be torn left or right (as shown in Symptoms of Some Common Deflection Problems or have multiple images superimposed horizontally. The situation where the picture is neatly split horizontally (which is what you might expect) is a special case where the frequencies are virtually the same. The key symptom common to all these is that there IS vertical lock (no blanking bar visible) AND there is no evidence that the deflection is even attempting to lock horizontally.

  This may mean that the horizontal sync signal is missing due to a bent, pushed in, or broken connector pin (pin 13) or other bad connection or a fault in the sync processing circuitry.

- Incorrect lock horizontal - torn picture (like a TV with the horizontal hold control misadjusted - if you remember these). This means that the sync signal is reaching the monitor but that it is having problem locking to it. Check the rate specifications - you may be exceeding them.

- Lack of sync vertical - rolls smoothly vertically. This may mean that the vertical sync signal is missing due to a bent, pushed in, or broken connector pin (pin 14) or other bad connection or a fault in the sync processing circuitry.

- Lock not stable vertical - jumps or vibrates vertically. This may be due to scan rate problems or a fault in the vertical sync circuitry of the monitor.

- Multiple or repeated images horizontally or vertically. There may be multiple images side-by-side, on top of each other, or interleaved. Most likely cause is driving the monitor with an incorrect scan rate. However, faulty circuitry could also be to blame.

Additional comments on some of these problems follow in the next few sections.

Horizontal lock lost

A monitor which loses horizontal lock when changing resolutions, momentarily losing the signal, or switching inputs may have a horizontal oscillator that is way out of adjustment or has drifted in frequency due to aging components. Alternatively, you may be running at scan rates that are not supported by your monitor. Check its user manual (yeh, right, like you have it!). Use the setup program that came with your video card to adjust the default scan rates to match the monitor. Not only will it lock better, you are less likely to damage the monitor by feeding it improper scan rates.

Note that the characteristics of this are distinctly different than for total loss of sync. In the latter case, the picture will drift sideways and/or up and down while with an off frequency oscillator, the torn up picture will try at least to remain stationary.

Assuming you are have your video card set up properly - double check anyhow - this could be a capacitor or other similar part. Or, the oscillator frequency may just need to be tweaked (particularly with older monitors). There may be an internal horizontal frequency adjustment - either a pot or a coil - which may need a slight tweak. If a coil, use a plastic alignment tool, not metal to avoid cracking the fragile core. There may be several adjustments for auto-scan monitors - one for each major scan range.

A schematic will be useful to locate the adjustment if any or to identify possible defective parts. If it is a heat related problem try cold spray or a heat gun in an effort localize the offending part.

Insufficient width (without hum bars)

If there are hum bars or wiggles in the picture, see the section: Reduced width picture and/or hum bars in picture.

If both width and height are affected, the cause is likely something common: low, low voltage power supply voltages or excessive high voltage (resulting in a 'stiffer' beam).

(From: Jerry G. (jerryg@total.net).)

Lack of width is usually caused by defective power supply, low horizontal drive to the yoke and flyback, defective circuits in the pincushioning amplifier section, excessive high-voltage caused by defective voltage regulation, and or excessive loading on the secondary side of the flyback.

Loss of horizontal sync (also applies to vertical) after warmup

The problem lies either in the horizontal oscillator or in the sync system. If it really is a problem with sync pulses not reaching the oscillator, the picture will move around horizontally and can be brought to hold momentarily with the hold control. If the picture breaks up into strips, there is a problem in the horizontal oscillator. If there is an accessible hold control try rotating it: if the frequency is too far off, the picture will not settle into place at any adjustment of the hold control. Look around the horizontal oscillator circuit: all of the oscillator parts will be right there, or check on the horizontal oscillator module. If only one resolution on a auto-scan monitor is affected, the there could be a separate oscillator circuit for each range.

Replicated or offset multiple images

Multiple images on the screen horizontally or vertically indicate that the scan rate is way off (by a factor equal to the number of complete pictures.) This could be a fault in the monitor or you could be running way outside of the monitor's specifications. Even slightly exceeding these for the horizontal or vertical may confuse the scan rate selection logic and result in the monitor setting itself with incorrect scan rate settings.

A situation where successive sweeps alternate position slightly resulting in double or triple images may be caused by a incorrect or out of range video timing, a bad component, or improper sync signals.

Check the settings of the video card and any sync termination or selection on the monitor. Beyond this, a schematic will be required.

Part of picture cut off

The following applies if the part of the picture is missing but not otherwise squashed or distorted. For example, 85% is missing but the portion still visible is normal size.

Wow! That's an interesting one, more so than the typical run-of-the-mill "my TV just up and died on me". Or, "my pet orangutan just put a hole in the CRT, what should I do"?

With a monitor, this is more likely than a TV. But the cause is probably not in the monitor (though not impossible). Check that your video parameters are set up correctly (particularly if you have full control of them as with Linux). You may have set the active too short or blanking too long.

If your video is confirmed to be OK (looking at it with an oscilloscope would be best), then with the size of the picture fragment correct but 85% missing, check waveforms going into the vertical output stage. The supply voltage is probably correct since that often determines the size. It almost sounds like the waveform rather than being mostly on (active video) and off for the short blanking period is somehow only on during the last part of the active video thus giving you just the bottom of the picture. If there is a vertical output IC, it may be defective or the blanking input to it may be corrupted. The problem may be as far back as the sync separator. Then again who knows, schematics would be really handy.

Bright or dark bars on edge of picture (horizontal or vertical)

These may be sharp-edged or blurry. The latter could result when a portion of the active video is unblanked during retrace.

- Where the entire picture is present, the problem is one of the video blanking not occurring properly beyond the picture boundary.

- Where part of the picture is cut off with a bright horizontal or vertical line at that point, it is either a video timing problem or a fault in the deflection circuitry preventing the beam from being where it is supposed to scan in enough time.

  You may be seeing part of the active video during retrace or as the beam reverses direction at the start or end of retrace. Horizontal timing problems would produce vertical bars on the right or left edge; vertical timing problems would produce horizontal bars at the top or bottom edge.

- If your video card permits control of video timing parameters, try reducing the relevant active time relative to the blanking period. The relevant software settings might be horizontal position, phase, size, and sync polarity. If this does not work, your video card may be incompatible with the monitor.

- If the problem just happened without any changes to the video source, the monitor may have a problem:

  - Deflection circuits - coil or capacitor, a power supply fault, position or size settings or control, or deflection yoke.

  - Video amplifier or drive (CRT neck board), or blanking circuits - chip decoupling capacitors or filter capacitors in scan derived power supplies. If the bars are significantly colored - not just shades of gray - then a video problem is likely.

An oscilloscope would help greatly in identifying the source of the problem.

Single Vertical Line

CAUTION: To prevent damage to the CRT phosphors, immediately turn down the brightness so the line is just barely visible. If the user controls do not have enough range, you will have to locate and adjust the master brightness or screen/G2 pots.

Since you have high voltage, the horizontal deflection circuits are almost certainly working (unless there is a separate high voltage power supply - almost unheard of in modern TVs but possible in some higher performance monitors).

Check for bad solder connections between the main board and the deflection yoke. Could also be a bad horizontal coil in the yoke, linearity coil, etc. There is not that much to go bad based on these symptoms assuming the high voltage and the horizontal deflection use the same flyback. It is almost certainly not an IC or transistor that is bad.

Single Horizontal Line

CAUTION: To prevent damage to the CRT phosphors, immediately turn down the brightness so the line is just barely visible. If the user controls do not have enough range, you will have to locate and adjust the master brightness or screen/G2 pots.

A single horizontal line means that you have lost vertical deflection. High voltage is most likely fine since there is something on the screen.

This could be due to:

1. Dirty service switch contacts. There is often a small switch on the located inside on the main board or perhaps accessible from the back. This is used during setup to set the color background levels. When flipped to the 'service' position, it kills vertical deflection and video to the CRT. If the switch somehow changed position or got dirty or corroded contacts, you will have this symptom. Flip the switch back and forth a couple of times. If there is some change, then replace, clean, resolder, or even bypass it as appropriate.

2. Bad connection to deflection yoke or other parts in vertical output circuit. Bad connections are common in TVs and monitors. Check around the pins of large components like transformers, power transistors and resistors, or connectors for hairline cracks in the solder. Reseat internal connectors. Check particularly around the connector to the deflection yoke on the CRT.

3. Bad vertical deflection IC or transistor. You will probably need the service manual for this and the following. However, if the vertical deflection is done with an IC, the ECG Semiconductor Master Substitution guide may have its pinout which may be enough to test it with a scope.

4. Other bad parts in vertical deflection circuit though there are not that many parts that would kill the deflection entirely.

5. Loss of power to vertical deflection circuits. Check for blown fusable resistors/fuses and bad connections.

6. Loss of vertical oscillator or vertical drive signals.

The most likely possibilities are in the deflection output stage or bad connections to the yoke. To locate the vertical output circuitry without a service manual, trace back from the deflection yoke connector. The vertical coils will be the ones with the higher resistance if they are not marked.

Intermittent jumping or jittering of picture or other random behavior

This has all the classic symptoms of a loose connection internal to the TV or monitor - probably where the deflection yoke plugs into the main PCB or at the base of the flyback transformer. TVs and monitors are notorious for both poor quality soldering and bad connections near high wattage components which just develop over time from temperature cycling. The problem may happen any time or more when cold or hot.

The following is not very scientific, but it works: Have you tried whacking the monitor when this happened and did it have any effect? If yes, this would be further confirmation of loose connections.

What you need to do is examine the solder connections on the PCBs in the monitor, particularly in the area of the deflection circuits and power supply. Look for hairline cracks between the solder and the component pins - mostly the fat pins of transformers, connectors, and high wattage resistors. Any that are found will need to be reflowed with a medium wattage (like 40W) or temperature controlled soldering iron.

It could also be a component momentarily breaking down in the power supply or deflection circuits.

Another possibility is that there is arcing or corona as a result of humid weather. This could trigger the power supply to shut down perhaps with a squeak, but there would probably be additional symptoms including possibly partial loss of brightness or focus before it shut down. You may also hear a sizzling sound accompanied by noise or snow in the picture, static in the sounds, and/or a smell of ozone.

If your AC power fluctuates, an inexpensive monitor may not be well enough regulated and may pass the fluctuations on as jitter. The video card is unlikely to be the cause of this jitter unless it correlates with computer (software) activity.

Horizontal output transistors keep blowing (or excessively hot)

Unfortunately, these sorts of problems are often difficult to definitively diagnose and repair and will often involve expensive component swapping.

You have just replaced an obviously blown (shorted) horizontal output transistor (HOT) and an hour (or a minute) later the same symptoms appear. Or, you notice that the new HOT is hotter than expected:

Would the next logical step be a new flyback (LOPT)? Not necessarily.

If the monitor performed normally until it died, there are other possible causes. However, it could be the flyback failing under load or when it warms up. I would expect some warning though - like the picture shrinks for a few seconds before the poof.

Other possible causes:

1. Improper drive to horizontal output transistor (HOT). A weak drive might cause the HOT to turn on or (more likely) shut off too slowly (greatly increasing heat dissipation. Check driver and HOT base circuit components. Dried up capacitors, open resistors or chokes, bad connections, or a driver transformer with shorted windings or a loose or broken core can all affect drive waveforms.

2. Excessive voltage on HOT collector - check LV regulator (and line voltage if this is a field repair), if any.

3. Defective safety capacitors or damper diode around HOT. (Though this usually results in instant destruction with little heating).

4. New transistor not mounted properly to heat sink - probably needs mica washer and heat sink compound.

5. Replacement transistor not correct or inferior cross reference. Sometimes, the horizontal deflection is designed based on the quirks of a particular transistor. Substitutes may not work reliably.

