The excitation to overcome the effect of the cross ampere-turns depends upon many variables but in machines designed in accordance with good practice it bears a fairly uniform relation to the cross ampere-turns, depending upon the value of the ampere-turns in gap and teeth, as follows:

Cross ampere-turns = (armature reaction ampere-turns) - back ampere-turns).

Field ampere-turns to compensate for cross ampere-turns is then  $K$  times (cross ampere-turns).

Where  $K$  has values as shown in Fig. 16 (given by Cramp, see Bibliography) thus the total field ampere-turns at full load is then equal to

$$F = (\text{Net ampere-turns for flux, section 19}) + A' + B'.$$

working with the saturation curve of the machine to effect of the cross ampere-turns on the saturation in

Constant for Cross Ampere-turns

This method is too elaborate and complicated to be of more value for educational than for practical purposes fully in the books by S. P. Thompson and E. (below).

used as described in section 23.

**Various Loads.**— At no load the excitation required necessary to produce a flux corresponding to the rated load corresponding to a current  $I$  the excitation is equal to the sum of: (1) that required to produce a flux where  $R$  is the total resistance of the armature between the brush and the resistance of the series field; (2) that required to overcome the back ampere-turns caused by  $I$ , and (3) that required to overcome the ampere-turns due to  $I$ . The process of calculation for no load and 21 for full-load conditions is, therefore, repeated

If the machine has a series field this should be laid out and the field coils are sometimes placed outside of, and concentric

For a compound-wound machine the ampere-turns required are equal to the difference between the full-load ampere-turns. As it is usual to shunt about 10% through a shunt resistance the number of series turns

$$A_s = \frac{\text{Ampere-turns required}}{0.75 \times \text{Load current}}$$

Each turn in square inches is taken equal to the full-load

wound in copper strap like a ribbon, the width being equal to the diameter of field spool if it is wound under the shunt winding, the two coils are placed side by side. The thickness of the cross-section divided by the width.

with an extra odd half turn to facilitate connection. The thickness of the cross-section is

$$\text{Thickness} + 0.016 \text{ for insulation} (A_s + 1).$$

Allowance for a layer of insulation inside and outside adds about 0.5 to the depth of winding.

The mean length of turn  $l_f'$  is (see Fig. 15):

For square pole  $l_f' = (\text{periphery of pole}) + 4 (\text{depth of winding})$ .

For round pole  $l_f' = \pi (f + \text{depth of winding})$ .

The resistance per spool is

$$r_1 = \frac{0.0093 l_f' f'}{12,000 g_1}$$

where  $g_1$  is the cross-section of a turn.

The total drop in voltage in the series field is  $0.75 r_1 I$  which should be 0.5 per cent and 1 per cent of the rated voltage.

**Shunt Field.** — The shunt field is required to give a certain number of ampere-turns, usually equal to the no-load ampere-turns. Let this number of ampere-turns per pole be  $F$ . At 1000 amperes per square inch the cross-section of copper in a coil would be  $F/1000$ . The total cross-section of the coil, including insulation, is determined by means of the space factor  $f'$ . Then the cross-section of the coil =  $\frac{F}{1000 f'}$ , where  $f'$  has a value of 0.5 if No. 18 B. & S. wire is used. Where very small wires are used  $f'$  becomes as small as 0.25 (see *Electrician's Handbook on Electromagnet Windings*).

The depth of winding will be

$$b_1 = \frac{F}{1000 f' c_1}$$

where

$c_1 =$  length of coil (see Fig. 17).

The superficial area will be (see Fig. 17)  $A_1 = 2 (f + b + 4 b_1) c_1$ .

The rise in temperature in  $^{\circ}\text{C}$ . of the coil will be from  $60^{\circ}$  to  $80^{\circ}$  per square inch of  $A_1$ ; thus for  $40^{\circ}$  rise on the spool the watts ( $w_1$ ) per spool will be from  $0.5 A_1$  to  $0.6 A_1$  depending upon the ventilating effect of the armature.

Voltage per spool under normal conditions, allowing 25 per cent to spare for rheostat, will be

$$e_1 = \frac{0.75 E}{p}$$

$$\text{Current in shunt field} = i = \frac{w_1}{e_1}$$

$$\text{Turns per spool} = h_1 = \frac{F}{i}$$

$$\text{Mean length of turn, in in.} = l_f = 2 (f + b + 4 b_1) \text{ or } \pi (f + b_1)$$

$$\text{Resistance per spool} = r_2 = \frac{e_1}{i}$$

Cross-section of conductor in sq. in. =

$$g_2 = \frac{0.0093 l_f h_1}{12,000 r_2}$$

The size of wire having a cross-section as nearly equal to  $g_2$  as possible is chosen and arranged in layers. Single cotton-covered wire is used. The

**CHOICE OF PERFORMANCE FROM DESIGN.** —  
 determining what will be the performance of a given

**24. Core-loss.** — The core-loss consists of hysteresis and eddy current loss in the armature teeth and core. It is best calculated by taking from the article on *Magnetic Properties of Iron* the hysteresis loss per cent at one cycle per second for the proper density and the eddy loss per cent at one cycle per second for the proper density and thickness of sheet. The values are substituted in the following formulae.

$$\text{Total loss in core} = V_c C_h f + V_c C_e f^2,$$

$$\text{Total loss in teeth} = V_t C_h f + V_t C_e f^2,$$

where

$V_c$  and  $V_t$  = volume in cubic inches of core and teeth respectively,

$C_h$  = constant from hysteresis loss curve for proper density,

$C_e$  = constant from eddy loss curve for proper density, and thickness,

$f$  = frequency.

A rough value for  $V_c$  and  $V_t$  can be conveniently obtained from the table for the calculation of the excitation, section 19. Then

$$V_t = \rho \times (\text{area path}) \times (\text{length of path}),$$

$$V_c = 2 \rho \times (\text{area path}) \times (\text{length of path}).$$

The calculation of the core-loss is one of the most unreliable and uncertain steps in the design, as the value calculated by theoretical principles is multiplied by a factor having a value between 1.5 and 3 to obtain the core-loss that will be found in the finished machine, on account of variations of flux caused by the teeth. This factor is obtained in commerce from tests on machines similar to the one being designed.

**25. Friction and Windage** can be calculated by formula for any line of similar machines but no method applicable in general case. Machines are designed so that the value of the friction loss very closely matches those given in the table in section 28. The true friction varies as the speed, and the windage as the square of the speed. In shunt machines the speed does not change much with the load so this loss may be assumed constant in this class of machines (*see Motors, Direct-current*).

**Stray Power Loss.** — This term is sometimes used to include core-loss and friction and windage.

**26. Excitation Loss or  $RI^2$  in Shunt Field.** — Since in a shunt machine the loss in the field rheostat is charged against the machine, the loss is equal to the terminal voltage multiplied by the current in the shunt. The loss is usually constant and only subject to the arbitrary variation of hand regulation.

**27.  $RI^2$  Loss in Armature Circuit,** including the brushes, series connections, varies as the square of the armature current, and, therefore, varies as the square of the load, and also irregularly to a small extent, on account of the variation of brush contact resistance with the value of the current. The temperature of the copper must also be considered. (*See Resistance and Conductance*.)

**28. Efficiency.** — The efficiency is the ratio of the output to the input, or the output and all losses. It is predetermined by estimating the value of the losses for the particular condition of load under consideration, as described in the preceding paragraphs.

If  $P$  = the output in watts and the symbols  $A$ ,  $B$ ,  $C$  and  $D$  respectively the values in *watts* of the various losses described in sections 25, 26 and 27 for the load  $P$ , then

$$\text{Per cent efficiency} = \frac{100 \times P}{P + A + B + C + D}.$$

num for that load at which the variable loss  $D$  is equal to the constant losses  $A + B + C$ . Hence the desirability of making a machine which is to be operated most of the time at this load.

**Losses and Efficiencies.**—An idea of a reasonable value for the losses of various sizes and the distribution of the losses is given in Table I. It must be remembered that the efficiency of a machine may vary throughout a wide range depending upon the load.

Friction (total), per cent	Excitation, per cent	Core-loss, per cent	Arm. $RF$ , per cent
6	6	4	4
5	4.2	3.2	3.6
4	3.6	3.0	3.4
3	3.0	2.8	3.2
2.6	2.2	2.2	3.0
2.3	2.0	1.7	2.6
2.2	1.8	1.6	2.4
2	1.6	1.4	2.0

is very important in a d-c. generator as compounding is necessary to give any desired voltage at full load. Most generators are overcompounded so that a certain portion of the load is met by a series field, which adjustment is made by trial.

The regulation of a shunt generator may be predetermined as follows: Let  $E_0$  be the total excitation in ampere-turns per pole to give the terminal voltage  $E$  at full load.  $C$  is made up of the m.m.f. to give the terminal voltage  $E$  at no-load and the m.m.f. to overcome armature reaction. Let  $E_0$  be the total excitation for an excitation  $C$  as shown by the no-load saturation curve.

$$\text{percent regulation} = 100 \frac{E_0 - E}{E}$$

The rise in temperature of the field coils was found in section 18. The temperature of the armature conductors was roughly checked by section 19. It is necessary to determine more accurately the probable rise in temperature of the armature conductors as the heat due to the core-loss and the armature windings. The following method is used to take account all the variables in this complex problem and gives very reliable results. It is indicated in Fig. 18.

The radiating surface of the core itself is taken as the sum of the surface of the two annular surfaces at the ends of the core and the two annular surfaces in the air ducts. The surface of the ducts is used since this surface is the most exposed to the external surfaces. It is assumed that the heat loss by this surface consists of the core-loss  $R_a I^2$  which occurs in the armature conductors embedded in the slots.

Fig. 18. Radiating Surface of Core

A part of the heat due to  $R_a I^2$  in the conductors flows from the copper to the slot insulation to the iron, if the temperature of the copper is higher than that of the iron. Sometimes, however, at light loads for instance, the temperature of the iron is greater than that of the copper and the flow of heat is reversed. This condition is taken care of in the following method.

The remainder of the heat due to  $R_a I^2$  is dissipated through the iron at the end connections to the surrounding air which is in motion due to the peripheral speed of the armature.

Power in watts dissipated by surface of armature core is

$$P_1 = \text{core-loss} + R_a I^2 \left( \frac{2L}{l} \right),$$

$I$  = full-load current;  $R_a$  = resistance of armature winding;  $L$  = length of core;  $l$  = mean length of armature turns.

Effective radiating surface of armature core in square inches is

$$A_1 = \pi DL + \frac{\pi}{4} (D^2 - D_2^2) (2 + d).$$

$D$  = outside diameter of armature (Fig. 15);  $D_2$  = inside diameter of core;  $d$  = number of air ducts.

Rise in temperature in  $^{\circ}\text{C}$ . of armature core above air is

$$T_1 = \frac{P_1}{A_1} t,$$

$t = 30$  for narrow, or high-speed armature; = 40 for long or low-speed armature.

Permeance of heat path from copper to iron through slot is

$$M = \frac{U_s L s}{k_1 d_1},$$

where

$U_s$  = perimeter of slot insulation;  $s$  = total number of slots;  $k_1$  = thermal conductivity of insulation;  $d_1$  = thickness of insulation in slot;  $L$  = length of core.

Heat power in watts transferred from copper to iron or vice versa is

$$Q_1 = M (T_c - T_1),$$

where

$T_c$  = rise in temperature of copper above air

Permeance of heat path from copper to air at end connections is

$$N = \frac{U_c l_c Z}{k_2 d_2 + k_3},$$

where

$U_c$  = perimeter of end connection;  $l_c$  = length of end connection;  $Z$  = number of bars or coil sides;  $k_2$  = 400 to 500;  $d_2$  = thickness of insulation at end connection;  $k_3 = \frac{170}{1 + 0.00025 V}$ ;  $V$  = periphery speed of armature, ft. per minute.

Heat power in watts transferred from copper to air by end connections is

$$Q_2 = N T_c.$$

Total power of  $R_a I^2$  in armature winding is

$$P_2 = Q_1 + Q_2 = M (T_c - T_1) + N T_c.$$

the temperature rise, in °C., of copper of con-  
air is

$$T_c = \frac{P_1 + MT_1}{M + N}$$

#### Constants and Choice of Values:

$T_1$  = temperature per watt per square inch at the surface of the  
copper in thermal potential from iron to air. It is af-  
fecting and by the length of the armature.

$T_2$  = temperature per watt per square inch for slot insulation  
thickness. For any other thickness  $d_1$ , the drop is  $k_1 d_1$ .

$T_3$  = temperature per watt per square inch for insulation on  
thickness is one inch,  $k_2 d_2$  for any thickness  $d_2$ .

$T_4$  = temperature per watt per square inch between the sur-  
face and the surrounding air. For stationary conditions  
velocity increases  $k_3$  decreases.

$T_5$  = temperature bound together in the slot but separate on leaving  
for using  $s$  and  $Z$  in the different equations.

**TEST-CURRENT MACHINES.** — Direct-current  
test machines have the following characteristics: efficiency, regulation, commu-  
tation necessary to subject a machine to actual full-load  
heating and commutation and it is desirable to do so  
but the efficiency is determined more accurately by  
a test which does not involve loading the machine.

Test machines are: (see also *Standardization Rules*.)

- (1). Efficiency, cold and hot.
- (2). Saturation curve.
- (3). Regulation.
- (4). Load run for commutation and regulation.
- (5). Commutation test.
- (6). Heating test.
- (7). Insulation test.

**Measurements** — The first measurements are made when  
the machine is at room temperature as the room, that is, after it has been  
allowed to cool depending upon its size. This is in order that the  
temperature and temperature may be accurately known.  
The field, series-field and armature winding proper are

**Winding.** — In measuring the resistance of the  
armature it is desirable to measure between two diametrically opposite  
brushes of a multiple-wound armature. The effective re-  
sistance calculated from this by the formula

$$R_a = \frac{4R'}{p^2}$$

where  $R'$  is as above, and  $p$  = number of poles.

**Winding.** — In measuring two-circuit series-drum  
armature between two commutator segments separated  
by a distance of one-half the circumference of the commutator divided by the number  
of brushes the effective resistance of the armature.

**Resistance.** — The resistance of the brushes and brush  
holders such as given in section 15 in the above section  
measured with the actual circuit is not very satisfactory.  
It is the practice to measure the resistance of the entire  
circuit to brush by the drop in potential method for several  
speeds with the armature being at rest. This is not accurate, however,  
as the contact resistance depends upon the speed.

2. **Saturation Curve.** -- The saturation curve is not of immediate importance in determining the quality of a machine but is more particularly of importance to the designing engineer. It is made by driving the armature at the rated speed and supplying current to the shunt fields from a separate source of potential. As the current in the shunt field increases the potential generated by the armature varies and this is measured by a voltmeter.

On account of the existence of the hysteresis loop (see *Magnetic Properties of Iron*) it is necessary to increase the field current gradually and never to reduce the value at any step until the maximum value has been reached. The curve is plotted with volts as ordinates, and field current or ampere turns as abscissæ and shows the typical knee curve of all saturation curves. Different curves are obtained with increasing and decreasing excitation as shown in Fig. 19.

Fig. 19. Saturation Curve

3. **Core-Loss and Friction, or Stray Power.** -- These tests are made with the same arrangement as used in determining the saturation curve, and are made at the same time. The machine to be tested is driven by a motor having a capacity about 10 per cent of the rating of the machine to be tested. All the losses and constants of this motor must be known.

First the machine under test is driven at the desired speed with no current in the fields and the power taken by the driving motor noted. The output of the driving motor is calculated and this gives the friction and core-loss of the large machine.

Then the large machine is excited and the power to drive it is determined. This power represents the core-loss plus the friction loss. Deducting the friction loss already determined, the values of the core-loss for various degrees of excitation are found. See also *Magnetic Properties of Iron*.

The combined core-loss and friction loss constitute the stray power.

4. **Load Runs.** -- The machine is run at the desired speed and the excitation adjusted to give the proper voltage at no load. The load is then added and the terminal voltage noted. If  $E_0$  = voltage at no load and  $E$  = voltage at full load, the efficiency is  $\frac{E_0 - E}{E}$ .

If the machine has not commutating poles it is necessary to make a preliminary test in order to set the brushes at that position which gives the least compromise in sparking at no load and full load. Commutation is improved by observing the action of the brushes at full load and 150 per cent load. The conclusions are a matter of judgment and experience, although the position of the brushes has been arbitrarily agreed upon and are represented in a series of pictures.

5. **Heat Runs** are made by operating the machine at full load for a certain period of time until the temperatures of the various parts that can be noted and the operation have become constant. The greater the capacity of the machine the longer will be the time necessary.

**Dead-load and Pumping-back Methods.** -- Heat runs may be made either by the "Dead Load" method in which a resistance load, such as a rheostat, is connected to the terminals and full rated load power is required to drive the machine; or by the Hopkinson or "Pumping-back" method in which two machines having similar characteristics are run together, one a generator to supply electrical power to the motor which in turn drives the generator by means of a belt or similar mechanical connection. For this test a "source of supply" is required which may consist of a source of either electrical

ount of power required is from 10 to 20 per cent machines. The connections are shown in Fig. 20, Fig. 21 for mechanical loss supply.

her resistance metal are then connected in multiple shunting current from the series field the voltage s desired. This shunt resistance is then made up cted in circuit. Before making the no-load adjust- cite the shunt field for a moment in order to over o section on *Parallel Operation* below.

fter the heat runs it is customary to apply a high- on of the machine. This consists of applying an each electrical circuit and the frame of the machine of the potential depends upon the capacity and nder test and is definitely specified in the Stand- . E. (q. v.).

**W AND PERFORMANCE.** — In the tables on the essential data including mechanical, electrical of four examples of direct-current machines. In

these data are included all the factors necessary to determine the efficiency, commutation and heating of the machines. Dimensions and weights in pounds. Performance data are deduced from tests.

**SERIES ARC-LIGHT GENERATORS.** — These machines are designed to give a constant value of current in the external circuit irrespective of resistance or counter e.m.f. in that circuit. This is accomplished by adjusting the voltage impressed on the external circuit to decrease whenever there is a tendency of the current to increase. The load usually consists of (20 to 50) of arc lamps connected in series, each taking about 40 volts. Each lamp requires the same value of current and the total voltage is proportional to the number of lamps in use. If a lamp is no longer needed it is shunted by a switch and the current in the remainder of the lamps remains constant because the generator automatically reduces the voltage supplied. Regulation of the current is obtained by two or more of the following methods: (1) high armature reaction which tends to weaken the field whenever the current increases; (2) movable brushes to vary the number of turns in series; (3) a series field arranged so that turns may be shunted, shorted or cut out; and (4) a high degree of saturation in the magnetic circuit so that the flux changes very slightly for considerable change of m.m.f.

The pole face density is usually quite high and the path of the flux is of high reluctance, whereas the path of the armature flux is of low reluctance; thus there is much field distortion. The machines are usually wound for 4000 volts. The *distorting* effect of armature reaction is usually taken care of by taking care of sudden and small variations of the load, and large variations of the load are taken care of either by moving the brushes to a new position giving either a lower or higher voltage, or by commutating some of the turns of the series field.

**Brush Arc Machine.** — This was the first arc-light machine to be put out. It consists of a ring armature having a winding of the open-circuit type. There are a number of spool-wound coils on the armature, diametrically opposite coils being connected in series to an independent pair of commutator segments. The brushes make a series connection of the various groups of coils, those of highest e.m.f. being connected in series, those of medium e.m.f. being shunted, and those of low e.m.f. being left out of circuit. The numerous field turns are on both sides of the ring armature. The two poles facing each other are of the same polarity so that the flux flows along the ring of the armature from one pole to the next pole on the same side of the ring. Regulation is obtained by shunting field turns and shifting the brushes for good commutation. An oil pump is used as a regulator to move the handle of the field regulator and to move the brushes.

**Thomson-Houston Arc Dynamo.** — This machine contains a Y-shaped armature with a three-part open-circuit winding. The three parts are being spaced at 120° on a ring armature and connected in "Y," the three parts going to the segments of a three-part commutator. The commutator segments are spaced between segments and a jet of air to blow out any arcs between segments. There are four brushes on the commutator, connected in series. At some part of each revolution two coils are in multiple, at other parts in series. A relay moves the brushes so that as the load increases the negative brushes move farther apart thus giving more voltage. As the load of a pair moves forward the other moves backward thus keeping them equidistant with respect to the neutral axis. The field structure is of a hollow cylindrical construction.

**Wood Arc-light Machine.** — This generator has a closed-circuit type of ring armature with a commutator having a large number of segments.

ing the brushes so as to vary the voltage available and the armature reaction balancing the field m.m.f.

**GENERATORS.**—This type of machine is also sometimes formerly incorrectly called uni-polar. Its method is based on the principle of the Faraday disk, which consisted of a metal disk rotating on an axis and projecting between the poles of a magnet. An e.m.f. is set up between the axis and the periphery. If brushes bearing on these two parts are connected to an external circuit, current will flow. The peculiar characteristic of a homopolar generator is that the conductor always cuts the flux in the same direction, and the induced e.m.f. is always in the same direction and is not reversed. Thus no commutator is

needed. The absence of a commutator is the feature which makes the homopolar generator. The homopolar generator presents many difficulties in high-speed applications, especially when driven by steam turbines. It is for this application that the design of a successful homopolar machine have been directed. In such machines, collector rings with brushes are used to collect the current from the conductors. These collector rings, however, present difficulties in design and operation on account of the high peripheral speed.

The rings are subject to a considerable centrifugal force, and the tendency of the current to arc between the brush and the collector ring is increased by the high rubbing speed.

The output of such a machine is not only unidirectional as in all other types of generators, but is really constant. But since there can be only a few conductors, the voltage generated is very low. The voltage generated is

$$E = Blv \times 10^{-8}$$

where  $B$  = magnetic flux density in gauss per sq. cm.,  $l$  = length of conductor in cm.,  $v$  = velocity in m. per sec., expressed,

$$E = \frac{NZ\phi 10^{-8}}{60} \text{ volts,}$$

where  $N$  = revolutions per minute,  $Z$  = conductors in series,  $\phi$  = total flux

per pole. — There are two types of homopolar machines, the radial type (Fig. 22) is like the Faraday disc and

Homopolar

Fig. 23. Axial Type of Homopolar Generator

consists of a disc revolving between the two poles of a cylindrical field. Brushes bear on the outer rim and the shaft to collect the current. The armature may be made of steel to reduce the reluctance of the magnetic path. The voltage of such a machine is limited to 10 or 15 volts, but the current may be very large. A variation of this type has two discs on the same shaft and the magnetic path so arranged that the voltage of the two discs may be added in series by brushes bearing on the peripheries of the two discs. The machine (Fig. 23) consists of a cylindrical steel armature with copper bars in the slots, the whole revolving in a cylindrical field so arranged that the magnetic flux is directed outward from the armature in a radial direction at all points. The stationary conductors on the armature are connected to slip-rings at both ends, and the brushes and stationary conductors, these conductors are connected to the brushes. The voltage of such a machine may be from 40 to 50 volts per conductor.

**Data on Large Axial Type Machine.** — In the *Trans. A.I.E.E.*, Noeggerath describes a machine of the axial type rated at 300 kw. for 3000 r.p.m. The armature has 12 conductors connected in series for each pole. The diameter of the armature is 19 inches and the length 12 inches. The peripheral velocity is 15,000 ft. per min. The armature is of cast steel and has cast steel collector-rings on it. The stationary conductors connected to the collector-rings together are placed in the face of the pole and thus they may be used to balance the armature reaction.

**Excitation.** — The armature reaction of such machines is very high and is not only a distorting effect. However, it weakens the field as the cross section of the field is weakened on one part more than it strengthens another due to saturation. A proper arrangement of the movable connections between the collector-rings and stationary conductors a m.m.f. may be set up which will strengthen the field and thus the machine may be compounded. These machines may be self-exciting but the resistance of the shunt fields must be very low in order that the machine may pick up on starting as the resistance in the brush contact is high. The drop in voltage in each brush contact is about 0.8 volt at full load but is higher before the current flows. It sometimes requires from 1.5 to 2 times the normal voltage of brush contact to start the current.

**Losses.** — Such a machine as described above has an efficiency of approximately 90 per cent at full load. The losses are made up principally of  $I^2R$  in the brushes. The field  $I^2R$  is low as the air gap is small for mechanical considerations. The armature  $I^2R$  is almost negligible due to the small current. The eddy losses are low if the flux density is constant in one zone of the armature but the density may vary along an element of the cylinder. The weight of the machine is about the same as for the usual d-c. machine. The proportion of copper is much lower than in the usual machines.

**SPECIFICATIONS FOR D-C. GENERATORS.** — The following memoranda are intended to assist in writing specifications. See also *Specifications*.

**Principal Characteristics and Conditions of Service.** — Service to be rendered, it is to be used, such as railway, lighting, etc. Voltage. Rated output in watts. Speed.

**Style and Description, Details of Construction.** — Type, whether simple or compound wound. Whether interpole. Details of speed and of prime mover and how generator is connected to prime mover, e.g. belt driven by steam turbine, reciprocating engine, water wheel, water wheel, gas engine, oil engine, etc., with vertical or horizontal shaft. If field is to be supplied, its characteristics, including the effect upon the

of all steps: accessibility of armature. If belt driven,

by Other Contractors. — See *Generators, Alternating-*  
*ding.*

**Tests.** — (See *Standardisation Rules of the A.I.E.E.*),  
at which ratings are to be based. Details of overload  
 $\frac{1}{4}$ ,  $\frac{1}{2}$ ,  $\frac{3}{4}$ , 1, and  $1\frac{1}{4}$  loads. (Whether rheostat losses  
rating efficiencies.) High potential tests of insulation.  
Effect of moisture upon insulation. When run at  
the load may be varied from zero to a stated per cent  
causing more than a stated variation of voltage, the field  
constant.

— In installing a d-c. machine the following precautions

with foundations the foundation bolts must be pro-  
vided in drawings.

Must be properly cleaned before being filled with oil.

Must be properly centered so that the air gap is correct at  
all points. Gages are used to measure the gap. The magnet frame  
must be properly connected. Test for polarity with a  
battery.

Must be properly connected. Test for polarity with a  
battery. Make sure that no field coils are reversed. For a self-  
excited machine is one particular connection of the field to the armature  
excitation.

Commutator must be smooth and polished; use sandpaper to polish  
and use emery cloth.

Brushes must be properly and accurately spaced around the com-  
mutator. Brushes must be sandpapered and fitted to the curvature of the com-  
mutator. The pressure on the brushes must be adjusted to the correct value  
pounds per square inch of contact surface.

Commutator must be thoroughly dried out by heating and the insulation

When starting up a single generator it is sometimes necessary  
to start by separately exciting the shunt fields for a moment to

enable the machine to "pick up" or generate voltage by self-excitation it  
is necessary to short-circuit most of the resistance of the regulating  
circuit with the shunt field. If the total resistance of the  
circuit is less than a certain critical value the machine will not "pick  
up" and the machine is allowed to stop.

— In order to operate a power station under economical  
conditions it is necessary to have a number of machines whose aggregate capacity  
will meet the maximum demand on the station. As the demand varies the  
operation is adjusted so that the machines running are  
at their rating, and, therefore, at a good efficiency.

**Parallel Operation.** — In order to operate shunt generators in parallel,  
they must be connected to the same bus-bars, it is only necessary to adjust them all to the  
same voltage, connect them to the bus-bars, and adjust the divi-  
dion of the load between the machines by weakening the field of the underloaded machine if the voltage

of the bus-bars is high, weaken the field  
of the underloaded machine.

**Compound Generators, Equalizer Connection.** — In order to connect compound-wound machines in parallel it is necessary to provide an equalizer connection which makes a common connection on all the machines at between the armature and the series field as shown in Fig. 24.

The function of the equalizer is to divide the load current at all times in the proper proportion between the series fields of the different generators. This prevents the machines from acting as series generators or differential motors which would cause short-circuits.

For compound-wound machines to operate successfully in multiple all machines connected to one set of bus-bars must have the same amount of compounding as well as the same voltage at no load. Due to saturation in the circuit it is not always possible to make the compounding curve a straight line, i.e., the increase in voltage directly proportional to the load. It is, therefore, necessary to investigate the compounding curves of machines before they are operated in parallel. With unlike compounding curves one machine may become overloaded while another is under-loaded, unless the field current of the overloaded machine is adjusted.

In connecting a machine in parallel with those in operation it is necessary to see that it has the proper polarity and voltage, that the equalizer circuit

Fig. 24. Parallel Operation of Compound-wound Generators

Fig. 25. Data on High-speed D.C. Machines

and that the switches are closed in the order 1, 2, 3, as shown in Fig. 24. If the other order is used the effect is the same as having no equalizer.

In shutting down one machine switch No. 3 must be opened first, then No. 2 and No. 1.

**COST, WEIGHT AND SPEED (Pre-war prices).** — In Figs. 26 and 27 will be found the weight and cost per kilowatt of direct-current generators for usual or standard speeds. Fig. 25 gives the weight and cost of high-speed machines for the suitable speeds shown by the curve. Fig. 28 gives the same information for a line of moderate-speed machines, generally

\* 1932 prices about 50 per cent higher than given by this curve.

er a line of slow-speed generators designed for direct con-  
es.

**GENERATORS, STATIC.** — (See also *Generators, Alternating-current; Dyn.*) In electro-therapeutic and X-ray work a unidirectional high-frequency current is desired and is often obtained by a kind of electric generator called a static generator. There are two types of static generators available for the purpose, the frictional machine and the influence machine.

**Frictional Machine.** — In the frictional machine two dissimilar substances are rubbed together in some form of rotating apparatus as shown in Fig. 1. A rotating glass plate *A* is rubbed on both sides by *BB* by two pieces of leather which are used and covered with the amalgam  $Zn, 1 Sn, 2 Hg$ . The glass is electrified positively and the charge is drawn off by the metal arcs *CC* which almost touch the *leathers*. Two silk aprons *DD* cover the glass between the rubbers and the metal points, to prevent the escape of the charge into the air. The rubbers are connected to ground to remove the negative charge which accumulates upon them.

Fig. 1. Frictional Machine

**Influence Machine.** — The influence machine generates an e.m.f. by electrostatic induction, the principle of the action being clearly shown (see Fig. 2) in a machine invented by G. Belli in 1831. Two spheres or disks *AA*.

are mounted on carriers and normally insulated from each other, are rotated about the shaft *B*. The two fixed plates *CC* are charged initially from some external source. When the carriers *AA* strike the position shown in the figure, a momentary connection is made to the neutralizing wire *DD* at the spring contacts *DD*. As a result of this connection between *A* and *A*, the carriers are

Fig. 2. Influence Machine

charged by induction, the charge on each being opposite to that of the adjacent plate. When the carriers rotate still further, the connections at *DD* are broken and the charges induced on the carriers become isolated. When the carriers are rotated through half a revolution from the position shown, they strike the rings *FF* and add their charges to the field plates *CC*.

**Wimshurst Machine.** — Many forms of influence machines based upon the above principles have been devised. The most successful designs were made by Repler, Holtz and Wimshurst. The Wimshurst machine, shown in Fig. 3, has exceeded most of the other forms because of its self-exciting powers and stability for work in all conditions of atmosphere. Two glass disks, *A* and *B*, are rotated close together and in opposite directions. A certain number of tin-foil carriers *CCC*, are mounted upon the outside surface of each plate. Neutralizing conductors *DD* for each disk are placed at right angles to each other. The collecting combs *EE* are connected to a condenser *F* and a spark gap *G* across which the discharge takes place. If two diametrically opposite

carriers on the back plate are charged positively and negatively respectively opposite charges will be induced upon the adjacent carriers on the front plate if they are connected by the neutralizing wire. The induced charges are isolated when this connection is broken and are drawn off at the collecting combs *EE*. In the Wimshurst machine induced charges in moving from the point of electrification to the collecting combs also serve to induce other charges on the back plate.

After a few revolutions of the disks, half of the carriers on each plate are charged negatively and half positively, giving a machine of reliable service and high power. Unlike the Holtz machine the Wimshurst machine does not reverse its polarity when the distance between the terminals is made greater than the sparking distance. Large influence machines are constructed with several plates revolving in opposite directions and connected in pairs, the whole being contained in a glass case to protect the plates from dust. A two-plate Wimshurst machine gives a spark of eight inches and a twelve-plate machine will give a spark of 13½ inches. The plates in these machines are approximately 30 inches in diameter and the machines give 6 sparks for each of the disks.

Fig. 3. Wimshurst Machine.

**GROUND CONNECTIONS.** — (See also *Grounding of Electric Circuits.*) A ground connection is a conductor buried in the earth and connected by conductors to other conductors or apparatus which are to be maintained at a certain potential, irrespective of the current which may flow through it. Usually a circuit is not grounded except at such points that under normal conditions no appreciable current flows to ground. A current may, however, be established through a ground connection due (1) to a lightning discharge, (2) to an accidental grounding of a live wire of a grounded circuit, and (3) to a cross between the grounded circuit and a high voltage ungrounded circuit; in the last instance the current through the ground connection is only the relatively small charging current between the other wires of the high voltage system and the ground (see *Capacity and Charging Current*).

**USE OF GROUND CONNECTIONS.** — Ground connections are used for the following purposes: (1) for lightning arresters, to afford a path to ground for the lightning; (2) for lightning rods on buildings, for the same purpose; (3) for steel transmission poles to give the current a short circuit to ground in case of insulator failure. Also as a lightning protection; (4) to bring the various points of circuits to ground potential and thus reduce the potential stresses of the system and minimize the danger of accident from shock; (5) to ground transformer cases, instrument cases, conduits, etc. to ground potential and thereby reduce the danger from shock; (6) to obtain an earth return for telegraph circuits; (7) for wireless telegraph systems to obtain the use of the earth's electrostatic capacity.

**GROUNDING TO CONDUCTORS USED FOR OTHER PURPOSES.** — Where an extensive system of water pipes buried in the earth is available, a satisfactory ground connection can be made directly to the pipes. Gas pipes are not suitable for ground connections, as in case of broken joints the resulting arc might ignite the escaping gas. Steam heat pipes are not insulated (and therefore partially electrically insulated) from the earth. Where there are two ground connections, one to an electric railway track and the other to a water pipe, there is danger that railway current may thereby be introduced into the water piping system and produce electrolysis. Sheaths of cables are not good ground as the cables might be injured by the currents in their sheaths, either from electrolysis or unforeseen heating. In fact, cable sheaths, like other buried conductors, have a tendency to collect stray currents from electric railways and special ground connections sometimes have to be made to permit these currents to escape without producing electrolysis. Steel frames of buildings present only a limited surface to ground at the foundations and are therefore only good when the current to be discharged will be proportionally small.

**Connections to Piping System.** — The National Electrical Code contains the following requirements:

*Size of Ground Wires.* — Not to be smaller than No. 6 A.W.G. copper for lightning arresters and must be large enough to carry current caused by or following discharge of arrester (Rule 15A1); not to be smaller than No. 8 A.W.G. for direct-current systems and must have at least one-fifth the carrying capacity of the grounded conductor, and not to be smaller than No. 8 A.W.G. for alternating-current systems but must have at least one-fifth the carrying capacity of the wire to which it is attached, except that it need not be larger than No. 0 A.W.G. (Rule A4).

*Method of Making Ground Connections.* — In connecting a ground wire to a piping system, the wire should be sweated into a lug attached to an approved clamp, and the clamp firmly bolted to the water pipe after all rust and scale

have been removed; or be soldered into a brass plug and the plug screw a pipe or pipe fitting.

**GROUNDING TO SPECIAL PLATES, PIPES, ETC.** — When buried conductors are not already available, direct connection to the earth may be made (1) by burying a plate in the earth, (2) by burying a wire in the earth, or (3) by driving a pipe vertically into the earth. The first form of ground connection is now generally accepted as the best. The methods of direct grounding are described in detail in the section below.

**Factors Affecting the Impedance of Ground Connection.** The impedance opposing the flow of current into the ground through a ground connection depends (1) upon the extent of metal surface in contact with the earth, (2) the thoroughness of this contact, (3) the wetness of the earth, (4) the distance between this ground connection and the ground connections (if any \*) to which the current leaves the earth.

The effect of the distance upon the impedance between the electrodes is the most important one, but is frequently overlooked. If the electrodes are close together, the impedance will be low on account of the shortness of the current path. If the distance between electrodes be increased, the impedance will be increased until a certain point is reached, after which it will steadily decrease on account of the increase in the cross-sectional area of the earth through which the current flows. Experiments by the Cunliffes (*Jour. I.E.E.*, 1909, Vol. 43, p. 449) showed that the "impedance" (probably meaning impedance) reached a maximum when the plates were about 25 feet apart, the decrease in "resistance" being 100 ohms per ohm for smaller or greater distances, as shown in Fig. 1. A curve by Creighton (*G. E. Rev.*, 1912, Vol. 15, p. 60) shows the resistance between grounds at various distances apart, the maximum resistance being maintained at 25 feet.

Fig. 1

Fig. 2

**Definition of the Resistance and Impedance of a Single Ground Connection.** — If the distance between ground connections be fixed and the potential from one of them  $G_1$  and a point  $P$  between them be plotted, the distance of  $P$  from  $G_1$  a curve such as  $G_1DA$ , Fig. 2, will be obtained. If two ground connections  $G_1$  and  $G_2$  are similar. If, on the other hand, the connection  $G_1$  has very much more perfect and extensive contact with the earth, the curve of potential drop will have the shape  $G_1DB$ . Both curves have the peculiarity of being steep near the electrodes and of becoming flat between them, indicating that the greater part of the resistance occurs near the electrodes.

\* The circuit may be completed by a displacement current, through the air, surface of the earth.

but the current is restricted to a limited area, practically no drop occurring as the current spreads out.

The impedance of the ground connection  $G_1$  is then defined as the ratio of the potential drop  $CD$ , to the current entering the ground at  $G_1$ , and similarly for the ground connection  $G_2$ . The resistance may be approximated by measuring impedance at different frequencies, and by extrapolation, finding the impedance at zero frequency. This will be the resistance.

**Resistance of Some Typical Ground Connections.** — The resistance of rod connections varies so greatly with the condition and nature of the soil, that data on resistance have only local application. The following tests are presented merely to give a general idea of the results which are obtained in practice.

Locality	Time of year	Description of soil	Type of ground connection	Dimensions	Depth	Ohms
Banc.	Feb.-June	Surface loam	Plate	1 ft. X 1 ft.	ft.	1940
	Feb.-June	Moist black loam	Plate	6 ft. X 2 ft. 3 in.	6	113
	Feb.-June	River bottom	Plate	1 ft. X 1 ft.	..	132
	Feb.-June	Gravelly soil	Pipe	1½ in.	5	630
	Feb.-June	Gravelly soil	30 Pipes	1½ in. each	5	13
	Feb.-June	Swampy soil	7 Pipes	1½ in. each	5	15
Del Mar.	Summer	Rock & loam fill	Plate	15 in. X 15 in.	6	155
Hydes.	Aug.-Sept.	Clay loam	Pipe	2½ in.	3¾	26.1
Hydes.	Feb.-Mch.	Clay loam	Pipe	2½ in.	3¾	120
Hydes.	June-July	Clay loam	Pipe	2½ in.	3.1	35.4
	Mch.-Apr.	Clay loam	Pipe	2½ in.	3.1	240

E. E. F. Creighton (*G. E. Review*, 1912, Vol. 15, p. 67) says: "If an iron pipe 1½ inch in diameter is driven into normally moist earth to a depth of 6 or 8 feet, it will usually have a resistance of about 15 ohms. Eight ohms may be considered unusually low, while dry soils may give a resistance of 56 ohms and upwards." Creighton also states that after a depth of several feet in the conducting stratum has been reached, each additional foot decreases the total resistance by the factor  $d/2$  where  $d$  is the depth in feet.

**DESIGN OF GROUND CONNECTIONS.** — It is as a rule impracticable to install a ground connection of sufficiently low conductivity to allow the passage of the maximum current it may have to carry without producing a considerable rise of voltage. The conductivity which a ground connection should have is therefore largely a matter of experience and judgment rather than a matter of exact calculation. Cheapness and durability usually determine the material, usually iron or copper, and the thickness.

**Copper Plates.** — Formerly the most common form of ground connection consisted of a copper plate embedded in charcoal or coke in moist earth. The use of coke is questionable, for the reason that the sulphur in the coke is likely to corrode the copper plate and thus increase its resistance. Some engineers are of the opinion that neither charcoal nor coke is of any particular use in connection with a ground plate. The corrosion of copper ground plates is greatly reduced by coating with tin. As the conductance of a ground connection is

not proportional to the area of the metal plate, the use of a single plate is an uneconomical method of obtaining a low resistance.

**Copper Wire or Ribbon.** — The wire or ribbon has the advantage of low resistance than a plate for the same area. The wire has the further advantage that no special material or connection is required. The wire may be used in a straight line or coiled with turns wide apart into a plane spiral. This form is sometimes made by wrapping a number of turns of wire around the butt of a pole before setting it.

**Pipes Driven into the Ground.** — The driven pipe or rod is probably the best of all forms of direct ground connections. The pipe is usually and is often galvanized or sherardized, from  $\frac{3}{8}$  inch to 2 inches in nominal size and 6 feet or more into the moistest ground available. The diameter of a pipe has little effect upon its earth resistance; thus a pipe 2 inches in diameter has an earth resistance only 6 to 12 per cent less than a pipe 1 inch in diameter (Creighton, *G. E. Rev.*, 1912, Vol. 15, p. 14). To facilitate driving, the pipe is sometimes provided with a pointed casting at the lower end and a cap at the upper end. The pipe has the advantage that it is cheap to install, as it is dug, and being driven vertically, it can tap any conducting stratum of soil which is practically accessible. It is highly efficient as regards current capacity per square foot of surface exposed to the earth, and while the resistance of a single pipe will exceed that of a large plate, a higher and more permanent conductivity can be obtained from several pipes driven at some distance from each other and connected in multiple, than from an equal expenditure in one single large ground plate. Ground pipes or plates in multiple should be driven less than 6 feet, and preferably 10 feet, apart, in order to avoid superimposing two zones of high current density.

If the ground available is naturally dry the conductivity may be increased by cupping out the soil around the pipe at the surface and adding a few pounds of salt and water. A neater form of earth unit is shown in Fig. 3. A receptacle of metal or earthenware of any available diameter is set around the pipe at the surface of the ground and covered by a lid. This receptacle will hold the salt. Its advantages lie in the easy construction of the connection and protection of surrounding vegetation from the saline water.

#### Pipe Grounds for Lightning Arresters.

— The General Electric Company recommends a large number of grounds at each installation. These numerous ground connections are joined together by a copper connection. It sometimes happens that a good ground cannot be conveniently made near the arrester, or that a better one can be made at a more distant point. In this case it is recommended that the principal ground be made at the more distant point, but that a ground of some sort, the best possible under the conditions, be made directly underneath the arrester.

**Connections to Ground Plates and Pipes.** — The wire connecting the lightning apparatus to be grounded to the buried conductor should lead directly to the ground with as few bends as possible; this is particularly important in the case of lightning arresters, in which case a flat strip is also better than a round wire. All exposed joints and those buried in the ground should be made in such a way that they will not rust off. The buried connection from a ground plate to the surface should be so protected that it will not rust off or be cut off by

Fig. 3.

connections are made for other purposes. It is also necessary that the connections be protected from mechanical injury and theft, from the surface of the ground above the level at which it can be reached. To insure reliability, connections should as far as possible be made so that their continuity can be determined by inspection.

**TESTS OF GROUND CONNECTIONS.** — Ground connections should frequently be tested to determine their continuity and occasionally to determine their impedance. Alternating current should be used, in order to avoid the effects of polarization. In order to pass a current through a ground connection it is necessary to have a second connection in order to complete the circuit. Where a large water-piping system is available for the return connection, an approximate measure of the resistance can be obtained by passing a current from the ground connection to an accessible part of the piping, say a hydrant, and computing the resistance by dividing the volts by the amperes. The resistance thus obtained includes both the resistance to be measured and that of the connection through the piping system. As the latter is probably much smaller and may be insignificant, the result gives an approximate idea of the resistance and locates a discontinuity as an infinite resistance, that is, no current flowing. Where there are two similar grounds, current may be passed from one to another and the sum of the two resistances, or the average resistance, obtained.

When a more accurate determination of the individual resistances of two or more ground connections is desired, the connections shown in Fig. 4 may be employed and a curve obtained by test, similar to that shown in Fig. 2. The apparatus required comprises a source of alternating current, a rod *P* which may be driven into the earth, a high resistance wire *BD* stretched between the two ground connections *G*<sub>1</sub> and *G*<sub>2</sub>, an ammeter *A* and a telephone receiver *T*. The contact *C* is slid along the resistance wire until the telephone receiver is dead. The drop of potential between *G*<sub>1</sub> and the rod is then the same as between *C* and the contact *C*. The drop between *G*<sub>1</sub> and *P* is therefore equal to

$$\frac{(\text{length of wire } BC)}{(\text{length of wire } BD)} \times (\text{total drop from } G_1 \text{ to } G_2).$$

By taking a series of observations with *P* driven into the ground at various points the curve of potential drop is readily plotted and the resistance of each ground connection, as defined above, readily obtained.

**CARE OF GROUND PLATES AND PIPES.** — The greatest trouble with ground plates and pipes arises from electrolysis, and periodic resistance measurements should be made as described above. When a ground connection shows an abnormally high resistance, it is usual to supplement it with a new ground connection, as it seldom pays to remove the old ones. Ground connections deteriorate rapidly if equipped with salt boxes; but even under the worst conditions they are likely to last many years. Practically no accurate measurements of the resistance of ground connections were made until quite recently, so that little is known about their life performance. J. L. R. Hayden cites the case of some pipe grounds which maintained the same average resistance for three years.

**SPECIFICATIONS FOR GROUND PIPES AND PLATES.** — (See also *side on Specifications*.) In the case of ground plates, the following data

Fig. 4.

should be specified: Material of plate (usually copper); size of plate; thickness; depth at which the plate shall be buried; amount of char and above it; method of connecting the plate to its cable or wire (soldered and bolted); whether the plate shall also be connected to the ground and if so, how.

In the case of pipe ground connections, the following data should be specified: Diameter of pipe; whether galvanized, sherardized, etc.; depth to which the pipe shall be driven; method of finishing the top of the pipe; height of the pipe shall project above the ground; whether the pipe shall be connected to track rails and if so, how.

**GROUND DETECTORS AND ARCING-GROUND SUPPRESSORS.** — A ground detector is a device for indicating an accidental ground on transmission line; an arcing-ground suppressor is an arrangement of switches and relays by means of which an arc tending to maintain an accidental ground automatically extinguished.

**GROUND DETECTORS FOR NORMALLY UNGROUNDED SYSTEMS.** — On ungrounded two-wire direct-current systems a voltmeter of the central-zero type connected between the ground and the middle point of a resistance joining the two line wires serves as a satisfactory ground detector. The direction of the deflection will indicate on which wire the ground has taken place, and the magnitude will indicate the nature of the ground. For alternating-current circuits, this method is unsatisfactory on account of capacity effects and also because of the higher voltages commonly involved.

**Electrostatic Ground Detectors.** — For single-phase ungrounded systems the simplest form of ground detector consists of two electrostatic voltmeters, each connected between one line wire and the earth. A ground on either wire causes an inequality in the readings of the two meters.

The more common form of ground detector operates as an electrostatic differential voltmeter. Fig. 1 shows diagrammatically the arrangement for a single-phase instrument. The movable vane  $V$  is connected to the earth, the fixed plates  $S_1$  and  $S_2$  are connected one to each of the two mains. Vane  $V$  will be equally attracted by the two plates unless the insulation resistances of the two line wires to ground are not equal, but will deflect from its normal position to one side or the other when a ground occurs.

The three-phase electrostatic ground detector for ungrounded circuits is made in two principal forms. One form consists of three separate elements, each similar to that used in the single-phase instrument, all three elements being in one case but having individual scales. Another form consists of a movable spherical vane, connected to the earth, and three fixed vanes, each of which is connected to one line wire. The movable vane in its normal position is equally distant from each one of the fixed vanes, but, in case of a ground on one line wire, it moves away from the fixed vane which is connected to the line wire on which the ground occurs. The principal parts of this instrument are clearly visible through the glass front of the instrument cover; hence no pointer and scale are needed. Two single-phase detectors will work satisfactorily on three-phase circuits, if the junction point of the two instruments is connected through a condenser to the third line wire.

Fig. 1. Single-phase Electrostatic Ground Detector

**Voltage Range.** — Commercial sizes of electrostatic ground detectors range from 650 volts to 22,000 volts for single-phase circuits, and from 1150 volts to 22,000 volts for three-phase circuits.

**Connections.** — Electrostatic ground detectors are usually not connected directly to the line wires, especially if the voltage is above 3300. Some types are furnished with special terminal studs containing high-resistance rods of graphite through which the instrument is connected to the line wires. Other types are connected to the circuit through condensers, commonly of tubular form. Although, in this case, the condensers practically insulate the instrument from the line, the leads connecting the detector and the condensers must be treated as high-tension conductors, i.e., they should be properly separated and

far enough from neighboring metal in order that disturbing capacity effect not be introduced. Therefore, the leads should be fairly short and must be enclosed in metal conduit.

**GROUND DETECTORS FOR NORMALLY GROUNDED TEMS.** — The methods outlined above, depending on the variable potential difference between mains and earth, do not apply to earthed system three-wire circuits with grounded neutral, or four-wire, three-phase circuit grounded neutral. The most usual method for earthed circuits is to connect an ammeter in the earth circuit between the earth plate and the line; hence any leakage current will have to pass through the ammeter. A low-range instrument is desired if slight grounds are to be detected. In order to protect the instrument from excessive currents, an arrangement may be made by which the instrument is short-circuited as soon as the current reaches a certain value, or a resistance may be inserted in the circuit to reduce the current to a safe value. By the second method a short-circuit due to a ground fault can be suppressed without interruption of service on the line in question. At the same time, however, the pressure on the other line wires with respect to earth will be raised to a higher value.

**ARCING-GROUND SUPPRESSORS.** — Interruptions to service and damage to apparatus are frequently caused by grounds which tend to produce arcing, due to the burning away of the conductor. Arcs of this kind may be intermittent, due, for example, to the swinging of the conductor back and forth. Arcing grounds may give rise to disastrous surges in the system. The ground suppressor, placed on the main bus at the generating station, prevents arcs to ground on a line wire by automatically grounding that line wire at the power station, thereby short-circuiting the arc. It is obvious, from the construction of the device, that it cannot be used on earthed systems.

A three-phase arcing-ground suppressor consists of the following parts:

(a) Three single-pole, motor-operated, oil circuit-breakers each connected between one phase of the power house main bus to the ground. These circuit-breakers are provided with interlocking relays, each of which has three contacts, which closes the tripping circuit of its own oil circuit-breaker while the other two open the tripping circuits of the other two circuit-breakers. Hence it is impossible to have more than one oil circuit-breaker closed at the same time. For use with overhead systems each circuit-breaker is equipped with a second-stroke lock device described later. The oil circuit-breakers are protected with the usual remote-control switches with red and green lights to be located on the station switchboard.

(b) Three single-pole, single-throw disconnecting switches for disconnecting the oil circuit-breakers.

(c) An electromagnetic selective relay for detecting the ground fault and operating the proper oil circuit-breaker. This selective relay is connected to the main bus through three Y-connected transformers of which the neutral of the high-tension side is grounded.

**Operation when used with Overhead Lines.** — The arcing-ground suppressor is suitable for overhead lines only when metal towers or poles of relatively low resistance are used, as on a wooden pole line the resistance of the poles is liable to prevent sufficient current flowing to ground to reduce the potential sufficiently to operate the phase selective relay.

The operation is as follows: If a ground occurs on one wire in the system, the unbalancing in the potentials of the grounded Y-connected transformers causes the phase selective relay to be operated in such a way that the proper interlocking relay is thereby energized. This closes the corresponding oil circuit-breaker.

the wire, on which the arcing ground has occurred,

Thus the arcing ground is almost instantly cleared, and opens automatically after a fractional part of a second, and the normal state of insulation of the line is reestablished. Whenever an arc is established, oscillations are set up, the duration of which depends on the resistance in the circuit (*see Transmission Lines*). To avoid dangers from such oscillations, a damping resistance is thrown in series before the switch rod closes the main contact after it has opened the main contact.

When permanently broken down by the arc, the line potential is brought to ground as soon as the metallic ground through the second-stroke lock device then operates; it locks the switch so that the second closing of the switch occurs immediately. In this case the system remains grounded on the second stroke to operate with the metallic ground. After the second stroke the oil switch is opened by the attendant.

**with Underground Cables.** — When the arcing-ground detector is used for the protection of cables, the second-stroke lock device is desirable for the oil circuit-breaker not to be opened until the feeder has been cleared, the reason being that the insulation of a conductor from the sheath is usually so small that a single arcing-ground produces a permanent fault, and the normal insulation is insufficient to re-establish an arc, even if it were automatically. The arcing-ground suppressor on cable systems, therefore, is desirable to a puncture in the cable and prevents the trouble which is caused by dangerous high-frequency surges due to arcing-ground. It is used to clear short-circuits between line wires.

**Arcing-ground Suppressor.** — The best location for the arcing-ground detector is at the power house, and directly connected to the main bus. It may be under the immediate observation of the station attendant, where the current supply is available, and where the more important case of grounds are usually performed.

A single-phase electrostatic ground detector costs from \$30 to \$60, and a three-phase electrostatic ground detector from \$100 to \$200. A three-phase arcing-ground suppressor for voltages up to 100,000 volts costs approximately from \$2200 to \$6000.

**GROUNDING OF ELECTRIC CIRCUITS.** — (See also *Ge Alternating-current; Ground Connections; Transformers.*) Some electric are operated insulated, that is with no intentional electrical connection any point of the circuit to the ground, while others are grounded by more conductors provided for the purpose.

Among the considerations influencing the decision of this point are: (1) of shock to persons touching the circuit; (2) danger of fire from escape of current, spark, or arc; (3) elimination of electrical oscillations set up in due to the sudden changes in current resulting from the making and breaking of an arc, usually to ground, usually referred to as an "arcing ground"; (4) grounds may give abnormal voltages particularly on a-c. circuits where an arc forms and is extinguished twice every cycle; (5) decreased strain on insulation in case of accidental ground; (6) the utilization of the ground conductors on or in the ground for carrying return currents; (7) the prevention of electrolysis and disturbance of telegraph and telephone systems by escaping to the ground.

**CURRENT PRACTICE REGARDING GROUNDING.** — The practice of different companies is not consistent with respect to insulation and grounding of various classes of circuits, the following rules probably represent the best practice at the present time.

(1) Low-voltage circuits should be insulated where they are in no way to direct or indirect crossing with other circuits of higher voltage.

(2) Low-voltage circuits should be grounded if there is any danger of contact with circuits of higher voltage.

(3) Intermediate voltage circuits should be insulated when practicable.

(4) Intermediate voltage circuits if grounded (600-volt railway circuit for example) should be handled only by experienced people and should be so arranged as to be safe to the public.

(5) High-voltage circuits are always dangerous and may be insulated or grounded according to other conditions than safety from shock.

The reasons for the above practice are discussed below.

**ELECTRIC SHOCK FROM GROUNDED AND UNGROUNDED CIRCUITS.** — Of the various considerations affecting the desirability of grounding a circuit, that of shock is perhaps the most important. (See *article on Shock, Electric.*) A person touching a circuit at any two points which there is a difference of potential will receive a shock. The danger and severity of shock from touching simultaneously two line wires of a circuit is not affected by grounding the circuit, but the danger or severity of shock from touching simultaneously either wire and the ground does depend upon whether the circuit is grounded or not.

It should be noted that the sensitiveness of different people to shock varies a great deal and that the severity of a shock depends as much on the resistance of the skin (whether dry or wet), and on the parts and organs of the body through which the current passes, as on the voltage. It is therefore not possible to say that any voltage used in practice is so low that under ordinary conditions it can give a dangerous shock. However, considering ordinary conditions and the result of a majority of the shocks, circuits of voltages up to and including 220-volts may be considered as not liable to cause a serious shock, whether grounded or ungrounded, and may be referred to as "low-voltage" circuits.

**Voltage to Ground of Grounded Circuit.** — When a circuit is intentionally grounded, the voltage of the grounded point is made permanently the same as the voltage of the ground.

every other point of the circuit becomes fixed with may be readily calculated (*see Kirchhoff's Laws in* en carries a definite, predetermined risk, instead of y be nothing or may be very great.

**Ungrounded Circuit.** — Under normal conditions insulated circuit is the same as that of the ground, nit having a potential above and the negative parts These differences of potential cause the positive and d like the plates of condensers, the positive wire and and the earth and negative wire the other. Th— ges on the wires will be equal and the resultant e zero in all cases. These condensers are in series etrical the two condensers will have equal capacity.— sitive wire will be as much higher than that of the wire is below earth potential. In an unsymmetrical positive and negative wires with respect to earth— cities.

**Ground Connection.** — In case of a ground, either e grounded point of the circuit is brought to ground ade in the voltage to ground of the positive and , and the resultant charge on the earth is no longer me by conduction from the circuit and must there— the ground connection. As long as there is a change e circuit due to the ground connection a current will anection. Such a current is only momentary in the ws as long as the ground continues with alternat— le on *Capacity and Charging Current.*

which flows through such a ground connection is voltage of the system and its electrostatic capacity tic capacity is proportional to the extent of the the miles of line of commercial circuits ordinarily to the voltage, it follows that the amperes to ground of the voltage of the circuit. The energy which can ccidental ground will be proportional to this current that is, will vary as the cube of the voltage. In the capacity to ground there may be a leakage ulation.

**Contact with High-voltage Circuits.** — Circuits e of 11,000 volts or over are generally of sufficient ufficient electrostatic capacity) so that a fatal shock to ground, due to the current passing to ground gh the circuit be otherwise perfectly insulated from

**Low Voltage Circuits.** — In general the power avail— at escaping from an insulated circuit to ground is case of contact with the two wires of the circuit. ass of circuits whose voltages are high enough to where contact is made with two points of the cir— give serious (or sometimes even appreciable) shocks he circuit is ungrounded. These circuits are inter— voltage (220-volt) and high-voltage (11,000-volt) This class includes 440- and 550-volt power circuits oo-volt primary circuits, if leakage is small.

**Shock from Low-voltage Circuit Crossed (in Contact) With Higher Voltage Circuit.** — When an insulated circuit becomes crossed with a higher voltage it becomes charged to the voltage of the latter circuit at the point of contact. It becomes practically a part of the higher voltage and is equally dangerous to touch. As its insulation is not designed for such abnormally high voltage, there is danger of shock even through the insulation of the conductor.

When a grounded circuit is crossed with one wire of a higher voltage this wire tends to come to ground potential, and the voltage of the other parts of the low-voltage circuit with respect to the ground remains the same. In cases where a very large amount of current escapes from the high-voltage circuit, this will be appreciably modified by the addition of a voltage drop due to the resistance or impedance drop in the low-voltage circuit due to the current drawn from the high-voltage circuit from point of contact to ground. If, for example, an outside wire of a three-wire, 110/220-volt, alternating-current circuit, with grounded neutral, should become crossed with a grounded circuit, a large amount of current may flow into it, which may escape to the ground after passing through the lamps on one side of the circuit or through the transformer secondary. The impedance of the part of the circuit containing the lamps and transformer may be high enough so that the voltage across the outside wire of the secondary may be raised to a dangerous voltage, perhaps that of the grounded neutral.

**Conclusions regarding Effect of Grounding with respect to Shock.** — The considerations on which above classification is based lead to the following conclusions:

(1) The insulating of low-voltage (under 220 volts) circuits does not decrease the danger of shock under normal conditions, but as such shocks would be very serious, there is little gain in safety through the insulation of the circuit.

(2) The grounding of low-voltage (under 220 volts) circuits greatly decreases the danger of fatal shocks in cases where the low-voltage circuits become crossed with one of higher voltage.

(3) The insulating of intermediate voltage circuits (440 to 2,200 volts) greatly decreases the danger of shock under ordinary conditions because such shocks are obtained from touching one conductor, and in such cases the electrostatic capacity is ordinarily so small that no appreciable current flows to ground.

(4) The grounding of intermediate voltage circuits (440 to 2,200 volts) does not greatly decrease the danger of fatal shock in case the circuit becomes crossed with one of higher voltage because the normal voltage of the circuit when grounded is itself dangerous.

(5) Neither the insulating nor grounding of a high-voltage circuit (over 11,000 volts) materially changes the danger of shock which is very great in either case.

**DANGER OF FIRE FROM GROUNDED AND UNGROUNDED CIRCUITS.** — In general, conditions which diminish the danger of shock also diminish the danger of fire.

The Rules and Requirements of the National Board of Underwriters is the principal authority on the subject of grounding from the standpoint of fire hazard. These rules, given in the National Electrical Code (1913), are abstracted in the following table.

**GROUNDING OF HIGH-VOLTAGE CIRCUITS.** — The grounding of low-voltage circuits is governed by considerations of danger of fire, while that of high-voltage circuits is for the purpose of increasing the reliability (continuity of service over the line), or of decreasing the cost

it	Grounding	Point of attachment of ground
	Prohibited	At one station only

**ounds by Metallic Grounding.** — In normally  
 circuits the current to ground is sometimes sufficient  
 in one of the wires and a grounded conductor near  
 it with it, producing a so-called "arcing" ground.  
 und to produce destructive voltages on the circuit.  
 the neutral or one wire of the circuit the rise of  
 s perhaps the main reason why many high-voltage

**ain by Grounding the Neutral.** — In high-voltage  
 ors is an important element. In an ungrounded  
 be large enough to stand full line voltage (between  
 become grounded accidentally. Where the neutral  
 the maximum voltage on any insulator can never  
 to ground. The voltages to neutral of a single-  
 cent of the voltage between lines, and the voltage  
 system is 58 per cent of the voltage between lines.  
 utral therefore requires insulators of from 50 to 58

per cent of those for same circuit with insulated neutral, or for the insulator the line voltage can be from 73 to 100 per cent higher with a grounded neutral than without. These figures neglect the fact that the maximum voltage is constant for grounded neutral, and occurs only for a short time at intervals with insulated neutral. In practice the same insulators are used whether the neutral is grounded or not, the factor of safety being determined when the neutral is grounded.

**Limiting Short-circuit Current by Resistance.**—In a grounded system every accidental ground becomes a short-circuit. As such short-circuits can be destructive to generating machinery, the current is sometimes limited by a resistance in the ground connection (usually made at the neutral point). The amount of resistance required depends on the per cent of short-circuit current which is permissible. The resistance has, however, the disadvantage that it increases the strain on the insulation, so that as the short-circuit current is reduced, the benefit to the insulation is also reduced. Where the system is grounded as a remedy for arcing grounds and no increased factor of safety of the insulator for normal condition of operation is desired, the use of a resistor in the ground connection is allowable.

**Use of Ground for Return Circuit.**—Connections to ground are made to serve as return paths for the normal current of the circuit, except for railways. Formerly many 500-volt direct-current power circuits, operated from overhead circuits which were necessarily grounded, used the ground as a return circuit, though usually only for small or outlying motors. Such connections can cause electrolysis in underground pipes and arcs, in cases where there are other foreign conductors over which the currents are returning, are avoided. Present practice on light and power distribution is to provide complete return circuits for all currents which will flow in a circuit under normal operating conditions. Where one conductor is to be intentionally grounded the return current into the ground may be prevented by grounding it at only one point or where, on account of great extent of circuit, grounds on same conductor are necessary at several points, the escape of current will be reduced to a minimum by making the ground connection on the neutral instead of an outside conductor.

(See also *Insulating Materials; Telegraph Instru- and Cables, Insulated.*) Gutta-percha is derived from latex of the bark of certain trees of the order *Dichopsia Gutta*, found chiefly in the Straits Settlements. The trees are felled immediately after the latex or gum collected as it exudes from incisions in the bark and from the leaves by digesting them in toluol. However, the latex is boiled in water and it is then ready for use becoming quite scarce and practically the whole available supply is made by cable makers.

When exposed to the air, changing from dark brown to black and becoming brittle.

When exposed to the air, changing from dark brown to black and becoming brittle.

**GUTTA-PERCHA INSULATION.** — For insulation gutta-percha is shredded and squeezed in warm water. It is then passed through fine-wire gauze and rolled into sheets. Its use varies differently by various manufacturers, the procedure being a secret. Like rubber it is applied to the wire by sheets or by strips. Unlike rubber it is used in the pure form and mixed with minerals. Gutta-percha is less porous than rubber and is a quality which makes it the best material for insulation. Its specific gravity is just above unity.

**RESISTANCE.** — The constant  $K$  in the formula

$$M = K \log \frac{D}{d}$$

is approximately, at 75° F. after one minute electrification. See

**COEFFICIENT OF RESISTANCE.** — The temperature coefficient of resistance of gutta-percha is of the same nature as that of rubber (see article on Rubber).

$$R_T = R_{75} e^{(T-75)C},$$

where  $R_T$  is the resistance at  $T^\circ$  F. and  $C$  a constant equal to 0.085. For values of  $e^x$  see *Exponential Functions*.

**RESISTANCE UNDER PRESSURE.** — Gutta-percha being used principally for insulation, the effect of pressure upon its resistance is important. At atmospheric pressure,  $R_p$  = resistance per square inch.

$$R_p = R(1 - 0.00023 p).$$

Cologne, 1903; also *India Rubber and Gutta-Percha*, L. and Falconnet, H., *India Rubber and Gutta-Percha*. H. K. *Dielectric Characteristics of Various Insulating Materials*, vol. 10, p. 114.

**HEAT AND THERMAL PROPERTIES.** — (See also *Temperatures and Thermometers; Thermodynamics, Principles of.*) Heat is said to be added to a body, or the body is said to absorb heat, (1) whenever its temperature rises, (2) whenever it passes from a solid to a liquid state, or (3) whenever it passes from a liquid to a gaseous state; when the reverse of these changes takes place the body is said to lose or to give out heat. A body can also give out (or give out) heat without any of these changes taking place, provided it gives out (or absorbs) at each instant an amount of energy of some other kind equivalent to that absorbed (or given out) as heat. The heat absorbed (or given out) by a body in virtue of a change in its temperature is called "sensible" heat; heat absorbed or given out in passing from one state to another is called "latent" heat. Experiment shows that heat may be considered as a form of energy.

**Symbol for Heat ( $H$ ).** — Both  $H$  and  $Q$  are commonly used to denote the quantity of heat. The symbol  $H$  is used throughout this article.

**UNITS OF HEAT.** — There are several arbitrarily chosen units of heat.

**15° Gram-Calorie or Small Calorie.** — The heat necessary to raise the temperature of 1 gram of water from 14.5° C. to 15.5° C. This is the unit most commonly employed in scientific work.

**Mean Gram-Calorie or Small Calorie.** — The  $\frac{1}{100}$ th part of the heat required to raise the temperature of 1 gram of water from 0° C. to 100° C., the latent heat of fusion and boiling not being included. According to Marks and Davis, *Tables and Diagrams, N. Y., 1912*, the 15° calorie and the mean small calorie differ by less than one-tenth of one per cent.

**Kilogram-Calorie or Large Calorie.** — The heat required to raise the temperature of 1 kilogram of water from 14.5° C. to 15.5° or the  $\frac{1}{100}$ th part of the heat required to raise the temperature of 1 kilogram of water from 0° to 100° C. The relation between the gram-calorie and the kilogram-calorie is  
1 kilogram-calorie = 1000 gram-calories.

**Ostwald Calorie.** — The heat required to raise the temperature of 1 gram of water from 0° C. to 100° C. This unit is frequently used by electrochemists.  
1 Ostwald calorie = 100 mean gram-calories.

**British Thermal Unit (B.t.u.).** — The heat required to raise the temperature of 1 pound of water 1° F. There is no general agreement as to which temperature shall be used; Peabody uses the degree from 62° F. to 63° F.

Marks and Davis define the British thermal unit as the  $\frac{1}{180}$ th part of the heat required to raise the temperature of 1 pound of water from 32° F. to 212° F. This unit, as defined by Marks and Davis is about 0.13 per cent greater than the unit as defined by Peabody. Marks and Davis's definition is adopted throughout this book; the difference between the two is negligible for ordinary practical work. The relation between the B.t.u. and the mean kilogram-calorie is  
1 B.t.u. = 0.25200 kilogram-calories.

**Mechanical Equivalent of Heat.** — This is the name given to the experimentally determined conversion factor between any heat unit and a unit of mechanical work; see *Units and Conversion Factors*. The fundamental relation is  
1 mean gram-calorie =  $4.1834 \times 10^7$  ergs.

This is the value given by Marks and Davis.

**Y AND SPECIFIC HEAT.**—The "thermal capacity" is the heat absorbed by the body per unit increase of temperature during this change in temperature no change of state, whether from solid to liquid or from liquid to gaseous form or no change of state. The thermal capacity of a body in question is the amount of heat energy from the body in question to raise its temperature by one degree. The thermal capacity *per unit mass* of a substance is approximately constant with increase in temperature; in the case of water the variation with temperature is quite marked. Calling  $C$  the thermal capacity of a substance the heat absorbed by a homogeneous body of mass  $M$  when its temperature increases from  $t_1$  to  $t_2$  is

$$H = CM(t_2 - t_1) \quad (1)$$

The thermal capacity per unit mass of water (between  $0^\circ\text{C}$ . and  $100^\circ\text{C}$ .) is 1.000 mean gram-calories per gram per degree centigrade, and its density is 1.000. The ratio of the thermal capacity per unit mass to the density is called the mean thermal capacity of water and is called the specific heat of a substance. The specific heat of a substance does not vary with temperature; the various quantities are measured; its thermal capacity is 1.000. When heat is expressed in mean gram-calories, and temperature in degrees centigrade, the thermal capacity is the same as the specific heat; compare with density and specific

**Absorbed or Given Out.**—

(Mean gram-calories per gram per  $^\circ\text{C}$ .)

Temperature.

The heat absorbed is

$$H = kCM(t_2 - t_1), \quad (2)$$

where  $k$  is the value:

VALUES OF  $k$

Substance	Unit of mass	Temperature scale	Value of $k$
	Gram	Centigrade	1.000
	Kilogram	Centigrade	1 000
	Pound	Centigrade	1 800
	Pound	Fahrenheit	1.000
	Gram	Centigrade	4 183
	Pound	Fahrenheit	1054
	Kilogram	Centigrade	$1.162 \times 10^{-3}$
	Pound	Fahrenheit	$2.928 \times 10^{-4}$

**Notes.**—In the table below are given the values of the thermal capacity per unit mass, when mass is in grams and temperature in degrees centigrade and heat in gram-calories.

**Constant Volume and Constant Pressure.**—In the case of a gas which absorbs heat and expands (contraction in a few cases) it does work on whatever opposes this expansion, part of the heat thus converted into mechanical work; see *Ther-*

In the case of solids and liquids the external work is negligible. In the case of gases and vapors, however, the external work is appreciable. The specific heat of a gas or vapor when it is heated so that it can do no external work, is called the specific heat at constant volume, and is usually designated by the symbol  $C_v$ . The specific heat of a gas or vapor when it is allowed to expand at constant pressure, and is usually designated by the symbol  $C_p$ . The ratio

$$\gamma = \frac{C_p}{C_v} \quad (3)$$

has a value, 1.40 approximately, for all ordinary (diatomic)

$\gamma = \frac{C_p}{C_v}$  FOR SOME GASES AT ATMOSPHERIC PRESSURE

(from Landolt-Börnstein Tables.)

When heat is supplied at a uniform rate to a piece of iron the rate of increase of temperature gradually increases (specific heat) until a certain temperature is reached. At this temperature is suddenly and in most cases greatly retarded. The reverse of this effect occurs when the sample is cooled. The temperature above this point, and under certain conditions, is not simultaneous reheating during the cooling. Any point at which there is a change in the slope of a heating or cooling curve is called a recalescence point; there is a very marked recalescence point at 750° C. and also one or more points at which the same effect occurs. The major recalescence point of ordinary iron is at 750° C. and 850° C.