6. CRT shorting internally. If this happens only once in two weeks, it may be diffuclt to track down :-(.

The HOT should not run hot if properly mounted to the heat sink (using heatsink compound). It should not be too hot to touch (CAREFUL - don't touch with power on - it is at over a hundred volts with nasty multihundred volt spikes and line connected - discharge power supply filter caps first after unplugging). If it is scorching hot after a few minutes, then you need to check the other possibilities.

However, it is possible that the deflection circuit is just poorly designed in the first place and it has always run hot (though it is unlikely to have always been scorching hot). There is no way to know for sure without a complete analysis of the circuit - not something that is a realistic possibility. In this case, the addition of a small fan may make a big difference in HOT survival. If you have it mounted on the case blowing on the HOT, add a filter to minimize dust infiltration.

It is also possible that a defective flyback - perhaps one shorted turn - would not cause an immediate failure and only affect the picture slightly. This would be unusual, however. See the section: Testing of flyback (LOPT) transformers.

Note that running the monitor with a series light bulb may allow the HOT to survive long enough for you to gather some of the information needed to identify the bad component.

Horizontal output transistors blowing at random intervals

The HOT may last a few minutes, days, months or years but then blow again.

These are among the hardest problems to locate. It could even be some peculiar combination of user cockpit error - customer abuse - that you will never identify. Yes, this should not happen with a properly designed monitor.

However, a combination of mode switching, loss of sync during bootup, running on the edge of acceptable scan rates, and frequent power cycles, could test the monitor in ways never dreamed of by the designers. It may take only one scan line that is too long to blow the HOT. Newer horizontal processor chips are quite smart about preventing HOT killing signals from reaching the horizontal driver but they may not be perfect.

On the other hand, the cause may be along the lines of those listed in the section: Horizontal output transistors keep blowing (or excessively hot) and just not as obvious - blowing in a few days or weeks instead of a few seconds but in this case, the HOT will likely be running very hot even after only a few minutes.

Another possible cause for random failures of the HOT are bad solder connections in the vicinity of the flyback and HOT (very common due to the large hot high power components) as well as the horizontal driver and even possibly the sync and horizontal oscillator circuits, power supply, or elsewhere.

Steve's comments on HOT replacement

(From: Steve Bell (service@bell-electronics.freeserve.co.uk).)

A HOT can fail on its own, but to save possibly having to change it again, I always check the following:

If there is an electrolytic capacitor in the base circuit, check it with an ESR meter. If you don't have one, change it, they are cheap. Check the tuning capacitor on the HOT collector for low value or open circuit. These are low value and fairly critical, a capacitance meter is ideal. If you don't have one, a crude way to check is to use an analogue meter on x100 ohms and watch the needle kick as the cap charges and compare to another cap same value. Follow the HOT collector to the FBT, then from the FBT to a B+ regulator circuit if used. These often use a T0220 style FET or power transistor, check for shorts. Locate the B+ filter cap on the feed from the regulate to the FBT. Look for bulges and check with ESR meter. These caps are typically 22 - 100 uF, 160 or 200V. Also visibly check the FBT for bulges or splits. The only way to be sure the FBT is OK is to check with a FBT tester/ringer or similar test equipment. Generally FBT's in monitors are quite reliable. This might sound like a lot to do, but when familiar with the circuitry it doesn't take long.

You could of course just change the HOT and all will be OK.

Vertical foldover

The picture is squashed vertically and a part of it may be flipped over and distorted.

This usually indicates a fault in the vertical output circuit. If it uses an IC for this, then the chip could be bad. It could also be a bad capacitor or other component in this circuit. It is probably caused by a fault in the flyback portion of the vertical deflection circuit - a charge pump that generates a high voltage spike to return the beam to the top of the screen.

Test components in the vertical output stage or substitute for good ones.

Jagged or uneven vertical sweep

(From: Matthias Meerwein (Matthias.Meerwein@rt.bosch.de).)

I recently fixed two CRT display devices that both developed a very similar problem: The vertical deflection was severely "jagged" with uneven line spacing and partial vertical foldover. One patient was a nameless el-cheapo 28-inch TV (1988 made), the other one a 14 inch ADI SVGA monitor (1991 vintage).

My first suspicions were bad contacts on the PCB or yoke connectors or isolation / connectivity problems inside the yoke. However, as the picture didn't change with warmup or tapping, those causes could be ruled out. Examining the vertical deflection waveform with the scope showed the problem being a parasitic high frequency oscillation around the vertical output ic. On the TV, the oscillation extended over the entire scan period, while the monitor exhibited the problem only near the vertical current zero cross.

In both cases I found the capacitor of the RC damping network on the amp output to be at fault. Replacing it fixed the problem in both sets. This is not the well-known dried-up-electrolytic problem described in the FAQ. The culprits were mylar caps (.1 and .47 uF) looking completely unsuspicious. They were probably a bit underrated voltage-wise (40 volts) so I replaced them with 100 volts rated ones. The 2.2 ohms resistor in series with the cap was fine in both cases.

Excessive width/pincushioning problems

This would mean that the left and right sides of the picture are 'bowed' and the screen looks something like the diagram below (or the opposite - barrel distortion).