#### MELTING POINT AND HEAT OF FUSION. —

When substances when heated to a definite temperature change from the solid state to the liquid state with no increase in temperature during the change. In the solid and liquid are kept thoroughly mixed, and the change is accompanied by a considerable absorption of heat. The temperature at which the change takes place is called the melting point or freezing point (the change takes place at the same temperature), and the heat absorbed is called the heat of fusion or heat of liquefaction; this heat is given out when the body solidifies. In the case of substances which are not crystalline, there is no definite melting point, the change from solid to liquid is gradual; such substances begin to melt at a lower

temperatures than that at which solidification begins during cooling. Melting points and heats of fusion for some common substances are given in Table III. The values printed in bold face type are recommended by the Bureau of Standards as suitable for pyrometer calibration.

**VAPORIZATION.**— Above the surface of any liquid there always exists a certain amount of the substance in a gaseous form, i.e., as a vapor, the amount of which depends upon the nature of the substance and upon the temperature and the pressure in the space occupied by the vapor and such other gases as may be present. In the case of a simple liquid evaporating in a space from which all other gases and vapors have been removed, the evaporation ceases when a definite pressure is established in this space, this equilibrium pressure depending only upon the temperature at which this space is maintained. This statement is true only when there always remains some unevaporated liquid; if all the liquid evaporates, then the equilibrium pressure also depends upon the mass of the vapor and the space which it occupies; as long as liquid remains, the equilibrium pressure depends only upon the temperature and is independent of the volume of the space and the mass of the vapor which it occupies. This equilibrium pressure for any given temperature is called (normal) "vapor pressure" or "vapor tension" at that temperature, and the vapor is said to be "saturated," i.e., each unit volume of the space contains the greatest possible mass of vapor which can occupy it at this particular temperature. Diminishing the volume of the space (at constant temperature) occupied by a saturated vapor causes some of the vapor to condense, and the vapor which is left remains saturated at the same pressure and temperature. Increasing the volume of the space (at constant temperature) causes more of the liquid to evaporate and the vapor still remains saturated at the same pressure and temperature, provided always that some liquid is left.

**Boiling Point and Heat of Vaporization.**— The temperature corresponding to any given pressure at which a vapor is completely saturated is called the "boiling point" of the liquid at this pressure. The temperature at which a liquid "boils" in the ordinary sense of the term is in general greater than the temperature of the saturated vapor above it, since the vapor in the ordinary sense is formed under a greater pressure than the vapor above the surface. The quantity of heat required to convert unit mass of a liquid into vapor at a given pressure is called the heat of vaporization or heat of evaporation of the liquid at this pressure; the same quantity of heat is given out by unit mass of vapor when it condenses at this same pressure. The boiling points and heats of vaporization generally given are for normal atmospheric pressure, viz.

two quantities for some common substances are

**Saturated Vapors; Gases.**—When the pressure exerted of the containing vessel is less than the saturation the vapor is said to be unsaturated or superheated. brought about either (1) by increasing the volume there is no longer any liquid left to evaporate, keeping (2) by raising the temperature of such a saturated constant, or (3) by a proper combination of (1) called "permanent" gases are superheated vapors, being very great. The distinction ordinarily made is that a gas is far removed, with respect to temperature, from the saturated state, whereas a comparatively small increase in the temperature of a vapor will saturate it. **Ordinary gases,** such as air and superheated vapors (where the more nearly do the relations hold), are called "perfect gases," and the following "law,"

$$pV = \frac{MRT}{\mu}, \quad (4)$$

where  $p$  is the pressure of the gas, and  $V$  is the volume occupied by it,

where  $M$  is the mass of the gas; see Table V below,

where  $R$  is the gas constant; \* see Table IV below,

where  $T$  is the absolute temperature of the gas, and  $\mu$  is the molecular weight of the gas, called the "gas constant," whose value is the same for all gases, and whose value is given in the following table in which the various quantities are expressed;

#### MOLECULAR WEIGHTS OF GASES

$\mu$	Gas	$\mu$
28.98	Chlorine ( $\text{Cl}_2$ ).....	70.93
26.02	Hydrogen ( $\text{H}_2$ ).....	2.016
17.03	Nitrogen ( $\text{N}_2$ ).....	28.02
44.00	Nitrous oxide ( $\text{N}_2\text{O}$ ).....	44.02
28.00	Oxygen ( $\text{O}_2$ ).....	32.00

can be deduced from purely thermodynamic relations (see *Principles of Thermodynamics*) on the assumptions: (1) that the product of the pressure and volume of a gas is a constant for any particular gas (*Boyle's or Mariotte's law*); (2) that the internal energy per unit mass of a gas depends only on the temperature of the gas (*Joule's law*); (3) that at constant volume the specific heat of the gas is independent of the volume and nature of the gas (*Joule's law*).

The specific heat of a mixture of perfect gases of different molecular weights is

$$= \frac{M_1 + M_2 + M_3 + \dots}{M_1 + M_2 + M_3 + \dots},$$

where  $M_1, M_2, M_3, \dots$  are the masses of the individual constituents and  $\mu_1, \mu_2, \mu_3, \dots$  are the molecular weights of the individual constituents and  $\mu_1, \mu_2, \mu_3, \dots$  are the molecular weights of the individual constituents.

pendent of its temperature. A gas which satisfies the above conditions is a "perfect" gas; all ordinary gases and highly superheated vapors satisfy these conditions approximately.

As a consequence of the above law the following relations must hold for a perfect gas; they also apply approximately to ordinary gases. In the symbols above, let

$C_v$  = specific heat at constant volume,

$C_p$  = specific heat at constant pressure,

$$\gamma = \frac{C_p}{C_v},$$

$W_{12}$  = work done on the gas when its pressure changes from  $p_1$  to  $p_2$ ,

$H_{12}$  = heat absorbed by the gas when its pressure changes from  $p_1$  to  $p_2$ ,

$J$  = mechanical equivalent of heat.

Then for a perfect gas, for an *isothermal change*, i.e., a change at constant temperature ( $T_1 = T_2$ )

$$W_{12} = p_1 V_1 \log_e \left( \frac{p_2}{p_1} \right), \quad H_{12} = \frac{W_{12}}{J},$$

and for an *adiabatic change*, i.e., no heat passes in or out of the gas

$$\frac{p_2}{p_1} = \left( \frac{V_2}{V_1} \right)^\gamma, \quad \frac{T_1}{T_2} = \left( \frac{V_2}{V_1} \right)^{\gamma-1} = \left( \frac{p_2}{p_1} \right)^{\frac{\gamma-1}{\gamma}}.$$

$$W_{12} = J C_v M (t_1 - t_2) = \frac{p_1 V_1 (t_1 - t_2)}{T_1 (\gamma - 1)}.$$

Any one of the four sets of units given in the following table (or consistent set) may be used in these formulas.

TABLE V. -- VALUES OF THE GAS CONSTANT  $R$  AND MECHANICAL EQUIVALENT  $J$

Notation	Units and constants			
$M$ = mass	kg.	grams	lb.	
$V$ = volume	cu. meter	cu. cm.	cu. ft.	
$p$ = absolute press.	kg. per sq. m.	dyne per sq. cm.	lb. per sq. ft.	atm.
$t$ = temperature	° C.	° C.	° F.	
$H$ = quantity of heat	kg.-cal.	gm.-cal.	B.t.u.	g.-cal.
$W$ = work	m.-kg.	erg	ft.-lb.	mech. equiv.
$T$ = absolute temp. =	$t + 273$	$t + 273$	$t + 460$	
$R$ = gas constant =	849	$0.832 \times 10^9$	1547	
$J$ = mechan. equiv. =	427	$4.19 \times 10^7$	778	

**Gas Saturated with Vapor.** -- Experience shows that when a liquid evaporates into a space already occupied by a gas (e.g., water evaporates into the atmosphere), evaporation ceases for any given temperature when a certain pressure (depending upon the temperature and the nature of the gas) is established in the mixture; or, if the pressure and temperature are maintained constant, then evaporation ceases when a definite amount of vapor has been produced. When a mixture of a gas and a vapor contains a certain maximum mass of vapor per unit volume of the mixture, the gas is said to be saturated with the vapor. Such a mixture may contain less of the vapor

amount; the ratio of the mass of vapor per unit volume to the maximum possible mass per unit volume at any temperature is called the "relative humidity" of the mixture. The relative humidity of a mixture (e.g., air and water vapor) can be determined by using a wet-bulb thermometer. (See the *Hygrometric Tables* of

**Amount of Moisture in Saturated Air.**—The following are approximate but sufficiently accurate for practical purposes for the amount of any gas and vapor which do not act chemically

of the mixture,  
 of the mixture,  
 temperature corresponding to  $t$ , see Table V above,  
 from Table V above,  
 weight of air; see Table IV above,  
 pressure of steam at the temperature  $t$ , to be taken from steam tables, see article on *Steam*,  
 volume of steam at the pressure  $p_w$ ; also to be taken from steam tables,  
 mass of unit volume of air at the pressure  $(p - p_w)$

at temperature  $t$ ,  
 mass of unit volume of the mixture.  
 that is the weight (mass) in lb. per cu. ft. of air saturated with water vapor at pressure (14.70 lb. per sq. in.) with water vapor at pressure  $p_w$  is the weight in lb. of the water contained in 1 cu. ft. of the mixture. The formulas  $\rho = 14.70 \times 144$  lb. per sq. ft.;  $p_w = 0.946 \times 144$  lb. per sq. ft.;  $T = 460 + 100 = 560^\circ \text{F.}$ ;  $\delta_m = \frac{0.946 \times 144}{560} = 0.06630$  lb. per cu. ft.;  $\delta_m = 0.002851$  lb. per cu. ft. Answer: The mixture weighs 0.06915 lb. per cu. ft. 0.002851 lb. of moisture per cu. ft.

**Partial Pressures.**—The above calculation is based on a determined relation, known as Dalton's Law, that the total pressure of a mixture of gases or vapors which do not react chemically upon each other for a given volume of the mixture is approximately equal to the sum of the individual pressures which each gas or vapor would exert if it alone filled this volume. For example, if a mixture of three gases A, B, and C, when mixed, a volume  $V$  and produce a pressure  $p$ , then gas A by itself would exert a pressure  $p_a$  when it alone filled the volume  $V$ , and gas B by itself would exert a pressure  $p_b$  when it alone filled the volume  $V$ , and similarly for gas or vapor C, then

$$p = p_a + p_b + p_c. \quad (7)$$

The pressures  $p_a$ ,  $p_b$ , and  $p_c$  are called "partial" pressures. Dalton's Law holds sufficiently accurate for most practical calculations.

Sublimation. — A substance passes directly from a solid to a gaseous form without passing through the liquid state. This is called sublimation. A common instance of this is the case of dry ice (solid carbon dioxide), which passes from solid to gaseous form at a temperature of  $-79^\circ \text{C.}$  and absorbs 140 gram-calories per kilogram.

**Heat Transfer.** — When a body is at a higher temperature than another, energy is transferred from the hotter to the colder

bodies, as is manifested by the changes in temperature or state which or actually do, take place, even though the intervening space is empty of matter. The energy thus transferred from one body to another empty space is called "radiant energy," or "radiant heat," and is of the same nature to the energy radiated in the form of light waves and electromagnetic waves. The waves of radiant heat have a length greater than those of light waves and less than that of the ordinary electromagnetic waves used in wireless telegraphy. Radiant heat is absorbed by, transmitted through, and reflected by, ordinary matter in much the same way that light waves are absorbed, transmitted and reflected. Matter which is transparent to light waves, however, may be practically opaque to heat waves; e.g., water absorbs practically all the heat waves which fall upon it.

When a hot and a cold body are separated by a fluid which is free to move, heat is transferred from the hot to the cold body by currents of the fluid flowing from one to the other; similarly, all parts of a fluid which is heated quickly come to approximately the same temperature. The transfer of heat by currents of the fluid itself is called "convection."

In the case of a hot and a cold body separated by a solid the transfer of heat, which may be very rapid, particularly when the separating medium is a metal, is probably due to an extremely rapid to-and-fro motion of the molecules which constitute the medium. In any event, the process is quite different from the transfer of heat either by radiation or by convection. It is described by the term "conduction" of heat. In a fluid heat is transferred both by conduction and convection.

An excellent brief treatment of Heat Transmission is given by I. A. I. E. E., *Trans.* 32, p. 301, Feb. 1913, including numerical data on conduction and convection.

**Radiation, Absorption and Reflection of Heat.** — The rate at which a hotter body radiates heat, and a colder body absorbs heat, depends on the state of the surfaces of the bodies as well as on their temperature. The rate of radiation and of absorption are increased by darkness and roughness of the surfaces of the bodies, and diminished by smoothness and polish. For this reason the covering of steam pipes and boilers should be smooth and of a light color; uncovered pipes and steam-cylinders should be polished.

The heat radiated by a body at a given temperature  $T$  to surroundings at a lower temperature is equal to the heat which this body would radiate at this same temperature  $T$  from surrounding bodies at a higher temperature. When a given quantity of radiant heat strikes a body, only part of it is, as a rule, absorbed, the rest being reflected.

Let  $H_i$  be the incident heat,  $H_r$  the reflected heat, and  $H_a$  the absorbed heat at temperature  $t$ , and let  $H_e$  be the heat which the body would emit at temperature  $t$  to bodies at a lower temperature; then

$$H_i = H_r + H_a,$$

$$H_a = H_e.$$

**Definition of "Black Body"; Stefan-Boltzman Law.** — A "black body" is defined as one that absorbs all radiations falling upon it, neither reflecting nor transmitting any. The radiation of such a body is a function of its temperature alone, and is identical with the radiation inside an enclosure the parts of which have the same temperature. By heating the walls of a cavity as uniformly as possible and observing the radiation through a small opening, a practical realization of a black body is obtained.

a body is found to obey the following law

$$= K \left[ \left( \frac{T}{1000} \right)^4 - \left( \frac{T_0}{1000} \right)^4 \right] At, \quad (8)$$

radiated in time  $t$  from such a body at an absolute temperature  $T$ , and  $T_0$  being the absolute temperature of the surrounding bodies maintained at an absolute temperature  $T_0$ .  $K$  is a constant. This relation is known as the Stefan-Boltzmann Law. When the absolute temperature  $T$  is the same as the absolute temperature  $T_0$ , this relation may be written

$$K \left( \frac{T}{1000} \right)^4 At.$$

The value of  $K$  from the Smithsonian Physical Tables (1914) is 1.374 when  $T$  is in absolute degrees and  $t$  in seconds. For  $T$  in centigrade degrees and  $t$  in seconds, the value of  $K$  is 5.75.

#### VALUES OF $K$

Unit of area (A)	Unit of time (t)	Temperature scale	Absolute zero	$K =$
sq. cm.	second	Centigrade	-273	1.374
sq. meter	hour	Centigrade	-273	0.000495
sq. ft.	hour	Fahrenheit	-460	0.00174
sq. cm.	second	Centigrade	-273	5.75
sq. in.	hour	Centigrade	-273	370.

**Reflecting Powers.** — The ratio of the heat radiated by a surface at a given temperature  $T$  to the heat radiated per unit area by a black surface at this same temperature  $T$  is called the reflecting power, or emissivity, of the surface at that temperature. A reflecting power of unity is a measure of the heat which would be radiated by a black surface at the same temperature, and is defined as the reflecting power of a black surface. The radiating power of a surface depends upon the temperature; at very high temperatures the radiating power approaches the value of unity, i.e., at high temperatures the radiating power of any surface approaches in value the total energy radiated by a black body. The table on page 738, taken in part from *Engineer's Pocketbook* and in part from Langmuir's *Engineering Thermodynamics* (1913) gives the approximate value of the radiating power of surfaces at ordinary temperatures.

The radiating power may increase its radiating power from 2 to 3 times, and rough surfaces may affect the radiating power of a rough surface.

— Whenever a difference of temperature is maintained between parts of the same body there is a transfer of heat from the warmer to the cooler part by the process described by the term "conduction," "diffusion," and convection.

**Conduction.** — Within a substance, the two sides of the layer being considered are small compared with its area. Let one side of this layer be at temperature  $T$ , the same at all points of this surface, and the other side be maintained at a constant temperature  $T_1$ ;

TABLE VI.—APPROXIMATE RADIATING AND ABSORBING

let  $A$  be the area of the layer (i.e., of one of its flat surfaces) and  $x$  the thickness of the layer. Then the amount of heat transferred through the layer in time  $t$  is,

$$H = \frac{K A (T - T_1)t}{x}$$

where  $K$ , called the "thermal conductivity," is approximately a constant for a given material, and is independent of the temperature difference  $T - T_1$ —this difference is small;  $K$  is not constant, however, for wide temperature differences, particularly in the cases of gases (see paragraph following Table V). Values of  $K$  are given in Tables VII and VIII. The reciprocal of the thermal conductivity, viz.,  $\rho = 1/K$ , is called the thermal resistivity.

The values of  $K$  given in the tables below are the values of this factor.  $H$  is expressed in gram-calories,  $A$  in sq. cm.,  $x$  in cm.,  $(T - T_1)$  in  $^{\circ}$  C. per second; i.e.,  $K$  is the number of gram-calories transmitted per second

Unit of heat	Unit of area	Unit of thickness	Unit of time	Unit of temp. diff.	
Gram-calorie.....	sq. cm.	cm.	second	$^{\circ}$ C.	1.
Kg-calorie.....	sq. m.	cm.	hour	$^{\circ}$ C.	3.
B.t.u.....	sq. ft.	inch	hour	$^{\circ}$ F.	29
Watt-seconds.....	sq. cm.	cm.	second	$^{\circ}$ C.	
Watt-seconds.....	sq. ft.	inch	second	$^{\circ}$ F.	85
Kw-hr.....	sq. m.	cm.	hour	$^{\circ}$ C.	4
Kw-hr.....	sq. ft.	inch	hour	$^{\circ}$ F.	

when a difference of temperature of 1° C. is maintained in this cube. For other units the value of  $K$  as given in the factor noted in the table at bottom of preceding page.

**Other than Thin Layers.** — The formula for  $H$  is only valid when the lines of flow are straight and perpendicular to the surfaces.  $T$  and  $T_1$  are temperatures of the surfaces of the substance, for example, in contact with a fluid, for example, in contact with a fluid. To take these facts into consideration accounts for the difference between the reported values of thermal conductivity and the values of  $H$  in other cases, formulas analogous to those for resistance and conductance must be employed; see *Resistivity*, Langmuir, Adams and Meikle, *Trans. Am. Electrochem. Soc.*, 1912, p. 301.

**Coefficient of Thermal Conductivity.** — In the case of a solid the internal thermal conductivity with temperature is given to a fair degree of approximation by the relation

$$K = K_0(1 + \alpha t), \quad (10)$$

where  $K_0$  is the conductivity at 0° C., say, and  $K$  is the conductivity at any temperature  $t$  and  $\alpha$  is a constant. The coefficient  $\alpha$  may be either positive or negative. The value for some of the common metals is given in the following table.

**Thermal Conductivity ( $K$ ) of Materials.** — In the following table are given the thermal conductivity of certain metallic substances respectively. The data are from Boltzmann, *Physikalisch-Chemische Tabellen*, 1912; *Arch. Eng.*, June, 1908; Hering, Carl, *Trans. A.I.E.E.*, 1908; *Trans. Am. Electrochem. Society*, 1912; Ordway, *Trans. Am. Electrochem. Society*, 1912; Coleman, J. J., *Engineering*, Sept. 5, 1884; Wolf, *Jour. Frank. Inst.* 1893; Peclet, *Practical Chem. Eng.*, Feb. 1909, p. 72; Brill, G. M., *Trans. Am. Electrochem. Soc.*, 1912, p. 301, Feb. 1913.

**Thermal Conductivity of Laminated Steel.** — The thermal conductivity perpendicular to the laminations depends upon the thickness of the laminations and the oxide scale or varnish on the laminations. G. E. Luke (*El. World*, 70, 1912) gives the following values for  $K$  in gram-calories per

	Pressure, pounds per square inch

g to Langmuir (*Trans. A.I.E.E.*, 31, p. 1220, 1912; n in a gas or liquid consists essentially in conduction n of the fluid of definite thickness, in which the heat fluid is negligible compared to that carried by con- n the temperature is maintained uniform because n the case of a vertical plane surface in air, when above the surrounding air, the heat loss by "free" alation of the surrounding air) is equal to that com- still air 4.3 millimeters thick adhering to the surface, the two faces of the film the temperature of the sur- f the room air respectively. Equation (11) should be aking  $x = 0.43$ .

surface radiating upward the convection loss is about for a horizontal plan surface radiating downward less, than from a vertical surface.

According to H. T. Gillette (*Eng. and Cont.*, 47, p. 573, June 27) equivalent film thickness for water is 1.27 millimeters when the water is stirred mechanically. The equivalent film thickness for steam is also much less than that for air.

The film thickness of 4.3 millimeters for air is for air at ordinary temperature and barometric pressure, with no forced ventilation. The mass is directly proportional to the absolute temperature of the air, and varies approximately inversely as the square root of the absolute temperature.

The free convection from a round wire or cylinder of any diameter may be calculated in a similar manner, except that the thickness of the air film upon the diameter of the wire, and account must be taken of the fact that the lines of heat flow are radial. Langmuir gives the following formula for watts carried off by convection from a length of 1 cm. of wire

$$W = s(\phi_2 - \phi_1),$$

where  $\phi_2$  and  $\phi_1$  correspond to the absolute temperature  $T$  of the wire and the absolute temperature  $T_1$  of the surrounding air (see table on p. 7), and  $s$  is the shape factor, defined by the relation

$$\frac{s}{B} = \frac{s}{\pi} \epsilon^{-\frac{2\pi}{s}},$$

where  $s$  is the diameter of the wire, in centimeters,  $B$  the film thickness in centimeters, and  $\epsilon$  the Napierian base. The values of the shape factor for wires in air at ordinary room temperatures and atmospheric pressure are given in the following table.

VALUES OF  $s$

$\frac{s}{B}$	$s$	$\frac{s}{B}$	$s$	$\frac{s}{B}$
0.02	1.85	0.5	5.21	5.0
0.04	2.22	1.0	7.40	6.0
0.06	2.47	1.5	9.30	7.0
0.08	2.67	2.0	11.1	8.0
0.10	2.85	2.5	12.8	9.0
0.20	3.60	3.0	14.5	10.0
0.30	4.20	3.5	16.1	12.0
0.40	4.75	4.0	17.8	14.0

**Forced Convection.** — Langmuir finds (l.c.) that the convection factor for plane surfaces in a stream of air is equal to that in still air multiplied by the factor  $\sqrt{\frac{v + 33}{33}}$ , where  $v$  is the velocity of the air in cm. per sec.

**Total Heat Transfer.** — Numerous formulas have been proposed for the total transfer of heat (radiation, conduction and convection) from pipes to the surrounding gas or vapor; see C. H. Herter, *Am. Soc. R. J.*, 4, p. 308, Nov. 1917; L. H. Fry, *A.S.M.E.J.*, 39, p. 843, Oct. 1917; and Barkley, *Bur. of Mines, Tech. Paper*, No. 114, 1915; E. E. W. *M.E.J.*, 37, p. 546, Sept. 1915.

**HEATING.** — Most substances expand when heated above 0° degrees and 4° C., quartz glass below - 84° C. contract with increase of temperature. When the substance is cooled by rapid cooling, slow changes in its dimensions which it has attained the same uniform temperature which is particularly marked in glass, is known as thermal stress and can be largely eliminated by prolonged heating at a low temperature or a very gradual cooling, i.e., by annealing.

Expansion of a homogeneous substance which is not subjected to any more or less permanent changes in its structure, by changes of temperature and the pressure or tension in it. In the absence of pressure or tension the amount of expansion caused by a change of temperature depends upon both the material of the body and the change of temperature.

**Expansion of Gases.** — In the case of gases, however, there are all the so-called permanent gases expanding about the same amount at 0° C. per degree centigrade increase of temperature, provided this remains constant throughout the expansion.

For ordinary gases, the expansion is given by the following equation, where  $V_0$  is the volume at 0° C. and  $V$  the volume at any other temperature  $t$  ° C., and  $V_0$  is the volume at 0° F., then

$$V = V_0 \left( 1 + \frac{t_c}{273} \right),$$

where  $t_c$  is the temperature in degrees centigrade and  $V_0$  is the volume at 0° F., then

$$V = V_0 \left( 1 + \frac{t_f}{460} \right).$$

273 and 460 are the absolute zeros on the centigrade and Fahrenheit scales respectively.

**Expansion of Liquids and Solids.** — Let  $l_0$  be the length of a liquid, at any standard temperature, say 0° C., and  $l$  the length at any other temperature  $t$ . Then the exact relation between  $l$  and  $t$  can be expressed as a series of the form

$$l = l_0 (1 + at + bt^2 + \dots),$$

where  $a$ ,  $b$ ,  $c$ , ... are coefficients for any given material and fixed reference temperature. The coefficients of the powers of  $t$  above the first are called the coefficients of expansion, and for small ranges of temperature the expansion is practically linear.

$$l = l_0 (1 + at)$$

The coefficient  $a$  in this formula is practically a constant for a given material and is not exceeding 100° C.; it is sometimes called the "coefficient of expansion" between the limits of temperature chosen. For a given material and 0° and 100° C., the mean coefficient of linear expansion is given by

$$a_0 = \frac{l_{100} - l_0}{100 l_0},$$

where  $l_{100}$  is the length produced by increasing the temperature from 0° to 100° C.

For each value of the standard or reference temperature, a different value must be used. For example, if a rod has a length  $l_0$  at 0° C.,

TABLE IX. — COEFFICIENTS OF LINEAR EXPANSION

 $l = l_0 (1 + \alpha t + \beta t^2)$ , temperature in °C.\*

 $\alpha_{20}$  = "true" coefficient at 20°C.

\* When the temperature is expressed in Fahrenheit degrees, the formulas

$$l = l_0 \left[ 1 + \frac{\alpha(t-32)}{1.8} + \frac{\beta(t-32)^2}{3.24} \right],$$

$$\alpha_{20} = \frac{\alpha_0}{1.8},$$

 where  $\alpha$ ,  $\beta$  and  $\alpha_{20}$  have the values given in the above table.

at  $t$  degrees, and  $\alpha_0$  is the mean coefficient of linear expansion, then  $l_t = l_0(1 + \alpha_0 t)$  and  $l = l_0(1 + \alpha t)$ , whence

$$l = l_0 [1 + \alpha_0 (t - h)]$$

$$\alpha_1 = \alpha_0 / (1 + \alpha_0 h)$$

is appreciable compared with unity then  $\alpha_1$  is not

of Linear Expansion. — The "true" coefficient of expansion at temperature  $t$  is defined as the rate of increase of length divided by the length at this temperature  $t$ , or

$$\alpha = \frac{1}{l} \cdot \frac{dl}{dt}$$

any temperature depends on the temperature.

Expansion of Liquids and Solids. — The volume expansion of liquids and solids may be expressed in exactly the same manner, viz.,

$$V = V_0(1 + \alpha t + \beta t^2 + \dots)$$

$$V = V_0(1 + \alpha t)$$

any temperature  $t$  is defined as

$$\alpha_t = \frac{1}{V} \frac{dV}{dt}$$

volumes at  $t$  degrees and at the reference temperature

when the coefficient of linear expansion is small and not excessive, the volume coefficient may be taken as the cube of the linear coefficient.

Values, determined from direct experiment, are given in the article on *Weights of Materials*.

#### EFFICIENTS OF CUBICAL EXPANSION

**FLASH POINT OF OILS.**—The flash point of an oil is the temperature which the oil must be raised before the vapor immediately above it will ignite upon the application of a flame. This temperature depends to a considerable extent upon the size of the flame, the method of applying it, and the dimensions of the containing vessel; see *Oil, Transformer*. The following values of the flash point for various oils are taken from J. Lewis' *Chemical Technology and Analysis of Oils, Fats and Waxes*.

### HEATS OF FORMATION, COMBUSTION AND SOLUTION

When two or more substances react chemically heat is generally either given out or absorbed. When heat is given out the reaction is called "exothermic" and when heat is absorbed the reaction is called "endothermic." The following tables give the heats of reaction for some of the more important processes; see *Landolt-Bornstein's Tables* for more complete tables. A minus sign indicates an endothermic reaction; i. e., an absorption of heat. The values are given these refer to independent measurements.

The values given are the total amounts of heat in kilogram-calories or absorbed per mol (see *Electrochemistry, Principles of*) of the product with the proportions of the reacting substances represented by the member of the reaction equation, the temperature at the beginning and end of the reaction being the same, i. e., room temperature. For example, reacting with 1 gram-atom of oxygen (16 kilograms, say) and 1 gram-atom of calcium (40.07 kilograms) both at room temperature, then the net amount of heat given out in the formation of one mole (16 + 40.07 = 56.07 kilograms) of calcium oxide when its temperature is brought back to room temperature is 136.5 kilogram-calories or 2.33 kilogram-calories per kilogram of calcium oxide.

OF FORMATION OF IMPORTANT COMPOUNDS

(in temperature unless otherwise stated.)

Equation	Kilogram-Calories* evolved per mol of product
$2\text{C} + 2\text{H} = \text{C}_2\text{H}_2$	-47.8 to -58.1

**HEATING OF BUILDINGS.** — (See also *Railways, Energy Requirements*.) The problem of determining the amount of heat necessary to maintain a room at a given temperature above the out-door temperature resolves itself into the determination of the amount of heat transmitted through the walls and floor; and the amount of heat necessary to raise the incoming ventilation air to the temperature of the air in the room.

**HEAT REQUIRED TO WARM INCOMING AIR.**— When a room is occupied by a number of people, the quantity of ventilating air required is often calculated on the basis of 1800 cu. ft. per person per hour. If this quantity is greater than that which leaks in through the cracks at doors, windows, etc., forced ventilation should be employed.  $\frac{1}{2}$  B.t.u. is required to heat 1 cu. ft. of air  $1^{\circ}$  F.

Let

$t$  = temperature of incoming air,  $^{\circ}$  F.,

$T$  = temperature of room,  $^{\circ}$  F.,

$Q$  = cubic feet of air per hour leaving room at room temperature.

Then the B.t.u. per hour required to heat this air to room temperature is also the amount of heat carried off by this air, is

$$H_p = \frac{Q(T - t)}{56}$$

**Infiltration of Air.**— The heat required to warm the air which infiltrates through cracks at windows and doors may be determined either by finding the volume of air  $Q$  which enters in this manner and applying equation (1) or the heat required may be expressed directly in terms of the size and leakage of cracks. Following the first method Carpenter proceeds as follows: Let

$C$  = cubical contents of room in cubic feet,

$N$  = number of air changes per hour,

then

$$Q = NC$$

where, for well constructed buildings,  $N$  has the values given in the following table.

Kind of room	$N$
Halls.....	3
Rooms on first floor.....	2
Rooms on second floor.....	1
Offices and stores, first floor.....	2 to 3
Offices and stores, second floor.....	1.5 to 2
Churches and public assembly rooms.....	0.75 to 1
Large rooms with small exposure.....	0.5 to 1

By far the greater portion of the infiltration is due to loose-fitting sash and the actual sash clearance determines the infiltration loss in any given case. In the general run of well constructed buildings this clearance should not be more than  $\frac{1}{16}$ " while for poor construction the clearance may be as much as  $\frac{1}{4}$ " heat loss by infiltration may be approximately determined by the use of the following values:

clearance. 1.2 B.t.u. per hr. per ft. of crack per ° F.  
 clearance. 2.4 B.t.u. per hr. per ft. of crack per ° F.  
 ..... 0.15 B.t.u. per hr. per ft. of crack per ° F.

By this method is determined by the total lineal  
 existing in the one outside wall having the greatest  
 surface, and not upon the total number of feet of  
 outside walls.

**HEAT LOSS DIRECTLY THROUGH WALLS, CEIL-**

ing heat may be conveniently referred to as the  
 though it is of course conducted through the walls  
 carried off both by radiation and convection. Let

$A$  = square feet,  
 $T_o$  = outside air,  
 $T_i$  = inside air,  
 $R$  = per square foot of radiating surface (wall, window,  
 etc.) per ° F. difference in temperature.

The radiation is

$$H_r = \sum KS (T - t),$$

where  $S$  are all the radiating surfaces. Certain additions  
 must be made to  $H_r$  as thus calculated to allow for the nature

of the total heat lost by radiation may be made by  
 using a surface factor,  $K = 1$  for all window surfaces and neglecting  
 other surfaces (Harding's rule).

To use the proper value of  $K$  for each kind of wall  
 requires the most accurate values of  $K$  are those given  
 which take into account not only the nature of the  
 material, but also the nature of both the inside and  
 outside air and the wind velocity of the outside air at the wall.  
 For a wall of thickness  $x$  inches, Harding's  
 rule is

$$K = \frac{1}{\frac{1}{K_1} + \frac{1}{K_2} + \frac{x}{C}}, \quad (3)$$

where  $C$  (or  $\frac{x}{C}$ ) are given in the following tables.

The thermal conductivity of plates, building paper or glass is so small that  
 it may be neglected in the calculations. If the wall is composed of several  
 layers in contact with one another (no air spaces) then

$$K = \frac{1}{\frac{1}{K_1} + \left( \frac{x_1}{C_1} + \frac{x_2}{C_2} + \frac{x_3}{C_3} + \text{etc.} \right)}, \quad (4)$$

where  $x_1, x_2, x_3$  are the thickness of the various materials in inches,  
 and  $C_1, C_2, C_3$  are the corresponding values of  $C$ .

**VALUES OF  $K_1$  FOR STILL AIR**

1.40	Glass Window.....	1.50
1.30	Sheet Asbestos.....	1.40
1.25	Magnesia Board.....	1.45
0.93	Wood (finished surface).....	1.40

The average value of  $K_1$  from above data is 1.34.

The value of  $K_2$  increases with the velocity of air over the surface. The value of  $K_2$ , for brickwork and wood, for various velocities of air or wind may be obtained by multiplying the values of  $K_1$  from the above by the following factors:

Velocity, miles per hour	Multipliers of $K_1$	
	Brickwork	Wood
5.....	2.38	2.19
10.....	3.20	2.71
15.....	3.76	2.95
20.....	4.22	3.02

In practice the exposed walls of a building are not subjected to a wind movement of more than 15 miles per hour in extremely cold weather.

\* Authorities: (1) Harding and Willard; (2) Norton; (3) Poenager.

NOTES—(a) Plastered both sides; (b) Plastered both sides with prepared gravel roofing applied to one side only.

**Air at Ceiling.**—It is recommended that an allowance be made to the specified inside temperature for ceiling or wall heights not exceeding 15 feet. For ceiling heights of 20 feet or more in estimating the temperature at 5 feet above the specified inside temperature to be maintained, which is 20 feet, the temperature of the air in the room at the level of the roof may be assumed as  $65^{\circ} + 30$  per cent

allowance to compensate for other than southern exposures, the correction factors, by which the calculated heat transmission is multiplied, are quite commonly used:

Northwest exposure where winds blow directly upon an important factor..... = 1.15 to 1.30  
 Moderately exposed..... = 1.10 to 1.20

**REQUIREMENTS.**—If there are no sources of heat already provided in the room, the number of B.t.u. which must be supplied per hour by the heating apparatus is

$$H = H_s + H_r,$$

where  $H_s$  is the value given above,  $H_r$  including the allowances for the presence of a number of people in the room, or a number of lights (as in a power house or substation) the additional heat given off by the people or apparatus is

$$H = H_m,$$

where  $H_m$  is the heat given off by the people and apparatus, and is calculated as follows:

**PEOPLE.**—A man at rest gives off about 400 B.t.u. per hour, and at work about 1,000 B.t.u. per hour. This quantity of heat is not of sufficient importance to account except in assembly halls and theaters.

The heat given off by the electric lamps in a room is equal to

(Wattage per lamp)  $\times$  (number of lamps)

The heat given off by the gas lamps may be calculated from the following data:

.....	150 B.t.u.
.....	700 B.t.u.
.....	1000 B.t.u.

and a gas lamp gives off 3 cu. ft. of gas per hour and a fish tail burner 5

**MOTORS.**—Motors and the machinery which they drive, convert all of the electrical energy supplied into heat in the room if the product being manufactured is not at a temperature the same as the room temperature. In this case

$$\text{Heat per hour} = 2550 \left( \frac{\text{H.P. Output to Motor}}{\text{Efficiency of Motor}} \right).$$

If the heat is taken from the machinery from the outside, then only the horsepower supplied is used, in which case

$$\text{Heat per hour} = 2550 \times (\text{Brake Horse-power}).$$

In high-powered mills the heat given out by the machinery is the cause of heating and is frequently sufficient to overheat the building even in winter weather, thus requiring cooling by ventilation the year round.

In a transformer substation, or other room from which electric energy is transmitted, the heat supplied by the electric apparatus is of course accompanied by losses in the apparatus. Note that a loss of 1 kw. is equivalent to 3.41 B.t.u. per hour.

**HEATING APPARATUS.**—For dwellings, shops, etc., hot-air, steam, or steam-heating systems are usually employed; for large buildings, hot-water systems are used. In substations or power houses (e.g., a hydro-electric station), the heat losses are not sufficient to provide enough heat, either steam or hot-water heaters are used.

Harding and Willard give the following values of  $K$  (=B.t.u. radiated per square foot per hour per  $^{\circ}$ F. difference in temperature between steam and room air) for direct steam radiators. These values of  $K$  were determined from tests on such radiators standing exposed in air at  $70^{\circ}$  with steam at a standard temperature difference of  $150^{\circ}$ .

VALUES OF  $K$  FOR DIRECT RADIATORS

Type Radiator	Height of Radiators		
	20 and 22 ins.	26 ins.	32 ins.
1 column.....	1.05	1.90	1.85
2 column.....	1.80	1.75	1.70
3 column.....	1.70	1.65	1.60
4 column.....	1.60	1.55	1.50
Flue, 42 square feet.....	.....	.....	.....
Window.....	1.85	.....	.....
Pipe coils.....	2.00	.....	.....
Wall (horizontal).....	1.95	.....	.....
Wall (vertical).....	1.90	.....	.....

\* Air entering flues at  $70^{\circ}$  and leaving same at  $152^{\circ}$ . (Allen.)

$K$  increases (1) as height of radiator is reduced and (2) as number of columns or width of radiator decreases. The variation in the value of  $K$  is approximately 0.2 per cent per degree F. above or below the standard range of  $150^{\circ}$ . Thus if a 3-column, 38-in. high, direct radiator is to be used in a room at  $60^{\circ}$  with steam at  $230^{\circ}$  we would have a temperature difference of  $170^{\circ}$  above standard, and the value of  $K$  would become  $(1.55 + 0.002 \times 20) = 1.61$ , and each square foot of radiation would give off  $1.61 \times 17$  B.t.u. per hour.

**HEATING AND COOKING BY ELECTRICITY.**— (See also *Heat and Thermal Properties; Insulating Materials; Resistance and Conductance; Wires, Resistance.*) Electricity may be used to generate heat for any heating or cooking operation that can be performed with any other source of heat. The facility with which the heat can be applied to exactly the place needed, and in exactly the quantities needed, usually gives results so far superior to those obtained with other heating agents, that the increase in the cost of the heat is often overbalanced by the increased benefits obtained in other directions.

**DESIGN OF HEATING UNIT.**— Let  $R$  be the resistance of the unit in ohms, and  $I$  the current, in amperes. Then the rate at which heat is developed at the unit is

$$P = 3413 R I^2 \quad \text{B.t.u. per hour.} \quad (1)$$

Let  $\rho$  = resistivity of the wire of which the device is made, in ohms per mil-foot,  $l$  = length of wire in feet, and  $s$  = cross-section of wire in circular mils. Then

$$R = \frac{\rho l}{s} \quad (2)$$

Values of  $\rho$  for some of the metals commonly used in heating units are given in Table I (see also *article on Wires, Resistance*).

**Temperature Elevation for Given Power Input.**— When a given heating device reaches a constant temperature, the rate at which heat is carried off

Fig. 1. Total Radiation and Convection in Still Air at 21° C.  
A = Dull Nickel; B = Rough Black Body; C = 2.3 In. W.I. Pipe.

from its surface by radiation and convection (assuming the heat lost by thermal conduction is negligible) is equal to the rate at which heat is developed in the

device. The rate at which heat is lost by radiation and convection both upon the extent and the nature of the surface and upon the difference of temperature between this surface and the surrounding air; see Fig. 1 and article on *Heat and Thermal Properties*.

**Resistance Materials.**—Metallic resistance materials are usually either in the form of rod, wire or ribbon, although cast shapes may be employed. The material chosen depends upon the temperature, the operating conditions, the space available and first cost. The following table contains some of the materials used

TABLE I.—DATA ON RESISTANCE MATERIALS

Material	Chemical composition (approx.) per cent	$\rho$ Spec. Res. ohms per cir.-mil.-ft.	Temp. coefficient per deg. F.
Pure nickel.....	.....	69	0.0039
Iron wire.....	.....	69	0.00635

Nickel-chrome.....	{ Ni 80 to 84 Cr 20 to 16	600	0.00006

**Galvanized Iron Wire** is a useful resistance material for electric applications in which the resistance element may be operated at a low temperature and in which a large temperature coefficient is not a disadvantage. It is sometimes used for air heaters. Plain iron wire is not suitable as it rusts too readily.

**Cast Iron** is useful in special cases of lower temperatures, particularly where a heater with considerable mass in itself is desirable.

**German Silver Wire** is limited in application due to the danger of crystallization.

**Copper-Nickel Alloys** produce wire of great uniformity and flexibility, capable of standing up under continuous heating at moderate temperatures.

**Thirty Per Cent Nickel Steel** has a high specific heat and fair temperature coefficient, but is subject to rusting unless protected from moisture and from the atmosphere.

**Nickel Chromium Alloys** are probably the best resistance materials now available for electric heaters. The cheaper grades such as Chromel, Nichrome, and Calido contain approximately 25 per cent iron, and this impairs their resistance to oxidation as compared to the better grades, such as Kanthal, Chromel "A," and Rayo, containing practically no other materials than nickel and chromium.

Nickel-Chromium alloys are covered with a coat of oxide that protects the material from further oxidation. This oxide does not scale off on re-

TABLE II.—NICKEL-CHROMIUM ALLOYS

heating and cooling. The resistance of various grades and sizes is shown Table II.

**Insulating Materials.** — Insulating material must be chosen with to the use to which it is to be put.

**Mica** is one of the best electrical insulators for heating purposes. Care must be exercised, however, in elements in which the resistor is to exceed 500 ohms because of the effect of the heat in the mica. Mica, being a crystalline material, will dehydrate if heated to the proper temperature. Some grades of mica will dehydrate near 500° C., while others will stand up to 1000° C. After dehydration, the electrical resistance of mica is reduced to such a low value that it becomes a good conductor. Furthermore, the dehydrated mica loses its mechanical strength. During the process of dehydration water vapor is given off which will attack the resistance material.

Mica is used in the form of solid plates of natural mica, and also in the form of built-up plates, using small pieces of natural mica and binding them together with a suitable bond. Since natural mica can be obtained in quantities only in small sizes, any support or insulator larger than a few inches in either dimension must be made of built-up mica.

The bonds for built-up mica are of two classes, volatile and non-volatile. Volatile bonds require heating to drive them out before the element is ready for use. Non-volatile bonds do not bake out and are to be preferred because they require this operation, and also because the small pieces of mica are held together more securely. The bond should be of such material as not to attack the resistance material at the working temperature.

**Porcelain** possesses high electrical resistance, but only certain grades are suitable for high temperature uses, because of the danger of cracking when undergoing the wide variations in temperature encountered. The insulator must be designed with care to avoid such cracking, even with the best of materials.

"**Lava**" is an excellent material but is much more expensive than porcelain.

**Asbestos** is quite hygroscopic, which interferes with its use in heating appliances, except in special cases. It is also incapable of withstanding high temperatures.

**Asbestos Lumber and Other Moulded Compositions** containing asbestos and other fibers have various special uses, but none are suitable for high temperatures.

**HOUSEHOLD APPLIANCES.** — The following is a partial list of usual household appliances and the energy required for each.

3-lb. flat-iron.....	250 to 300
6-lb. flat-iron.....	550
9-lb. flat-iron.....	635
Toaster.....	450 to 550
Table stoves.....	500 to 600
Table grills.....	600
Percolators.....	350 to 400
Waffle irons.....	600
Water cup.....	300 to 500
Reflector radiator.....	600
Warming pad.....	25 to 50
Hair curler.....	15 to 20
Immersion water heater.....	300 to 500
Ranges.....	5000 to 8000

**Electric Flat-iron.** — The heating element is usually of flat nickel-chromium ribbon approximately  $\frac{1}{16}$  inch wide by 0.005 inch thick. The

for this ribbon is a flat plate of mica which is similar in shape to the bottom of the iron. The insulating plates are of mica also and are slightly larger than the ribbon form or support. The resistance ribbon is wound so as to distribute the heat over the ironing surface as desired. The usual ground test for this class of devices is 900 volts A.C. cold and 500 volts A.C. at working temperature. In elements of this type of construction the heat density of the ribbon is approximately 30 watts per square inch of total surface of the ribbon. The density of the heat distributed over the bottom area of the iron averages approximately 25 watts per square inch.

The usual working temperature of the bottom surface of a flat-iron is about 300° C. (562° F.) while the temperature of the element is about 350° C. (662° F.). When the iron is not used and the current left turned on, the temperature will rise until the heat radiated equals the input. This will occur when the bottom surface is near 600° C. (1112° F.), at which time the element will be near 700° C. (1302° F.).

**Toasters.** — Toasters of the vertical type usually have vertical heaters, similar in principle of construction to flat-iron heaters, except that the wire is exposed to radiate freely upon the bread.

**Household Ranges.** — Electric ranges are made in a variety of shapes and sizes to suit the various needs of the users. A range consists of one or more ovens and one or more open hot plates or burners. The type most generally used is the "Cabinet" type, having the oven on the same level as the top burners, and located at either end of the range. Other types have the oven beneath the open burners, and others the oven elevated above them corresponding to similar types of gas ranges.

Ovens are insulated with an insulating material such as mineral wool or air and asbestos to prevent heat loss. They are equipped with one or two heaters according to the design. The maximum input per cubic inch varies from 0.40 to 0.70 watt per cubic inch for the ordinary sizes. Oven heaters are either of the open coil, enclosed coil, or sheathed wire construction.

Top burners for open cooking are from 6 to 12 inches in diameter, averaging about 8 inches. These burners operate at from 20 to 30 watts per square inch of upper surface. They are of various types, such as open coils supported in grooves in a porcelain disc, coils enclosed in a circular casting and insulated with mica or porcelain, or cast-in type of enclosed element.

The total capacity of the usual range is from 5000 to 8000 watts depending on the size of the oven and number of open burners.

**The Cost of Cooking** depends on the number of persons in the family, the kind of meals served, the skill of the user, and the rate for current. The curve in Fig. 2 gives an idea of the power requirements for electric ranges under average conditions. This does not include the power required for lights, extra appliances, water heating, etc.

**INDUSTRIAL APPLIANCES.** — Electrically heated appliances have been developed for a very large number of uses. The following list contains only a few of the more common devices.

Tailor's Pressing Irons  
Solder Pots

Glue Pots  
Scaling Wax Heaters

Fig. 2.

Soldering Irons  
 Branding Irons  
 Hatter's Irons  
 Velouring Stoves

Hot Tables  
 Press Blocks  
 Chocolate Warmers

Usually the cost of the energy to operate such devices is immaterial in view of the great advantage gained in speed, convenience, safety, and uniformity of operation.

**INDUSTRIAL APPLICATION UNITS.** — These are small heaters complete in themselves with supports and terminals which have been designed to meet a wide variety of applications of heat to machines and appliances in which heated surfaces or spaces are essential to their successful operation. Usually the application involves only minor changes in the construction of the machine to accommodate the electric units. Terminals are provided for connecting up the units.

Such units are usually provided in standard voltages of 110 and 220 volts, although the larger units for ovens are suitable for operation in series at 550 volts. Some of the types and applications of these units are described in the following paragraphs.

**Cartridge Heaters.** — A tubular unit having terminals at one or both ends and designed to be inserted in holes drilled in castings which require heating, such as embossing presses, hot moulding presses, shoe machinery ironing machines, machine irons, etc., is called a cartridge heater. Nickel chrome resistance material is used for the heater and is wound on a central core of porcelain or lava and insulated from the outer tube of brass by cement or mica. Cartridge heaters may be used in applications up to 300° C.

#### G. E. CARTRIDGE TYPE UNITS

Symbol No.	Length in inches	Diameter in inches	Watts
142	2.39	0.498	100
151	2.51	0.748	200
102	3.9	0.933	250
9	4.87	0.933	70
11	4.87	0.933	140
48	4.87	0.933	440
63	5.	1.291	300
103	5.	1.291	600
104	5.	1.291	900
162	8.5	1.291	1000

**Steel-clad Heaters.** — This is a flat type of element consisting of a flat form on which a resistance element is wound, insulated with flat plates of mica and enclosed in a casing of sheet steel pressed flat on the element. Terminals are usually located at one end.

This unit is made in a wide variety of sizes and is suitable for hot-press heating, hot tables, heating rolls, small ovens, etc., in which the uniform distribution of heat is desired. A few of the standard sizes available are given listed in the following table.

## WESTINGHOUSE STEEL-CLAD HEATERS

Length of heater, inches	Width, inches	Thickness, inches	Watts	Volts
10	2 1/4	3/16	350	55
12	2 1/4	3/16	500	110
15	2 1/4	3/16	650	110
21	2 1/4	3/16	1000	110
12	1 1/4	3/8	175	110
24	1 1/4	3/8	350	110

**Space Heaters.** — These are similar to the steel-clad heaters, except that one terminal is located at each end. The 24-inch length is a standard size and is suitable for a wide variety of applications, of which the following is a partial list. The unit is 1 1/4 inches wide, 3/16 inch thick, and is supplied in two designs, one for 110 volts and the other for 220 volts, the rating being 500 watts in either case.

Small Industrial Ovens  
Blue-print Driers  
Hoist Cabs  
Ticket Booths

Watchmens' Houses  
Elevator Cabs  
Laundry Driers

**Industrial Oven Heaters.** — These heaters are designed for the larger sizes of industrial ovens. They are of nickel-chromium ribbon wound over porcelain bushings and assembled into a metal frame. Exposed heating ribbon is used to give free radiation into the oven space. The heating is done partly by radiation and partly by convection. Terminals are provided at the ends for connections. Units are usually made up for 110-volt and 220-volt service. Two 220-volt units may be connected in series for 440 volts. Complete sets of suitable connection straps and insulators are provided to accompany the heaters.

**INDUSTRIAL ELECTRIC OVENS.** — Electric heat has been applied to ovens for japanning, lithographing, paint drying, lacquer dyeing, core baking, armature baking and many other purposes requiring temperatures up to 600° F. The absence of fumes and gases, reduction in fire hazard, ease of control, and increased production have in many cases justified even increased costs of heat. Ovens are of the usual kiln type, the semi-continuous type, or the continuous type.

A **Kiln-type Oven** is usually rectangular in shape with a door at one end into which the material to be baked is loaded. When the oven has been loaded, the door is closed and current turned on. When the baking has been completed, the current is turned off, door opened and work removed.

A **Semi-continuous Oven** has doors at both ends and a new load is pushed in at one end while the finished load is removed from the other end.

In a **Continuous Oven** the work is carried through the oven on a continuous conveyor loading at one end and discharging at the other at a uniform speed.

Heaters are installed along the side walls or on the floor. A space of 8 to 10 inches from the wall or floor should be provided. Over the heaters a screen of expanded metal or wire mesh can be installed to prevent work dropping on the heaters and connections.

Control is usually by magnetic switches. Door switches are sometimes provided so that when the doors are opened the main switches also open. A thermostat is usually used to regulate the temperature by turning the current off as may be needed. This thermostat operates through a relay to control the main magnetic switches.

110, 220, or 440 volts of any frequency and either single phase, two, or three phase can be used. Direct current up to 550 volts can be used.

**Heat Required for Industrial Oven.** — In calculating the heat requirements, the following losses and uses of the heat must be carefully determined.

**Heat to Raise the Temperature of the Work, Including Trucks.** The total weight of the material to be baked, the initial and final temperatures, and the specific heat must be known. Dividing the heat required by the time allowed gives the heat per hour needed. The japan or paint can be ignored. The heat required to heat the trucks or hangers is calculated in the same way for each.

**Heat to Raise the Temperature of Oven Walls.** — The insulation material in an oven wall absorbs heat in the period of heating up even though it be fairly good heat insulator. The usual method is to average the temperatures of the inner and outer surfaces, and subtract the initial temperature to obtain the average temperature rise. This is multiplied by the weight of the material to obtain the total heat required. Dividing this by the time allowed for the heating operation gives the rate at which heat must be supplied.

The interior framework and oven lining of metal are heated on the same rate as to the same temperature as the work in the oven, and can be calculated in the same way.

In the case of a kiln-type oven the interior cools down somewhat during the period when the doors are open for emptying and reloading. For this reason a portion of the heat must be replaced with each charge. This may be one-quarter to one-half of that required on the first bake.

**Radiation Losses from the Oven.** — This depends upon the wall and door construction. It is of prime importance that the amount of metal exposed by opening through the oven walls from the inner to the outer surfaces be reduced to a minimum. Average radiation loss from a metal oven with two inches of insulation (air-cell asbestos or magnesia) and door at one end only will be approximately 50 watts per square foot of total outside surface of oven, with an interior temperature of 400° F. Exact figures for radiation losses cannot be given, but it is controlled to such a great extent by the design of doors, corners, vents, etc., as well as by the thickness and character of the insulation.

**Ventilation.** — The amount of ventilation required depends upon the nature of the product to be baked. Ovens for japanning, paint drying, core baking and other operations that give off gases or vapors require ventilation. When japan or paint is used that contains a volatile solvent of combustible nature, good ventilation is necessary to reduce the danger of fire or explosion. The danger is much more remote with an electrical oven than with a gas or fuel-heated oven because of the uniform temperature regulation obtainable with an electric oven. Ventilation also removes the gases given off during the baking and improves the surface obtained.

For japanning ovens from ten to twenty changes of air per hour are usually allowed. To calculate the heat required the volume of the oven is multiplied by the weight of a cubic foot of air at the oven temperature, times the temperature rise, times the specific heat of air, times the number of changes per hour.

**Totals.** — Adding together the heats required for each of the items throughout the time allowed will give the total heat. Dividing by the

the heat will be required. If the heat is calculated by 3415 to get the power input in kw.

The average figures of inputs for various oven sizes are ample, however, it may be stated that for japanning baking period, the input would be around 100 watts for the oven.

Electrically heated bread-baking ovens are made reel type.

They come with from one to five or six shelves. The greater the bread capacity per square foot of floor space is usually placed in each shelf, although in the smaller ovens under the bottom shelf may be used. In the latter case the air in the oven are depended on to carry the heat. Ducts are provided at the sides or back to assist

the reel carrying six to eight bread trays which rotates and the trays are placed on the bottom.

The capacity is from 30 to 600 loaves and from 4 kw. to 75 kw. The consumption will be from 100 to 200 watt-hours per one loaf depending on the size of oven, kind of bread and skill of operator.

**ANNEALING FURNACES.** — Furnaces for these temperatures up to 2000° F., are available in various sizes. They consist of a fireclay lining, either solid or sectional, to be used. This is surrounded by a wall of heat insulating material of the highest grade of nickel-chromium material or rod. In order to utilize a heavy cross-section of material a voltage lower than the usual 110 volts is provided by transformer.

For the size of furnace it is necessary to calculate the amount of heat required to raise the temperature of the material and also to estimate the heat loss from the furnace. The frequency of opening and closing doors and the amount of air entering, as the radiation through an open door is very important.

For more detailed information should be consulted for more detailed information.

**HOISTS, ELECTRIC.** — (See also *Cranes; Elevators; Motors, Inc. Applications of; Telpherage.*) A hoist is a machine for raising and lowering weights. The most common application is in mines, to which service the following article is devoted.

The hoists most generally used are of the drum type, the drums being cylindrical or conical or a combination of the two. As a rule two drums operating in balance are used for each hoist. The weight of the skip, or car or cage carrying the ore, is balanced by a similar empty skip which is lowered in the second compartment simultaneously with the hoisting of the loaded skip. At the bottom, first, the loaded skip being dumped at the top and the empty one loaded at the bottom, and the cycle being repeated. The difference between balanced and unbalanced hoisting is that the static load when working unbalanced is greater than when working balanced, and the change of load due to the rope is one as great.

**Preliminary Data.** — In dealing with hoisting problems the following data are required:

- Present and ultimate depth of shaft.
- If inclined, give angle of inclination with horizontal, or grade, in per cent.
- Weight of material per trip.
- Weight of skip or cage and car.
- Diameter and weight of rope.
- Size of tail rope, if used.
- Rope speed.
- Number of trips per hour.
- Time required for loading and unloading.
- Double or single drum.
- Diameter and weight of drums.
- Motor geared or direct connected.
- Hoist balanced or unbalanced.
- If balanced, will unbalanced operation ever be necessary?

Besides the above, the ordinary data of the power supply system must be known; also the restrictions as to permissible peak loads, so as to make it possible to decide whether a load equalizing set will be required.

For cylindrical hoists the power required for the various periods of the cycle can be figured directly in horse-power. For conical drums the problem is somewhat more complicated and a moment diagram is usually first figured and plotted, and then converted into horse-power.

**SYSTEMS OF ELECTRIC HOISTING.** — Of the large number of systems of electric hoisting which have been proposed, by far the greater number can be included in the three following systems:

1. Those driven by induction motors.
2. Those driven by direct-current motors, power for which is supplied by a motor-generator set.
3. Those driven by direct-current motors, power for which is supplied by a flywheel motor-generator set.

**1. Induction-motor System.** — In the first and simplest system the speed of the direct-connected induction motor is controlled by a variable resistor in the rotor circuit. The advantages of this system are: simplicity, low cost, high motor efficiency when the hoist is running at full speed (approximately 90 per cent), no power consumed when the hoist is at rest. The disadvantages are: low motor efficiency during acceleration (approximately 45 per cent), no power is returned to supply system during retardation.

the power consumption for small movements of cage, fluctuation of power demand.

2. **Direct-current Motor System.**—In the second system the hoist is driven by a separately excited direct-current motor, receiving power from the generating-current supply system through a synchronous or induction motor-generator set. The hoist motor is controlled by varying the voltage of the generator, which is separately excited, one generator being used for each motor. Advantages of the system are: high motor efficiency during acceleration, loss of large portion of energy during retardation. The disadvantages are: low combined efficiency of the equipment when running at full speed (probably not better than 82 per cent), loss in motor-generator set when hoist is at rest, high initial rotor expense, fluctuation of power demand.

3. **Direct-current System with Flywheel.**—The third system takes advantage of the low first cost and efficiency of the flywheel (*see Flywheels for Load Equalization*) as a means for storing and returning large quantities of power for short intervals. This system is similar to the second, except for the addition of a flywheel to the induction-motor-generator set, and an automatic regulator for varying its speed. In its most common form this regulator consists of a water rheostat connected in series with the induction-motor rotor. The resistance is varied by means of movable electrodes suspended from an arm mounted on the shaft of a small induction motor, which is connected in series either directly or through series transformers, with the induction motor of the flywheel set. The regulator motor is so connected that its torque opposes the weight of the electrodes, which are partially counterbalanced to reduce the size of the regulator motor to a minimum, and to permit of an adjustment of the regulator for different values of line current. When the line current exceeds the value for which the regulator is adjusted, the torque of the motor overbalances the weight of the electrodes, lifting them and inserting resistance in the armature circuit of the induction motor. This causes it to slow down, and allows the flywheel to assist in driving the generator during the peak loads.

**Steam vs. Electric Systems.**—A comparison between a steam system and these three electrical systems is given in the following table, in which the fuel and ore ratios for each are given for a small installation hoisting from a 2000-foot level, and a large installation hoisting from a 6000-foot level.

In addition to the saving in fuel which may be realized by the use of electric hoists instead of steam hoists, there is a very material reduction in the labor, the

Installation	Hoisting system	Coal burned, tons per day	Ore hoisted, tons per day	Ratio tons ore to tons coal
Small, hoisting from 2000-foot level.	Steam	47	1780	40
	Electric, first system	13	1780	137
	Electric, second system	15	1780	119
	Electric, third system	16	1780	110
Large, hoisting from 6000-foot level.	Steam	65.5	1580	24
	Electric, first system	23	1580	69
	Electric, second system	24	1580	66
	Electric, third system	25	1580	63

cost of which is chargeable against the hoist. This may amount to that of one or two men in the boiler house if power is developed by the mine pany, or of the whole boiler house force if power is purchased, and free the wages of one man in the hoist house.

**Power Consumption.** — So many factors enter into the cost of electric hoisting that each individual case must be analyzed separately. An approximate estimate of the power consumption would be from  $1\frac{1}{4}$  to  $2\frac{1}{4}$  kilowatt-hours per 1000 ton-feet, the tonnage, in the case of unbalanced hoisting, including weight of the ore and skip, while for balanced hoisting only the ore.

**SPECIFICATIONS FOR ELECTRIC HOIST.** — The following standards are intended to assist in writing specifications. See also article on *Hoists, Electric* and the article on *Specifications*.

**Principal Characteristics and Conditions of Service.** — General description and use of hoist. Motor voltage and frequency (*see articles on Motors, Electric*). Mechanical rating, i.e., load to be lifted a specified height in a specified proportion of time above load will be carried and of time machine is at rest.

**Details of Construction.** — Length of hoisting rope and whether rope is to be supplied. If so, details of rope and of hook or other device. Details of construction. Lubrication details. Materials of principal parts.

**Performance and Tests.** — Maximum load to be lifted. Maximum speed of descending. How tests are to be conducted.

**HYDRAULICS.** — (See also *Dams; Hydrology; Pipes and Piping; Power Plants, Hydro-Electric Turbines, Hydraulic; Turbines, Hydraulic, Speed Regulators* of.) Hydraulics comprises the principles and laws governing the motion and mechanical reactions of liquid bodies. There are two general divisions of the subject: Hydrostatics, which refers to liquids at rest; and Hydrodynamics, which refers to liquids in motion. This article will be confined to that portion of the subject which relates more directly to the problems met with in the study of water-powers.

**Head and Pressure.** — In water power terminology the word *head* means the difference in level of water between two points. It is usually expressed in feet. The pressure of water in a pipe for instance, is usually given as so many feet head and not as so many pounds per square inch. The relation between head in feet,  $h$ , and pressure in pounds per square inch,  $p$ , is as follows:

$$h = 2.31 p,$$

$$p = 0.433 h.$$

These formulas assume 62.4 lb. as the weight of 1 cu. ft. of water. See also *Units and Conversion Factors*.

**FLOW THROUGH PIPES.** — See articles on *Pipes and Piping* and *Water Wheels, Speed Regulation of*.

**FLOW THROUGH OPEN CHANNELS.** — The term channel includes all forms of closed conduits when flowing partly full as well as ordinary stream beds or canals. The rate of flow in such a case depends upon the slope given to the water surface. It is difficult to treat analytically the flow in natural channels, because of the wide divergence in shape of cross-section and nature of sides and bottom of channel. Only artificial channels are considered here, although the same formulas apply to any section of natural channel which has the same cross-section throughout.

**Velocity and Friction Head.** — The total head required to transport water in an open channel is used in creating velocity and in overcoming friction.

The "velocity head," or head required to impart a given velocity of flow to water, may be expressed by the equation,

$$h_v = \frac{v^2}{2g},$$

where  $h_v$  is the head in feet,  $v$  is the average linear velocity in the channel in feet per second, and  $g$  is the acceleration of gravity, or 32.16. The theoretical head required to increase the velocity from  $v_1$  to  $v_2$  is therefore,

$$h_s = \frac{v_2^2 - v_1^2}{2g}.$$

All changes in velocity should be made gradually to prevent the formation of eddies which result in additional friction loss.

The difference in elevation between the water surface at any two points in a channel of constant cross-section is the "friction head" or head required to overcome friction between those points. The friction head per unit of length depends upon the cross-section, shape and roughness of the channel.

**Chezy's Formula.** — This formula gives the relation between the linear velocity of the water, hydraulic radius and the slope and a coefficient which must be determined experimentally, viz.,

$$v = C\sqrt{rs},$$

where  $v$  = linear velocity of water in feet per second,  $r$  = hydraulic radius in feet,  $s$  = slope of stream (i.e., the difference in elevation between two points on the water surface divided by the slope distance between the two points measured along the surface) and  $C$  is an experimentally determined coefficient which may also be expressed by the empirical formula given below.

**Hydraulic Radius.** — This term is used to designate the quotient of the area of a cross-section, e.g.,  $ABCD$  in Fig. 1, by the *wetted* perimeter of the channel walls and bottom,  $AB + BC + CD$  in Fig. 1.

Fig. 1.

Fig. 2.

**Best Section to Use.** — Hydraulically, the most advantageous cross section to use is that having the maximum value of the hydraulic radius  $r$ . The semi-circle is therefore the best but is the most difficult to construct and to maintain. Of trapezoidal cross-sections the half hexagon is the best and of rectangular cross-sections the half square. In unlined earth channels the trapezoidal cross-section must be used. Of these sections the best to use is shown in Fig. 2. The angle  $\alpha$  is determined from the character of the soil. The sides and bottom are made tangent to a semi-circle having its center at the water surface.

Practically, however, the area to be adopted must be that which will result in a minimum construction cost for the same slope in water surface, and this applies to canals, flumes and all other types of channels. In Fig. 1, for example, if the surface of the ground were considerably above the water surface, a minimum of excavation would correspond to a relatively deeper and narrower channel having a slightly larger area to retain the same slope for the given discharge.

**Kutter's Formula.** — This is the formula in common use for expressing the coefficient  $C$  in Chezy's formula in terms of the slope, hydraulic radius and the characteristics of the channel.

$$C = \frac{41.65 + \frac{0.00281}{s} + \frac{1.811}{n}}{1 + \left(41.65 + \frac{0.00281}{s}\right) \frac{n}{\sqrt{r}}}$$

where  $r$  and  $s$  are as above, and  $n$  is the "coefficient of roughness" depending upon the characteristics of the sides and bottom of the channel. Approximate values of  $n$  are given below. For a more extended list see *Bibliography*.

	Value of $n$
Best type of metal flumes.....	0.011
Concrete lining of smoothest kind, and well constructed clean wooden flumes with surfaced lumber.....	0.012
Clean wooden flumes of unplanned lumber, and average troweled concrete linings.....	0.015
Average concrete linings, not troweled, having prominent form marks, best conditions of canals in earth and best brickwork.....	0.016
Very rough concrete linings with deposits of gravel and moss, inferior brickwork, good rubble.....	0.018
Well constructed canals in firm earth or fine packed gravel free from vegetation.....	0.020
Worst type of ordinary metal flumes.....	0.022

	Values of $n$
Average canals in earth.....	0.033
Canals in earth with occasional weeds and stones, and smoothest canals in rock cut.....	0.025
Canals in earth with a rather heavy growth of weeds and large rocks in bottom.....	0.030
Canals in bad condition and average canals in rock cut.....	0.035
Canals in rather rough rock cut.....	0.040

**FLOW OVER WEIRS.** — In hydraulics the term "weir" is used in general to designate any kind of a dam across a stream, and in particular to designate a vertical notch, usually rectangular, by means of which the quantity of water passing a given point may be determined, *Fig. 3.*

**Definitions Regarding Weirs.**

— The "crest" is the horizontal edge of the weir. The "head" on a weir is not the depth of water over the crest, but is the difference in level between the crest and the reservoir surface, measured far enough away from the weir to avoid the surface curve or sharp slope near the crest. A "fully contracted" weir is one in which each end of the weir is at a distance of at least 3 times the head from the sides of the channel. A "suppressed" weir is one in which the sides of the channel (smooth and vertical) form the end of the weir. The "velocity of approach" is the velocity of the water in the channel leading to the weir. For a given head on the weir the quantity of water passing the weir depends somewhat upon the velocity of approach.

*Fig. 3.*

**Weir Formulas.** — The weir formulas of Francis, Bazin, Fletcy and Stearns, Smith and others are each based on somewhat different experimental conditions. Therefore, to measure accurately the discharge over sharp-crested weirs, that formula should be used which is the result of experiments on weirs of the same general type and made under similar conditions.

Francis' formulas are given below. They are applicable only to vertical, rectangular weirs having

- (1) Sharp, smooth, bevelled edges on the downstream side as shown in *Fig. 3* (or a thin metal plate bolted to a wooden board may be used for the edge of the weir).
- (2) The crest of the weir at least three times the head above the bottom of the channel.
- (3) A length of crest at least three times the head on it.
- (4) A head not greater than 2 feet nor less than 0.5 foot.
- (5) A velocity of approach not greater than one foot per second.

Let  $Q$  = cu. ft. of water per sec. flowing over weir,

$H$  = measured head on weir, in ft.,

$h$  = head in ft., due to velocity of approach,

$H_1$  = "effective" head on weir, in ft.,

$b$  = breadth of weir (length of crest) in ft.

Then for a *fully contracted weir*

$$Q = 3.33 (b - 0.3 H) H_1^{3/2}$$

and for a *suppressed weir*

$$Q = 3.33 b H_1^{3/2},$$

when the cross-section of the stream immediately above the weir is more than  $6bH$  the effect of the velocity of approach is negligible and  $H_1$  may be taken equal to  $H$ . When the cross-section of the stream is less than  $6bH$ , then

$$H_1^{3/2} = (H + h)^{3/2} - h^{3/2}.$$

For the determination of the discharge over weirs having other than sharp crests, the same general equations may be used; but the coefficient, 3.33 may be altered as indicated by experiments (see *Horton's paper listed in Bibliography*)

**Determination of Velocity Head ( $h$ ).** — First take  $H_1 = H$ , and from the above formula calculate  $Q$ . This value of  $Q$  divided by the cross-section of the channel immediately above the weir gives an approximate value for the velocity of approach  $V$ . The head due to the velocity of approach is the approximately  $h = \frac{V^2}{64.32}$ . Recompute the discharge  $Q$ , calculating  $H_1^{3/2}$  from the measured head  $H$  and this value of  $h$ . This will usually give the discharge very closely.

If desired, a new value of  $V$  may be found from this new value of  $Q$  and a third value of  $Q$  computed, using for  $h$  a value based on the new value of  $V$ . This method will be recognized as one of successive approximations. Generally one, and never more than two, recomputations are all that are necessary. In using the weir formulas given it is necessary to adhere to this method strictly, as the constants in the formulas were derived by using this method.

**OTHER METHODS OF MEASURING FLOW.** — The rate of discharge of a channel or natural stream may also be measured by means of floats, a Pitot tube, or a current meter. These devices are briefly described below.

**Floats.** — When a stream is of reasonably regular cross-section for a little distance, this method is applicable. Sticks about  $1/4$  inches in diameter, sufficiently weighted at one end so that they will float upright in the water, should be used. Surface floats are unreliable because of the influence of wind, skin friction of the water, etc. The floats are started at the beginning of a measured course and the time which they take to reach the end of the course is accurately taken. The velocity of the stream is thus obtained; this multiplied by the area of the cross-section gives the rate of discharge.

The floats should be started from various points in the width of the stream in order to obtain the average velocity as nearly as possible. They should be long enough to come as close as practicable to the bottom of the stream without touching, in order to average the velocities, which are variable throughout the depth of the stream. This method is less accurate than the use of the current meter.

**Current Meters.** — The ordinary current meter is essentially a wheel revolved by the water and held with its axis perpendicular to the direction of flow by means of vanes. Some means of recording the revolutions are provided. The meter must be rated by drawing it through still water at various measured speeds. Elaborate apparatus for meter rating is maintained by the Government and by various universities. Measurements of the velocity of the stream are made at frequent intervals across the stream and at varying depths, and the average velocity determined; this multiplied by the cross-sectional area of the stream for the height of water existing at the time gives the rate of discharge.

**Pitot Tube.**—This is merely an open tube having a right-angle bend, the one end is placed in the stream in the position shown in Fig. 4, the lower end being directed against the current. The height  $h$  to which the water rises in the tube above the surface of the stream is equal to the velocity head, or the linear velocity of the stream is

$$v = \sqrt{2gh},$$

where  $h$  is in ft.,  $g = 32.16$  ft. per sec. per sec., and  $v$  in ft. per sec. This formula does not apply to the flow through a pipe, since the pressure head must also be taken into account. For measuring the flow in pipes a differential gage of this type may be used, but the Venturi meter (see below) is better suited to such measurements.