However, the obvious symptoms may just be excess width as the curved sides may be cut off by the CRT bezel.

```

This geometry is the natural state of affairs with linear scan waveforms if there were no correction. Normally, a signal from the vertical deflection that looks something like a rectified sinewave is used to modify width based on vertical position. There is usually a control to adjust the magnitude of this signal and also often, its phase. It would seem that this circuit has ceased to function.

If you have the schematics, check them for 'pincushion' adjustments and check signals and voltages. If not, try to find the 'pincushion' magnitude and phase adjustments and look for bad parts or bad connections in in the general area. Even if there are no adjustment pots, there may still be pincushion correction circuitry.

If the pincushion controls have absolutely no effect, then the circuit is faulty. With modern digital setup adjustments, then it is even tougher to diagnose since these control a D/A somewhere linked via a microprocessor.

Pincushion adjustment adds a signal to the horizontal deflection to compensate for the geometry of the CRT/deflection yoke. If you have knobs, then tracing the circuitry may be possible. With luck, you have a bad part that can be identified with an ohmmeter - shorted or open. For example, if the pincushion correction driver transistor is shorted, it will have no effect and the picture will be too wide and distorted as shown above.

However, without a schematic even this will be difficult. If the adjustments are digital this is especially difficult to diagnose since you don't even have any idea of where the circuitry would be located.

Faulty capacitors in the horizontal deflection power supplies often cause a similar set of symptoms.

Uncorrectable pincushion distortion with new monitor

> "I just bought a new Sony 200SX 17" monitor and I just can't get the pin-cushion control to work right. If I get the outer edges straight then any window an inch or so from the edge will curve like crazy. The only way around this is to shrink my screen size so I'll have 3/4 in or so of black space. This is very irritating since I am not getting the 15.9" viewable size as advertised. Is this normal?"

(From: Jeroen H. Stessen (Jeroen.Stessen@philips.com).)

The distortion that you describe is called 'inside pincushion'. Normally it can be corrected by a dynamic S-correction circuit. Maybe Sony didn't do a too good job on this, or none at all. It may also be that the correction is optimized for certain horizontal scan frequencies only, as dynamic S-correction is a resonant circuit. You might want to test at another frequency.

(From: markmtf@earthlink.net).)

You may have a monitor that is at the edge of the acceptance tolerance, (which is a defined acceptable variation for cost and production yield reasons). A typical worse case tolerance may be up to 3mm of a deviation from a straight line for the edges. This applies for all monitors and all manufacturers. Of course some companies actually control the variation better than others, (and some just say they do).

For reference; try using the "Recall" function which will set the adjustments to the original factory settings. (This assumes that your video timing matches the preset timing used in the factory). Check the infamous user manual.

Deflection yoke testing

A faulty deflection yoke can affect the geometry (size and shape) of the raster, result in insufficient high voltage and/or other auxiliary power problems, and blow various components in the low voltage power supply or elsewhere.

- A simple test to determine if the yoke is at fault for a major geometry problem (e.g., a keystone shaped picture) is to interchange the connections to the yoke for the axis that is not affected (i.e., the vertical coils if the width is varying from top to bottom). If the raster/picture flips (indicating that you swapped the proper connections) but the shape of the raster remains the same - the geometry is unchanged, the problem is almost certainly in the deflection yoke.

- Where high voltage (and other flyback derived voltages) are reduced and other problems have been ruled out, unplugging the deflection yoke (assuming no interlock) may reveal whether it is likely at fault. If this results in high voltage and a relatively clean deflection waveform or returns the power supply or deflection chip load to something reasonable, a defective yoke is quite possible.

  CAUTION: powering a TV or monitor with a disconnected yoke must be done with care for several reasons:

  - The CRT electron beam(s) will not be deflected. If it turns out that the yoke is the problem, this may result in a very bright spot in the center of the screen (which will turn into a very dark permanent spot quite quickly) :-(. Disconnecting only the winding that is suspect is better. Then, the other direction will still scan resulting in a very bright line instead of a super bright spot. In any case, make sure the brightness is turned all the way down (using the screen/G2 control on the flyback if necessary). Keep an eye on the front of the screen ready to kill power at the first sign of a spot or line. Disconnecting the CRT heater as an added precaution would be even better unless you need to determine if there is a beam.

  - Removing the yoke (which is effectively in parallel with the flyback) increases the inductance and the peak flyback voltage on the HOT. In the extreme, this may blow the HOT if run at full line voltage/normal B+. It is better to perform these tests using a Variac at reduced line voltage if possible.

  - The deflection system will be detuned since the yoke inductance plays a very significant role in setting the resonance point in most designs. Don't expect to see totally normal behavior with respect to high voltage. However, it should be much better than with the faulty yoke.

- If possible, compare all measurements with a known good identical deflection yoke. Of course, if you have one, swapping is the fastest surest test of all! In many cases, even a not quite identical yoke will be close enough to provide useful information for testing. However, it must be from a similar piece of equipment with similar specifications - size and scan range. Don't expect a color TV yoke to work in a high performance SVGA monitor!

Note: the substitute yoke doesn't have to be mounted on the CRT which would disturb purity and convergence adjustments but see the caution above about drilling holes in the CRT face plate!

The deflection yoke consists of the horizontal coils and vertical coils (wound on a ferrite core), and mounting structure. Little magnets or rubber/ferrite strips may be glued in strategic locations. DO NOT disturb them! In rare instances, there may be additional coils or other components mounted on the same assembly. The following deals only with the actual deflection coils themselves - the other components (if any) can be tested in a similar manner.

Where the test procedure below requires removal of the yoke, see the section: Removing and replacing the deflection yoke first.

- Horizontal - the horizontal section consists of an even number of windings hooked up in parallel/interleaved with half of the windings on each of the two ferrite core pieces.

  The horizontal windings will be oriented with the coil's axis vertical and mounted on the inside of the yoke (against the CRT neck/funnel). They may be wound with thicker wire than that used for the vertical windings.

  - Resistance check - This may be possible without removing the yoke from the CRT if the terminal block is accessible. Disconnect the individual windings from each other and determine if the resistances are nearly equal. Check for shorts between windings and between the horizontal and vertical windings as well.

    Typical resistance of the intact windings (at the yoke connector assuming no other components): TV or NTSC/PAL monitor - a few ohms (3 ohms typical), SVGA monitor - less than an ohm (.5 ohms typical).

  - Inspection - Look for charring or other evidence of insulation breakdown due to arcing or overheating. For the horizontal windings, this will require removing the yoke from the CRT since little if any of the windings are visible from the outside. However, even then, most of the windings are hidden under layers of wire or behind the ferrite core.

  - Ring test. See the document "Testing of Flyback (LOPT) Transformers". This deals with flyback transformers but the principles are the same. Disconnecting the windings may help isolate the location of a fault. However, for windings wound on the same core, the inductive coupling will result in a short anywhere on that core reducing the Q.

- Vertical - The vertical section is usually manufactured as a pair of windings wired in parallel (or maybe in series) though for high vertical scan rate monitors, multiple parallel/interleaved windings are also possible.

  The vertical windings will be oriented with the coil's axis horizontal and wound on the outside of the yoke. The wire used for the vertical windings may be thinner than that used for the horizontal windings.

  - Resistance check - This may be possible without removing the yoke from the CRT if the terminal block is accessible. Disconnect the individual windings from each other and determine if the resistances are nearly equal. Check for shorts between windings and between the horizontal and vertical windings as well.

    Typical resistance of the intact windings (at the yoke connector assuming no other components): TV or NTSC/PAL monitor - more than 10 ohms (15 ohms typical), SVGA monitor - at least a few ohms (5 ohms typical).

  - Inspection - Look for charring or other evidence of insulation breakdown due to arcing or overheating.

The accessible portions of the vertical windings are mostly visible without removing the yoke from the CRT. However, most of the windings are hidden under layers of wire or behind the ferrite core.

- Ring test - Since the vertical windings have significant resistance and very low Q, a ring test may be of limited value.

Deflection yoke repair

So you found a big black charred area in/on one of the yoke windings. What can be done? Is it possible to repair it? What about using it for testing to confirm that there are no other problems before ordering a new yoke?

If the damage is minor - only a few wires are involved, it may be possible to separate them from each other and the rest of the winding, thoroughly clean the area, and then insulate the wires with high temperature varnish. Then, check the resistances of each of the parallel/interleaved windings to make sure that you caught all the damage.

Simple plastic electrical tape can probably be used for as insulation for testing purposes - it has worked for me - but would not likely survive very long as a permanent repair due to the possible high temperatures involved. A new yoke will almost certainly be needed.

Testing of flyback (LOPT) transformers

How and why do flyback transformers fail?

Flybacks fail in several ways:

1. Overheating leading to cracks in the plastic and external arcing. These can often be fixed by cleaning and coating with multiple layers of high voltage sealer, corona dope, or even plastic electrical tape (as a temporary repair in a pinch).

2. Cracked or otherwise damaged core will effect the flyback characteristics to the point where it may not work correctly or even blow the horizontal output transistor.

3. Internal shorts in the FOCUS/SCREEN divider network, if present. One sign of this may be arcover of the FOCUS or SCREEN sparkgaps on the PCB on the neck of the CRT.

4. Internal short circuits in the windings.

5. Open windings.

More than one of these may apply in any given case.

First, perform a careful visual inspection with power off. Look for cracks, bulging or melted plastic, and discoloration, Look for bad solder connections at the pins of the flyback as well. If the TV or monitor can be powered safely, check for arcing or corona around the flyback and in its vicinity,

Next, perform ohmmeter tests for obvious short circuits between windings, much reduced winding resistances, and open windings.

For the low voltage windings, service manuals may provide the expected DC resistance (SAMs PhotoFact, for example). Sometimes, this will change enough to be detected - if you have an ohmmeter with a low enough scale. These are usually a fraction of an ohm. It is difficult or impossible to measure the DC resistance of the HV winding since the rectifiers are usually built in. The value is not published either.

Caution: make sure you have the TV or monitor unplugged and confirm that the main filter capacitor is discharged before touching anything! If you are going to remove or touch the CRT HV, focus, or screen wires, discharge the HV first using a well insulated high value resistor (e.g., several M ohms, 5 W) to the CRT ground strap (NOT signal ground. See the section: Safe discharging of capacitors in TVs and video monitors.

Partially short circuited windings (perhaps, just a couple of turns) and sometimes shorts in the focus/screen divider will drastically lower the Q and increase the load the flyback puts on its driving source with no outputs connected. Commercial flyback testers measure the Q by monitoring the decay time of a resonant circuit formed by a capacitor and a winding on the flyback under test after it is excited by a pulse waveform. It is possible to easily construct testers that perform a well. See the companion document "Testing of Flyback (LOPT) Transformers" for further information.

Picture size suddenly becomes larger (or smaller)

You are playing your favorite game (read: addiction) and suddenly, the picture size increases by 20% and the brightness may have changed as well. What part should I replace? I only used my phasers on the #3 setting!

Unfortunately, I do not have a crystal ball. There are a number of parts that could be faulty and no way of know for your monitor and your symptoms which it is. Sorry, you will almost certainly have to have it professionally repaired or replaced.

What it sounds like is happening is that the circuitry that selects internal components depending on scan rate have failed in some way. They could be making an incorrect selection or the power supply could be faulty and applying an incorrect voltage to the horizontal and vertical deflection circuits. The brightness changes since it is not compensated for properly.

Burning up of various size or centering resistors

Check the capacitors that couple the yoke to to ground. If they become reduced in value or develop a high ESR, the current will be diverted to other components with unfortunate and rapid consequences.

Picture shifted horizontally

The first thing to determine is if this is a position or phase problem:

- A fault with horizontal position means that the entire raster is shifted left or right. This is almost certainly a monitor problem. If you turn up the brightness control, the edges of the scan lines will probably be visible on one side.

    - Assuming the position or centering controls do not work at or or have insufficient range, check for a defective centering pot and bad centering diodes and other components in their vicinity. If digitally controlled, you will probably need a schematic to find the cause.

    - If the monitor was dropped, the yoke or other assembly on the CRT neck may have shifted (though there would probably be other symptoms as well).

    - Monochrome monitors have centering rings on the CRT neck which may have be knocked out of adjustment. Color monitors adjust the centering electronically since magnetic rings would mess up the purity and/or convergence.

- A fault with horizontal phase means that the raster is still centered on the screen but the picture itself is shifted (and may have some wrap-around) within the raster. This could be a fault in the monitor or video card or incorrect settings in the software setup for the video card.

    - If this happened while trying out this monitor on a different or modified computer, just after you have done a software upgrade, or just after something strange happened (like your PC's CMOS settings got corrupted - monitor settings are generally not in the CMOS setup but may have been affected at the same time), reset the monitor's controls to their default or middle position and then use the software setup or install program that came with your video card to set scan rates, size, position, and sync polarity.

    - Some monitors have a user accessible horizontal phase control in addition to horizontal position. This adjusts the delay in the sync circuits so check that area of the electronics if the control doesn't work or have enough range.

- There could also be a problem with base drive to the HOT. This may result in position, phase, size, and linearity errors as the scan being initiated too soon or too late.

    - Weak drive to the HOT due to faulty components in the base circuit or driver stage might result in the HOT coming out of saturation early. The picture would be shifted to the right and the HOT might run excessively hot and blow.

      WARNING: The case of the HOT has >1,000 V spikes and B+ when off - don't touch with power on or until you confirm no voltage is present after pulling plug.

    - If marginal, a drift of position, phase, size, and linearity with warmup is also likely. Check for dried up electrolytic capacitors and use cold spray to isolate other bad components. If the drive becomes too weak, the HOT may blow after after being on for a while.

---

4. Back to Monitor Repair FAQ Table of Contents.

High Voltage Power Supply Problems

Identifying HV voltage problems

In addition to the obvious "monitor screen is as black as a coal mine" symptom, problems in the high voltage power supply can result in a variety of brightness, raster geometry, and other picture problems as well as arcing, corona, or other sights, sounds, and smells not normally associated with a properly functioning monitor. This chapter deals with some of these. Other video related problems will be dealt with in the chapter: "Raster, Color, and Video Problems".

High voltage power supply fundamentals

Most, monitors derive the high voltage for the CRT second anode (THE high voltage, focus, and (sometimes) screen (G2) from the horizontal deflection system. This technique was developed quite early in the history of commercial TV and has stuck for a very simple reason - it is very cost effective. A side effect is that if the horizontal deflection fails and threatens to burn a (vertical) line into the CRT phosphors, the high voltage dies as well. Of course, if the vertical deflection dies....

Some auto-scan monitors utilize a separate high voltage supply. One reason for this approach is to decouple the horizontal deflection from the HV in auto-scan monitors thus simplifying the design.

Usually it is a self contained inverter module. It if can be opened, then repair may be possible. With a separate HV supply, there is no need for a HV flyback transformer on the mainboard. Some designs may use a separate HV supply including a flyback which is part of the mainboard but is self contained and independent of the horizontal deflection system.

Most TV and monitor (flyback) high voltage supplies operate as follows:

1. Horizontal output transistor (HOT) turns on during scan. Current increases linearly in primary of flyback transformer since it appears as an inductor. Magnetic field also increases linearly. Note: flyback is constructed with air gap in core. This makes it behave more like an inductor than transformer as far as the primary drive is concerned.

2. HOT shuts off at end of scan. Current decreases rapidly. Magnetic field collapses inductively coupling to secondary and generates HV pulse. Inductance and capacitance of flyback, snubber capacitors, and parasitic capacitance of circuitry and yoke form a resonant circuit. Ideally, voltage waveform across HOT during flyback (retrace) period will be a single half cycle and is clamped by damper diode across HOT to prevent undershoot.

3. Secondary of flyback is either a single large HV winding with HV rectifiers built in (most often) or an intermediate voltage winding and a voltage multiplier (see the section: What is a tripler?). The output will be DC HV pulses.

4. The capacitance of the CRT envelope provides the needed filtering to adequately smooth the HV pulses into a DC voltage. Sometimes there is a separate HV capacitor as well.

5. A high resistance voltage divider provides the several kV focus voltage and sometimes the several hundred volt screen (G2) voltage as well. Often, the adjustments for these voltages are built into the flyback. The focus and screen are generally the top and bottom knobs, respectively. Sometimes they are mounted separately. This or a similar divider may also provide feedback to control high voltage regulation.

What is a tripler?

In some TVs and monitors, the flyback transformer only generates about 6-10 kV AC which is then boosted by a capacitor-diode ladder to the 18-30 kV needed for modern color CRTs. The unit that does this is commonly called a tripler since it multiplies the flyback output by about 3 times. Some TVs use a quadrupler instead. However, many TVs and monitors generate the required HV directly with a winding with the required number of turns inside the flyback transformer.

Triplers use a diode-capacitor ladder to multiply the 6-10 kV AC to 18-30 kV DC. Many triplers are separate units, roughly cubical, and are not repairable. Some triplers are built in to the flyback - it is probably cheaper to manufacture the HV diodes and capacitors than to wind a direct high voltage secondary on the flyback core. In either case, failure requires replacement of the entire unit.

For external multipliers, the terminals are typically marked:

- IN - from flyback (6-10 kV AC).
- OUT - HV to CRT (20-30 kV DC).
- F - focus to CRT (2-8 kV).
- CTL - focus pot (many megohm to ground).
- G, GND, or COM - ground.

Symptoms of tripler failure are: lack of high voltage or insufficient high voltage, arcing at focus protection spark gap, incorrect focus voltage, other arcing, overload of HOT and/or flyback, or focus adjustment affecting brightness (screen) setting or vice-versa. Where there is overloading, if you disconnect the tripler and everything else comes back to life (obviously, there will be no HV or picture), then it is very likely bad.

High voltage shutdown due to X-ray protection circuits

A monitor that runs for a while or starts to come on but then shuts down may have a problem with the X-ray protection circuitry correctly or incorrectly determining that the high voltage (HV) is too great (risking excessive X-ray emission) and shutting everything down.

A side effect of activation of this circuitry is that resetting may require pulling the plug or turning off the real (hard) power switch.

Was there anything else unusual about the picture lately that would indicate an actual problem with the HV? For example, has it suddenly gotten brighter than normal or has the size decreased? If this is the case, then there may be some problem with the HV regulation. If not, the shutdown circuit may be overly sensitive or one of its components may be defective - a bad connection of leaky cap (or zener).

If the horizontal frequency is not correct (probably low) due to a faulty horizontal oscillator or sync circuit or bad horizontal hold control (should one exist!), HV may increase and trigger shutdown. Of course, the picture won't be worth much either! With a multiscan monitor, this could happen if the mode switching is faulty resulting in incorrect component settings for a given scan rate. A symptom might be HV shutdown when switching into scan ranges.

The HV shutdown circuit usually monitors a winding off of the flyback for voltage exceeding some reference and then sets a flip flop shutting the horizontal drive off.

On some Sony models, a HV resistive divider performs this function and these do fail - quite often. The red block is often called a 'HV capacitor' (but is technically the 'HSTAT' unit because it has a control for horizontal static convergence) and is a common cause of immediate or delayed shutdown on certain Sony monitors and TVs. With these failures, the HV doesn't become excessive but the sense voltage rises due to leakage with the voltage divider. See the section: Apple/Sony monitor dies after variable length of time.

Low or no high voltage

Most of these problems are due to faults in the horizontal deflection system - shorted HOT, shorted windings or HV rectifiers in the flyback, defective tripler, or other bad parts on the primary side of the flyback.

In addition, with auto-scan monitors, the incorrect voltage or other component could be selected due to a logic fault or a problem with the selection relay or other circuitry.

However, if you discover an inch layer of filth inside the monitor, the HV could simply be shorting out - clean it first.

In most cases, these sorts of faults will put an excessive load on the horizontal output circuits so there may be excessive heating of the HOT or other components. You may hear an audible arcing or sizzling sound from internal shorts in the flyback or tripler. Either of these may bet hot, crack, bulge, or exhibit visible damage if left on with the fault present.

Many modern monitors do not regulate HV directly but rather set it via control of the low voltage power supply to the HOT (B+), by snubber capacitors across the HOT, and the turns ratio of the flyback. The HV is directly related to the B+ so if this is low, the HV will be low as well. Faulty snubber capacitors will generally do the opposite - increase the

HV and the X-ray protection circuits may kick in. However, low HV is also a possibility. The only way the turns ratio of the flyback can change is from a short which will manifest its presence in other ways as well - excessive heating and load on the horizontal output circuits.

While a shorted second anode connection to the CRT is theoretically possible, this is quite unlikely (except, as noted, due to dirt).

Excessive high voltage

Any significant increase in HV should cause the X-ray protection circuits to kick in and either shut down the set or modify the deflection in such a way as to render it harmless.

Symptoms include arcing/sparking of HV, smaller than normal picture, and under certain scenarios, possible excessive brightness.

Causes of the HV being too high are:

1. Excess B+ voltage to the HOT. The likely cause is to a low voltage regulator failure.

2. Open snubber capacitors across the HOT. These are under a lot of stress and are located near hot components so failure is possible.

3. Incorrect excessively long scan drive to HOT caused by failure of horizontal oscillator/sync circuits. However, other things like the HOT will probably blow up first. The picture will definitely be messed up. This is more likely with auto-scan monitors than TVs since what is too long for one scan range may be correct for another and the selection circuitry is confused or broken.

4. Failure of HV regulator. Actual HV regulators are uncommon today but the HV may controlled by a feedback voltage from a divider (focus or screen, or its own) or a secondary winding on the flyback setting the B+ or drive timing. This may result in an underscanned (smaller than normal) picture if only the HV and not the deflection voltages as well are derived from the same supply.

In one example of (4), a arcing of the HV in a Conrac studio monitor resulted in the destruction of the HV switchmode inverter transistor (this used a separate HV supply) and a fusable resistor. The cause was an open HV feedback resistor divider allowing the HV to increase drastically.

Snaps, crackles, and other HV breakdown

Various problems can result in occasional or sustained sparking or arcing sounds from inside the monitor. Note that a static electricity buildup is common on the front of the screen. It is harmless and there iss nothing you can do about it anyhow.

The following may result in occasional or sustained sounds not commonly associated with a properly working TV or monitor. There may or may not be flashes or blanking of the screen at the same time as the audible noise. See the same-named sections that follow for details.

- Arcing, sparking, or corona from CRT HV anode (red wire/suction cup).
- Arcing at CRT sparkgaps.
- Arcing from flyback or vicinity.
- Arcing due to bad connections to or disconnected CRT return.
- Flashovers inside the CRT.

Arcing, sparking, or corona from CRT HV anode (red wire/suction cup)

Symptoms could include a sizzling corona or more likely, an occasional or rapid series of sharp snaps - possibly quite loud and quite visible - from the anode cap on the CRT to the grounded coating on the outside of the CRT or a chassis ground point (or any other conductor nearby). Corona is a high resistance leakage through the air without total breakdown. The snapping is caused by the sudden and nearly complete discharge of the CRT anode capacitance through a low resistance ionized path similar to lightning.

There are two likely causes:

1. Dirt, dust, grime, around and under the suction cup on the CRT are providing a discharge path. This may be more severe in humid weather. Safely discharge the HV and then remove and thoroughly clean the HV suction cup and the area under it and on the CRT for several inches around the HV connection. Make sure there are no loose wires or other possible places for the HV to discharge to in the vicinity.

2. The high voltage has gone through the roof. Usually, the X-ray protection circuitry should kick in but it can fail. If cleaning does not help, this is a likely possibility. See the sections: High voltage shutdown due to X-ray protection circuits and Excessive high voltage.

Arcing at spark gaps and gas discharge tubes on CRT neck board or elsewhere

These are protective devices intended to breakdown and divert excessive voltage away from the CRT (usually).