Fig. 4. Pitot Tube

**Venturi Meter.**—This meter, Fig. 5, serves as a simple and accurate means of measuring the discharge through a pipe. The meter consists essentially of an hour-glass-shaped section of a pipe, with smoothly rounded internal walls, into which are fitted two gages as shown. The planes of the internal openings of the gage pipes are at right angles to the direction of the current. Referring to Fig. 5, let

Fig. 5. Venturi Meter

$a_1$  = area, in sq. ft., of the cross-section at A,

$a_2$  = area in sq. ft., of the cross-section at B,

$h_1$  = reading of gage at A, ft. of water column,

$h_2$  = reading of gage at B, ft. of water column,

$g$  = acceleration due to gravity, ft. per sec. per sec.,

$C$  = a coefficient, ranging from 0.94 to 1.00, which takes into account the friction in the meter.

Then the discharge through the pipe in cu. ft. per sec. is

$$Q = C \frac{a_1 a_2}{\sqrt{a_1^2 - a_2^2}} \sqrt{2g(h_1 - h_2)}.$$

Ordinary pressure gages may be used at A and B, and their reading converted to feet of head, with a correction added for height of gage above center of meter.

**HYDROLOGY.** — (See also *Hydraulics; Power Stations, Hydro-Electric.*) In the broadest sense, hydrology is the science of water, including its properties; the phenomena and natural laws associated with it, its distribution over the earth's surface, and in fact everything relating to water as a physical entity. As ordinarily employed, however, the term is limited to include only those laws and properties which have to do directly with its distribution over the earth's surface, particularly the relations between rain-fall, natural drainage, and the flow of water in rivers.

**Hydrological Data Required in Water-power Engineering.** — To determine the probable amount and character of power output of a water-power development, it is necessary to estimate the probable usable run-off of the stream and its flow characteristics. The characteristics of a stream are usually represented by its minimum flow and its variation from day to day and year to year.

**ESTIMATING STREAM FLOW.** — The probable discharge characteristics of a stream may be estimated in various ways depending upon the data available.

**Long-term Stream Gagings.** — The most accurate method of estimating the water available from a given stream is to make direct measurements of the discharge over a long enough period to be reasonably representative of what may be expected in the future. Records covering a period of ten to twenty years should be sufficient for all practical purposes, if rainfall records over a much longer period are available for comparison.

Such measurements are made at a suitable place and the elevation of water surface or "gage height" is recorded for a sufficient number of discharges to determine a "rating curve," see Fig. 1. It is then only necessary to make daily observations of the gage height to obtain a daily record of stream flow.

The U. S. Government has maintained gaging stations for a number of years on many streams in this country. These records are published in the Annual Reports of the U. S. Geological Survey (1888 to 1900) and in the Water Supply and Irrigation Papers (1896 to date) also issued by the U. S. Geol. Survey.

**Short-term Stream Gagings.** — Short-term stream gagings, while useful for comparative purposes, are, in themselves, of little value in estimating accurately the probable future discharge. If, however, a near-by stream of similar characteristics or another point on the same stream has been gaged over a considerable period, the relative discharge characteristics can be determined approximately from a comparison of simultaneous average monthly discharges as indicated in Fig. 2. The longer records of the nearby stream can then be used if each average monthly discharge is modified according to the curve.

In the absence of long-term records on a nearby stream, a rough estimate of future discharge can be obtained from a study of long-term rain-fall records, but the result so obtained is not satisfactory and should be used with caution.

**No Stream Gagings.** — If no gagings on the stream have been made, it becomes necessary to estimate the discharge from discharge records of nearby streams of similar characteristics. Such records, however, must be modified as indicated by a comparison of rain-fall records; or, in the absence of rain-fall records, a comparison of the rain-producing characteristics on the two water-

Fig. 1.

ies, and a study of the physical features of those areas which affect the "run-off," or percentage of rain-fall which finds its way to the stream.

Fig. 2.

In the absence of discharge records on nearby streams, there is little hope of estimating accurately the probable future discharge. Even if long term rain-fall records are available, there is no satisfactory method by which the run-off can be determined even approximately.

**RAIN-FALL AND RUN-OFF.** — The discharge of a stream bears some relation to rain-fall on the tributary drainage area and depends upon the percentage of rain-fall which ultimately finds its way to the stream. Of the total rain-fall over a given period, a portion is lost by evaporation—directly to the atmosphere or utilized by vegetation. The rest appears as run-off.

As mentioned heretofore, it is necessary, in the absence of stream-flow records, to use the records of nearby streams modified in accordance with the relative rain-fall and run-off characteristics of the two drainage areas. The necessary modification is difficult to determine accurately, and becomes increasingly difficult the farther apart the two streams, particularly if on opposite sides of a large range of hills. A brief discussion of the numerous agencies affecting rain-fall and run-off are given in the following paragraphs.

**Rain-fall.** — Rainfall varies materially in different localities, not only in annual precipitation but in its seasonal distribution. The U. S. Weather Bureau has published data and maps indicating the variation in mean annual precipitation throughout this country. The influences most affecting the deviations of local rain-fall from the general mean are the local topographical characteristics, the direction of prevailing winds and the altitude.

Moisture-laden winds, diverted upwards by mountain ranges, expand, cool, and condensation appears in the form of rain or snow. Thus the side of the range subjected to the prevailing winds will have the greater rain-fall.

In general, rain-fall seems to increase with the altitude; but in some cases

\* Including snow, ice, etc., i.e., total precipitation.

the effect of the topographical features on the prevailing winds may modify the general law. A knowledge of the conditions affecting local rain-fall is useful in the interpretation of published rain-fall data and particularly in comparing the rain-fall characteristics of two areas where sufficient rain-fall gaging stations are not available for that purpose.

Rain-fall is usually expressed in inches, the number of inches being the depth of rain water which would be caught in a vessel with vertical sides set out the open. The records of rain-fall may be obtained from the United States Weather Bureau in Washington, D. C. Records covering as extended period and as wide a portion of the watershed under consideration as is practicable should be obtained. Too absolute dependence should not be placed on these results, as the intensity of rain-fall at different places in the drainage area of the stream under consideration may be quite variable, not only in general, but also in particular storms. It is conceivable that a station for recording rain-fall might be located at a point in an area where the annual precipitation is far above or below the average.

**Run-off.**—Among the many influences governing the relation between rain-fall and run-off and the distribution of run-off for a given period, the most important are:

- The geological formation,
- The topography,
- The nature of the vegetation,
- The extent of lakes and swamps,
- The amount of previous ground saturation,
- The rate and amount of rainfall,
- The mean temperature and wind velocity.

Run-off passes to the stream as surface flow or ground water flow. In rocky or clayey, hilly country the run-off passes quickly to the stream or its tributaries and a relatively small percentage of the rain-fall disappears in evaporation. Such drainage areas therefore are characterized by a larger percentage of run-off but a considerable divergence between maximum and minimum flow. The latter characteristic makes them less attractive for power purposes unless large storage reservoirs are used.

Flat or rolling, impervious areas with many lakes or swamps are subject to considerable evaporation but the run-off is more uniform.

The best condition is a flat or rolling country with pervious soil. With such conditions a large part of the rain-fall seeps quickly underground with comparatively little evaporation. Ground water takes months in some cases to reach the stream and affords a supply during seasons of drought.

Evaporation is considerably more constant than run-off. Consequently the percentage run-off is usually much larger for high rain-falls than for low. Evaporation is known to increase with the temperature, although many other meteorological conditions affect it greatly.

The influences controlling run-off are so numerous and inter-connected that it is practically impossible to estimate closely the monthly or seasonal stream flow from rain-fall data; although a rough approximation of total annual run-off can be obtained. A knowledge of the factors affecting rain-fall and run-off are particularly useful if modified discharge records on one stream are to be used in estimating the probable discharge of another stream.

**STORAGE RESERVOIRS.**—“Primary” or uninterrupted power corresponds to the minimum flow of the stream. “Secondary” power corresponds to the flow above the minimum, or that power which is available only part of the time. Primary power is sometimes essential to the fulfillment of contracts.

The natural minimum flow of small streams is usually not large enough to permit of the successful installation of primary power developments. In such cases it becomes necessary to install turbines having a capacity considerably in excess of the minimum natural flow, and to provide steam or other auxiliary power to supplement the water power during periods of drought, or to provide storage reservoirs to hold back the excess or unusable flow until such times as the natural flow is insufficient. The reservoirs may be required to supply a deficiency extending over a few months or a series of years, depending upon the extent of the development in relation to the natural flow.

For use in fixing the required size of the reservoir, an investigation should be made to determine the minimum season, year or series of years, as the case may be, which may be expected to occur in the future.

Storage reservoirs are also used to partially regulate the flow of the stream. When thus used, they augment the primary power and increase somewhat the total available secondary power.

Allowance should always be made for evaporation from large storage reservoirs, which may modify the discharge records of previous years. Evaporation from free water surfaces varies from 20 to 100 inches, depending upon local conditions.

**Load Factor.** — All water is wasted which passes the water power plant in excess of the demand. The demand is fixed by the capacity of the installation and the load factor. The "load factor" is the ratio of the average load to the peak load, and ordinarily varies from 30 per cent to 80 per cent, depending upon the nature of the market. The load factor varies from day to day and from season to season. The daily load factor on Sundays is usually considerably lower than on week days, particularly in winter, when a large part of the load is used for lighting and all mills are shut down. Lighting, railway loads and many other loads vary considerably with the seasons. In most developments, the pond at the power dam is large enough to regulate the daily and week-end flow with in the capacity of the plant, so that it is only necessary to consider the average weekly or monthly load in determining the power available and the required capacity of storage reservoirs.

**Hydrographs.** — Fig. 3 represents a hydrograph of a stream showing a continuous graph of the discharge. The ordinates indicate the "second feet" or

Fig. 3. Hydrograph.

cubic feet per second flowing at any time during the period covered. For large reservoirs, average monthly flow may be plotted instead of average daily flow with a considerable saving of labor. The period should cover a length of time

sufficient to indicate the operation of the reservoir during the time of minimum flow. The flow demand, or flow corresponding to the average power demanded is also indicated. This is not necessarily a straight, horizontal line as shown; but may vary with the seasons as hereinbefore explained. The shaded area represents the deficiency of natural flow and hence the amount of storage required to provide continuous or primary power. It is measured in "second-feet-days."

One second-foot-day requires 86,400 cubic feet of reservoir capacity. The maximum draft on the reservoir occurs at the end of the shaded area, after which there must be sufficient excess natural flow above the demand line to fill the reservoir again.

**Mass Curves.** — Another method of indicating storage requirements is by means of a mass curve, Fig. 4. Each ordinate indicates the total natural flow

Fig. 4. Mass Curve.

since the date of the beginning of the curve, expressed in cubic feet, second-feet-days, second-feet months or other terms as may be convenient. The slope of the curve at any time indicates the rate of flow at that time. The flow demand is laid off on this curve, as indicated, beginning at the time when the natural flow is at the point of becoming deficient. The required capacity of the reservoir is indicated by the maximum difference,  $AB$ , between the ordinates to the two curves. The reservoir will have its maximum draft at  $B$  and will be full again at  $C$  where the two curves come together.

**HYPERBOLIC FUNCTIONS.** — (See also *Derivatives; Integrals; Series, Mathematical.*) Hyperbolic functions are an extension of the trigonometric functions to those cases where the use of the latter gives rise to imaginary or complex angles. From the relations,

$$\cos x = \frac{e^{jx} + e^{-jx}}{2}$$

$$\sin x = \frac{e^{jx} - e^{-jx}}{2j}$$

where  $j = \sqrt{-1}$ , it follows that, putting  $x = js$ :

$$\cos js = \frac{e^s + e^{-s}}{2} \quad (1)$$

$$-j \sin js = \frac{e^s - e^{-s}}{2} \quad (2)$$

Expressions (1) and (2) are both real quantities when  $s$  is real, that is, when the angle  $js$  is imaginary. The first expression is called the hyperbolic cosine of  $s$ , abbreviated and pronounced "cosh"; the second expression is called the hyperbolic sine of  $s$ , abbreviated sinh and pronounced "shin." Hence, using  $s$  for the variable,

$$\sinh s = \frac{e^s - e^{-s}}{2}$$

$$\cosh s = \frac{e^s + e^{-s}}{2}$$

The hyperbolic tangent, cotangent, secant and cosecant are defined as follows:

$$\tanh s = \frac{\sinh s}{\cosh s}$$

$$\coth s = \frac{\cosh s}{\sinh s}$$

$$\operatorname{sech} s = \frac{1}{\cosh s}$$

$$\operatorname{csch} s = \frac{1}{\sinh s}$$

The hyperbolic angle  $s$  is a number analogous to radians in circular measure; it is never expressed in degrees.

**Period of the Hyperbolic Functions.** — Adding  $2\pi$  to an angle does not change the value of the trigonometric functions; they are therefore said to have a period equal to  $2\pi$  radians. Hyperbolic functions, however, have no true period, but adding  $2\pi j$  to the hyperbolic angle does not change the values of the functions; hence these functions have an imaginary period,  $2\pi j$ .

**Table of Hyperbolic Functions.\*** — Below is given a table of hyperbolic functions.

\* More complete tables of hyperbolic functions may be found in the *Smithsonian Mathematical Tables*, by G. F. Becker and C. E. Van Orstrand, Washington, 1909 and in *Tables of Complex Hyperbolic and Circular Functions*, by A. E. Kennelly, Harvard Univ. Press, 1914.

**Example.** —  $\sinh 0.83 = 0.9286$ ,  $\cosh 0.83 = 1.3647$ ,  $\tanh 0.83 = 0.6809$ .

**Approximate Formulas.** — Note that for  $x$  less than 0.1,

$$\sinh x = x \text{ with an error of less than } 0.2 \text{ per cent.}$$

$$\cosh x = 1 + \frac{x^2}{2} \text{ with an error of less than } 0.09 \text{ per cent.}$$

For  $x$  greater than 6,

$$\sinh x = \cosh x = \frac{e^x}{2} = \frac{1}{2} \log_{10}^{-1} (0.43429 x)$$

with an error of less than 0.01 per cent.

**Anti-Functions.** — If  $a = \sinh x$ , then  $x$  is the angle whose hyperbolic sine is  $a$ ; this may be expressed symbolically

$$x = \sinh^{-1} a$$

which is read " $x$  equals the angle whose hyperbolic sine is  $a$ ." The angle is also called the "anti-hyperbolic sine" or the "inverse hyperbolic sine" of  $a$ . Similarly for the other hyperbolic functions. (See *Trigonometric Functions* sub-heading *Anti-functions*.) The following relations exist between the anti-hyperbolic functions and the natural logarithms:

$$\sinh^{-1} x = \log (x + \sqrt{x^2 + 1})$$

$$\cosh^{-1} x = \log (x + \sqrt{x^2 - 1})$$

$$\tanh^{-1} x = \frac{x}{2} \log \left( \frac{1+x}{1-x} \right)$$

**Relations among Functions of the Same Angle.** —

$$\cosh^2 x - \sinh^2 x = 1$$

$$1 - \tanh^2 x = \frac{1}{\cosh^2 x}$$

$$\coth^2 x - 1 = \frac{1}{\sinh^2 x}$$

$$\sinh(-x) = -\sinh x$$

$$\cosh(-x) = \cosh x$$

$$\tanh(-x) = -\tanh x.$$

See also the definitions given above.

**Sum and Difference of Two Angles.** —

$$\sinh(x+y) = \sinh x \cosh y + \cosh x \sinh y$$

$$\cosh(x+y) = \cosh x \cosh y + \sinh x \sinh y$$

$$\tanh(x+y) = \frac{\tanh x + \tanh y}{1 + \tanh x \tanh y}$$

$$\sinh(x-y) = \sinh x \cosh y - \cosh x \sinh y$$

$$\cosh(x-y) = \cosh x \cosh y - \sinh x \sinh y$$

$$\tanh(x-y) = \frac{\tanh x - \tanh y}{1 - \tanh x \tanh y}$$

**Product of the Functions of Two Angles.** —

$$\sinh x \sinh y = \frac{1}{2} [\cosh(x+y) - \cosh(x-y)]$$

$$\sinh x \cosh y = \frac{1}{2} [\sinh(x+y) + \sinh(x-y)]$$

$$\cosh x \sinh y = \frac{1}{2} [\sinh(x+y) - \sinh(x-y)]$$

$$\cosh x \cosh y = \frac{1}{2} [\cosh(x+y) + \cosh(x-y)]$$

**n Angle. —**

[W. A. DEL MAR.]

**IGNITION, ELECTRIC, FOR INTERNAL COMBUSTION ENGINES.**— (See also *Batteries, Primary; Batteries, Storage; Internal Combustion Engines; Starting and Lighting Systems.*) It is the function of the ignition system of an internal combustion engine to initiate the burning of the charge of fuel within the engine cylinder at the proper instant in the cycle, i.e., when the explosive mixture of gasoline vapor and air is at or near the point of maximum compression. The typical system, see Fig. 1, comprises

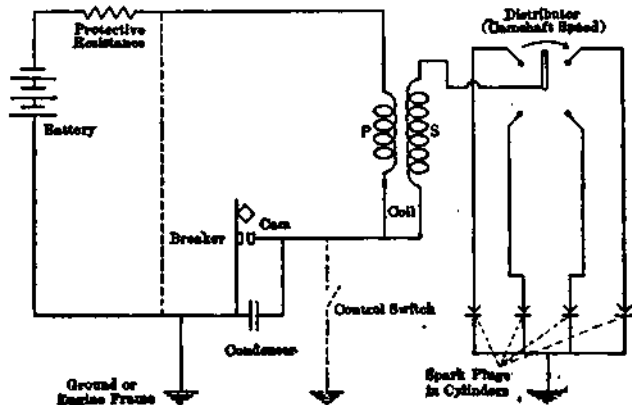

Fig. 1. Circuits of Typical Single-spark, Jump-spark Ignition System. Solid lines show battery system. If the battery and resistance are omitted, the dotted connections added, and the "coil" taken to represent the windings of a magneto, the circuits become those of a high-tension magneto ignition system.

(1) a source of electrical energy (battery or magneto generator); (2) a timer for correlating the production of the spark with the rotation of the engine (this may be either a "timer" or "commutator" which closes the primary circuit of a vibrator system at the proper instant, or a "breaker" which interrupts the primary circuit of an induction coil); (3) an induction coil (which may be incorporated as part of the magneto) for transforming the energy to a high voltage; (4) a distributor for leading the high voltage discharge to the successive cylinders in the proper sequence; and (5) a spark plug in each cylinder to provide a fixed insulated gap at which the igniting spark is produced.

**IGNITION OF GASES.**— Combustible gases and vapors when mixed with air in the proper proportion (15 of air to 1 of gasoline by weight is approximately the theoretical combining ratio) become explosive. That is, a flame started in the mixture is self-propagating with a velocity which varies greatly with the material and the proportions of the mixture, and is greater as the pressure and temperature of the mixture are increased, but so far as is now known is independent of the character of the igniting source. For gasoline engines the velocity is of the order of 10 meters per second, and consequently the spark should be timed to occur several thousandths of a second before the piston reaches upper dead center, so that the charge may be practically all ignited at the beginning of the power stroke. Since this desired time interval corresponds to a different angular interval at different engine speeds, means are usually pro-

or automatically advancing the angular position of increase of speed. At starting the spark should be dead-center to avoid "back firing." For a rich mixture a certain intensity of spark is required (*Proc. Phys. Soc., London, 31, p. 168, 1919*), which is due to a fixed amount of energy. At high voltages passing the gap may be made much less than in inverse proportion and still produce ignition. The intensity needed for gasoline and air is 0.002 joule at 5000 volts. This is the electrostatic energy stored in a capacity of which is roughly the capacity of the usual spark plug when charged to a sparking voltage of 5000 volts. An ordinary system produces a spark at all, ignition is practically impossible. The supposed advantages of a "hot" or "fat" spark are where carburetion is imperfect, as with heavy duty engine, much of the charge is in the form of spray and under such conditions it is quite possible that a spark of low energy content may be advantageous by vaporizing the fuel. It is to be noted that the hottest magneto spark (0.2 joule) can vaporize only 0.0007 cu. cm. of gasoline, and that an ordinary spark supplied by the combustion of only 0.000006 cu. cm. of

gasoline may be defined as the passage of an electric spark through a gaseous medium and the distinction between it and a solid spark is here. There are two main types of spark:

**Disruptive Spark**, such as is produced by the discharge of a condenser through a circuit of small resistance. The current in such cases is of great amplitude, oscillates in frequency and is rapidly damped out, the entire discharge lasting for less than a second. The sparks in air are bluish white, produce little effect, but will not readily ignite solid materials. It is, however, as effective as the other type of spark

**Spark or Arc** is produced by the discharge of a condenser through a circuit of small resistance. The current is of small value (0.1 ampere or less), is unidirectional, and may last for several thousandths of a second. It is bluish or orange, quiet, of greater apparent "thickness" and density, readily ignites paper or cotton.

For a combination of both kinds of spark. The coil and spark plug form a condenser which discharges a spark from the coil.

**IGNITION SYSTEMS.** — Electric ignition systems may be

**Low-tension Systems**, in which the current flows through a coil of high inductance and through a pair of electrodes in the cylinder. At the proper point in the cycle the contact mechanism and the resulting arc ignites the mixture. A magneto with a single winding is often used in place of an induction coil. The mechanical complexity of this system is a disadvantage in compression engines. It is now little used.

**High-tension Systems**, in which a sufficiently high secondary winding of an induction coil or magneto, by

the breaking of current in a primary winding, to produce a spark across a fixed length inside the cylinder. Jump spark systems may be further classified as:

**Vibrator Systems**, in which the primary current is interrupted repeatedly by a vibrating contact during the part of the stroke when a spark is required. The contact is vibrated as in an electric bell or buzzer either by the flux from the core of the main induction coil, or by a small auxiliary relay. The frequency of the vibrations is of the order of several hundred per second, but even then in high-speed engines there would be time for only a few vibrations during the entire expansion stroke, and the net result is that of a single-spark system.

**Single-spark Systems** are those in which a single spark is produced during each engine cycle by the mechanical opening of the primary circuit contacts. This is by far the most common type of system.

Ignition systems may also be classified according to the primary energy as battery, magneto, and dual:

**Battery Systems** draw current (0.5 to 5 amperes) at low voltage (usually 6) volts from a battery of storage or dry cells through the primary of an induction coil and the "breaker" contacts (see Fig. 1). In the closed circuit type the breaker is closed for a fixed fraction of each engine cycle which, at moderate engine speeds, gives a time of closure about

the electrical time constant  $\left(\frac{L}{R}\right)$  of the primary circuit. Consequently

the primary current has time to build up to nearly its final value  $\frac{E}{R}$  before

the circuit is broken. At higher speeds this final value is not reached and the spark energy is correspondingly decreased. At low speeds the full value of current would flow continuously and produce excessive heating in the circuit. This is obviated in some systems by a series resistor with a temperature coefficient which is so heated by the excess current that the increasing resistance limits the standstill current to a moderate value.

In the open-circuit type the breaker is closed for a period very short compared to the time constant of the primary circuit and which is independent of engine speed. The maximum current would be very low and never attained and the spark energy is independent of engine speed.

**MAGNETOS** are electric generators which have a permanent magnet structure and are supplied with mechanical energy from the driving shaft of the engine. Magnetos are classified as "low tension" or "high tension" systems; the former a single winding generates current at relatively low voltage which is transformed to high voltage by an external coil as with a battery system; the latter a secondary winding is placed over the primary and the magnet serves the double function of generator and transformer.

Magnetos are also classified as one-spark or two-spark. In the one-spark type one end of the secondary is grounded through the primary and the other end is connected through a single distributor to one spark plug at a time. In the two-spark magneto both ends of the secondary winding are highly insulated and connected through the two parts of a double distributor to two spark plugs in the same cylinder. The ignition of the charge from two widely separated points in the combustion space, secured either in this way or by two separate magnetos, hastens the rapidity of inflammation of the charge and may increase the power several per cent.

Magnetos may be classified according to their construction as follow

**Shuttle Armature Type.**—This most widely used construction permanent magnet  $M$  is provided with soft iron or steel poles  $N$  and  $S$  each of which subtends an arc of about 120°. The armature core is of the cross-laminated as much as possible. The ends of the winding extend to the ends of rotor about three times the length of the yoke. Ball-bearings are used and the air-gaps reduced to a minimum. The armature has a primary coil of few turns (No. 22) and outside of this a secondary of many turns (approx. 10,000) of wire. The layers are insulated with oiled silk. The outside of the secondary has an additional insulation because of the high voltage turns which is produced at the spark. The circuits of the secondary are closely analogous to those in a transformer as shown dotted in Fig. 1. The secondary is connected by a well-insulated carbon brush to the central

Fig. 2. Cross-section of Shuttle Armature, High-tension Magneto.

brush either of the brush type, in which a carbon brush on the central arm rubs in succession against metal inserts on a rotating block which are in turn connected to the spark plug leads; or of the jump type in which the arm passes over (about 0.010 inch clearance) the fixed projecting contact. This construction avoids trouble from the accumulation of carbon and the resulting flashing of the spark between inserts. The block is preferably made of a molded phenolic material to resist heat, but the surface over which the brush rubs is ground to reduce arcing troubles.

The primary winding is connected to the armature core and to the other end of the machine by a carbon brush. The other end is connected to a block which supports one of the breaker contact points. This point is carried on a grounded lever which is actuated by a cam-follower so as to open the circuit abruptly at each revolution. The contact surfaces are usually of tungsten. Though tungsten is used to a considerable extent in the design of a condenser of 0.1 to 0.2 microfarad capacity mounted in parallel with the contacts and serves to reduce arcing otherwise occur. This condenser is usually of mica, to some extent. It should be capable of withstanding a voltage of 1000 v. a-c. A brush bearing on the insulated block may be used as a control switch to ground, thus permanently short-circuiting the device inoperative when it is desired to stop the type of magneto furnishes two sparks per revolution. The engine must be driven at crankshaft speed.

**Stationary Core Type.**—In this type (Fig. 3) the coils are stationary on a laminated core with extended pole pieces. Between these pole pieces are soft iron blocks which are carried on opposite sides of a rotating shaft. The blocks are enlarged at opposite ends to form disks in proximity to the respective poles of the U-shaped permanent magnet. The direction of rotation is along the line joining the poles of the mag-

net and perpendicular to the axis of the coil and to the line joining pieces of the inductor. This type has the advantage of having the coil stationary and it is consequently easier to insulate the high voltage leads. The type described gives two sparks per revolution, but constructions using four

Fig. 3. Schematic Drawing of Polar Inductor-type Magneto.

rotor blocks of alternate polarity give a correspondingly greater number of sparks per revolution.

**Sleeve-inductor Type.** — This machine contains a field system and an armature like the shuttle type but the armature is fixed in position and its magnetic axis is at right angles to that of the field. Between the two segments in what corresponds to the greatly widened air gap, there rotates a cam or non-magnetic sleeve containing two soft iron segments subtending approximately  $90^\circ$ . A complete rotation of the sleeve reverses the flux through the armature core four times, so that by a proper cam four sparks per revolution can be produced.

**Oscillating Magnetos.** — Among the other numerous types there are mentioned the oscillating magnetos in which the armature is rotated through a fraction of a revolution against a set of springs which on release snap quickly across the position of flux reversal, and thus produce a spark.

Still another type of igniter properly classed as a magneto has only a single winding of many turns of fine wire. The translatory motion of a pair of iron cores into and out of magnetic contact with the poles of a permanent magnet reverses the flux through the coil so rapidly that sufficient voltage is induced to produce a spark. Both of these devices are, however, limited in speed and are used mainly on stationary engines.

**Impulse Starter Coupling.** This attachment is often inserted between the engine and any of the foregoing types of magneto to assist in starting, by producing a sudden rotation of the magneto armature at the time when the engine is being cranked slowly. At low speeds a latch prevents the motion of the magneto rotor until the driving shaft has rotated through a considerable angle and has wound up a spring located between the housing member and the rotor. When the engine has turned to upper dead center the latch is displaced by a cam. The released rotor is spun rapidly by the engine past the firing position and a spark is produced in the cylinder. A similar device renders the latch entirely inoperative at speeds above 150-200 r.p.m. and the magneto is then directly driven from the engine. The angular velocity during the impulse is equivalent to a speed of about 800 r.p.m.

**DUAL IGNITION SYSTEMS** involve the combination of two more or less independent ignition systems on a single engine. The terms "dual," "duplex," and "double" are used in different senses by different makers to designate such combinations the purpose of which is to provide: (1) The addition to magneto ignition of some auxiliary to assist in starting; (2) A factor of safety in case of failure of one system, and (3) a slight increase of engine power resulting from two sparks in a single cylinder. Among the many possible combinations are the following:

- (1) A high-tension magneto system with a battery which can be connected in series with the magneto primary and breaker for starting.
- (2) A high-tension magneto with a small auxiliary hand-driven magneto carrying their secondary current through the same distributor segments. With this arrangement, which is widely used on heavy truck and airplane engines, the hand magneto is usually connected to an auxiliary distributor arm which is retarded one segment behind the regular arm, thus avoiding back-fire.
- (3) A low-tension magneto and a battery feeding a common induction coil, distributor and plugs.
- (4) A high-tension magneto fitted with an additional breaker mechanism. This is in series with a battery and induction coil, the secondary of which supplies the same distributor as the magneto, only one system being operative at a time.
- (5) Two completely independent systems supplying separate sets of spark plugs. These may be two similar magnetos or battery systems as on most airplane engines or a magneto and a battery system.
- (6) Battery systems having both vibratory and single-spark breakers but with other elements in common are sometimes called "dual," and if the vibrator is of high pitch are called "high frequency."

**HIGH-FREQUENCY SYSTEMS**, properly so called, such as the Lodge and the Dean systems, utilize the oscillating discharge of a condenser to produce frequencies of several thousand cycles per second. The former system is closely analogous to the series gap system and is very effective in firing spark plugs which are heavily shunted by carbon deposits.

**CYCLE OF OPERATION.** — The detailed operation of any type of jump spark ignition system can be most clearly understood by splitting up the complete cycle of operation into a number of separate periods during each of which the phenomena proceed under fairly definite electrical conditions, each period in turn being separated from the preceding and following one by an abrupt change of conditions.

**Period 1** includes the building up of primary current and the consequent storage of magnetic energy, as a result of either the impressed voltage from the battery, or the voltage generated by the rotation of the magneto armature. In the former case the current builds up exponentially and gradually approaches its closed circuit value. In the case of the magneto, although the e.m.f. wave generated by the rotation is very peaked, the short circuit current wave at moderate and high speeds is rather flat-topped and sufficient current exists to produce a spark if "break" occurs over a range of about 90 electrical degrees in each half wave. At slower speeds the current wave is much more peaked and a spark can be produced over only a narrow timing range. To obviate this limitation magnetos are frequently so constructed that the pole pieces (or in polar-inductor types the coil and core) can be rotated with the breaker cam, and the "break" occurs always at the same point in the electrical cycle, though it is shifted with respect to the engine cycle.

The normal current at break is usually about 5 amperes in either battery or

magneto systems. The inductance of the latter is, however, usually greater, so that the available magnetic energy  $\frac{1}{2}Lb^2$ , and hence energy in the spark is correspondingly larger.

The discharge of the battery on closed circuit, or the operation of the as a short-circuited a-c. generator, is suddenly interrupted by the the breaker contacts by the cam and Period 2 begins.

**Period 2.** — This is of extremely short duration (of the order of a second), and extends from the opening of the primary contacts to the of the spark at the spark plug, but is of great importance, since the or failure of the spark is determined by whether or not the induced voltage during the period rises to a value equal to the breakdown voltage spark plug gap.

At the beginning of the period the primary current continues to flow but into the primary condenser instead of through the breaker contacts. The current rapidly charges the condenser, raising the voltage at its terminals, introducing a back e.m.f. into the primary circuit. This causes a decrease in the primary current and in the magneto-motive force acting on the core in the resultant flux. This decrease in flux induces a voltage in the secondary which is greater than that in the primary in approximately the ratio

$$\left( \mu = \frac{S_2}{S_1} = 50 \text{ to } 60 \right);$$

and this voltage in turn sets up a secondary current which charges the secondary condenser (capacity  $2 \times 10^{-6}$  microfarads) of which the secondary winding, distributor and spark plug form one "plate," and the grounded frame and engine the other "plate." The transformation of energy from magnetic to electrostatic form, and its discharge in primary and secondary condenser, continues until either the voltage is high enough to jump the spark gap, or until all the energy has been converted to electrostatic form. In normal operation the former result occurs with a small part (about 10 per cent) of the magnetic energy has been transformed. When, however, the system by reason of too small current at break or too small spark gap is just at the limit of sparking, the following relation holds:

$$E_s = I_b \mu \sqrt{\frac{L_1}{C_1 + \mu^2 C_2}}, \quad \text{approx.}$$

Where

- $E_s$  = limiting secondary voltage (volts)
- $I_b$  = primary current at break (amperes)
- $\mu$  = ratio of turns secondary to primary
- $L_1$  = self-inductance of primary (henries)
- $C_1$  = capacity of primary condenser (farads)
- $C_2$  = capacity of secondary condenser (farads)

The above equation is useful as indicating the variation of  $E_s$  with  $I_b$  and  $C_2$  but, in computing absolute voltages, the result must be corrected by a factor of from 0.5 to 0.7 to allow for losses.

In most magnetos

$$C_2 = \frac{C_1}{\mu^2} \quad \text{roughly}$$

In case the secondary terminals are shunted by a resistance, as is the case when the spark plugs are fouled with carbon deposits, the maximum voltage is much less than that given by equation (1), but can be roughly estimated from the following considerations: If the secondary were short-circuited, a current equal to  $\frac{I_b}{\mu}$  were induced in it after "break," the magnetomotive

be the same as before "break," and there would be no induced e.m.f. Consequently this current  $\frac{I_b}{\mu}$  is the limit-  
*ary winding* can ever supply. A fouling resistance  
 induce misfiring practically constitutes such a short-  
 across such a resistance is therefore always somewhat  
 $IR$  drop, viz.,

$$E_s = \frac{I_b}{\mu} S. \quad (3)$$

current  $\frac{I_b}{\mu}$  is about 0.1 ampere and hence a 3000 volt  
 if shunted by 30,000 ohms.

attainment of breakdown voltage of the spark gap dur-  
 ing conducting and the secondary condenser discharges  
 condenser type of discharge, which, as explained above, is  
 enough to produce ignition.

completion of the condenser spark the magnetic energy  
 is to deliver an inductive spark for a duration of several  
 until the entire energy is dissipated. The secondary  
 decreases linearly with time, giving a wave roughly  
 spark delivered by a magneto is usually of decidedly  
 for a battery system, both because of the greater  
 inductive energy, and also because the voltage generated in  
 rotation may (in case the spark is fully advanced) force  
 current across the gap.

The function of the spark plug is to maintain within  
 a gap of definite breakdown voltage between two  
 is almost universally grounded on the cylinder wall.  
 requirements are that the sparking voltage should not  
 the insulation resistance should be at least 100,000  
 and be practically gas-tight. In the most severe cases  
 the plug must satisfy these requirements while under  
 pounds per square inch, while immersed in a medium  
 in temperature between 0 and 2500° C., and in an  
 to deposit soot on the surface of the insulator.

-- The various manners in which a spark plug may

**Carbon Deposit Causing a Short Circuit.** — This  
 frequent cause of trouble and results from excess oil, too  
 whose insulator operates at too low a temperature. It  
 is so shaping the insulator that part of it is hot enough  
 shielding the insulator with baffles that it is not exposed  
 (Auxiliary Gap below.)

**Oil Causing Open Circuit.** — The breakdown  
 voltage is greater than that of an equal thickness of compressed  
 air. The presence of a drop or film of oil on the electrodes may  
 reduce the voltage of the gap to a value in excess of that generated  
 at light loads and on starting, where an excess  
 of oil on the cylinder. Small electrodes so shaped as to drain the oil  
 can reduce this trouble.

(3) **Cracking of Insulator.** — This may result from mechanical shock or differential thermal expansion. The trouble is absent in mica plugs, and can be greatly reduced in others by the use of the special porcelains recently developed for spark plugs, which have relatively high mechanical strength and thermal conductivity and small thermal expansion.

(4) **Pre-ignition.** — This occurs in hot high-compression engines and results in loss of power and overheating. The remedy is short thick electrode and thorough cooling of the plug.