This is rarely due to a defective sparkgap or gas discharge tube but rather is a safety mechanism like a fuse designed to protect the internal electrodes of the CRT if the focus or screen voltage should become excessive. The sparkgap breaks down first and prevents internal arcing in the CRT. These sparkgaps may be built into the CRT socket as well.

Arcing at a sparkgap or a glowing or flashing discharge tube may be accompanied by total loss of picture or bad focus, brightness or focus fluctuations, or any of a number of similar symptoms. A common cause is a breakdown inside the focus divider (usually part of the flyback or tripler) but could also be due to excessive uncontrolled high voltage due to a failure of the B+ regulator or HOT snubber capacitor, or (ironically) even a short inside the CRT.

- Spark gaps may be actual two or three pin devices with seemingly no insides, part of the CRT socket, or printed on the circuit board itself.

- Gas discharge tubes look like small neon lamps (e.g., NE2) but could be filled with some other gas mixture to provide a controlled higher breakdown voltage.

Therefore, like a fuse, don't just replace or disable these devices, locate and correct underlying problem. The CRT makes an expensive fuse!

Spark gaps and gas discharge bulbs on CRT neck board or elsewhere

These are protective devices intended to breakdown and divert excessive voltage away from the CRT (usually).

- Spark gaps may be actual two or three pin devices with seemingly no insides or printed on the circuit board itself.

- Gas discharge bulbs look like small neon lamps (e.g., NE2) but could be filled with some other gas mixture to provide a controlled higher breakdown voltage.

Arcing at a spark gap or a flashing or glowing gas discharge tube may indicate excessive high voltage, a short in the focus/screen divider network of the flyback, a short in the CRT, or some other fault resulting in abnormally high voltage on its terminals.

Arcing from flyback or vicinity

Arcing may be visible or audible and result in readily detectable levels of ozone. Note that very slight traces of ozone may not indicate anything significant but if the TV smells like an office copier, there is probably some discharge taking place.

WARNING: It is possible for arcing to develop as a result of excessive high voltage. Symptoms might be a smaller than normal excessively bright picture but this may not be able to be confirmed until the flyback is repaired or replaced. See the section: Excessive high voltage.

- On the HV output, it will probably be a loud snapping sound (due to the capacitance of the CRT) with associated blue/white sparks up to an inch or more in length. If the arc length is short enough, this may turn into a nearly continuous sizzling sound with yellow/orange arc and melting/burning plastic.

- Prior to the HV rectifier, it will likely be a continuous sizzle with orange/yellow/white arc and melting/burning plastic or circuit board material.

- Internal arcing in the flyback may be audible and eventually result in a bulging and/or cracked case (if some other component doesn't fail first as this would take some time to develop).

- A corona discharge without actual sparks or a visible well defined arc is also possible. This may be visible in a totally dark room, possibly more likely when the humidity is high. A thorough cleaning to remove all dust and grime may be all that is needed in this case.

- If the arc is coming from a specific point on the flyback - a crack or pinhole - this may be patched well enough to confirm that the rest of the monitor is operational and a new flyback is worth the money. Otherwise, there is no way of knowing if the arcing may have damaged other circuitry until a replacement flyback - possibly money wasted - arrives.

  To attempt a repair, scrape off any dirt or carbon that is present along the path of the arcing and its vicinity. Then, clean the area thoroughly with alcohol and dry completely. Otherwise, the dirt and carbon will just act as a good conductor and the arcing will continue under your repair! Several layers of plastic electrical tape may be adequate for testing. Multiple coats of high voltage sealer or non-corroding RTV silicone (if it smells like vinegar - acetic acid - as it cures, this may get in and affect the windings) would be better if the objective is an actual repair. A thick layer of Epoxy may be even better and affected less by possible HV corona. Either of these may prove to be a permanent fix although starting the search for a source for a new flyback would not hurt just in case. The arc most likely did damage the insulation internally which may or may not be a problem in the future.

  Also see the section: Dave's complete procedure for repair of an arcing flyback.

- In some cases, the pinhole or crack is an indication of a more serious problem - overheating due to shorted windings in the flyback or excessive secondary load.

- If the arc is from one of the sparkgaps around the CRT, the CRT socket, or the plastic 'alignment base' on the CRT itself, this could also be a flyback problem indicating internal shorts in the focus/screen network.

- If the arcing is inside the CRT, this could indicate a bad CRT or a problem with the flyback focus/screen network and no or inadequate sparkgap protection.

Where repair seems possible, first, clean the areas around the arc thoroughly and then try several layers of plastic electrical tape. If the TV works normally for say, an hour, then there is probably nothing else wrong and you can try for a proper sealing job or hope that tape holds out (put a few more layers on - each is good for about 8-10 kV theoretically).

Once I had a TV where the main problem was a cracked flyback arcing but this took out one of the fusable resistors for the power supply to the *vertical* output so the symptoms included a single horizontal line. Don't ask me to explain - replacing that resistor and the flyback (the flyback tested good, but this was for someone else) fixed the TV.

In another case, a pinhole developed in the flyback casing probably due to poor plastic molding at the time of manufacture. This resulted in a most spectacular case of sparking to a nearby bracket. A few layers of electrical tape was all that was needed to affect a permanent repair.

However, replacement is really the best long term solution both for reliability as well as fire risk.

(From: Bert Christensen (rosewood@interlog.com).)

It may well last a long time. The insulation breakdown was probably in the area of the rectifier section rather than the flyback section. I have repaired several units in the same way but I have generally replaced the flyback before sending back to the customer. I am worried that the repair will not hold and that a fire could start. I have no desire whatsoever to be sued by some fire insurance company.

I am always reminded by the experience that Zenith had with its System 3 chassis a few years ago. They burned and caused many house fires including one in the governor's mansion in Texas. Zenith spent mega bucks on that one. They also spent mega-bucks on their 'safety capacitor' mess a few years before that.

Dave's complete procedure for repair of an arcing flyback

(From: Dave Moore (penguin@datastar.net).

First I clean the afflicted area with Electromotive spray from Autozone. It's for cleaning alternators. On Z-line I remove the focus control and wash with the alternator cleaner and a tooth brush until all dirt and carbon deposits are removed. Then I take an xacto knife and carve out the carbonized hole where the arcing broke through. Then take your soldering iron and close the hole by melting adjacent plastic into it. (clean any solder off your iron with solder-wick first). Then cut some plastic off of some other part off the flyback where it wont be needed and use this to plastic weld (with your iron) a hump of a patch into and over the arc hole. Smooth and seal with iron. Next apply as thick a layer of silicone rubber as you can and let dry overnight.

Arcing due to bad connections to or disconnected CRT return

The Aquadag coating on the outside of the CRT is the negative plate of the HV filter capacitor. If this is not solidly connected to the HV return, you will have your 25 kV+ trying to go where it should not be. There should be a wire solidly attached to the CRT neck board or chassis. Without this, voltage will build up until it is able to take some other path - possibly resulting in damage to sensitive solid state components in the process. Therefore, is is important to rectify the situation.

Warning: If you find this disconnected, don't just attach it anywhere. You may instantly kill ICs or other solid state components. It must be connected to the proper return point on the CRT neck board or chassis.

Flashovers inside the CRT

Due to sharp edges on the electron gun electrodes, impurities, and other manufacturing defects, there can be occasional arcing internal to the CRT. Properly designed HV, deflection, and power supply circuits can deal with these without failing but not all monitors are designed well.

There is nothing you can do about flashovers assuming your HV is not excessive (see the section: Excessive high voltage. If these persist and/or become more frequent, a new CRT or new monitor will be needed.

Ozone smell and/or smoke from monitor

Smoking is just as bad for monitors as for people and usually more quickly terminal (no pun....).

White acrid smoke may indicate a failed electrolytic capacitor in the power supply probably in conjunction with a shorted rectifier. Needless to say, pull the plug at once.

A visual inspection should be able to easily confirm the bad capacitor as it will probably be bulging and have condensed residue nearby. Check the rectifier diodes or bridge rectifier with an ohmmeter. Resistance across any pair of leads should be more than a few ohms in at least one direction. Remove from the circuit to confirm. Both the faulty diode(s) and capacitor should be replaced (though the capacitor may work well enough to test with new diode(s).

If a visual inspection fails to identify the smoking part, you can probably plug the monitor in for a few seconds until the source of the smoke is obvious but be prepared to pull the plug in a real hurry.

If the smell/smoke is coming from the flyback, then it has probably gone belly up. You may be able to see a crack or bulge in the case. While the flyback will definitely need to be replaced, it is likely that nothing else is wrong. However, it might be prudent to use a Variac when performing initial testing with the replacement just in case there is a secondary short circuit or excess HV problem.

X-ray and other EM emission from my TV or monitor?

X-ray radiation is produced when a high velocity electron beam strikes a target containing heavy metals. In a modern TV or monitor, this can only take place at the shadow mask/aperture grille and phosphor screen of the CRT.

For X-rays, the amount of radiation (if any) will be proportional to brightness. The energy (determined by the CRT high voltage, called kVP in the medical imaging field) is not affected. This is one reason many monitors and TVs are designed with brightness limiting circuits.

In any case, there will be virtually no X-ray emissions from the front of the CRT as the glass is greater than an inch thick and probably contains some lead for added shielding. Also see the section: Should I be worried about X-ray exposure while servicing a TV or monitor?.

Electromagnetic radiation (EM) is produced mostly from the deflection yoke and to a lesser extent from some of the other magnetic components like transformers and inductors. Depending on monitor design (some are specifically designed to reduce this), EM emissions can vary quite a bit. Frequencies range from the 50/60 Hz of the power line or vertical scan rate to several hundred kHz in the AM broadcast band. The intensity and spectral distribution will vary depending on horizontal and vertical scan rate.

A totally black screen will reduce X-ray emission to zero. It will not affect EM emissions significantly as most of this comes from the magnetic parts, particularly the deflection yoke.

There is no measurable microwave, IR, or UV radiation.

I refuse to get into the discussion of what, if any, health problems result from low level EM emissions. There is simply not enough data.

Should I be worried about X-ray exposure while servicing a TV or monitor?

The only source of X-rays in a modern TV or monitor is from the CRT. X-rays are generated when a high velocity electron beam strikes a heavy metal target. For anything you are likely to encounter, this can only happen in a vacuum - thus inside the CRT. The higher the voltage, the greater the velocity and potential danger. Really old TVs (prior to around 1975) may still have HV rectifier and regulator tubes - other sources of X-rays. However, modern TVs and monitors implement these functions with solid state components.

The thick front CRT faceplate protects users adequately but there may be some emission from the thinner sides. At 25-30 kV (quite low as X-ray energies go) X-rays will be stopped by almost any metal so what you have to worry about is where there are no shields. In addition, the CRT glass usually contains some lead compounds to block X-ray emissions.

Other than lowering the brightness (or high voltage!), there isn't anything you can do to reduce X-ray emission from the front of the monitor. Any sort of add-on screen (grounded or otherwise) unless it is made of thick leaded glass, will have no significant effect on X-rays. If you are still concerned, sit farther away.

However, realistically, there is very little danger. I would not worry about exposure unless you plan to be sitting for hours on the sides, behind, or under the TV or monitor - with a picture (there will be none if the screen is black).

It is interesting that even those 1.5" Watchman and .5" camcorder viewfinder CRTs have X-ray warning labels even though the high voltage used with these isn't anywhere near high enough to be of any concern!

More on radiation from TVs and monitors

(From: Jerry Greenberg (jerryg50@hotmail.com).)

Your standard TV set or monitor should not exceed about 0.2 mR/Hr of radiation from a distance of 5 cm from any part of the cabinet. Most TV monitor equipment is less than half of this amount.

The CRT has a coating on the inner wall of its glass envelope, and also there is a metal shadow mask or aperture grill in the front. There is also a metal shroud around its parameter.

The type of emission from the CRT is known as soft X-Ray emission. This is because it is low power, and is in the lower X-Ray region.

The X-Ray emission is strongest at the rear of the TV set because there is some opened area where the electron gun is located. But, this is very weak as well. The radiation from a TV or monitor is not being focused to one point, and is also below the threshold level of being dangerous.

The long term effect of the total radiation from normal operating TV equipment is not fully known. However, the effect of X-Ray radiation is accumulative over time if there are no breaks in between the exposures. As for standard focused X-Rays like the ones used in a medical or security facility, these and most of their effects are well known.

As for normal working TV equipment, when used normally, the total radiation is less that what you would get when walking on the street. There are many satellites beaming down signals, radio and TV broadcast stations, communications systems, and then cell phones.

The X-Ray radiation in a TV set is emitted from the effect of the High Voltage drive generating the electron beam. If the High Voltage exceeds the designed safety limit for the CRT, then there is concern that the X-Ray radiation may have some effect on anyone that is in close proximity to the CRT. The amount of by which the high voltage exceeds the design specfifications will determine the total X-Ray emission. Since this emission is not focused into a fine area, its immediate danger is also greatly reduced.

All TV sets by law must have in their design some type of protection to shut the TV down if there is excessive High Voltage, excessive High Voltage current drive, and a number of other safety criterias.

There is also the concern about electromagnetic radiation. In fact all radio frequencies are based on electromagnetic radiation (EMR).

There was a great concern about the low frequency EMR. This would come from the power supply, deflection amplifier stages, and then from the deflection yoke and flyback transformer. There different types of EMR from TV sets.

Concerning TV's and monitors, this radiation worry comes up from time to time. If a woman is pregnant it would be wiser for her to not expose the unborn baby by working close to a terminal or monitor. This nonexposure is a good policy to make sure that everyone is safe rather than suffer any type of damage or health risks.

As for a safety concern for a mother to be, or a small baby, they can be in front of a TV set but at least 5 to 7 feet away. From this distance there should not be any danger at all.

The above is from my personal observations and is very general. I have also read various publications over the years that pertain to this subject.

I have a personal concern about the radiation from TV sets and monitors because I do an extensive amount of service on these. I am also doing a lot of picture tube changes in monitor equipment. I am then exposed for a few hours because I must do the purity and convergence setups of these sets. I have some days where I work 10 to 12 hours doing TV and monitor service work.

If you want a TV monitor that will put out near zero X-Ray radiation, and very low electromagnetic radiation, then go for one of the new LCD flatscreen monitors.

Flyback got wet

You put your can of Coke where????

Who says these FAQs cannot be funny?

Needless to say, unplug the monitor immediately. Inspect around the target area for obviously blown or damaged components. Test fuses and fusable resistors. Remove all traces of liquid - especially sugary or corrosive liquid. Use water first and then alcohol to promote drying. Repair burnt solder connections and circuit board traces. Once the monitor is entirely dried out, power it up - preferably through a series light bulb and/or Variac until you are sure nothing else will let loose. Look, listen, and smell for any unusual behavior. If it now works, then consider yourself lucky. If not, there may be damage to transistors, ICs, or other components.

Another cause of this is using spray cleaner or a too wet rag on the front of the CRT (other parts of the monitor, for that matter). Any liquid which drips inside (all too likely) may short out circuitry on the mainboard with very expensive consequences.

Blooming or breathing problems

There are several symptoms that are basically similar:

- Blooming is defined as an expansion of the raster or horizontal sections of the raster with bright material. For example, switching between dark and light picture causes the size of the picture to expand by 10%. A slight change in size is unavoidable but if it is greater than 1 or 2 percent from a totally black image to a full white one, this is either an indication of a defective monitor or one that is badly designed. The cause is poor low or high voltage regulation.

  Check the B+ to the horizontal deflection. This is usually well regulated. If it is varying in sympathy to the size changes, trace back to determine why the low voltage regulator is not doing its job. The reason for the size change is that the high voltage is dropping and reducing the stiffness of the electron beam.

- Expansion of the raster width in areas of bright imagery is an indication of short term regulation problems. The video drive may be interacting with the other power supplies. Check for ripple - this would be at the vertical scan rate - in the various regulated power supplies. The cause may be a dried up electrolytic capacitor - once you locate the offending voltage, test or substitute capacitors in that supply.

In both these cases, if this just started after some work was done to the monitor, the brightness limiter and/or video drive may simply be set so high that the monitor cannot supply enough current to the high voltage. If the brightness is acceptable with these turned down slightly and still have acceptable brightness, then there may be nothing wrong.

- Breathing is defined as a periodic change in the size of the raster which may be independent of what is displayed or its severity or frequency may be related to the brightness or darkness of the image. This is another type of regulation problem and may be caused by bad electrolytic capacitors or other components in the low voltage power supplies.

  If the monitor uses a switchmode power supply or low voltage regulator separate from the horizontal deflection, first check its output(s) for a variation in voltage at the breathing rate. Test with a light bulb or resistor load to confirm that the problem is here and not the deflection or remainder of the monitor.

- A condition with somewhat similar symptoms is bad focus - fuzzy picture - but only with bright (high beam current) scenes. This could be just a matter of adjusting the focus control but may also indicate sub-optimal filament voltage due to bad connections or components in the filament circuit, or a tired worn CRT. You won't get high beam current without some serious spot blooming (a fat beam because too much cathode area is used) and you will get cathode 'poisoning' after prolonged use.

  Visually inspect the neck of the CRT for the normal orange glow of the filaments and check for bad connections and bad parts.

Erratic focus or screen (G2) voltage and/or controls on flyback

Symptoms may include fluctuating focus or brightness. In extreme cases, the result may be a too bright or dark picture or other behavior caused by breakdown in the Focus/Screen(G2) divider network.

Usually, this will require flyback replacement to repair reliably. Sometimes, the section with the controls can be snapped apart and cleaned but this is not common.

First, just try rotating the screen (G2) control back and forth a few times. This may clean up the contacts and eliminate the erratic behavior. Possibly, positioning it a bit to one side of the original location will help. Then, use the individual or other master background/bias adjustments to compensate for the improper brightness.

If pressing in on the erratic control helps to stabilize the setting, you might try adjusting it to the optimal position and then put a dab of hot-melt glue (or Superglue if you can manage not to stick your fingers together) on the shaft to hold it with a little more contact force.

If none of this helps, here is a 'well it's going in the dumpster anyhow' procedure to try:

After discharging the CRT (so you don't get zapped) drill a tiny hole in the plastic cover near the bad control. Be careful you don't damage anything inside - you just want access to the contacts of the controls. Use a hand drill with, say, a 1/16" bit. Don't drill more than about 1/8" deep which should enter the airspace. Then spray some contact cleaner through the hole and work the controls. Wait sufficient time (say, 24 hours) for everything to dry COMPLETELY and see if behavior changes (or it works at all).

This is a 'you have got to be kidding' type of repair so no guarantees :-).

If by some miracle it does work, fill the hole with a drop of RTV or just put a couple of layers of electrical tape over it.

Focus/Screen divider bypass surgery

This is kludge number 41256 but may be the difference between a bit more life and the dumpster.

If the previous extreme measures don't help, then it may be possible to simply substitute a good divider network externally.

Note that if there is evidence of internal breakdown in the divider of the original flyback (hissing, cracks, overheating, bulging case, etc.), this will not work unless you can disconnect it from its HV connection.

There are two issues:

1. Is this a stable situation? Even if you provide an external substitute, the parts inside the flyback may continue to deteriorate eventually resulting in other more total failure of the flyback or worse.

2. If you provide an external focus/screen divider, it must be done is such a manner (including proper mounting and super insulation) such that it cannot be called into question should there be a fire where the monitor is even the slightest bit suspect.

Various size external focus/screen divider networks can be purchased but whether this is truly a cost effective solution is not obvious.

(From: Larry Sabo (sabo@storm.ca).)

I just ordered a 'bleeder resistor' from Data Display Ltd (Canadian sub of CCS) to use as a cure for flybacks with flaky focus/screen pots. It contains focus and screen pots, and costs Cdn$ 16.99, which is a lot less than a complete flyback, that's for sure. I expect it will be compatible with quite a wide range of flybacks.

I have used bleeder resistor assemblies from duff flybacks a couple of times with good success. You connect the HV lead into the HV cap of the original flyback, ground all pins of the sub flyback, and use the focus and screen leads from the sub bleeder assembly in place of the originals.

Looks like hell but works fine. Mounting (and securing) the substitute is a challenge given the limited space available. I only use this approach on what would otherwise be uneconomical to repair, and always advise the owner or customer of the cobbling job. It also enables you to verify whether it is the flyback that needs replacement, versus the CRT.

Decaying or erratic focus or screen (G2) voltages

The following applies to both CRT focus voltage (which should be a few kV) and screen or G2 voltage (which should be several hundred V).

> "The screen voltage will come up to normal after sitting over night, 400 V or so. After approximately 5 minutes or slightly longer, I hear a slight arcing. From that point on, the screen voltage will wander anywhere from 75 V up to maybe 150 V. Adjustment of the screen control on the flyback has only a small effect and is not permanent. Removing the CRT pcb results in the screen voltage returning to normal."

This is very likely a short between electrodes inside the CRT unless there is something on the neck board that is breaking down as a result of some connection to the CRT. The flyback should largely not know the difference with the socket plugged into the CRT. However, on rare occasions, there is contamination within the 'plastic alignment base' on the end of the CRT neck. (It is possible to *carefully* remove the plastic piece and clean the CRT glass/pins. Reinstall the plastic piece if it is still intact or leave it off - just take care in replacing the CRT neck board.)

One possibility is that glue used to hold components down on some circuit boards has deteriorated and turned conductive. Check for tan to brown stuff shorting traces on the CRT neck board. If this is present on the focus or screen traces or wires, it may just be your problem. Scrape off all of the old glue and then clean thoroughly. Repair any damaged traces.

What happens to the HV? A HV breakdown possibly inside the CRT would result in all the voltages being dragged down.

What happens to the picture?

If you connect a charged HV capacitor (guessing a couple hundred volts, a couple microfarads) between G2 and G1 or focus, you **will** know if tapping the neck results in a momentary short! I cannot predict whether this will be a temporary cure or permanent killer. See the section: Rescuing a shorted CRTRescuing a shorted CRT.

Here is another thing to try: put a 100 M ohm or so resistor between SCREEN and the CRT socket. This should not affect the behavior much until the failure occurs. Then, check the voltage on both sides with a high impedance voltmeter (1000 M). If the CRT is arcing, it will be much lower on the CRT side and will probably fluctuate. You can play similar games with focus voltage.

Disconnecting flyback wire(s) from CRT driver board

In some cases, there may be one or more separate wires running to directly to the CRT socket. These are typically for focus which has a relatively high voltage so better insulation is needed but there may be no obvious means of removal should flyback replacement be needed.

One alternative is simply to cut the wire(s) in a location that is well away from any place to short out, solder, and then do a most excellent job of insulating the splice. If there is more than one wire, make sure to label them first if they aren't color coded.

However, you may find that the cap on the CRT socket snaps off using a thin knife blade or screwdriver. The wire may be soldered or just pressed in place in such a way that pulling it out is difficult or impossible without removing the cover. If there is more than one wire, label them before removal unless the locations are clearly marked.

Sometimes the color is stamped on the plastic but there may just be a designation like "A" and "B".

(From: Raymond Carlsen (rrcc@u.washington.edu).)

The last one I worked on puzzled me for a few moments. See if you can see a space between the little cup (where the wire enters the socket) and the socket itself. Pry up on the cap with a knife and it should pop right off. The wire is soldered to a pin under it. Don't apply heat for very long... you may melt the socket.

Focus or screen voltage drifts after warmup only when CRT is connected

> "I have a 3-5 yr old monitor that loses screen voltage. I believe that the problem is specific to the CRT or the flyback, either one is a guess I'd rather be sure of prior to ordering a part.
>
> The screen voltage will come up to normal after sitting over night, 400 V or so. After approximately 5 minutes or slightly longer, I hear a slight arcing. From that point on, the screen voltage will wander anywhere from 75 V up to maybe 150 V. Adjustment of the screen control on the flyback has only a small effect and is not permanent. Removing the CRT pcb results in the screen voltage returning to normal.