(5) **Conduction through the Insulator.** — At high temperatures a ceramic body becomes to some extent a conductor of electricity and different varieties of porcelain differ greatly in this property. The better grades, however, show so little of this effect that it is seldom of serious importance in engine operation.

(6) **Minor Troubles,** such as warping and corrosion of the electrodes may usually be avoided by proper design and material.

**Construction of Spark Plugs.** — Spark plugs are built in a very great variety of forms, most of which show very little improvement over the simple and conventional type (Fig. 4). Numerous tests have shown that gas-tightness is a matter of workmanship rather than of design.

Fig. 4. Cross-section  
Typical Two-piece  
Spark Plug.

The insulator and the shell are usually held together either by a threaded bushing, as indicated, or by crimping the edge of the metal shell over the shoulder of the insulator. The latter construction is rather cheaper, but prevents the removal of the insulator for cleaning, and also, unless carefully done, is liable to set up undue strains in the porcelain. Either construction can be made satisfactorily tight. The inner end of the shell is frequently nearly closed, leaving a small annular spark gap around the electrode. Such "closed end" plugs are suitable for "oily" engines. Steel is usually preferable to brass for the shell, as the latter conducts more heat to the outer part of the insulator.

Mica and various ceramic bodies (steatite, lava, glass, quartz, etc.) are used as insulators. The former has the advantage of freedom from cracking, but gives a surface which is somewhat more liable to collect carbon.

The electrodes are usually of nickel or nickel-manganese alloy, but occasionally copper or silver is used in very hot engines. They are made in a great variety of shapes, although this has no observable effect on the character of the spark except as it affects the breakdown voltage of the gap. This voltage depends on the length of the gap, the shape of the electrodes, the density of the gas, the temperature, and possibly the materials of the electrodes, and upon the rate at which the voltage is applied. The voltage increases nearly linearly with the density of the gas, whether the density results from increased pressure or lowered temperature. For the usual gap length (0.020 inch) the sparking voltage is between 2000 and 6000 volts, depending on the compression ratio of the engine. When the electrodes are at a higher temperature than the gas, the sparking voltage is very considerably decreased below the value to be expected from the density.

**Auxiliary Gaps.** — If a well-insulated spark gap of proper length is connected in series with a spark plug which is so heavily shunted by carbon that it normally does not fire, the plug will often be found to spark satisfactorily. The beneficial effect of this simple device is due to the fact that it prevents a flow of secondary current during Period 2 (see *Cycle of Operation* above), until the volt-

terminals is high enough to break down the external full voltage is suddenly applied to the spark plug if its break down voltage is less than that of the demand, in cases where failure to fire is caused by insufficient on the plug electrodes, the introduction of a permanent. Devices of this type are widely advertised "Energizers" and extravagant claims are made as to efficiency and economy, which, however, are justified only in serious misfiring previous to their installation.

The principal overall test of an ignition system is its ability to spark gaps satisfactorily, as many gaps being provided for. The most generally used (but far from satisfactory) "point" gap shown in Fig. 5. "The third or teaser gap is left insulated but when properly adjusted provides a spark which provides a backup gap. Such a spark is provided between the main electrode of about 8000 volts, and in its operation when a pulse from a spark is applied to a two-point gap.

When a set of these gaps is used, excessive arcing at the gap that at which it will fire is also tested for to see if they will just fire at the limit should for most engines at 1000 r.p.m. Similar tests are made with the gaps shunted with 100,000 ohms of carbon fouling. The gaps can be tested by long runs in the type of engine

used, since conditions of oil, temperature, etc., vary in the laboratory should show less than 1 cc. per cc. of pressure of 15 kg. per square centimeter (225 pounds) show no cracks when the insulators are quenched in water at 150° C.; and should withstand 25,000 volts a-c. and the outer surface of the insulator when tested. Report No. 51-III, National Advisory Committee

**COSTS.** — The standard dimensions adopted by the Engineers for magnetos for 4 and 6 cylinder engines

**ILLUMINATION, INTERIOR.** — (See also *Illumination, Illumination, Street; Vision, Laws of.*) The chief problems in interior illumination are: (1) to render visible certain objects or surfaces so as to avoid injury of the eyes, and to enhance in effectiveness all operations on good vision; (2) to reveal in their true values the architecture and decoration of interiors; and (3) to produce intrinsic artistic effects through control of the color, intensity and direction of light. Engineering practice has been developed mainly with reference to the first of these problems, the other two are often of chief importance and must at all times be considered. For a discussion of the hygienic aspects of illumination, see *Vision, Hygiene of.*

**Advantages of Good Light.** — The advantages of good light are so important that a list of its principal effects may seem commonplace. They are of such great importance, however, particularly in their relation to factory work, that they should receive careful attention. The main advantages of good light, including the effects of bright and cheerful surroundings in factory buildings, include the following:

1. A tendency to reduce accidents.
2. Promotes greater accuracy in workmanship.
3. Contributes to increased production for the same labor cost.
4. Tends to reduce eye strain.
5. Helps to improve working and living conditions.
6. Affords greater contentment among the employees.
7. Order and neatness around the shop are encouraged.
8. Supervision of the men is made easier.

It is rather interesting to note that items 4, 5, 6, 7 and 8 all have a bearing on accident prevention in factory work.

**Reference Surfaces.** — Illumination problems are usually worked out with reference to one or more planes or surfaces whose illumination can be taken as an index to the meeting of the general requirements. Unless special conditions dictate otherwise the plane selected is usually horizontal and is located at a height of from 2½ to 3 feet above the floor, corresponding with that of desks, counters, work benches, etc. In many cases other surfaces, such as walls, faces of shelving, stacks of books, etc., are more significant than the ordinarily chosen horizontal plane. The proper reference surface for the illumination of show windows is usually a surface inclined or curving upward to the base of the window. In many art galleries and on the stage of a theater the proper reference planes are vertical. The most significant reference surface for any problem should be selected by a study of the special requirements.

**Coefficient of Utilization.** — The ratio of the luminous flux received by a reference plane to that produced by the light sources used for its illumination is known as the coefficient of utilization of the system. The light received by a reference plane is often termed useful flux to distinguish it from the total flux output of illuminants. The above terms may be very misleading if used indiscriminately, for the flux received by other surfaces than a reference surface is usually essential to the effectiveness of a system of illumination.

**DIRECT, INDIRECT AND SEMI-INDIRECT ILLUMINATION.** — Methods of illumination may be classified according to the manner in which light is delivered to the working surfaces. Direct light is that received from lamps and their accessory shades and reflectors. Indirect light is that received by reflection from some extended diffusing surface, as a ceiling. Systems of illumination are either direct, indirect or semi-indirect. In a direct system the illuminants, including their reflectors and shades, are exposed to the view of the worker.

of their light in the direction of the reference areas. Walls and ceilings is received as an auxiliary component. Lower surfaces of a room have the highest illumination. Shadows, the sharpness of which vary inversely with polished or glazed surfaces may produce an annoying glare, due to the specular reflection of the exposed light source. These are a source of great annoyance and fatigue. The intensity and in some cases exaggerate relief effects, as aids to vision where color differences are slight.

Lighting conceals all primary sources and distributes light uniformly, usually white ceilings and upper walls. The ceiling has the highest illumination. Shadows are eliminated. Glare from visible light sources is avoided. The glare of glazed surfaces is generally inappreciable. The glare on the lower surfaces of a room is very great. The indirect system is frequently stated to closely approximate uniformity, is not strictly true, however, for daylight though it has a diminishing gradation of illumination from the window to the room. The faintness of shadows with indirect lighting produces relief effects.

Indirect lighting mediates between the two extremes. The light sources are hidden by inverted bowl reflectors of translucent glass, which give a moderate amount of direct light and reflect the rest.

There is an absence of agreement as to the most desirable amount of indirect light. It is desirable that the brightness of the working surface be equal or slightly exceed that of the ceiling. The indirect lighting is adequate to create a normal relief effect and to provide working surfaces to a value above that of the background. (T. W. Rolph (*Trans. Ill. Eng. Soc.*, Vol. 7, pp. 234) reports satisfactory results are secured with a direct component.

Indirect lighting which has proved very satisfactory in certain cases is the inverted bowl fixture system, in which the component of direct light under the bowl may be controlled by the choice of density of the bowl.

By this means it is possible to keep the brightness of the working surface down to practically any degree that may be thought desirable of particular value where Mazda C lamps, with their reflectors, are used within the bowl of the fixture.

In such systems outlined a large allowance must be made for the relief effect. Critics of indirect lighting assert that the absence of shadows and the reversal of the customary gradation of light, by copying, distract attention, distort the sense of distance and depth. Others find the same aspects advantageous and hold that the relief effect by specular reflection outweighs other considerations. The inequalities of direct lighting avoided by the indirect lighting are due to unshaded and poorly-located lamps rather than to the indirect lighting. Several investigators have studied the relative illumination for equally effective vision by the different systems. The results are inconsistent and are probably due to incidental differences in contrast between working surfaces and backgrounds and to the location of visible light sources. It is agreed that with equal skill and care, first, semi-indirect lighting second and indirect lighting are the best methods of utilization.

**Direction of Illumination.**—There is no well-defined direction of illumination. Daylight white is desirable for exact

color matching and for color printing, but is not essential for other purposes. The Moore carbon-dioxide tube reproduces daylight white with great accuracy and also closely approaches daylight in diffusion. True white may be obtained from arc and incandescent lamps by the aid of color screens which cut out the hues present to excess. Magnetite arcs and nitrogen-filled tungsten lamps are best adapted to this process. Of the illuminants in common use the white flame arc and the intensified carbon arc give the nearest approach to white. The nitrogen-filled tungsten lamp surpasses other incandescent lamps in whiteness. The ordinary tungsten lamp and the best grade of incandescent mantles are somewhat unlike in tone, but differ about equally from daylight. Light having a predominant hue, as that of the mercury arc, is superior for the revelation of fine detail. Light of amber tint is regarded as softer and more comfortable than light of bluish or greenish tint. The tint of indirect light is modified by the color of the reflecting walls and ceilings.

In determining the direction of light the avoidance of glare and the uniformity of the visual field is most important. In the display of art objects and in the study of natural details the dominant direction should be carefully chosen to give a correct sense of relief. An inversion of light and shade by artificial light compared with daylight is especially to be avoided. Head and hand shadows are especially to be avoided in reading and in mechanical operations. The old rule of light from above the left shoulder is an excellent one. It is found advantageous in schoolrooms, offices and drafting rooms to locate the lamps and tables with the windows to the left of those at work and to direct the artificial light sources from symmetrical positions toward the windows to give a directive effect similar to daylight.

**QUANTITY OF LIGHT AND NUMBER OF ILLUMINANTS REQUIRED FOR DIRECT LIGHTING.**—The intensities of illumination required for various purposes are given in the article on *Vision, Laws of*. The simplest illumination problems are those in which a uniform illumination of  $E$  foot candles is required on a horizontal plane of  $A$  square feet. The useful flux required is then  $EA$ . If a factor of utilization  $K$  is known or assumed for the conditions in the room the total flux  $F$ , in lumens, to be produced by the illuminants is

$$F = \frac{EA}{K}$$

The total watts of electric power or the cubic feet per hour of gas consumed to produce the required flux is found by dividing the required flux by the efficiency per watt or per cubic foot per hour given by the type of light source under consideration.

#### LUMENS ON REFERENCE PLANE PER WATT, ELECTRIC LIGHT

(Lamps and glassware are assumed to be clean and at a height above the reference plane not exceeding 15 feet.)

Lamp	Reflector or globe	Ceiling	Walls
Tungsten	Silvered reflector	Light	Light
Tungsten	Prismatic reflector	Light	Light
Tungsten	Prismatic reflector	Light	Dark
Tungsten	Enamelled reflector	Light	Light
Tungsten	Enamelled reflector	Light	Dark
Gem	Prismatic reflector	Light	Light
Gem	Prismatic reflector	Light	Dark
5-amp. d.c. arc	Opal inner globe	Light	Medium
Mercury arc	Enamelled reflector	Medium	Medium

REFERENCE PLANE PER CUBIC FOOT OF GAS  
PER HOUR

assumed to be clean; new mantles; height above reference  
plane, 700 B.t.u. per cu. ft.)

Reflector or globe	Ceiling	Walls	Effective lumens per cu. ft. per hour
Plain globe	Light	Light	49
Plain globe	Light	Dark	27
Plain reflector	Light	Light	85
Plain reflector	Light	Dark	50
Automatic reflector	Light	Light	140
Automatic reflector	Light	Dark	128
Knobbed ball	Light	Light	101
Knobbed ball	Light	Dark	75
Chamber globe	Light	Light	66
Chamber globe	Light	Dark	48
Chamber globe	Light	Light	87
Chamber globe	Light	Dark	65

For the lumens per watt or per unit of gas consumption  
values, see *Lamps, Incandescent; Lamps, Arc and Gas*

**THE FLUX.**—The preliminary estimates for most prob-  
lem can be made with fair accuracy from the preced-  
ing values based on laboratory and service tests.  
(*Vol. 3, p. 518, and Vol. 4, pp. 321, 849, 885.*)

**PLANS.**—Having found the total wattage or rate of gas  
consumption the next step is to select a proper number and  
spacing. It is seldom possible to produce a uniform illumination  
at a radial distance greater than the height of the lamp  
and it is practically impossible to avoid shadows from a single  
lamp. A uniform spacing of several lamps is necessary  
for direct lighting. The use of many small units with  
uniformity and reduces shadows. The use of few large  
units promotes economy. In many cases a compromise must  
be made between the two plans. The various spacing schemes in vogue are  
of three types, viz.: (a) a long and narrow room with a single  
line of lamps, the spacing about equal to the width of the  
room divided into squares with lamps located at the  
center of each square preferably not greater than twice the  
height of the lamps above the reference plane; (c) lamps at corners  
and spaced at not more than twice suspension height  
and the spacing from lamp to lamp. Plans of these  
types are shown on page 1.

In the spacing of lamps very careful attention should be given  
to the use of ceiling space. Each bay or division may properly  
be spaced as this will greatly reduce the shadows cast by  
the lamps. It is possible to secure a very uniform illumination  
and a symmetrical distribution if a certain critical ratio of  
spacing is used. The value of this critical ratio depends on the

form of light distribution, as shown by the prototype curves of Fig. 10 in the article on *Illumination, Laws of*. These critical ratios, while of interest, are scarcely ever so exact as to warrant the placing of too much dependence upon definite numerical figures, and it should also be remembered that where uniform illumination is necessary, direction of light and shadows are usually of importance as well as uniformity. According to Harrison, it is difficult to obtain illumination results which are satisfactory in all of these respects with a spacing ratio greater than 1.67.

Keeping in mind that there are numerous types of reflectors such as those of metal, opal glass, and the like, the following notes on Holophane and on X-ray units are included merely to illustrate the meaning of the critical ratio mentioned in the preceding paragraph.

Holophane reflectors for tungsten lamps are made in three types, viz., extensive, for wide spacing, the critical ratio of height to spacing being 0.5; intensive, for medium spacing, the critical ratio being 0.67; focussing, for high suspension and close spacing, the critical ratio being 1.33. A spacing chart for Holophane and for X-ray reflectors is shown in Fig. 2. With a ratio of height to spacing below the critical value the light is spotted. With a higher ratio the illumination remains uniform, but with some loss of utilization efficiency, due to the increased absorption of light by the walls. The efficiency does not follow an inverse square relation to the height in any case and is but slightly affected

Fig. 1. Spacing Schemes for Direct Lighting

Fig. 2. Maximum Spacing of Reflectors for Uniform Illumination

when the walls are of light color and the reflectors give a strong downward distribution. In very large rooms the effect of suspension height on utilization efficiency is trifling. The suspension height should if possible be sufficient to remove the light sources from direct lines of vision.

**Single-lamp Units vs. Clusters.** — A single-lamp electric unit is less

of several lamps having the same total candle-power. The cross-absorption of light in clusters may be as high as 10 per cent. Gas clusters of the so-called "arc" type have an advantage over single-mantle lamps in heat conservation and facility of remote control. In fact, single-mantle lamps offer a small range of candle-power.

**Point-by-point Calculations of Illumination.** — Such calculations are very useful in checking up the distribution of illumination. The method of calculation is described in the article on *Illumination, Laws of*.

**METHODS OF INDIRECT LIGHTING.** — The process of determining the power required to produce a given illumination of any area by indirect means is the same as that outlined above for direct lighting, a suitable value of the efficiency of illumination being used. There are two types of indirect lighting, the bowl and the cove. Indirect lighting from suspended bowls affords greater flexibility in light distribution than cove lighting and is capable of producing more uniform and efficient effects. The efficiencies of utilization obtainable with indirect bowl lighting are given by the National X-ray Reflector Co. as ranging from 0.20 to 0.32 with dark walls and from 0.24 to 0.34 with light walls for ratios of minimum floor dimension to ceiling height of from 1.0 to 3.5; the ceilings are assumed to be painted white and an allowance of 20 per cent for loss of light by dust and lamp aging is included in these values. The proper suspension height for indirect bowl units is approximately three-quarters the height of the room. In spacing the units a symmetrical arrangement at the centers of ceiling squares is highly desirable. The maximum dimension of such a spacing square or rectangle should not exceed a certain ratio to the ceiling height for the best results, viz., for ceiling heights below 12 feet, the maximum ratio is 1.5; for ceiling heights from 12 to 17 feet, the maximum ratio is 1.75; above 17 feet, 2.0.

In the cove type of indirect lighting the lamps are placed in the trough of the cove with axes horizontal, and are backed with a trough reflector of high efficiency. Light is thus thrown to the upper surface of the cove and from it reflected into the room. Cove lighting about the base of a flat-domed ceiling is somewhat more effective than with a flat ceiling. Dust tends to collect on lamps and reflecting surfaces and seriously reduces the average efficiency of the system.

**MAINTENANCE OF EFFICIENCY.** — Loss of efficiency in lighting systems may be due to the aging of lamps, failure to maintain proper lamp voltage, and the collection of dirt on lamps, reflectors, shades and the reflecting surfaces of the room. Systematic inspection and cleaning are essential if the most economical results are to be secured from large systems. Lamps should be replaced when the bulbs become badly blackened. Globes and reflectors should be cleaned at least once a month for most effective service. C. E. Clewell, *Factory Lighting*, p. 48, reports that a depreciation test of an office installation of tungsten lamps in glass reflectors showed a gradual loss of efficiency which reached a steady value of 19 per cent in 30 days. A similar test in a factory showed a gradual reduction of efficiency which reached a steady value of 48 per cent in 24 days.

In the table on page 804 are given the approximate losses expressed as percentages of the initial illumination on the working plane are taken from *Lighting Data of the Edison Lamp Works* by A. L. Powell for April, 1920.

Arc lamps depreciate in efficiency between trimmings and cleaning from 15 to 20 per cent due to the collection of ash on the inner globes. Arcs are relatively little affected by outside dirt and are quite generally preferred to incandescent

to the ceilings of rooms with indirect lighting to prevent the accumulation of dust and the loss of whiteness.

**SPECIAL LIGHTING PROBLEMS.** — In art galleries for the exhibition of paintings a moderate general illumination should be provided from sources giving good diffusion. Paintings should be illuminated by direct light received from concealed sources several feet in front of, and slightly above, the level of the paintings. The direction of this light should be carefully studied to avoid specular reflection from glass or glossy portions of paint. For good color effects the light should approach as near as possible the color of daylight. Sculpture is effectively lighted by indirect or semi-indirect methods, but the illuminants may properly be suspended along the side of the room containing the windows to obtain directed illumination sufficient to reproduce the relief effects of daylight.

In ritualistic churches it is important to produce a brilliant illumination of the sanctuary with a large vertical component by means of concealed lamps. The distribution of lamps in the nave should be chosen to reveal the architectural effects of the structure. Large and low-hanging pendant fixtures in the axis of the room are generally undesirable. Bracket clusters, groups of small incandescent lamps worked into the capitals of pillars, and small pendant fixtures in the arcades can be used with excellent effect. In non-ritualistic churches adequate reading light is desired at all pews. Brilliant light sources in the field of vision are especially to be avoided. If a balcony is used the light sources should be hung high and thoroughly diffused. The platform should be brightly lighted, but by light sources not visible to the auditors.

Stages and platforms in theatres and public halls should have high illumination, especially in vertical planes, but the light sources should be entirely concealed.

Office desks should be lighted with a view to preventing head and hand shadows and glare from glossy surfaces. Well-diffused general lighting with a dominant component from above the left shoulder is perhaps the best solution of the problem. When local lighting is required a pendant lamp in a deep conical reflector of green flashed opal glass suspended at a height above the desk of 2 to 2.5 feet and near the left edge of the desk will fulfill all requirements.

Show windows should be lighted by entirely concealed light sources placed at or above the upper edge of the window. Illumination should be designed for a surface which is inclined or concave upward from the lower edge of the window. On brilliantly lighted business streets a very high illumination of 20 foot-candles or more is necessary to attract attention. On less brilliantly-lighted streets the illumination may be reduced in proportion. The lamps should be backed by highly efficient reflectors. The form of light distribution

dimension of the window, the degree of concentration of the height to the depth of the window space. Tests (Ill. Eng. Soc., Vol. 8, p. 555) show that the coefficients of surface depend on the ratio of height to depth of results cited range from 58 per cent for a height to depth of 2. Show cases in the aisles of stores require show-window lighting. In brightly-lighted rooms the height of the case must be very high to gain attention. Show cases are required and these may properly be placed in the upper dihedral angles of the case. Tubular and recessed lighting, due to their space economy.

**ILLUMINATION, LAWS OF.** — (See also *Angles; Photometric Quantities; Vision, Laws of.*) Light may come from either a point source or a finite source. Serious errors may result from the application of the laws of point sources to the illumination from finite areas, due to the non-parallel rays. These errors are negligible, however, when the distance separating the light source and the illuminated surface exceeds ten times the greatest projected dimensions either in a plane normal to the mean direction of light. For definitions and quantities see *Photometric Quantities*.

**LIGHT FROM A POINT SOURCE.** — When the light comes from a point source the "inverse square" and the "cosine" laws apply:

**Inverse Square Law.** — The illumination from a point source varies inversely as the square of the distance from the source. This law rests on the geometrical fact that the spherical area intercepting light flux varies as the square of its radius.

**Cosine Law.** — The illumination received by an element of surface varies as the cosine of the angle of incidence. The basis of this law is also geometrical. These two laws may be stated thus:

$$E = \frac{I \cos \alpha}{r^2},$$

where  $E$  = intensity of illumination in foot-candles;  $I$  = intensity of the light source in candle-power;  $\alpha$  = angle of incidence of light on the illuminated area and  $r$  = distance in feet from the light source to the point illuminated.

**Calculation of Light Flux and Mean Intensities from Point Sources** — Let  $I_\theta$  be the mean intensity of a light source at an angle  $\theta$  from the axis about which the light distribution is symmetrical, usually the vertical axis. The flux within an elementary zone at this angle of inclination is then

$$dF = I_\theta d\omega = 2\pi I_\theta \sin \theta d\theta.$$

The flux within any finite zone about the axis of distribution may be found by integration when the law of distribution is known. In general, however, it is necessary to employ graphical means of integration for this purpose. The mean intensity within any finite zone cannot be found by direct average, since each beam bears a weight proportional to  $\sin \theta$ . The graphical methods described below are the most serviceable.

**Protractor Methods.** — This method is adapted to quick approximations of mean zonal, mean hemispherical and mean spherical intensities. The method assumes a sphere of light distribution divided into zones of equal solid angular content, i.e., of equal altitude. A direct average of the mean intensities of the several zones gives the general mean for all the zones included, since each component zone bears equal weight. For convenience it may be assumed generally that the mean intensity in any zone agrees closely with that at the angle which bisects the area of the zone. Fig. 1 shows a convenient subdivision of the sphere based on this assumption. To obtain the mean spherical candle-power the intensities at all the angles indicated by radial lines are averaged. This result multiplied by  $4\pi$  gives the total flux from the source. Similarly the average of the intensities at the angles indicated in either hemisphere gives the mean hemispherical candle-power, which may be multiplied by  $2\pi$  to obtain the hemispherical light flux. The average taken at the three lowest positions gives the mean intensity

Fig. 1.

low  $60^\circ$  and this value, multiplied by  $\pi$ , gives the flux within the  $0^\circ - 60^\circ$  zone. For convenience in practice a transparent protractor may be prepared with the reference angles shown by black lines. This protractor may be placed over the polar distribution curve and the values for averaging read off directly. The accuracy of the method depends on the regularity of the distribution curve.

**Flux-o-lite Diagram.**—(Fig. 2.) This diagram is constructed from the polar distribution curve by drawing vertical reference lines tangent to the candle-power circles, with uniform intermediate divisions as desired. To find the flux within any zone the horizontal projection of the mid-zone intensity is measured on the scale created by the vertical reference lines. Multiply this value by the constant which corresponds to the arc of the zone in the accompanying table.

The flux within any angular limits is found by summing the components from

Fig. 2. Flux-o-lite Diagram

Arc of zone, degrees	Constant
5	0.546
10	1.096
15	1.64
20	2.18
25	2.72
30	3.25

the several zones included. For accuracy a large number of small component zones should be taken. For proof, it is readily shown that the solid angular content of any zone is equal to

$$4\pi \sin \theta \sin \frac{\pi}{2}$$

where  $\pi$  is the arc of the zone in degrees and  $\theta$  the bisecting angle measured from the vertical axis. The above constants in each case equal  $4\pi \sin \pi/2$  and the horizontal projections read from the diagram are in each case equal to the assumed mean intensity of the zone times the sine of the bisecting angle.

**Rousseau Diagram.**—(Fig. 3.)

The Rousseau diagram admits of considerable accuracy, but involves the measurement of area. The arcs of the several zones of distribution are projected horizontally on the line  $abc$ . The intercepts equal the altitudes of the several zones and are therefore proportional to their several solid angular contents, with a total  $abc$  equal to  $4\pi$ . On each projection line is laid off from  $abc$  a length equal to the radius of the polar

A = Beam 80 c.p. Lamp    B = Beam with Reflector  
 Area  $abc'f' = 12000$  For  $A, F_m = 743.4$  1702.5  
 Area  $abc'ef = 12000$  For  $B, F_m = 632 \div 1750.3$   
 Absorption of Reflector =  $162.5 = 19.86\%$

Fig. 3. The Rousseau Diagram

curve at the corresponding angle. The terminal points are then connected by the smooth curve *def*. The area *abcdef* so inclosed represents the total flux since

$$\text{Area } abcdef = \int_0^{4\pi} I d\omega = 4\pi I_s$$

The total flux is

$$F_s = \frac{4\pi \times \text{area } abcdef}{\text{length } ac}$$

The flux in any zone, e.g., between  $0^\circ$  and  $60^\circ$ , is

$$F_z = \frac{4\pi \times \text{area } abef}{\text{length } ac}$$

The mean intensity between any angular limits is equal to the portion of the area *abcdef* between those limits divided by the corresponding portion of the base line *abc*. This method is to be preferred to the others outlined where accuracy of a high order is desired, as in the measurement of the light absorption of reflectors, globes, shades, etc. In such cases the number of points of the photometric distribution curve determined by direct measure and referred by projection to the line *def* should be as large as practicable.

**Calculation of Illumination at Points.**—In Fig. 4 let *A* be the location of an illuminant and *P* a point at which the illumination from *A* is to be determined. The three most important cases of this problem refer respectively to the illumination of elements of surface at *P* located in horizontal and vertical planes and in a plane normal to the light path *AP*. From the laws of inverse squares and of cosines (see above) the horizontal illumination at *P* is

Fig. 4.

$$E_h = \frac{I_s \cos \theta}{d^2} = \frac{I_s \cos^3 \theta}{v^2}$$

The vertical illumination at *P* is

$$E_v = \frac{I_s \sin \theta}{d^2} = \frac{I_s \sin^3 \theta}{h^2}$$

The normal illumination at *P* is

$$E_n = \frac{I_s}{d^2} = \frac{I_s \cos^3 \theta}{v^2} = \frac{I_s \sin^3 \theta}{h^2}$$

Calculations of this type are facilitated by a chart (Fig. 5) showing the value of  $\theta$  for various values of *v* and *h*, and by tables giving the values of the illumination constants  $\cos^3 \theta/v^2$ ,  $\sin^3 \theta/h^2$ , and  $\cos^2 \theta/v^2$  for various values of *v* and *h*. Such tables are given below.

The horizontal illumination at any point equals the intensity of the light source in its direction (see Fig. 5) multiplied by the constant in the above table

corresponding to its location. With a few exceptions near the bottom of the table, direct interpolations are correct to within 2 per cent. To compute vertical illumination at any point, exchange the vertical and horizontal distance components and use the constant so found.

The normal illumination at any point equals the intensity of the light source in its direction (see Fig. 5) multiplied by the constant in the above table corresponding to its location.

**Calculation of Solid Angle Subtended by Illuminated Area.** — In many cases it is desired to compute the total flux of light which falls upon a plane area from an approximate point source. This problem resolves itself into two elements, (1) to determine the mean intensity acting toward the illuminated plane, to which the methods previously described apply, and (2) to determine the solid angle subtended by the area illuminated at the source of light. The following theorems apply to the latter problem.

The solid angle subtended by a circle with the light source in its axis (Fig. 6) is

$$\omega = 2\pi (1 - \cos \alpha).$$

ded by a rectangle, one corner of which is directly be-  
 (Fig. 7), is

$$\omega = \tan^{-1} \frac{ac}{hd}$$

If  $S$  falls on one edge of the area, the latter may be  
 es to meet the above theorem.  
 within the area, the area may  
 sections. When the projec-

city of illumination, except in that portion of the room lying outside the row of lamps. By aid of well-designed reflectors it is possible to closely approximate the typical distribution curves for certain ratios of spacing to height and this ratio is important as a criterion in the selection of reflecting devices.

**ILLUMINATION, STREET.** — (See also *Illumination, Interior; Illumination, Lanes of; Lamps, Arc; Lamps, Incandescent; Lighting Plants.*) Street lighting is intended to promote public safety, facilitate travel and business, and reveal architectural effects during hours of natural darkness. Experience shows that good street lighting attracts traffic and stimulates retail trade. The most important factors affecting the degree of street illumination required are the density of traffic, prevalence of retail business, degree of police supervision needed and the architectural importance of the thoroughfare. In moderate and dim light vision depends primarily on differences of brightness and is but slightly assisted by color distinctions. Objects may be seen directly and in some detail against a darker background, but are seen in mass or silhouette against a brighter background.

**Requirements of Street Lighting.** — The most important streets require sufficient illumination for direct and detail vision to clearly reveal vehicles, persons, obstructions, irregularities of the pavement, and to permit the easy reading of timepieces and addresses, which calls for an average of about 0.5 foot-candle and a minimum of about 0.2 foot-candle on the most important, working surface. Uniform illumination without deep shadows, which may be obtained by well-diffused light sources with fairly close spacing, is highly desirable on important streets.

Secondary streets with moderate evening traffic and orderly conditions require greater illumination at intersections than at intermediate points. The silhouette aspect of vision is very important in such streets and emphasizes the need of fairly bright and even roadway illumination without spots of deep shade from foliage. An average illumination of about 0.1 foot-candle and a minimum of about 0.06 foot-candle meet the reasonable requirements of such streets. In this range of intensities the eye is highly susceptible to glare. Brilliant light sources without diffusing globes and suspended at a low level often largely defeat their purpose under these conditions.

Minor streets with scattered buildings and infrequent travel require mainly beacon lighting, equivalent in intensity to moderate moonlight, or normal illumination varying from a minimum of about 0.02 foot-candle to an average of about 0.03 foot-candle. At such low intensities the need of good diffusion at light sources is most acute, but is quite generally neglected for reasons of supposed economy.

**Reference Planes.** — Street illumination in America is usually referred to normal reference planes (i.e., perpendicular to the light rays), and to horizontal planes in Europe. There is wide diversity in the elevation of reference planes, the most common levels being that of the pavement and that of a plane four feet above the pavement. The use of normal planes of reference takes satisfactory account of the light from but one source, while it is possible to sum up the light received from all directions on horizontal planes. It is evident from the cosine law of incidence that the horizontal illumination from low and distant lamps is less in magnitude and more difficult of exact measurement than the normal component. Normal illumination is a more useful index to the visibility of upright objects. Small objects as cards and timepieces are instinctively held normal to the rays of the nearest lamp. The vertical component of street illumination should have due consideration for its importance in revealing the architecture of buildings and assisting in the recognition of persons.

**TYPES OF ILLUMINANTS.** — The illuminants most extensively used in street lighting are as follows: (For detailed descriptions and data see *Lamps, Arc, Lamps, Incandescent; and Gas Lighting.*)

**Electric Arc Lamps on Series Circuits**, including (a) carbon arcs of open d-c., enclosed d-c. and enclosed a-c. types, with standard currents of 6, 7.5 and 9.6 amperes; (b) flame carbon arcs of open d-c., enclosed d-c. and enclosed a-c. types, with standard currents of 6.6, 7.5 and 9.6 amperes; and (c) metallic or luminous arcs of open d-c. type with standard currents 4.0, 5.5 and 6.6 amperes, arranged for suspension and pedestal mounting.

**Electric Arc Lamps on Multiple Circuits** at or near 110 volts, including (a) carbon arcs of open d-c., enclosed d-c. and enclosed a-c. types; (b) flame carbon of open d-c., enclosed d-c. and enclosed a-c. types; and (c) quartz tube mercury arcs.

**Electric Incandescent Lamps, Series Type**, are made only in the gas filled design with standard currents of 5.5, 6.6, 7.5, 15 and 20 amperes, and a range of candle-power of from 60 to 1000.

**Electric Incandescent Lamps, Multiple Type** at or near 110 volts or from 10 to 1000 watts.

**High-pressure Gas Lamps** of upright and inverted types, including (a) compressed gas, (b) compressed air and (c) compressed gas and air types.

**Low-pressure Gas Lamps** of upright and inverted types, including (a) single mantle lamps and (b) clusters of 3, 4 and 5 mantles.

**Naphtha Vapor Mantle Lamps** of self-contained, upright type with nominal candle-power of from 45 to 60.

**Relative Advantages of Various Street Illuminants.**—The advantages of electric lighting over gas lighting are (1) superior flexibility in sizes and possible locations, (2) greater ease of maintenance, (3) availability of white color, and (4) ease of control from central points with series circuits. The advantages of gas over electricity are (1) lower probability of interruption by accident, (2) steadiness of light and (3) the low intrinsic brilliancy of mantles.

Both electric and gas lamps suffer fluctuations due to unsteady pressure, but these conditions are more easily regulated in electric systems. Skillful maintenance is necessary to insure the proper efficiency of all street lamps, but affords a simpler problem in the case of electric lamps. High-pressure gas lamps require maintenance of an exceptionally high order.

Gas lamps are usually lighted by hand or by local automatic clock devices, though a few methods of central control have been devised. Naphtha vapor lamps are difficult to maintain in good efficiency and require costly attention, as each lamp must be filled by hand and heated by a blast torch before lighting. Such lamps should be used only where electric or gas lighting from central systems is not available.

Series electric lamps tend to economy in power distribution and to simplicity of central control. Separate mains must be used for all circuits requiring central control. Lamps operated in multiple from regular mains are lighted and extinguished by hand or by special clock switches. The high voltage of series circuits involves elements of danger and liabilities to interruption by accidents not found in parallel systems. Parallel systems can employ metal poles and grounded supports with greater safety. Incandescent electric lamps provide a very wide range of candle-power and involve smaller expense for maintenance and renewals than arc or gas lamps. On well-regulated circuits incandescent lamps surpass all other street illuminants in steadiness. The effectiveness of incandescent lamps as commonly installed without diffusing shades is often badly impaired by glare.

The color of light is relatively less important in street lighting than in interiors. White is generally preferred, as satisfying a sense of naturalness. Yellow and green have superior penetrating power in fog and smoke.

**Small vs. Large Units.**—Large units are generally more efficient than

and units and involve relatively less expense for installation, maintenance and operation per unit of light production. With proper spacing the light of such units can be more completely utilized on roadways and produces a more uniform illumination. Small units lend themselves more readily to decorative schemes and to the lighting of shady streets and curving roadways. The effect of numerous small units at low levels, especially when unshaded, is distinctly more obtrusive and glaring than a small number of high power sources hung very high and well diffused.