>
> I cannot find the source of the arcing, as it happens quickly and I have always been on the other side of the set when it happens. I have replaced the crt socket, thinking the spark gap was arcing. I have checked the CRT for G1 and HK shorts on a sencore crt checker, it checks good, but I am aware that since it is an intermittent problem, that the checker probably will not catch it."

This is very likely a short between electrodes inside the CRT unless there is something on the neck board that is breaking down as a result of some connection to the CRT. The flyback should largely not know the difference with the socket plugged into the CRT. However, on rare occasions, there is contamination within the 'plastic alignment base' on the end of the CRT neck. (It is possible to *carefully* remove the plastic piece and clean the CRT glass/pins. Reinstall the plastic piece if it is still intact or leave it off - just take care in replacing the CRT neck board.)

One possibility is that glue used to hold components down on some circuit boards has deteriorated and turned conductive. Check for tan to brown stuff shorting traces on the CRT neck board. If this is present on the focus or screen traces or wires, it may just be your problem. Scrape off all of the old glue and then clean thoroughly. Repair any damaged traces.

What happens to the HV? A HV breakdown possibly inside the CRT would result in all the voltages being dragged down.

What happens to the picture?

If you connect a charged HV capacitor (guessing a couple hundred volts, a couple microfarads) between G2 and G1 or focus, you **will** know if tapping the neck results in a momentary short! I cannot predict whether this will be a temporary cure or permanent killer.

Here is another thing to try: put a 100 M ohm or so resistor between SCREEN (or FOCUS) and the CRT socket. This should not affect the behavior much until the failure occurs. Then, check the voltage on both sides with a high impedance voltmeter (>1000 M). If the CRT is arcing, it will be much lower on the CRT side.

5. Back to Monitor Repair FAQ Table of Contents.

Raster, Color, and Video Problems

Blank picture, power light on, digital controls (if any) active

Does 'blank picture' means a totally black screen with the brightness and contrast controls having no effect whatsoever? Or, is there is no picture but there is a raster - light on the screen? The direction in which troubleshooting should proceed differ significantly depending the answer.

Verify that you computer has not simply entered power saving mode and blanked the screen or shut off the monitor video and power circuits entirely.

Confirm that the video source is not defective or blank - try another one.

Here are some questions:

1. Is there any light on the screen at any settings of the brightness and contrast controls, and/or when switching channels. Can you see any raster scanning lines?
2. Can you obtain a raster of any kind by adjusting the screen (G2) control (probably on the flyback) or master background or brightness?
3. Looking in the back of the monitor, can you see the glow of the CRT filaments?
4. Do you get that static on the front of the tube that would indicate that there is high voltage?

If the answer to all of these is 'no', then you have a power supply and/or deflection problem. Refer the the section: No picture but indications of power.

Possible causes of no raster:

- No or low high voltage (low voltage, deflection, or high voltage power supply failure).
- Fault with other voltages like G1 or screen (G2) to CRT.
- Filament to CRT not getting powered.
- Drive to CRT bad/shut off as a result of fault elsewhere. For example, failure of the vertical deflection may disable HV or blank the screem to protect the CRT from burn-in due to the very bright horizontal line that would result. With some monitors, it is possible that the X-ray protection circuitry will blank the screen.

Possible causes of no video: problem in video input, video amplifiers, video output, cutoff due to other fault.

It could be as simple as a bad connection - try gently prodding the boards with an insulated stick while watching the screen. Check for loose connectors and reseat all internal connectors.

Brightness control has no effect

The following assumes that the picture is fine but the brightness is fixed - probably at too high a level. However, there could be several interrelated problems if a common supply voltage were missing, for example.

If it is a knob, then it should be varying the control grid (G1) voltages relative to the cathodes (K) of the CRT. This is not likely to be a very complex circuit. If you do not have a schematic, start by tracing from the control, check continuity and solder connections. Check the control itself for proper operation with an ohmmeter. A power supply going to one side of the control (negative probably) may be missing. Tbe control grid voltage will end up on the little board on the neck of the CRT - check there as well for bad solder connections or open resistors.

If brightness is a digital control, then you will need a schematic unless there is an obvious bad connection.

No color - black and white picture

This means absolutely no color - equivalent to a black and white picture. Not even a hint of color.

If you are using a composite video input, troubleshoot the chroma circuitry like you would a TV - see the document: Notes on the Troubleshooting and Repair of Television Sets.

This is an extremely unlikely failure mode for a computer monitor unless you are using a composite video input. It is most likely to a software driver or program problem. Sometimes, the PC will think that the monitor you have connected is not capable of color and certain programs will then display in B/W no matter what. This may be due to an initialization problem - possibly a race condition during the boot process - especially likely if you are using an older video card with a new fast processor.

First, confirm that the source is actually in color - try the monitor on another computer or vice-versa.

Check the settings of any mode switches - in rare cases there is a color/mono switch or button.

Note that to the average person, the obvious question becomes: is my color picture tube bad? The answer is a definitive NO. It is virtually impossible for a defective CRT to cause a total loss of color. A defective CRT can cause a lack of a primary color - R, G, or, B which will mess up the color but is not likely to result in a black and white picture.

One color is too weak or too strong

If the problem is slight and/or has gradually gotten worse, this may just require an adjustment of the color brightness/background/bias and/or color gain/drive controls inside the monitor. See the section: Brightness and color balance adjustment.

Even if it appears as though there is an excess, this may actually be a reduction in one of the primary colors. For example, a magenta tinge is represents a reduction in the strength of the green signal.

- Too high an intensity for one of the color channels will result in a tint of one of the primaries: red, green or blue.
- Too low an intensity for one of the color channels will result in a tint of the complement of one of the primaries: yellow, cyan, or magenta.
- Problems mainly in the shadows or dark areas of the picture usually represent a fault with brightness/bias/background.
- Problems mainly in the highlights or bright areas of the picture usually represent a fault with the gain/drive.

A color that that is now suddenly brighter or darker than normal resulting in incorrect color balance or a tint in the background could be due to a number of causes:

- Bad cable or pin bent on cable connector.
- Bad connections or bad component in video amplifier or on CRT neck board for that color.
- Weak gun in CRT (reduced color).
- Bad video card or incorrect software color map settings.
- For monitors with sync-on-green capability, the monitor may think you are using sync-on-green when in fact you have separate sync. In particular, this may result in a problem with excessive green:

  (From: Bob Myers (myers@fc.hp.com).)

  Some monitors provide a user-selectable setup option for "sync-on-green" vs. separate syncs. Sometimes, this doesn't really change where the sync itself is coming from. In those cases, it's automatically detected but *does* change where the reference level for the video is expected to be. You might try checking this setting, if you have it, and changing it back and forth to check the effect. It's not likely to be the problem in a separate-sync system like a PC, but weirder things have happened and it's easy and cheap to check out.

Psychodelic color

The means colors that are not normal and that adjustment of the user controls is not able to correct it so that all colors of the picture are properly displayed at the same time. For example, you are unable to get any yellows or blues in picture that should have these colors.

- If you are using a composite video input, troubleshoot the chroma circuitry as you would a TV - see the document: Notes on the Troubleshooting and Repair of Television Sets.
- Confirm that the input is not a weird color video - try another software program or video source. We have a draftsperson who always sets up his Windows color scheme in this manner - we keep wishing it is the monitor as **that** could be fixed!
- Verify that this is not a missing color problem - one of the primary R, G, or B, has disappeared. If so, refer to the section: Intermittent, flickering, or missing colors.
- If this is a monitor with BNC connectors and you are using them, make sure you had the video termination switches set correctly (75 ohms if this is the only monitor or the last monitor in a daisychain; HiZ if an intermediate monitor in a daisychain.) A very common cause of unbalanced or blooming colors assuming the monitor itself is good is incorrect settings of the termination.
- A bad connection, bad component, or short circuit in the video circuitry or CRT neck board could also result in strange colors.

Monitor manufacturing quality and cold solder joints

Any intermittent problems with monitors that cause random sudden changes in the picture brightness, color, size, or position are often a result of bad connections. Strategically placed bad connections can also cause parts to blow. For example, a bad connection to the SCR anode in a phase controlled power supply can result in all the current passing through the startup resistor, blowing it as well as other components. I had a TV like this - the real problem was a bad solder joint at a pin on the flyback. Thus, erratic problems, especially where they are power or deflection related, should not be ignored!

Bad solder joints are very common in monitors due both to poor quality manufacturing as well as to deterioration of the solder bond after numerous thermal cycles and components running at high temperature. Without knowing anything about the circuitry, it is usually possible to cure these problems by locating all bad solder connections and cleaning and reseating internal connectors. The term 'cold solder joint' strictly refers to a solder connection that was either not heated enough during manufacturing, was cooled too quickly, or where part pins were moved before the solder had a chance to solidify. A similar situation can develop over time with thermal cycling where parts are not properly fastened and are essentially being held in by the solder alone. Both situations are most common with the pins of large components like transformers, power transistors and power resistors, and large connectors. The pins of the components have a large thermal mass and may not get hot enough during manufacturing. Also, they are relatively massive and may flex the connection due to vibration or thermal expansion and contraction.

These problems are particularly common with TVs and monitors - especially cheaper monitors.

To locate cold solder joints, use a strong light and magnifier and examine the pins of large components for hairline cracks in the solder around the pin. Gently wiggle the component if possible (with the power off). Any detectable movement at the joint indicates a problem. With the power on, gently prod the circuit board and suspect components with an insulated tool to see if the problem can be effected.

When in doubt, resolder any suspicious connections. Some monitors may use double sided circuit boards which do not have plated through holes. In these cases, solder both top and bottom to be sure that the connections are solid. Use a large enough soldering iron to assure that your solder connection is solid. Put a bit of new solder with flux on every connection you touch up even if there was plenty of solder there before. However, remove any obvious excess. Inspect for solder bridges, sliver, splashes, etc. before applying power.

Why can't monitor manufacturers learn to solder properly?

I can think of several potential reasons - all solvable but at higher manufacturing cost.

1. Mass of large component leads (like shields) does not get adequately heated during manufacture leading to latent cold solder joints. While they may look ok, the solder never actually 'wetted' the heavy pins and therefore did not form a good mechanical or electrical bond.

2. Thermal cycles and differential thermal coefficients of circuit boards, traces, and solder. While it is not easy to do anything about the material properties, using plated through-holes or a similar mechanical via would greatly increase the surface area of the joint and prevent the formation of cracks.

3. Vibration. This is also directly related to the single sided circuit boards without plated through-holes to strengthen the joints.

4. Lack of adquate mechanical support (single sided circuit boards without plated through-holes (vias).

I believe that the single most significantimprovement would come about by using plated trhough-holes but this would add to the cost and apparently the consumer is not willing to pay more for better quality and reliability! Some designs have used rivlets - mechanical vias instead of plated ones. While this is good in principle, the execution has often been flawed where cold solder joints resulted between the rivlets and the circuit board traces due to lack of adequate process control.

Monitors, due to their generally higher cost compared to TV sets, should be better constructed but not always.

Intermittent, flickering, or missing colors

This is a catch-all for some of the most common monitor problems. Most of the causes boil down to bad connections of one form or another. However, defective components like bias resistors on the CRT driver board or in the video circuitry could also be at fault.

Note that due to the additive color scheme used in all emissive color displays like CRT or flat panel TV sets and video monitors, a single missing primary color (red, green, or blue) will result in the following appearance (for a white screen):

```
  Missing Color        Appearance
------------------------------------------------
     Red               Cyan (blue-green)
     Green             Magenta (reddish-purple)
     Blue              Yellow
```

This may best be observed with a test pattern a color on-screen display for which you recall the proper colors.

- Does whacking the monitor have any effect? If so, then bad connections are confirmed. If the color(s) come and go suddenly, then it is most likely *not* a CRT problem. The bad connections could be at the VGA cable, video driver board on the neck of the CRT, or elsewhere (see below).

- If the color fades in and out with a delay of about 10-15 seconds, it is probably intermittent power to the CRT filament for that color and probably means a bad CRT since the three filaments are wired in parallel inside the CRT. One of the internal connections has come loose.

  Look in the neck of the CRT to make sure all three filaments are glowing orange. If one is out or goes on and off, toss the monitor. Replacing the CRT is probably not worth it. However, if they all go on and off together (all colors would be fading in and out though perhaps not quite in unison), then bad connections for the CRT filaments on the CRT neck board are indicated.

Possible causes of intermittent or missing colors:

- VGA or other video input cable. Sometimes these develop intermittent problems at the connector to the VGA board. These may be internal to the cable in which case it will need to be replaced or if you are handy and have infinite patience, you can replace just the VGA connector.

  Alternatively, the male pins of the cable may not be making good contact with the female VGA socket. First try contact cleaner. If this does not work, gently squishing the male pins with a pair of needlenose pliers may provide temporary or permanent relief if the pins are a tad too small. However, if you go too far, you can damage or break the pins or cause the female socket to become enlarged and loose fitting for any other monitor you may use.

  If this just happened after reconfiguring your system and reconnecting the monitor or installing a new monitor, check your video connector - you may have bent over or pushed in pins 1, 2, or 3 - the R, G, and B video signals respectively.

  If you find a bent pin, ***carefully*** straighten it with a pair of needlenose pliers. If it is pushed in, try to grab onto it and pull it out - then put a drop of Epoxy or other adhesive at its base (don't get any on the part of the pin that makes contact) to prevent it from being pushed in again.

  There may be cold solder joints on the VGA board itself at the VGA connector. These can be resoldered.

- Printed circuit board on the CRT neck. This is a common location for cold solder joints. Check with a bright light and magnifying glass for hairline cracks around the pins of larger parts. Prod and tap with an insulated tool to see if the problem is effected. Resolder if necessary.

- Cold solder joints elsewhere in monitor usually around the pins of large parts such as transformers, power transistors and resistors, and internal connectors. Inspect with a strong light and magnifier if necessary.

- Internal connectors that need to be cleaned and reseated. Remove, clean with contact cleaner, burnish, and replace.

- Bad filament connections inside the CRT (gradual fade in and out or one filament not lit). Replace CRT or monitor.

To narrow down the problem:

- Locate the output for the bad color on the video driver board on the neck of the CRT. This will probably read a significantly higher voltage than the corresponding pins for the good colors. A circuit problem is likely - probably on this board but it could be in other parts of the video circuitry.

- Test components on this board for the good and bad color channels. A shorted transistor or open resistor can kill one channel. Swap parts between good and bad colors to confirm.

- Gently pull the CRT neck board off of the CRT and replace it. This will tend to clean the contacts.

- Connect an output of the video circuit/chip that is working (i.e., a color that appears on the screen) to *all* three color drivers on the CRT neck board.

  - If you now get a more-or-less black and white picture (there may be a moderate color tint as the relative intensities of R,G,B may not be balanced), the problem is likely with the circuitry on the mainboard.

    Note: the picture will be the intensity of only one color channel so it will not be quite *normal* in any case.

  - If you still have missing or messed up colors, the problem is on the CRT neck board or with the CRT.

Some commentary on monitor and TV whacking

Anytime that intermittent symptoms are experienced, I recommend gently whacking the patient to determine if mechanical shock or vibration affects the behavior. Here are a couple of responses to this suggestion.

(From Marc Gelfond (71363.1700@CompuServe.COM).)

I just love the bit about "whacking it". It brings to mind an episode from the old Andy Griffith show, where a new fangled piece of electronics gear, was broght into Emmets repair shop. After many long hours of fruitless troubleshooting, out of frustration Emmet gave the thing a whack, and sure enough it fixed the problem.

As we say in the Telephony business, it "CCWT" or Came Clear While Testing. Another saying is that it "CCBFM" Came Clear By F------ Magic!!

(To which Gavin Adams (gaa@hopi.com) comments):

In the video industry we had a saying concerning malfunctioning gear:

> "If it's broke, hit it with a hammer"
> "If that doesn't fix it, paint it and sell it"

My DEC 16" monitor is case in point. Evey once in a while it would lose sync, and smacking it would bring it back (sometimes a few smacks). Recently it gave up the ghost completely, and after the local DEC office gave me a quote of $900 to fix it (Bermuda), I ordered a new Viewsonic 17" for the same price.

I ripped the guts out of the DEC beast, painted it with a marble finish, put plants in it, and sold it! :>

Ghosts, shadows, or streaks in picture adjacent to vertical edges

Complaints about these kinds of problems are very common especially as the screen resolution and necessary video bandwidth keeps increasing. Most are due to cable and video termination deficiencies and not actual monitor defects.

The video signals for red, green, and blue (or just a single signal for monochrome) are sent over cables which are generally 75 ohm transmission lines. These are coaxial cables that may be combined inside a single sheath for VGA, SVGA, MACs, and many workstations but may be separate coaxes with BNC (or other) connectors for other video applications.

Without going into transmission line theory, suffice it to say that to obtain good quality video, the following conditions must be met:

- A good quality of cable must be used. This means one in which the characteristic impedance is close to the optimum 75 ohms, one which has low losses, and one which has good shielding. For installations using BNC connectors, a good quality of 100% shielded RG59U is often used. The BNC connectors must be properly installed or they will contribute to mismatch problems.

- Where multiple monitors are to be connected to a single video source, all wiring is done in a daisy chain fashion. The only taps permitted are the minimum necessary to connect each monitor to the chain. This usually means a BNC-T connector or a pair of connectors on the monitor for each video signal. T connections with cable must be avoided. (BNC cables only - SVGA monitors cannot be daisy chained without additional hardware.)

- Only the last monitor in the chain should be terminated in 75 ohms. All of the others must be set to Hi-Z. Monitors with BNC connectors will usually have one switch or a switch for each color to select termination.

Monitors for PCs, MACs, and many workstations usually have built in termination and do not offer the choice of Hi-Z. This means that without a video distribution amplifier, it is not possible to connect multiple monitors of this type to a single video source with any expectation of a good quality display.

Even adding a short extension cable or using an A-B monitor select box may result in unacceptable image degradation especially at higher scan rates.

Failure to follow these rules will result in video ringing, ghosts, shadows, and other unsightly blemishes in the picture. It is often not possible to control all aspects of the video setup. The cable is often a part of the monitor and cannot easily be substituted for a better one. The monitor may not have properly designed circuitry such that it degrades the video regardless of the cable and display board quality. The display card itself may not have proper drivers or source termination.

Ironically, the better the video card, the more likely that there will be visible problems due to termination. This is due to the very high bandwidth and associated signal edge rates.

Some examples of common termination problems:

- Overly bright picture with trails following vertical edges, perhaps with periodic ringing. This is due to a missing termination. Check if the monitor is set for Hi-Z instead of 75 ohms. If there is no switch, then the termination may be faulty or the monitor may need an external resistor. For BNC connectors, plug-on terminations are available.

- Bright ghost images adjacent to vertical lines. This may indicate that the terminating resistor is greater than the impedance of the cable. You may be using Ethernet Thinnet cable by accident which is RG58 with an impedance of 50 ohms.

- Dark picture and ghost images adjacent to vertical lines. This may indicate that the terminating resistor is too low - multiple monitors on a chain all set for 75 ohms instead of just the last one. Or, an improper type of cable such as audio patch cord.

- Fuzzy vertical edges. This may indicate a poor quality cable or a run which is just too long. For high resolutions such as 1280x1024, the maximum cable length may be as short as 25 feet or less for poor quality cable. Better cable or fiber-optic repeaters may be necessary.

- Other similar problems - check cables for defective or improperly installed connectors. This is especially applicable to cables with BNC or UHF type connectors which require a kind of artistic talent to assembly properly and consistently. Throw out those extension cables and switch boxes!

If only 1 or 2 colors (of the R, G, and B) are effected, then look for improper switch settings or bad connections (bad cable connectors are really common) on the problem color cables.

General streaks or lines to the right of bright or dark areas

The problem is that on a white background the various objects leave a shadow to their right. Not a duplicate image but more like horizontal dark streaks on the white background. Also it seems that high intensity colors display very bright but low intensity colors are overly dark (almost black). The contrast and brightness adjustments may make no difference.

This could be a number of things but they are all in the video amplifier and probably not the CRT driver board though this is possible. Dried up filter capacitors could result in video dependent ripple on the power supply lines. Bad coupling capacitors could result in similar symptoms but probably for only one color, not all of them.

Since all colors are effected, look for something common like a bad power supply. With a scope, this would probably be rather easy even without schematics. If the brightness and contrast controls do nothing, this would suggest some fault in their general area or the IC or transistors they control in the video amps - and that this is not a CRT problem. Locate the video amp IC if it uses one and locate a pinout - this should be enough to determine which signals are faulty.

First, do check carefully for bad connections and other obvious failures.

This could also be a symptom of a bad CRT but this would be unusual with a not-ancient monitor (and not if the brightness and contrast controls have no effect).

Washed out picture

If you can obtain a full intensity raster by varying the brightness or screen control, then your problem is most likely in the video amplifiers or power for the video amplifiers.

If, however, the screen control varies the brightness but will not get a bright raster, you probably have problems either with the HV power supply or the filament supply for the CRT - is there the normal bright orange glow at the base of the CRT? If it is dim or very reddish, there may be a marginal connection or bad component in the filament circuitry.

Retrace lines in picture

During the time the electron beam is returning from right to left at the end of a line and bottom to top (over the course of multiple lines), it is supposed to be result in no visible light on the screen. However, a number of faults can result in visible retrace lines.

The appearance will likely be a general reduction in contrast from the visible horizontal retrace on every scan line and two dozen or so diagonal lines lines (lower left to upper right) resulting from the vertical retrace.

The retrace lines may be either white or gray (possibly with a slight color tint due to unequal settings of the color adjustments) or a primary color - red, green, or blue. Anything in between is also possible but less likely.

White/gray retrace lines

Where all colors are involved - the lines are essentially white or gray (or with a slight tint due to slight unequal settings of the color adjustments), look for something common like an incorrectly adjusted screen (G2) or master brightness/background/bias control or a problem in one of these circuits, a defective power supply or a problem in the blanking circuitry:

- Screen (G2) or master brightness/background/bias control - mark setting and then see if a slight adjustment removes the retrace lines. See the chapter: "Monitor Adjustments". Of course, if this happened suddenly, the problem is not due to a misadjusted control though a dirty pot is possible - turn it back and forth - this might clean it and restore normal operation.

- Power supply or connection to CRT neck board - insufficient voltage will result in the CRT never totally blanking. Check (usually scan derived) power supply components (from flyback).

- General power supply - check B+ for correct value and ripple. A main power supply fault might result in these symptoms (and usually many others).

- Blanking circuit - this may be a part of the video/chroma chip or separate. Check waveforms to determine if the blanking pulses are making it to the video output.

Red, green, or blue retrace lines

Where only one color is showing, suspect an incorrectly adjusted individual background/bias control or bad part on the CRT neck board for that color.

- Individual brightness/background/bias control(s) - mark setting of pot for the problem color and then see if a slight adjustment removes the retrace lines. See the chapter: "Monitor Adjustments". Of course, if this happened suddenly, the problem is not due to a misadjusted control though a dirty pot is possible - turn it back and forth - this might clean it and restore normal operation.

- Component or connection on CRT neck board - insufficient voltage to or incorrect biasing of the video driver for this color can result in the CRT never totally blanking. Compare voltages and signals, and swap components between good and bad channels to confirm.

- Blanking circuit - this may be a part of the video/chroma chip or separate. Check and compare waveforms of good and bad colors to determine if the blanking pulses are making it to the video output.

There is a slight possibility that a bad CRT may result in visible retrace lines. To eliminate this possibility:

- Disconnect the filament - all evidence of a picture, raster, and retrace lines should disappear once the filaments/cathodes have cooled (15 seconds or so. If there are still visible retrace lines, the CRT is suffering from cold or field emission from someplace (may not even be the cathode).

- Turn down the screen (G2) control on the flyback (usually). If one color remains no matter how you set the control, again there is some kind of weird emission from the CRT. However, if white/gray retrace lines remain, the problem may be in the screen supply.

See the section: Bad CRT causing retrace lines.

Bad CRT causing retrace lines

(From: Jeroen H. Stessen (Jeroen.Stessen@philips.com).)

The TV which I bought last started developing retrace lines after a month or so of use. I took it back to the lab for warranty (special deal) and had it examined by the real experts. They found that even with the filament supply disconnected and VG2 at 0V the screen would still light up. They could even see that the electrons weren't even coming from the cathode. That was with only the picture tube in a test rig. So in this case the obvious conclusion had to be that the tube was bad, and it was replaced (32" 16:9 SF, very $$). It had something to do with processing problems during manufacturing of the electron guns.

So even if this was a rare case, it *can* happen that retrace lines are due to a bad picture tube. It's more usual to suspect the VG2 (screen voltage) or a defect somewhere in the RGB video path.

Red, green, or blue full on - fog over picture

This could be a heater-cathode (H-K) short in the CRT, a failure of a component in the chroma circuits or video output (driver board), or bad connections there or elsewhere.

Don't panic - heater-cathode shorts in CRTs can often be worked around.

Note: before proceeding, it is a good idea to make sure that the screen is degaussed - else you could be attempting to track down problems with the wrong color!

Some simple tests can confirm or rule out other possibilities.

- Compare the voltages for the video drive signals to the CRT on the little board on the neck of the CRT with the CRT both connected and unplugged. A schematic will help greatly in locating these signals.

    - If there is a significant difference especially on the bad color, then the CRT is a likely candidate. Try tapping the neck of the CRT GENTLY (with it plugged in and while viewing a picture) to see if it is an intermittent problem.

    - If there is no significant difference, you may have a bad driver or a problem in the chroma circuits.

- Look for bad connection/cold solder joints, probably on the little board on the neck of the CRT. Use an insulated stick to gently prod the board and its components in an effort to induce/cure the problem. Look carefully for hairline cracks around the component leads.

- You can swap components between two colors and/or test with an ohmmeter on that driver board to determine what is bad. The nice thing about color monitors and TVs is that there three copies of each of these components. Swapping and/or comparisons between these is an excellent diagnostic technique.

- Another simple test: Disconnect the cathode for the full-on color from its drive. If it is still full-on, there is probably an H-K short in the CRT since the only way to get each color on the screen is via the cathode connection to the CRT neck board. If it is removed and there is still that color, the current must be taking another path inside the CRT.

- Alternatively, interchange the outputs of the bad color with a good one by jumpering on the video driver board (on the CRT neck). If the bad color changes, then the problem is in the circuitry and not the CRT.

  Here is the procedure in more detail (example for red full on):

  (From: J. K. Emerine (jkemerine@aol.com).)

  To identify if the fault is in the crt or a control problem try this (WITH SET OFF):

  On the CRT board, lift the output end of the green cathode final resistor. Do the same with the offending red cathode's resistor. Use short insulated jumpers to 'swap' drive signals - drive the red cathode with the green drive and the green cathode with red drive. (Note that if this problem only occurs after a warmup period, color at turn on will be - well - wierd, but it is just a test.)

    - If the symptom returns = 'goes red' the CRT is shorting. (See the section: Providing isolation for a CRT H-K short. --- Sam.)

    - If instead the symptom becomes 'goes green' then the red drive leg has the fault and the CRT is probably good. (In this case, there may be bad connections or a bad component on the CRT drive board or further back in the chroma circuitry. --- sam)

Totally white screen (probably with retrace lines)

There may or may not be any indication of a picture. This may be a problem in the high voltage power supply (SCREEN, G2), loss of power or a fault in the video output drivers, other video amp problems, or a bad (shorted) CRT.

Is focus still reasonably sharp? If not, try adjusting it (usually on the flyback or a separate little panel). If changing focus affects brightness significantly, there is a short between the two supplies - either in the HV power supply or CRT. See the section: Bad focus and adjustment changes brightness. In this case, changing SCREEN (G2, also on the flyback) may also affect focus or may not do anything.

Try adjusting SCREEN. If it has no affect, a problem in its power supply from the flyback is possible. If you have a high impedance voltmeter (not just a DMM, the resistance of the voltage divider supplying SCREEN is hundreds of M ohms), check it while changing the SCREEN control. If it does not change, you have found a definite problem.

Assuming that adjusting FOCUS and SCREEN result in normal behavior and do not strongly interact, the problem is likely in the video circuitry or output drivers.

Check the power to the CRT video output drivers on the little board on the neck of the CRT. If this failed, all three video outputs will be full on. If you have a scope, look at the video outputs - they should be varying between over 100 V and a low value. If they are missing or very low all the time, there is a problem further back in the video chain.

See the other sections relating to brightness and high voltage problems as well.

Shorts in a CRT

Occasionally, small conductive flakes or whiskers present since the day of manufacture manage to make their way into a location where they short out adjacent elements in the CRT electron guns. Symptoms may be intermittent or only show up when the TV or monitor is cold or warm or in-between. Some possible locations are listed below:

- Heater to cathode (H-K). The cathode for the affected gun will be pulled to the heater (filament) bias voltage - most often 0 V (signal ground). In this case, one color will be full on with retrace lines. Where the heater is biased at some other voltage, other symptoms are possible like reduced brightness and/or contrast for that color. This is probably the most common location for a short to occur.

- Cathode to control grid (K-G1). Since the G1 electrodes for all the guns are connected together, this will affect not only the color of the guilty cathode but the others as well. The result may be a very bright overloaded *negative* picture with little, none, or messed up colors.

- Control grid to screen (G1-G2). Depending on circuitry can result in any degree of washed out or dark picture.

- Screen to focus (G2-F). Screen (G2) and focus voltage will be the same and the controls on the flyback will interact. Result will be a fuzzy white raster with retrace lines and little or very low contrast picture. Symptoms will be similar to those of a flyback with breakdown in the focus/screen divider network.