**Ratings of Street Lamps.**—Street lamps are variously rated in candle-power, watts and rate of gas consumption. Much confusion is caused by loose use of the term candle-power, which in different cases refers to mean horizontal, maximum, mean spherical, mean lower hemispherical and merely nominal values. Horizontal and maximum candle-power or that at any specified angle are significant only when comparing lamps having a definite form of light distribution in common. Mean spherical candle-power gives the gross light output of a lamp without any index to the effectiveness with which it may be utilized. It is an appropriate rating for a bare luminous element without accessories. The mean lower hemispherical candle-power is perhaps the best single index to the available light output of a lamp, but it cannot be conveniently measured in service. Candle-power ratings are sometimes of a purely nominal nature, e.g., the 1200 and 2000 candle-power ratings applied to carbon arc lamps denote lamps consuming 330 and 480 watts respectively.

The rated candle-power of gas and gasoline mantle lamps usually represents the maximum intensity which a given type of lamp can produce commercially. This rating almost invariably exceeds the average results in service by a wide margin due to imperfect maintenance, and can serve only as an index to the type of lamp referred to.

Incandescent electric lamps are rated in nominal horizontal candle-power, on the arbitrary bases of 1 candle-power for each 10 lumens of the actual initial performance. Such a nominal rating corresponds approximately to the old actual horizontal candle-power rating.

The candle-power rating of incandescent lamps installed on streets with reflectors is often taken to imply the actual average intensity at some angle between  $15^{\circ}$  and  $25^{\circ}$  below horizontal. A test of 130 incandescent lamps with flat enameled metal reflectors in service, which was made by the writer in 1913, showed the average candle-power of such units at  $25^{\circ}$  below horizontal to be 111.6 per cent of the rated horizontal candle-power of the lamps.

It should be noted that with the development of the Mazda C lamp a dome reflector has superseded to some extent the older flat radial reflector.

Indefinite candle-power specifications in lighting contracts have caused much litigation. Arc lamps of all types are preferably rated in watts, as affording the only accurately measurable index to their performance. The specification that a reasonable average of candle-power as indicated by a prescribed photometric test shall be maintained is recognized as a valuable check on the quality of maintenance and service.

Fig. 1. Spacing Schemes for Street Lamps

**SPACING OF LAMPS.** — The plans of lamp spacing most widely include: (1) center suspension at street intersections only; (2) center suspension at street intersections with one intermediate center suspension; (3) suspension at street intersections and one intermediate curb unit; (4) units, located opposite each other; (5) curb units, staggered; and (6) park-way with a line of posts down its center. Several examples are shown diagrammatically in Fig. 1. Plan A, or single center line spacing is an effective method of using high-power units. Lamps may be hung on wires between poles or buildings or from mast arms projecting over the roadway. In some cases lamps are mounted directly on poles or standards in a centerway or series of safety isles. Center suspension is especially desirable where one lamp is placed at an intersection. Plan B, or parallel spacing, and staggered spacing, are best adapted to the brilliant lighting of main thoroughfares with high-power units and the lighting of ordinary streets with smaller lamps. The staggered arrangement favors the meeting of a definite minimum illumination of roadway with the smallest number of lamps. Plan C, or single side line spacing, sacrifices symmetry and uniformity for the convenience of running electric circuits or gas piping on but one side of the street. Plan D, or arch lighting, is adapted only to incandescent lamps; it tends to give a street a festive appearance, but is not an effective method of illumination. Plan E, or parkway lighting, is of obvious value where the roadway is divided as shown.

**Side vs. Center Mounting.** — Fig. 2 shows the effect of center mounting on the per cent of the total light which falls within the limits of the roadway.

Fig. 2. Per Cent of Light from Arc Lamps which falls within Limits of the Roadway.

- |  |  |

of various widths. These curves all refer to a mounting height of 20 feet above the street level. The lamps with side mounting are assumed to be over a sidewalk which is distant from the nearer street line by an amount equal to one-fourth the total width of the street. The higher efficiency of center mounting is evident. (Data by P. S. Millar, *Trans. Ill. Eng. Soc.*, Vol. 5, p. 658.)

It is obvious that mounting the lamp at the street intersection permits the light to shine up and down both streets and hence utilizes a much larger portion of the light than when the lamp is not mounted at the street intersection.

reason, street intersection units, usually on suspension mounting, are likely to continue in use for a considerable time in the future.

Various attempts have been made to increase the percentage of light thrown on the street by reflectors of special design which deflect lengthwise of the street and which would otherwise be thrown to the sides. These have had a very limited acceptance.

Excellent use of large units at intersections and small units at intermediate points may be made on secondary streets, especially where foliage interferes with the distribution of light at distances. On curved roadways it is preferable to locate the lamps on the outer sides of the curves, as they are then visible at greater distances.

**Height of Suspension.** — The spacing of lamps should be laid out with due regard to the height of suspension of the lamps and the degree of minimum illumination to be provided. In many cities a standard height of mounting is employed with each type of lamp. When such is the case, spacing problems are readily solved by the aid of diagrams such as shown in Fig. 3. Taking account of the suspension height and the light distribution curve of each lamp in its normal service condition, the horizontal distances from the axis of the lamp at

Fig. 3. Spacing and Illumination Plan for a Minimum Normal Illumination of 0.04 Foot-candle

which various normal intensities of illumination are produced at an appropriate level, as that of the street or at a height four feet above the street, are computed by the point-by-point method. Using these distances as radii, circles are drawn to scale about a center representing the axis of the lamp and are marked with the corresponding intensity of illumination. These diagrams are preferably made on translucent tracing cloth and several of each type should be prepared. A plan of the space to be lighted is drawn to the same scale on a separate paper and the circle diagrams are used as templates for various trial spacings until the desired result is obtained. The circles then furnish points for the plotting of illumination profiles or contours at the center line and curb lines, from which the approximate average illumination is readily computed. The illustration shows an appropriate location for 4-ampere magnetite arcs, with globes at street intersections, and 60-candle-power series incandescent lamps with flat enameled metal reflectors at intermediate points, to produce a minimum normal illumination of 0.04 f.c. on a section of street 80 feet wide and 480 feet long lying between centers of intersecting streets.

**Selection of Height of Suspension.** — The most appropriate suspension height for a street lamp depends on its light output, form of distribution and intrinsic brilliancy, and upon the degree of minimum illumination required. It is practically impossible to realize uniform illumination from large arcs and high-pressure gas lamps without higher suspension than that commonly employed. The usual result is a bright spot immediately about the lamp and low

illumination at mid-points. The contrast so produced reduces the efficiency of the light.

A high ratio of suspension height to horizontal spacing tends to improve uniformity of light distribution and to increase the distance over which a lamp can provide illumination above a specified minimum value. A ratio of height to distance is especially desirable when the maximum light intensity of the lamp is more than  $30^\circ$  below the horizontal.

The following example may be taken. In Fig. 4 polar curve (a) represents a 510-watt magnetite arc with clear globe and (b) to a 450-watt d-c. flame arc with vertical electrodes and a light opal globe. The illumination curves show normal illumination at various distances for various suspension heights. In case (a) the maximum intensity is but  $10^\circ$  below the horizontal and little illumination at distant points is obtained by employing a suspension height exceeding 100 feet. In case (b), however, the maximum intensity is much lower on the pole and a much higher suspension could advantageously be employed. Figure 5 shows the effect of height of suspension of these two lamps on the normal illumination at various distances.

The actual suspension height is often determined by the exigencies of the situation, by the length of wooden poles available, and by the necessity of distributing light below the foliage of trees. It must be recognized that a lamp with high mounting throws a smaller total percentage of its light

Fig. 4. Polar Light Distribution Curves of (a) 6.6-ampere Magnetite Arc with Clear Globe and (b) 450-watt Enclosed Flame Arc

Numbers on curves are horizontal distances (feet) from source

Fig. 5. Effect of Height of Suspension of Arc Lamps of Fig. 4 on Normal Illumination at Various Distances

on the street, and that the gain is from the better distribution of light at points.

In drawing conclusions concerning mounting heights from the foregoing, well to remember that the influence of greater mounting heights is to permit wider spacing and that wider spacing tends to decrease installation and operating costs. The decreased blinding influence which is likely to result from greater mounting heights is worthy of careful consideration.

Sweet suggests the use of the letter "M" for the ratio of spacing to mounting height and the approximate relation between various values of M and uniformity of illumination on the street surface according to Sweet is in the table on the top of page 819.

**LIGHTING SCHEDULES.**—All-night schedules provide for a total of from 3830 to 4000 hours of operation. The former total requires lighting 30 minutes after sunset and extinguishing an hour before sunrise; the latter involves one half-hour longer burning each night. The "Philadelphian moonlight schedule" allows lamps to remain unlighted on nights when t

Ratio of maximum to minimum illumination  
on the street surface

Other than refractor	Holophane refractor
to 1	33 to 1
to 1	14 to 1
to 1	5 to 1
to 1	2 to 1

Other nights the lamps are lighted one hour before one hour after moonrise. This schedule calls for an of operation. The "Frund system" ignores the moon ch the provision of the moonlight schedule apply, 3000 hours. As a large portion of the cost of street ges the saving of reduced schedules as compared with uch less in proportion than the reduction of hours. old issues a detailed set of lighting schedules for the es being furnished for northern, middle and southern tes.

**LIGHTING (Pre-war figures).** — The cost of street n an annual price per lamp or fixture for a specified g. This cost may properly include all fixed charges essories as well as a due proportion of the charges on nd other appliances assignable to the service, all costs ls involved in the service, and a reasonable charge for se costs naturally vary with the character of the dis- poles, rate of depreciation of lamps and the cost of y. Depreciation rates on street lamps and special g them are apt to reach or exceed 10 per cent, due to average prices charged per year for various types of ll-night schedules in a representative group of cities

**FOR ELECTRIC STREET LAMPS; ALL-NIGHT SCHEDULE**

	Cities aver- aged	Average rate	Maximum rate	Minimum rate
.....	27	\$63.00	\$80.00	545.00
.....	40	87.00	100.00	74.00
rc. ....	16	70.00	85.00	60.00
.....	6	29.50	39.00	18.50
.....	16	23.25	28.00	15.00
.....	4	20.00	28.00	18.50
.....	16	18.00	22.50	12.50

The increasing use of large Mazda C lamps makes the cost of such units of interest. The following rates are taken from one of the large Public Utilities and may be taken as representative.

Number of lamps	400 C. P.	600 C. P.	1000 C. P.
1 to 250 lamps.....	\$66.00	\$80.00	\$104.00
251 to 750 lamps.....	61.88	75.00	97.50
751 to 1250 lamps.....	57.75	70.00	91.00
1251 to 1750 lamps.....	53.63	65.00	84.50
Over 1750 lamps.....	49.50	60.00	78.00

Single-mantle gas lamps are usually furnished on an all-night schedule of prices ranging from \$20 to \$25 per annum. In many of the smaller cities special display systems of incandescent electric lamps are operated on main business streets, the expense being assumed jointly by the city and the occupants of the adjoining property. The lamps are usually arranged in arches, festoons or clusters on pedestals, and are often operated from constant-potential mains to permit the turning off of part of the lamps after midnight. These systems are usually maintained by the operating company and charged for on a flat rate basis.

E. *Light, Photometry and Illumination*; Trotter, A. P., *Illumination, Its Distribution and Measurement*; Bloch, L., *The Science of Illumination*, London; *Trans. Ill. Eng. Soc.*; *Trans. A.I.E.E.*; *Proc. Nat. El. L. Assoc.* See also *Bibliography* in article on *Illumination, Interior*.

**INDETERMINATE FORMS.** — (See also Derivatives.) Let  $f(x)$  and  $F(x)$  be any two functions of  $x$  and let  $y = \frac{f(x)}{F(x)}$ . For certain values of  $x$ , both  $f(x)$  and  $F(x)$  may be zero, making  $y$  equal to  $\frac{0}{0}$ , an expression which, considered alone, may be anything between 0 and  $\infty$ . Its true value may, however, be determined from the nature of the functions  $f(x)$  and  $F(x)$  by the following process, which involves finding the derivatives of the two functions. If  $y_1 = \frac{0}{0}$  when  $x = x_1$ , then

$$y_1 = \left. \frac{\frac{d}{dx} f(x)}{\frac{d}{dx} F(x)} \right|_{x=x_1}$$

which expression may have a perfectly determinate value. For example if

$$y = \frac{x^2 - 4}{x^2 - 8}$$

and  $x = 2$ , then

$$y_1 = \frac{0}{0} = \frac{2x}{2x^2} \Big|_{x=2} = \frac{4}{12} = \frac{1}{3}.$$

If the ratio of the derivatives is still indeterminate, differentiate numerator and denominator again and, if necessary, repeat the process until a determinate form is obtained.

When  $y = \frac{f(x)}{F(x)}$  reduces to the indeterminate form  $\frac{\infty}{\infty}$  for any particular value  $x_1$  of  $x$ , the corresponding value of  $y$  is

$$y_1 = \left. \frac{\frac{d}{dx} \left( \frac{1}{F(x)} \right)}{\frac{d}{dx} \left( \frac{1}{f(x)} \right)} \right|_{x=x_1}$$

When  $y = f(x) \times F(x)$  reduces to the indeterminate form  $0 \times \infty$  for any particular value  $x_1$  of  $x$ , the corresponding value of  $y$  is

$$y_1 = \left. \frac{\frac{d}{dx} f(x)}{\frac{d}{dx} \left( \frac{1}{F(x)} \right)} \right|_{x=x_1}$$

**INDUCTANCE AND INDUCTIVE REACTANCE.**—(See *Alternating Currents; Electricity and Magnetism, Principles of; Skin Effect; Transmission Lines.*) The phenomena of self and mutual inductance are described in the article on *Electricity and Magnetism, Principles of*. In general when the current  $i_1$  in a circuit, No. 1 say, is varying at the rate  $\frac{di_1}{dt}$ ,

potential drop, in the direction of the current (or back e.m.f.) is induced in the circuit, which may be written

$$v_{11} = L_1 \frac{di_1}{dt},$$

where  $L_1$  is called the coefficient of self induction, or self inductance, or simply the inductance, of the circuit. Similarly, when a second circuit, No. 2 say, is in the vicinity of No. 1 and the current  $i_2$  in No. 2, is varying at the rate  $\frac{di_2}{dt}$ , an additional potential drop is induced in circuit No. 1 equal to

$$v_{12} = M_{12} \frac{di_2}{dt},$$

where  $M_{12}$  is called the coefficient of mutual induction, or simply the mutual inductance, of one circuit with respect to the other.

When the currents in both instances are sine-wave currents of effective values  $I_1$  and  $I_2$  respectively and of frequency  $f$ , the effective values of these potential drops are

$$V_{11} = x_1 I_1 \quad \text{and} \quad V_{12} = x_{12} I_2 \quad (1)$$

and  $V_{11}$  leads  $I_1$  by 90 degrees, and  $V_{12}$  leads  $I_2$  by 90 degrees, and

$$x_1 = 2\pi f L_1 \quad \text{and} \quad x_{12} = 2\pi f M_{12}. \quad (2a)$$

$x_1$  is called the inductive self-reactance, or simply the inductive reactance of circuit No. 1. (see *Alternating Currents*), and  $x_{12}$  is called the inductive mutual reactance of one circuit with respect to the other. The mutual inductance, and therefore the mutual reactance, between any two circuits is the same for No. 1 with respect to No. 2 as for No. 2 with respect to No. 1, i.e.,  $M_{12} = M_{21}$  and  $x_{12} = x_{21}$ .

The total inductive drop in any circuit due to the variation of the current in this and in any number of neighboring circuits is

$$v_1 = L_1 \frac{di_1}{dt} + M_{12} \frac{di_2}{dt} + M_{13} \frac{di_3}{dt} + \text{etc.} \quad (2)$$

For sine-wave currents of frequency  $f$  the total inductive\* drop is, in vector notation (see *Alternating Currents*),

$$V_1 = j(x_1 I_1 + x_{12} I_2 + x_{13} I_3 + \dots). \quad (2a)$$

**Units of Inductance and Reactance.**—The practical unit of inductance is the henry, the c.g.s. electromagnetic unit the abhenry (also called a "centimeter"), and the c.g.s. electrostatic unit the stathenry. Inductances are fre-

\*  $i_2$  is to be considered positive with respect to  $i_1$  when the flux lines threading No. 1 due to the current in No. 2 thread through No. 1 in the same direction as the flux lines due to the current in No. 1.

† In addition to these drops there are also the resistance drop and such other back e.m.f.'s as may be present. See *Alternating Currents*.

ently expressed in thousandths of a henry, i.e., in millihenrys. The units of inductance are the same as the units of resistance (q.v.) See *Units and Conversion Factors* for the interrelations of the various units.

**Total Inductance of Two or More Circuits in Series.**—When several circuits, having the coefficients  $L_1, L_2, L_3$ , etc., and  $M_{12}, M_{13}, M_{23}$ , etc., are connected in series the currents  $i_1 = i_2 = i_3 = \text{etc.} = i$ , say, and the total induced e.m.f. is  $\mathcal{E} = \mathcal{E}_1 + \mathcal{E}_2 + \mathcal{E}_3$ , etc., or

$$\mathcal{E} = \left[ (L_1 + L_2 + L_3 + \text{etc.}) + 2(M_{12} + M_{13} + M_{23} + \text{etc.}) \right] \frac{di}{dt}.$$

Hence the resultant or total inductance is

$$L = (L_1 + L_2 + L_3 + \text{etc.}) + 2(M_{12} + M_{13} + M_{23} + \text{etc.}). \quad (3)$$

This relation makes possible the accurate calculation of the self inductance of a coil of a number of turns when the self inductance of each turn and the mutual inductance of each pair of turns are known.

**RELATION BETWEEN FLUX, CURRENT AND INDUCTANCE.**—When the permeability of the conductors and of the medium between and surrounding them is constant (e.g., when the conductors and medium are non-magnetic substances), the self and mutual inductances are constants, independent of the values of the currents, for any given arrangement, shape and size of the circuits. Under these conditions the total number of linkages (*see Electricity and Magnetism, Principles of*) between the flux lines linking any particular circuit, No. 1, and the turns forming that circuit may be expressed by the relation

$$\lambda_1 = L_{11}i_1 + M_{12}i_2 + M_{13}i_3 + \text{etc.}, \quad (4)$$

where

$L_{11}i_1 = \lambda_{11}$  = the linkages between the flux lines due to the current  $i_1$  in circuit No. 1 and the turns of circuit No. 1,

$M_{12}i_2 = \lambda_{12}$  = the linkages between the flux lines due to the current  $i_2$  in circuit No. 2 and the turns of circuit No. 1, etc.

Hence the common definition of inductance as "linkages per unit current." In certain simple cases the linkages per unit current may be calculated from the configuration of the circuit or circuits, starting from the fundamental relations given by equations (35), (36) and (29) in the article on *Electricity and Magnetism, Principles of*.

**Internal Flux, Internal Inductance and Internal Reactance.**—In the case of a wire of finite cross-section the various "filaments" of which the wire may be considered as made up are not all linked by the same number of flux lines, and consequently the back e.m.f.'s induced in the various filaments are different, tending to produce a non-uniform distribution of current. This variation in the induced e.m.f. from filament to filament is due only to that portion of the total flux which actually cuts the wire in question; it may therefore be called the "internal flux," and that portion of the inductance or reactance corresponding to this internal flux may be designated as the "internal inductance" and "internal reactance" respectively. Although the internal flux tends to produce a non-uniformity in the distribution of current, this effect is counteracted by the resistance of the wire and for ordinary non-magnetic wires at frequencies under 60 cycles per second the current remains practically uniformly distributed over the cross-section of the wire. See article on *Skin Effect*.

**FORMULAS FOR SELF INDUCTANCE.**—The following formulas, unless otherwise noted, are taken from a very comprehensive paper on the calculation

of inductance by Rosa and Grover in the *Bull. Bur. Stand.*, Vol. 8, No. 1, p. 1912, in which the accuracy of the various formulas is thoroughly discussed and many others given, as well as tables to minimize the labor of calculation. See also Dwight, H. B., *New Formulas for Reactance Coils*, Proc. A.I.E.E., Sept., 1915.

Unless otherwise stated all formulas are in c.g.s. electromagnetic units; the conversion factors are given in the article on *Units and Conversion Factors*.

**Self Inductance of a Single Circular Turn formed by a Wire of Circular Cross-Section.** — Let  $a$  = mean radius of the turn, in centimeters,  $r$  = radius of the wire, in centimeters; then the self inductance is

$$L = 4\pi a \left[ \left( 1 + \frac{r^2}{8a^2} \right) \log_e \frac{8a}{r} + \frac{r^2}{24a^2} - 1.75 \right]. \quad (5)$$

This formula is derived from an infinite series in  $\frac{r}{a}$ , hence for  $\frac{r}{a}$  large it is approximate only; however, for  $\frac{r}{a}$  less than 0.1 which covers all ordinary cases, the error is less than 1 part in 100,000.

**Mutual Inductance of Two Co-axial Circles.** — Dimensions as in Fig. 1, all in centimeters. Put

$$k = \sqrt{1 - \left( \frac{m_2}{m_1} \right)^2}, \quad k_1 = \frac{m_1 - m_2}{m_1 + m_2}$$

For  $k < 0.2$  use the formula

$$M = \frac{\pi^2 k^2}{4} \sqrt{Aa} \left[ 1 + \frac{3}{4} k^2 + \frac{75}{128} k^4 + \frac{245}{512} k^6 + \dots \right]. \quad (6)$$

the general term in the brackets being

$$\left( \frac{3 \cdot 5 \cdot 7 \dots (2n+1)}{4 \cdot 6 \cdot 8 \dots (2n+2)} \right)^2 \frac{(2n+2)}{(2n-1)} k^{2n}.$$

For  $k > 0.2$  use the formula

$$M = \pi^2 k_1^{3/2} \sqrt{Aa} \left[ 1 + \frac{3}{8} k_1^2 + \frac{15}{64} k_1^4 + \frac{175}{1024} k_1^6 + \dots \right]. \quad (6a)$$

the general term in the brackets being

$$\left( \frac{n+1}{2n+1} \right) \left[ \frac{3 \cdot 5 \cdot 7 \dots (2n+1)}{4 \cdot 6 \cdot 8 \dots (2n+2)} \right]^2 k_1^{2n}.$$

**Self Inductance of a Long Solenoid\* of Circular Cross-Section.** — Let

$l$  = axial length of solenoid in centimeters,

$n_1$  = number of turns per centimeter length, i.e., total number of turns =  $n_1 l$ ,

$a$  = mean radius of the solenoid in centimeters

Then for  $\frac{a}{l}$  small, the self inductance is, to a first approximation,

$$L = 4\pi^2 n_1^2 a^2 l. \quad (7)$$

There is a considerable error in this formula, due to the end effect, but the variations in  $L$  due to changes in  $l$  are almost exactly proportional to the changes in

\* By a solenoid is meant a coil in which the wire forms a uniform, straight cylindrical helix.

Fig. 1.

and hence this formula may be used for calculating the corresponding variations in  $L$  as long as  $\frac{a}{l}$  remains small.

**Self Inductance of a Single-layer Short Solenoid of Circular Cross-Section.** — For such a solenoid (see Fig. 2) the summation formula, equation (3), becomes when there are  $n$  turns,

$$L = nL_1 + 2(n-1)M_{12} + 2(n-2)M_{13} + 2(n-3)M_{14} + \dots + 2M_{1n}, \quad (6)$$

where  $L_1$  is the self inductance of a single turn,  $M_{12}$  is the mutual inductance of the first and second turns or any two adjacent turns,  $M_{13}$  is the mutual inductance of the first and third or of any two turns separated by one, etc., and  $M_{1n}$  is the mutual inductance of the first and last turns.  $L_1$  may be calculated from equation (5) and the  $M$ 's from equation (6) or (6a). The general equation (3) may also be used to calculate the self inductance of a coil of any number of layers, but the calculation becomes tedious.

**Self Inductance of Circular Coil of Rectangular Section (Fig. 3).** — Dimensions as in Fig. 3, all in centimeters, also

$$N = \text{total number of turns,} \\ R = 0.2235(b+c).$$

Then to a degree of approximation sufficient for most practical purposes

$$L = 4\pi a N^2 \left\{ \log_e \frac{8a}{R} \left( 1 + \frac{3R^2}{16a^2} \right) - \left( 2 + \frac{R^2}{16a^2} \right) \right\}. \quad (9)$$

See also Doggett, L. A., *Elec. W.*, 63, p. 259, Jan. 31, 1914.

**Mutual Inductance of Two Concentric Co-axial Solenoids.\*** — All dimensions being in centimeters, let

- $l$  = one-half the length of the shorter coil,
- $x$  = one-half the length of the longer coil,
- $A$  = radius of outer coil (which may be either the shorter or longer coil),
- $a$  = radius of the inner coil,

$$d = x \sqrt{1 + \left(\frac{A}{x}\right)^2},$$

$N_1$  and  $N_2$  = the total number of turns in the first and second coils respectively.

Then as a first approximation, for  $\frac{A}{x}$  small, the mutual inductance between the two coils is

$$M = \frac{2\pi^2 a^2 N_1 N_2}{d}. \quad (10)$$

By calculating a sufficient number of terms the mutual inductance may be obtained exactly from the formula

$$M = \frac{2\pi^2 a^2 N_1 N_2}{d} \left[ 1 - \frac{A^2}{2d^2} \frac{4l^2 - 3a^2}{4} - \frac{A^4}{8d^4} \frac{(4x^2 - 3A^2) 8l^4 - 20l^2 a^2 + 5a^4}{8} - \frac{A^2(8x^4 - 20x^2 A^2 + 5A^4)}{16d^2} \frac{(64l^6 - 336l^4 a^2 + 280l^2 a^4 - 35a^6)}{64} - \dots \right]. \quad (10a)$$

\* One solenoid inside the other with their centers coinciding.

Fig. 2.

Fig. 3.

**Mutual Induction of Two Co-axial Circular Coils Each of Rectangular Section (Fig. 4).**—Dimensions as in Fig. 4, all in centimeters.  $N_1$  and  $N_2$  represent the total number of turns on the two coils respectively. The following formula, known as the "formula of quadratures," is sufficient exact for most practical cases:

$$M = \frac{N_1 N_2}{6} (M_1 + M_2 + M_3 + M_4 + M_5 + M_6 + M_7 + M_8 - 2M_0), \quad (11)$$

where  $M_0$  is the mutual inductance of the two central turns  $\alpha_1$  and  $\alpha_2$  in Fig. 4.  $M_1$  is the mutual inductance of the circle through  $\alpha_1$  and the circle through 1,  $M_2$  is the mutual inductance of the circle through  $\alpha_1$  and the circle through 5, etc. These mutual inductances  $M_0, M_1, \dots, M_8$  may be calculated from equation (6) or (6a). When the sections of the two coils are small compared with their distance apart,  $M_0 = M_1 = \dots = M_8$  and equation (11) becomes

$$M = N_1 N_2 M_0. \quad (11a)$$

Fig. 4.

**INDUCTANCE OF STRAIGHT CONDUCTORS.**—The inductance of a circuit formed by straight conductors, such as the wires of a transmission line, may be considered from two points of view, viz., (1) each conductor may be looked upon as having a certain *self* inductance independent of the position of the other conductors forming the circuit or circuits and a *mutual* inductance with each of these conductors or (2) when the conductors are symmetrically arranged and the currents in them bear a fixed relation to one-another, as in a two-wire single-phase or symmetrical three-wire three-phase transmission line, each conductor may be looked upon as having a *total* inductance which takes into account both its self inductance and its mutual inductance with respect to the other wires. In the case of a 2-wire line the total inductance of the loop formed by the two conductors is twice the total inductance of each conductor; in the case of more than two wires the "loop inductance" has no simple physical meaning.

In the following paragraphs are given the formulas for *self*, *mutual* and *total* inductance *per conductor* for straight conductors of various sections and for various arrangements of such conductors. The formulas are all in c.g.s. electromagnetic units unless otherwise specified; see *Units and Conversion Factors*.

**Self Inductance of a Single Straight Round Wire, Return Neglected.**—Let

- $l$  = length of wire, in centimeters,  
 $d$  = diameter of round wire, in centimeters,  
 $r = \frac{d}{2}$  = radius of round wire, in centimeters.

Then for a round wire the self inductance is

$$L' = 2 \left[ l \log_e \frac{l + \sqrt{l^2 + r^2}}{r} - \sqrt{l^2 + r^2} + \frac{l}{4} + r \right] \quad (12)$$

$$= 2l \left[ \log_e \frac{2l}{r} - \frac{3}{4} \right] \text{ approximately.} \quad (12a)$$

Where the permeability of the wire is  $\mu$ , and that of the medium outside is unity and the frequency low (12a) appears in the form

$$L' = 2l \left[ \log_e \frac{2l}{r} - 1 + \frac{\mu}{4} \right]. \quad (12b)$$

The last formula is of theoretical interest only, as the value to assign to  $\mu$  is doubtful and when such wires are used even for currents of moderate frequency the skin effect is appreciable; see article on *Skin Effect*.

**External and Internal Self Inductance of a Round Wire.** — The self inductance of a round wire may be considered as made up of two parts, viz. the inductance due to the flux *external* to the wire and that due to the flux *within* the wire. The first or "external" inductance is

$$L_e = 2l \left[ \log_e \frac{2l}{r} - 1 \right], \quad (13)$$

and the "internal" self inductance is

$$L_i = l \frac{\mu}{2}. \quad (13a)$$

**Self Inductance of a Hollow Tube of Circular Section, Return Neglected.** — The *external* inductance is the same as for a solid wire, i.e., equation (13), taking for  $r$  the external radius of the tube. The *internal* inductance of the tube, putting  $r_2$  = external radius and  $r_1$  = internal radius, is

$$L_i = 2 \mu l \left[ \frac{r_2^4}{(r_2^2 - r_1^2)^2} \log_e \frac{r_2}{r_1} - \frac{1}{4} \frac{3r_2^2 - r_1^2}{r_2^2 - r_1^2} \right]. \quad (14)$$

The term in the square brackets is always less than  $\frac{1}{4}$ , i.e., the internal inductance of a hollow tube is always less than the internal inductance of a solid wire; see equation (13a). In the limit, where  $r_1 = r_2$  (tube with infinitely thin walls), the *internal* inductance is zero.

**Self Inductance of a Straight Bar or Strip, Return Neglected.** — For a straight bar of a non-magnetic substance and of rectangular cross-section the self inductance, neglecting the return circuit, is

$$L' = 2l \left[ \log_e \frac{2l}{a+b} + \frac{1}{2} + \frac{0.2235(a+b)}{l} \right], \quad (15)$$

where  $a$  and  $b$  are the lengths of the two edges, in centimeters.

This formula is not applicable to thin strips at close spacing; see H. B. Dwight, *El. Rev. and West. Elec.* 70, p. 1087, June 30, 1917.

**Mutual Inductance of Two Parallel Straight Wires or Bars.** — See Fig. 5. Same notation as above and in addition

$D$  = distance between centers of the two wires, in centimeters.

Fig. 5.

Then the mutual inductance between the two is

$$M = 2 \left[ l \log_e \frac{l + \sqrt{l^2 + D^2}}{D} - \sqrt{l^2 + D^2} + D \right] \quad (16)$$

$$= 2l \left[ \log_e \frac{2l}{D} - 1 + \frac{D}{l} \right] \text{ approximately,} \quad (16a)$$

when the length  $l$  is great in comparison with  $D$ .

Equation (16), which is an exact expression when the wires have no appreciable cross-section, is not an exact expression for the mutual inductance of two parallel cylindrical wires, but is not appreciably in error even when the section is large and  $D$  is small if  $l$  is great compared with  $D$ .

Equation (16) is also applicable, with a practically negligible error to bars of rectangular section and in fact to the mutual inductance between any two parallel conductors of any section and external to each other, e.g., between an overhead wire and a rail, the distance  $D$  being the distance\* between the centers of gravity of the two sections.

**Mutual Inductance Between a Tube and an Interior Wire.** — Using the same notation as for equation (14) above the mutual inductance in this case is

$$M = 2l \left[ \log_e 2l - \frac{r_2^2 \log_e r_1 - r_1^2 \log_e r_2}{r_2^2 - r_1^2} - \frac{1}{2} \right]. \quad (16b)$$

**Total Inductance of a Two-wire Transmission Line.** — Let the two wires (Fig. 5) be designated as No. 1 and No. 2 and the currents as  $i_1$  and  $i_2$ . Since  $i_2 = -i_1$ , from equation (2) the total inductive drop in each wire is

$$v_1 = (L_1 - M_{12}) \frac{di_1}{dt}.$$

The total inductance of each wire is then  $L = L_1 - M_{12}$ , where  $L_1$  is given by equation (12) or (14) and  $M_{12}$  by equation (16). For a length so great that  $l$  and  $D$  are negligible compared with  $l$ , this total inductance per wire for equal round wires becomes

$$L = 2l \left[ \log_e \frac{2D}{d} + \frac{\mu}{4} \right],$$

where  $d$  is the diameter of each wire. The total inductance of the line per unit length of wire† is

$$\left. \begin{aligned} L &= \frac{\mu}{2} + 2 \log_e \frac{2D}{d} && \text{abhenries per centimeter} \\ &= 0.01524\mu + 0.14037 \log_{10} 2D/d && \text{millihenries per 1000 feet} \\ &= 0.08047\mu + 0.74113 \log_{10} 2D/d && \text{millihenries per mile,} \end{aligned} \right\} \quad (17)$$

where  $D$  and  $d$  may be expressed in any units of length provided they are both expressed in the same units. The formulas given in equation (17) also apply approximately to stranded wires, provided  $d$  is taken as the diameter of the solid wire having a cross-section equal to that of the copper in the stranded wire. i.e., the inductance of a No. 0000 stranded wire on a given spacing is approximately the same as that of a No. 9000 solid wire on the same spacing.

Tables of  $L$  and the corresponding reactances for 25 and 60 cycles for various sizes of wires and various spacings are given below.

The above formula is not applicable to conductors at close spacing when the frequency is high; see F. B. Silsbee, *Elec. W.*, 68, p. 125, July 15, 1916.

**Total Inductance of a Rectangle.** — Let  $L_a$  = self-inductance of long side,  $L_b$  = self-inductance of short side (calculated from the proper formulas, 12 to 15) and let  $M_a$  = mutual inductance between the two long sides and  $M_b$  = the mutual inductance between the two short sides (calculated from formula 16); then the total inductance of the rectangle is

$$L = 2(L_a - M_a) + 2(L_b - M_b)$$

\* Accurately, the geometrical mean distance between the two areas; see *Bull. Bur. Stand.*, 1912, Vol. 8, pp. 125 and 126. For round wires, solid or tubular, the geometrical mean distance between them is exactly the distance between their centers.

† To obtain the total inductance of both wires multiply by twice the length of the line.

**SELF INDUCTANCE OF SOLID NON-MAGNETIC WIRES\***  
 Millihenries per 1000 FEET of each wire of a single-phase or of a  
 symmetrical three-phase line

\* The reactances given in this table also apply, with a practically negligible (about 1 per cent) to ordinary stranded wires of the same cross-section.

**of a Concentric Cable.**—In a similar manner the inductance of a concentric main may be found from equations (3), (13), and (14). The formula for the total inductance per unit length of cable

$$\left[ \frac{1}{2(d_2^2)^2} \log_e \frac{d_2}{d_1} - \frac{d_2^2}{2(d_2^2 - d_1^2)} \right] \text{ abhenries per centimeter,}$$

where  $d_1$  = internal diameter of inner conductor, assumed solid,  $d_2$  = external diameter of outer conductor.

**Three-wire Transmission Line.**— Let the wires be numbered 1, 2, and 3; and the three currents in the direction away from the line be  $i_1$ ,  $i_2$ , and  $i_3$ . From equation (1) the inductive drop in

$$\left. \begin{aligned} v_1 &= L_1 \frac{di_1}{dt} + M_{12} \frac{di_2}{dt} + M_{13} \frac{di_3}{dt}, \\ v_2 &= M_{12} \frac{di_1}{dt} + L_2 \frac{di_2}{dt} + M_{23} \frac{di_3}{dt}, \\ v_3 &= M_{13} \frac{di_1}{dt} + M_{23} \frac{di_2}{dt} + L_3 \frac{di_3}{dt}. \end{aligned} \right\} \quad (18)$$

express the  $M$ 's in terms of the radii and distances apart of the wires, from equations (12) or (14) and (16).

**Equilateral Arrangement.**— For ordinary three-phase work the three wires are arranged in an equilateral triangle. The sum of the three line currents at any instant is zero, hence

$$-i_1, (i_1 + i_2) = -i_3, \text{ and } (i_1 + i_3) = -i_2.$$

If the three wires are all of the same size and are arranged so that they form an equilateral prism, a common arrangement,  $L_1 = L_2 = L_3 = L$ , and the inductive drops per unit length in the three

$$v_1 = L \frac{di_1}{dt}, \quad v_2 = L \frac{di_2}{dt}, \quad v_3 = L \frac{di_3}{dt}. \quad (19)$$

are the same as in equation (17), numerical values of which may be found in any tables.

The equivalent effective value  $I$  and frequency  $f$ , the inductive drop per unit length of line has the effective value

$$V = 2\pi fLI \quad (19a)$$

in this particular wire by 90 degrees, irrespective of whether the current is in or out, the only condition being that no current returns to the line by any other conductor than the three line wires.

**Wires in the Same Plane.**— Let the three wires of the line be numbered 1, 2, and 3; and let No. 2 be the middle wire and Nos. 1 and 3 be at equal distances ( $D$  between centers) from the middle wire. Under these conditions, considering unit

length of line, as in (17), taking  $D$  as the distance between either outer wire and the middle wire,

$$\begin{aligned} &0.3863 \text{ abhenries per centimeter} \\ &386.3 \text{ millihenries per 1000 feet} \\ &386.3 \text{ millihenries per mile.} \end{aligned}$$

The instantaneous value of the current is  $i = I \sin \omega t$ , where  $f$  is the frequency,  $I$  the current

Then equations (18) for the inductive drops in the three wires become, provided only that  $i_1 + i_2 + i_3 = 0$ ,

$$\left. \begin{aligned} v_1 &= L \frac{di_1}{dt} - M \frac{di_2}{dt}, \\ v_2 &= L \frac{di_2}{dt}, \\ v_3 &= L \frac{di_3}{dt} - M \frac{di_1}{dt}. \end{aligned} \right\}$$

Such an arrangement, therefore, causes an unbalancing of the system, when the wires are far apart, so that  $L$  is large compared with  $M$ , the effect slight. It can be avoided by transposing the wires at intervals.

**Inductance of Overhead Wires With Earth Return.** — This case is susceptible of a definite solution, since the inductance depends upon the distribution of the return current in the earth. When the current returns through one or more rails immediately below the wire, the leakage current to the earth may be neglected and the wire and rails\* treated as linear conductors, apply the formulas given above. When there is no metallic return circuit, an approximate solution may be obtained by considering the earth as equivalent to "images" of the overhead wires in the plane of the earth's surface, i.e., considering the return circuit as consisting of the same number of wires as there are overhead, these fictitious return wires being the same distance below the earth as the actual wires are above it. The value of the inductances as thus calculated can never be greater than the actual inductances but will usually be slightly less than the actual values.

**EFFECT OF FREQUENCY ON INDUCTANCE.** — See article *Skin Effect*.

**BIBLIOGRAPHY.** — Rosa and Grover, *Formulas and Tables for the Calculation of Mutual and Self-Inductance*, Bull. Bur. Stand. 1912, Vol. 8, p. Russell, A., *Alternating Currents*; Jacobs, A. M., *Mutual Inductance of Two Straight Wires which are not Parallel*, A.I.E.E.J., 39, p. 244, March, 1922; Dwight, H. B., *New Formulas for Reactance Coils*, Proc. A.I.E.E., Sept., 1916; Dwight, H. B., *Reactance Values for Rectangular Conductors*, Elec. J., 16, p. 252, June, 1919; Dwight, H. B., *Reactance of Stranded Conductors*, Elec. W., 61, p. 828, April 19, 1913; Coursey, P. R., *Calculation and Design of Inductances*, Electrician, 75, p. 841, Sept. 10, 1915.

\* The external self-inductance of a rail is practically the same as that of a round wire taking for  $r$  the perimeter of the rail divided by  $2\pi$ ; see equation (13). The internal self-inductance depends upon the permeability  $\mu$  and the frequency of the current. The internal inductance, however, is small compared with the external inductance and for approximate calculations may be neglected. See *Rails, Tract and Third; Trolley Systems Overhead*.

**INDUCTION COILS.** — (See also *Electricity and Magnetism, Principles of; Electromagnet Windings; Ignition, Electric.*) An induction coil is a device which transforms a low direct e.m.f. to a high alternating e.m.f. of unsymmetrical form. The single-winding coil, called a primary coil, is used extensively in gas-engine ignition and in automatic gas lighting, and the double-winding coil, called a secondary coil, is used for the excitation of X-ray tubes, gas-engine ignition, automatic gas lighting, electrotherapeutics and wireless telegraphy.

**PRIMARY INDUCTION COIL.** — The primary induction coil consists of a single coil wound upon an iron core made up of a compact bundle of soft-iron wires. To obtain a spark from such a coil it is connected in series with a battery and some kind of "make-and-break" contact. When the circuit is closed, the current increases gradually according to the expression,

$$i_t = \frac{E}{R} \left( 1 - e^{-\frac{Rt}{L}} \right),$$

where  $i_t$  equals the current at any time  $t$  seconds after the circuit is closed,  $E$  equals the e.m.f. of the battery,  $R$  equals the resistance in ohms and  $L$  equals the inductance in henries of the entire circuit, and  $e$  the base of the natural system of logarithms. The shape of the current curve at "make" is shown in the curve  $AB$  (Fig. 1),\* which is an oscillograph record taken when an e.m.f. of 4 volts is impressed upon a primary coil of 1 ohm resistance and 0.01 henry inductance.

Fig. 1.

If the circuit is opened when the current reaches some value, such as  $B$  (Fig. 1), the current decreases rapidly to zero as shown in the curve  $BC$ . Since the e.m.f. induced in such a coil at any instant equals  $L \frac{di}{dt}$  when the current falls from  $B$  to  $C$ , the e.m.f. induced in the coil will be many times that of the battery e.m.f. and a spark will be established between the open contacts at "break." For use in connection with gas engines the "make and break" contacts are located within the cylinder. Reliable ignition is obtained when about 0.02 joule is dissipated in the spark at "break." Since the energy dissipated as heat in the spark is converted from the electromagnetic energy stored up in the coil, it follows that the coil must have an inductance and carry a current at "break"

such that the energy stored up, i.e.,  $\frac{1}{2} LI^2$ , will exceed the required value of 0.02 joule. In practice it is customary to design the coil and time of contact so that  $\frac{1}{2} LI^2$  equals about 0.04 joule, such coils having an efficiency of about 50 per cent. One-half of the energy put into the coil is then used up in heating the conductors and metallic parts by  $I^2R$  and hysteresis losses.

**SECONDARY INDUCTION COIL.** — The secondary coil has two separate windings wound about an iron core, one of few turns called the primary winding and the other of many turns called the secondary winding. The primary winding is connected in series with a battery and an interrupter (described below). The spark is produced between the terminals of the secondary winding. In most cases a condenser is shunted across the interrupter to prevent sparking at

\*This and the following oscillograph records are due to Bailey, B. F., *Elec. W.* 1910. Vol. LV, p. 613.

that point. Since the e.m.f. induced in each turn linked by the magnetic flux is the same, the e.m.f. induced in the secondary winding, neglecting leakage, will equal  $\frac{N_s}{N_p}$  times that induced in the primary winding, where  $N_s$  and  $N_p$  equal the respective number of turns on the secondary and primary windings. Secondary coils which give sparks as long as 5 feet have been constructed in this manner.

**Effect of Shunting Interrupter with Capacity.**—(See also *Ignition, Electric*.) When the interrupter is shunted by a capacity the e.m.f. induced in the secondary winding becomes oscillatory. This effect of the capacity is well shown in the oscillograph records given in Figs. 2 and 3. In each case a high non-inductivi-

Fig. 2.

Fig. 3.

resistance is connected across the secondary terminals, and the curves indicate the variation of the primary current and the secondary e.m.f. In Fig. 2 the interrupter is unshunted by a condenser, and as a result the secondary e.m.f. increases at "break" and decreases to zero without oscillation. In Fig. 3 the interrupter is shunted by a condenser and the secondary e.m.f. becomes oscillatory. The form of the e.m.f. curve in any actual case is not shown accurately by Fig. 3 except at the time of "break," since the resistance between the terminals of a spark gap decreases rapidly after the spark is established. In Fig. 4 a low resistance is connected across the secondary terminals and shows the general form of the e.m.f. curve after the spark is established.

Although not shown by the curves owing to difference in scale, the capacity shunted around the interrupter also increases the secondary e.m.f. above the value obtained without the capacity. Assuming that no spark is formed at the

Fig. 4.

interrupter, it may be shown that the e.m.f. of the secondary equals  $\frac{N_s}{N_p} \sqrt{\frac{L}{C}} I_b$ ,

where  $L$  equals the inductance of the primary in henries,  $C$  equals the capacity of the condenser in farads and  $I_b$  equals the primary current at "break" in amperes. If  $C$  is made so low that a spark appears at the interrupter, the above formula no longer holds and the secondary e.m.f. will be greatly reduced.  $C$  should then be made as small as possible but of sufficient size to suppress the spark at the interrupter.

**Insulation.**—The conductors in the secondary winding must be heavily insulated to withstand the very high e.m.f. induced in that winding. In most

uses a double-covered silk insulation impregnated with some insulating compound is used. In large induction coils the secondary winding is built up of several flat coils insulated from each other by ebonite or fiber disks. The coils are so wound that the electrical connections are made alternately at the top and at the bottom of the respective coils.

**Dimensions of Three-inch Coil.** — The general dimensions of parts of a three-inch induction coil, as reported by S. R. Bottone, *Radiography (London, 1898)*, are given following: Iron, bundle of No. 20 (B. & S. G.) annealed iron wire,  $1\frac{1}{4}$  in. diameter, 23 in. long. Primary winding, four layers of No. 12 double silk-covered copper wire, about  $4\frac{1}{2}$  lb. Ebonite tube over primary, 12 in. long, 2 in. inside diameter,  $2\frac{1}{2}$  in. outside. Two ebonite heads, 5 in. square,  $\frac{1}{2}$  in. thick. Seven vulcanized fiber circlets (for sections),  $1\frac{1}{2}$  in. diameter,  $\frac{7}{8}$  in. thick,  $2\frac{1}{2}$  in. central aperture. Secondary winding, 4 lb. No. 36 double-silk-covered wire. Platinum-tip contact breaker, height from base to center of iron hammer,  $2\frac{1}{2}$  in., size of iron head of hammer  $\frac{3}{4}$  in. diameter,  $\frac{3}{4}$  in. long. Base (fitted with false bottom to contain condenser), 18 in. long by 9 in. wide by  $2\frac{3}{4}$  in. deep. Condenser, 144 sheets of tin foil, size 6 by 12 in., interleaved with 144 sheets of paraffined paper 8 by 13 in.

**Dimensions of Six-inch Coil.** — Similar dimensions for a 6-inch induction coil, as reported by Bottone, are given following: Iron, bundle of No. 16 (B. & S. G.) annealed iron wire,  $1\frac{1}{2}$  in. diameter, 15 in. long. Primary winding, four layer of No. 12 double silk-covered copper wire, about 5 lb. Ebonite tube over primary 14 in. long,  $2\frac{1}{4}$  in. inside diameter,  $2\frac{3}{4}$  in. outside. Ebonite heads 6 in. square,  $\frac{3}{8}$  in. thick. Seven vulcanized fiber circlets  $5\frac{1}{4}$  in. diameter,  $\frac{1}{2}$  in. thick, with  $2\frac{3}{4}$  in. central hole. Secondary winding, 7 lb. No. 38 double-silk-covered copper wire. Platinum-tip contact breaker, height from base to center of hammer, 3 in. size of hammer head, 1 in. diameter, 1 in. long. Base (fitted with false bottom to contain condenser), 20 in. long by 10 in. wide by  $3\frac{1}{2}$  in. deep. Condenser, 144 sheets of tin foil, size 6 by 12 in., interleaved with 144 sheets of paraffined paper, 8 by 13 in.

**Interrupters.** — An interrupter should be so designed that it will close the circuit for a definite time by easy adjustment and will open the circuit at the end of that time as quickly as possible. Two distinct types, the mechanical and the electrolytic interrupter, are in common use. Mechanical interrupters may be divided into the following forms: hammer, atonic, commutator and mercury interrupters. Of the electrolytic interrupters the Wehnelt type is the most popular.

**Hammer Interrupter.** — In the hammer interrupter, shown in Fig. 5, the circuit is opened at A when the core B attracts the iron mass C mounted at the free end of the spring blade D. Since the core attracts the iron mass only when the circuit is closed and loses its attraction when the circuit is opened, the spring blade is set in vibration and opens and closes the circuit in rapid succession. This type is used extensively in connection with small coils. The contacts at A are usually tipped with platinum to withstand the intense heat developed by sparking. The rapidity of the "break" is not great enough for large coils, and when a large current must be broken, trouble is experienced in keeping the contact points in good condition.

Fig. 5. Hammer Interrupter

**Atonic Interrupter.** — In the atonic interrupter, shown in Fig. 6, the free end of the iron strip P is attracted as in the hammer interrupter and is

returned to its original position by the spring *R*. The circuit is opened at the contacts *ab* when the free end of *P* strikes the blade *L*. Interrupters constructed in this manner open the circuit quicker than do the hammer type since the attracted member is moving faster at the instant of "break." The period of the atonic interrupter may be varied within wide limits by regulating the tension on the spring *R* by means of the thumb-screw *M*.

Fig. 6. Atonic Interrupter

**Commutator Interrupters** are often used when the primary current is too large to be broken by the hammer or atonic interrupters. A brush bearing upon a revolving disk, built up of conducting and insulating segments, makes and breaks the circuit at any desired rate, depending upon the speed of the motor which drives the disk.

**Mercury Interrupters** are specially adapted to circuits of high e.m.f. In the *plunger* type a pointed electrode is alternately immersed and withdrawn from a cup of mercury, the moving electrode being set in vibration magnetically as in the hammer interrupter, or by the positive action of a cam driven by a motor. The mercury cup is covered with a layer of oil so that the spark is quickly extinguished when the moving electrode is withdrawn into the oil. In the *turbine* type a small stream of mercury is directed upon the periphery of a revolving toothed wheel. The circuit is made when the mercury stream strikes a tooth and is broken when the mercury stream passes through a slot between the teeth. The toothed wheel is rotated at high speed by a motor which also drives a small mercury pump.

**Wehnelt Interrupter.** — The Wehnelt interrupter has two fixed electrodes which are immersed in dilute sulphuric acid. The anode consists of a small platinum wire insulated by glass except at its tip end. The cathode usually consists of a sheet of lead. If the electrolyte is well circulated, an interrupter of this kind will give about 450 interruptions per second with 24 volts impressed upon the primary circuit. When used with large coils the electrolyte heats up quickly, and a cooling coil is sometimes immersed in the electrolyte to control the temperature.

**Tesla Coil.** — In some cases, as in wireless telegraphy, electro-therapeutics, etc., where a unidirectional e.m.f. is not required, but an e.m.f. of high frequency is desired, a Tesla coil may be used in place of an induction coil. The construction of a simple Tesla coil is shown in Fig. 7. In the primary circuit a primary winding of few turns and a small spark gap are shunted by a condenser. Secondary and primary windings are wound together upon an air core. If an alternating e.m.f. of from 5,000 to 10,000 volts is impressed upon the primary the condenser is charged until the voltage across the primary gap breaks it down. The condenser then discharges through the gap, producing an oscillating current in the primary winding. The oscillating current in the primary induces a high-frequency e.m.f. in the secondary, which is sufficient to break down the long secondary spark gap.

Fig. 7. Tesla Coil

W., *Elek. und Mach.*, 1907, Vol. 25, P. 337.

**INSULATING MATERIALS, MISCELLANEOUS.** — (See also *Lambric, Varnished; Electricity and Magnetism, Principles of; Gutta Percha; Insulating Materials, Testing of; Paper, Impregnated; Rubber; Wires and Cables, Insulated.*) Materials used in the insulation of electrical apparatus may be classified as follows (see also *Standardisation Rules of A.I.E.E.*):

1. Vitreous, including glass, enamel, etc., 2. Stony, such as slate, marble, etc., asbestos, porcelain, etc., 3. Osseous, such as bone and ivory, 4. Resinous, including shellac, resins, copal and other gum, 5. Bituminous, as bitumen, asphaltum, pitch, etc., 6. Waxy, including bees-wax, paraffin, etc., 7. Elastic, such as india-rubber, ebonite, gutta-percha, etc., 8. Oily, including various oils and fats of animal and vegetable origin as mineral petroleum, 9. Cellulose, including dry wood and paper, cotton, celluloid, etc., 10. Silk and allied animal tissue such as catgut, 11. Sulphur, 12. Amber, 13. Molded insulations.

**SELECTION OF INSULATING MATERIAL.** — In selecting an insulating material for any special purpose and in predetermining accurately the behavior of such a material under working conditions, it is desirable that the following electrical, physical and chemical properties of the material should be known as far as they apply to the use in question.

*Electric.*—

Dielectric strength (kilovolts per mm. at puncture).

Dielectric loss.

Specific inductive capacity; Direct-current; Alternating-current.

Conductivity or resistivity. Surface leakage.

Temperature coefficient of resistance.

*Physical.*—

Specific gravity and specific weight.

Hardness.

Toughness.

Brittleness.

Ductility.

Workability.

Flexibility (with reference to varnished cloths, etc.).

Strength (tensile, compressive and shearing).

Fracture (fibrous, crystalline or amorphous).

Ability to take polish.

Melting point.

Shrinkage.

Adhesiveness.

Effect of high temperature (electric arc).

Effect of low temperature.

Artificial aging test.

Porosity.

Viscosity.

Flash and fire test.

Film-making power.

Rate of drying.

Penetration.

Absorption of moisture.

Amount of volatile matter given off at prescribed temperatures.

*Chemical.*—

Proximate composition.

Solubility in water, oil, etc.

Effect of moisture and moist air.

Weathering qualities.

Chemical effect upon metals in contact.

Presence of acid.

**DIELECTRIC STRENGTH.** — According to best authorities, an insulating material should be homogeneous and free from moisture in order to have high dielectric strength. In addition, some authorities claim it should also have a low specific inductive capacity (permittivity). These claims are based on experiments made on some of the more important insulations. Whether they apply to all insulations in general is a question which requires more extensive experiments before it can be answered definitely. However, enough experi-

ments have been made to warrant that these claims be given consideration in choosing insulating material for uses in which very high dielectric strength is required.

The breakdown voltage is influenced by the size and shape of electrode, frequency and wave shape of the applied voltage, time of voltage application and the temperature of the insulation. The literature on the subject is not always clear on these points nor is there a standard practice adopted.

The Continental Fiber Company has adopted the practice of using sharp needle points on test specimens over 0.125 inch thick and disc electrodes in diameter for test specimens 0.125 inch thick or less, and raising the voltage at the rate of 5000 volts per second from zero to puncture voltage.

Table I illustrates the effect of the thickness of the test specimen on the dielectric strength of porcelain. The effect may be greater or less for other insulating materials. It is obvious, however, that a standard thickness of test specimen should be adopted in order to obtain comparable values of dielectric strength of the various insulations.

TABLE I.—DIELECTRIC STRENGTH OF PORCELAIN  
DIFFERENT THICKNESSES OF TEST SPECIMEN  
(Peek: Dielectric Phenomena in High Voltage Engineering)

Total thickness, mm.	Kv./mm.
0.5	16.0
1.0	14.5
2.0	12.4
5.0	11.0
10.0	9.6
15.0	9.2

Table II illustrates the effect of the time of application of voltage on the dielectric strength. The table also shows the effect of temperature on the dielectric strength. The voltage is applied at 25° C.

TABLE II.—VARIATION OF DIELECTRIC STRENGTH WITH  
TIME OF APPLIED VOLTAGE  
(Peek: Dielectric Phenomena in High Voltage Engineering)

Material	Thickness, mm.	Time to puncture, min.	25° C. kv/mm.

was thoroughly dried prior to impregnation with oil. If moisture the effect of temperature may be opposite from paper (see article on *Fibre*). It follows, therefore, that preferably be tested at a definite relative humidity at a definite time of application of voltage should be standardized comparable results.

dielectric strength of various insulating materials. The all obtained under the same test conditions. The literature values were obtained seldom stated the test conditions cannot be used to compare absolutely the dielectric strengths but will serve only as a guide in choosing materials of a dielectric strength.

**LEAKAGE** is due to a film of moisture on the surface of the insulation. This moisture may contain soluble salts and condensed gases, and carbon dioxide from the air. This film may indeed be removed, on cleaned quartz glass, it has been found to be from a thin layer of wax. Waxy materials have no surface film because the moisture on the surface tends to draw into drops instead of spreading over the surface. Resistivity according to Curtis is independent of voltage and relative humidity being constant. The temperature range was  $25^{\circ}$  to  $30^{\circ}$  C. with relative humidity at 25 per cent. The resistivity of most insulating materials decreases upon exposure to light. The results obtained by Curtis indicate that a few minutes of ultra-violet light will produce the same or sometimes more leakage than would be produced in years by sunlight.

Surface leakage is defined as the resistance between two opposite edges of a square of one centimeter square. The values in Table III are those obtained by Curtis at temperatures from  $25^{\circ}$  to  $29^{\circ}$  C. and are given for 30 and 90 per cent relative humidity. The test voltage was 200 volts.

Surface leakage should be distinguished from volume leakage. The surface moisture film under high voltage is soon removed and is replaced by a new film. The surface leakage is soon generated with the leakage current. Then a new leakage current is produced by the oxidation of the insulation with ozone generated at the surface. The oxidation is formed by local ionization of the surrounding air. If the insulation is covered with an oil such as blown linseed oil prior to testing, the oxidized film can be greatly reduced, and the surface leakage will be increased. Even though all the actual surface leakage is removed, the flash-over voltage would still be limited by the surface leakage, which, for a given leakage distance, depends on the position and shape of the electrodes, relative specific inductive capacity of the insulation and the shape of the insulation (contour of the insulation). The surface leakage at all existed the flash-over voltage would be limited by the surface leakage of the air between the electrodes. (Adapted from *Phenomena in High Voltage Engineering*).

Tables of values are available on the flash-over voltage of insulations, this is given in Table III.

**RESISTIVITY** of insulating materials in general follows Ohm's law. The resistivity of any consequence is a few vegetable oils, as for example, castor oil, in which the resistance decreases with increase in the applied voltage. The resistivity varies with the amount of moisture present in the material. In Shrader's work on the effect of moisture, he found that the resistivity of an insulating material, which is generally considered non-porous, had a resistivity of  $26 \times 10^{10}$  ohm-cm. ordinarily, but in a vacuum, had a resistivity of  $8 \times 10^{14}$  ohm-cm., or 3000

insulations as great. As to the effect of temperature, Curtis found that in 55 of the insulations which he investigated, the ratio of the resistivity at 20° C. to that at 10° C. varied from 1 to 5.3.

The values given in Table III are for 100m temperature at ordinary atmospheric humidity. The unit used is the resistance to the current flowing through the material between two opposite faces of a centimeter cube, no surface leakage being present.

**DIELECTRIC LOSS** is due to the following causes:

With either d-c. or a-c.

1. Ionization of occluded gases.
2.  $I^2R$  losses due to leakage current.

With a-c. only.

3. Oscillatory movement of particles of higher or lower specific capacity than the surrounding medium, due to the charges induced on them being alternately attracted and repelled by the electrodes.
4.  $I^2R$  losses due to displacement current.

Generally, dielectric loss varies as the square of the voltage up to a certain dielectric stress at which the loss begins to increase faster than the square of the voltage. The increase occurs when the occluded gases or other particles of low specific inductive capacity begin to ionize. This has the effect of greatly increasing the dielectric stress on the particles of high specific capacity which soon rupture. Dielectric loss therefore has a bearing upon the dielectric strength of insulations especially when the voltage is applied indefinitely.

Table IV gives dielectric loss of varnished cloth and oil treated paper. No data are available on insulations in general.

The power-factor of insulation is the ratio of the power dissipated in it (i.e., the dielectric loss) to the apparent power delivered to it.

As the charging current and therefore the apparent power increases, with the specific capacity, it is obvious that low power factor may result either from low dielectric loss or high specific capacity. The power factor is therefore not a good indication of the quality of insulation.

**THE PHYSICAL PROPERTIES** of insulating materials are given in Table V. The degree of hardness is not listed because it has been determined for only a very limited number of materials. Furthermore, there seems to be no agreement in the unit chosen to express the degree of hardness. Transverse strength is not given because no standard method for making this test has been adopted. Very few values can be found in the literature for shearing strength and so this property is also omitted.

Souder and Hidnert found that the expansion of insulating materials is a function of the temperature, medium in which the material is heated (air or oil), time, rapidity of heating or cooling. Of these factors the medium is the most important for materials which absorb moisture in considerable quantities. The values given for the linear temperature coefficient of expansion are those obtained in an air medium with the exception of Continental-Bakelite which, when heated in air, has an irregular expansion.

**MOLDED INSULATIONS** may be classified as Hot Molded Insulations and Cold Molded Insulations.

Hot Molded Insulations are subjected to heat and pressure simultaneously in the mold. Three classes of binders are used.

1. Gums, such as shellac and copal which become soft and plastic when heated and hard when cold. These gums are mixed with short asbestos fiber, cotton fiber, ground mica, infusorial earth, barytes or any of a great variety of materials.

‡ measured in an oil bath.

A proper combination of gums and fillers is selected to obtain the desired result. These materials are mixed by the use of a grinder, hot rollers or a solvent which afterwards is driven off. The mixed material is heated to fuse the binders and then placed in a heated mold. The charged mold while hot is pressed in a co

press to produce the desired form and then allowed to cool and harden under pressure. Insulations molded thus are generally mechanically weak, have high dielectric strength, soften and distort at about 40 to 60° C. and low in cost.

2. Synthetic Resin such as that produced by the mixture of phenol and formaldehyde in the presence of ammonia. These chemicals combine to form a liquid varnish which has the remarkable property of hardening upon heating without softening upon subsequent heating even when heated to carbonization.

A variety of other chemicals can be used. In this pure form the insulation is translucent with a beautiful variety of colors and takes a high polish and is known as synthetic amber. Examples of this product are on the market bakelite, condensite, and redmanol. A molding mixture consists of this resin, wood flour, asbestos fiber or other materials, molded in a hot press and allowed to set. The resin in solution may be spread on paper or fabric which is then pressed together and heated to drive off the solvent. An example of such a product is micarta. Insulations of this group have great mechanical strength, high dielectric strength and in most cases, resist temperatures up to 150° C.

3. Vulcanizing Agent. Hard rubber or vulcanite is an example of this group. Crude rubber is mixed with fillers and a vulcanizing agent, such as sulphur and then vulcanized in molds under heat and pressure. These insulations have high resistivity, fair mechanical strength, and distort under slight loads even at room temperature.

Cold Molded Insulations are made by the use of two classes of binders.

1. Binder dissolved to mix with a filler, the solvent of which is expelled after the mold is completed. The binder may be (a) a pitch dissolved in benzine or naphtha, (b) phenolic resin dissolved in alcohol or benzol, heat being continued after the solvent is driven off the mixture to polymerize or harden the resin and (c) silicate of soda dissolved in water, the water being expelled from the mixture in a drying oven. The filler used with these binders is generally asbestos. The characteristics of each are: (a) soften at 60° C., fair in mechanical strength and in dielectric strength, and low cost; (b) does not soften up to 150° C., and not as strong mechanically, nor as good electrically as the hot molded insulations; (c) weak mechanically and electrically, resists high temperatures, but hygroscopic.

2. Set by chemical action: Examples of this group are: (a) Portland cement with asbestos fiber, the excess water being driven off by heating; and (b) lime and silica mixed with water properly treated and used with a filler of asbestos or magnesia. The properties of each are (a) not weakened by moisture, fair electrically up to 400° C., mechanically fair, porous in structure, but can be made weatherproof with a coating which will limit the temperature in use; (b) mechanically weak and resists very high temperature.

**MISCELLANEOUS INSULATIONS.** — Insulating materials are often described in general terms without specific data. A material is said to be "heat proof" which may mean that it will not deteriorate when used continuously at some temperature within the range of 30° and 250° C. Dielectric strength is sometimes quoted without reference to the thickness of the test specimen. If the test has been made on a very thin specimen, the dielectric strength obtained will be misleading to those who are not aware of the law of the increase of dielectric strength with the decrease of the thickness of the test specimen. Claims may be made that an insulating material is insoluble in certain solvents and is weatherproof. Such claims are not absolute. They are only general and refer to ordinary conditions found in the use of insulations. If the working conditions are unusual and severe, specific information should be obtained on the appropriateness of the insulation under consideration.

The more important types of insulation are described in alphabetical order in the following pages.

ivity and specific inductive capacity, and a dielectric most purposes except very high voltage apparatus and articles on *Corona* and *Spark Gap*.

is made by compressing scrap amber. It is now in as surface leakage is concerned is the equal of native surface should be well cleaned to avoid surface leakage deliquescent salts in handling it with the fingers.

aking in a vacuum silicate of sodium, asbestos, fossil alcohol. It is moulded in heated moulds, under high of Ambroin will resist very high temperatures and are fields. Ambroin is only slightly hygroscopic as com- ors of the same nature. (Adapted from Hobart and

ic organic substance resulting from the chemical conden- maldehyde (General Bakelite Co., N. Y.). It may be as a solid. The liquid Bakelite is useful for the impreg- ls, for enameling under heat and pressure and as a bind- ompounds. The solid Bakelite is unaffected by water, all chemicals. It does not melt or soften at ordinary

machine temperatures; it is destroyed only at temperatures in the vicinity of 300° C. It is easily and accurately moulded and may be made to take any color. It compares favorably with rubber and gutta-percha in every way except that it is not as flexible as those substances. The moulded insulation will withstand a temperature of 90° to 450° C., depending on the filler used.

**Bakelite-Dilecto** is made by hot pressing paper which has been saturated with raw bakelite. It is furnished in five different grades in the form of sheets, tubes and rods. If immersed in water for eight days, it will absorb from 1 to 6 per cent of its weight of water, depending upon the grade. In general, it is considered non-hygroscopic and resists ozone indefinitely. It withstands a temperature of 105° C. continuously and 150° C. for short periods of time without deterioration. Its chemical inertness is similar to that of Bakelite. It can be worked with any machine shop tool and takes a splendid polish.

**Bakelite Micarta** is primarily an insulating material but can be used for many other purposes as for example, pinions and gears, the wearing properties of which are better than rawhide. It is furnished in the form of sheets, rods, and tubes and can be machined accurately and takes a good polish. For short periods of time, it will withstand a temperature of 140° C. Its chemical inertness is similar to that of Bakelite.

**Bitumen.** — See section on *Asphalt*.

**Byarlyte.** — See section on *Asphalt*.

**Cambrie, Varnished.** — See separate article on *Cambrie, Varnished*.

**Cellon** is obtained by heating cellulose in a closed glass vessel with acetic anhydride to 180° C. or 110° C. if hydrocellulose is used. When sulphuric acid is used as a catalyser, the reaction occurs at about 55° C. The resulting mass is thinned by adding acetic acid. The cellon is precipitated by adding water, benzine or ether and afterwards washed thoroughly with water. It is then dried at a temperature not exceeding 100° C. The finished product is furnished in either a hard or flexible form in any desired color. Its specific gravity is 1.35 and its dielectric strength is 30 kv. per mm. It can be shaped with any tool, polished and becomes elastic in boiling water and can then be pressed into moulds.

**Celluloid** (xylonite) is a dried solution of gun-cotton (pyrolin) and oil. It may be machined or moulded into any form by softening in boiling water. Its dielectric strength is very much reduced at high temperatures, and it is very combustible. It is only slightly hygroscopic.

**Coal-tar Pitch** is the residue remaining after the fractional distillation of coal tar. It flows at low temperature and when cold is quite brittle. Symons gives its dielectric strength as 3000 volts per millimeter.

**Condensite** is a hard infusible substance, the chief constituent of which is a resinous gum, made by the reaction between phenol and formaldehyde. Condensite is produced by combining this gum under heat and pressure with a hardening agent. It is supplied in three grades; for plastic moulding, for impregnating and as a cement. It can, in general, be moulded to an accuracy of .002 in. plus or minus, with all kinds of metal inserts.

It is non-inflammable, non-corrosive, and infusible, insoluble in oils, most acids and other solvents and shrinks but one-fifth of one per cent in moulding. The impregnating material is used in connection with metal, wood, paper, cardboard, rubber, leather, etc. The plastic cement is used for fastening together the parts of porcelain insulators, for sealing terminals in porcelain bases, etc.

The value given for dielectric strength in Table I was obtained between blunt needle points, normal temperature, oil immersion, 60 cycles, and the voltage applied for about 10 seconds. Flash-over voltage as tested by the Bureau of

Standards at radio frequency was 25 kv. between skirted stubs  $\frac{3}{8}$  in. apart on a specimen 4 inches by 4 inches by  $\frac{3}{8}$  inch thick.

The carbonization point is 287° C. Condensite will withstand temperatures of 148° to 215° C. continuously, depending upon the filler used. The shearing strength is 5000 pounds per square inch.

**Condensite-Cellulose** is claimed to be non-hygroscopic and impervious to oils or acids. It has no corrosive effects at ordinary temperatures and can be used in the weather. It is furnished in sheets, rods, tubes and in plastic moulded state for filling irregular spaces in which it will afterwards harden.

**Condensite Celoron** is a new insulating material on the market. The composition of this material has not as yet been published. It has a high dielectric strength and has excellent physical properties.

**Condufine** is made especially for insulating cable joints and end bells. Aside from having good insulating qualities, it has very desirable physical properties. It does not become brittle at low temperatures but remains plastic. The upper temperature limit of plasticity is 95° C. when it suddenly changes over to a very mobile liquid state completed at 110° C. When this filling compound is used in connection with a cable cell, known on the market as "Conducell," cable joints are obtained which are claimed to be uniform in quality and construction.

**Continental Bakelite** is made by hot pressing canvas or cloth which has been saturated with raw Bakelite. It is furnished in two grades, CB and CBL, in the form of sheets, rods and tubes. It is non-hygroscopic. It absorbs only 2 per cent of its weight of water when immersed for eight days. It withstands 105° C., continuously and 150° C. periodically without deterioration. It can be machined and takes a good polish. Its chemical inertness is equal to that of Bakelite.

**Copal** is a resinous substance, which makes a colorless varnish when dissolved in alcohol, oil of turpentine or linseed oil. Copal is easily fused, is very inflammable and is quite brittle when cold.

**Cornimit** is made from fish offals by a Danish process. It is not as hygroscopic as galalith and has higher electrical resistance. The cost of it is very low compared with other insulations.

**Dorrite** can be moulded or stamped into any commercial size or shape. It is said to be fire-proof, acid-proof and water-proof. A specimen 3.2 mm. thick, or 7.6 cm. square, after being immersed in water for 70 hours is reported to withstand 40 kv. without signs of leakage or change.

**Ebonestos** is an English product made of asbestos fiber impregnated and treated with various gums and is moulded accurately under heat and pressure. It is furnished in four grades: (a) Bright and natural finish, hard and short grained, and low softening point. (b) Dull black finish, hard and short grained, softening point 100° C. (c) Tough fibrous material with varnish finish and softening point of 80° C. (d) Coarse fibrous fire-proof material. A specimen of grade "A" after being immersed for 48 hours in brine had an electrical resistance of  $5 \times 10^{12}$  ohm-cm.

**Ebonite.** — See section on *Rubber, Hard.*

**Elasterite.** — See section on *Asphalt.*

**Electrobestos** is an English product and is an asbestos compound which will withstand temperatures up to 900° C. at 500 volts. It is used in heating and cooking devices and arc lamps.

**Electrose** has been in use for thirty-two years. It is a composite insulation which does not tarnish metals because no sulphur is used in its vulcanization. Its compressive strength is 10,000 pounds per square inch. Its temperature

coefficient of expansion is very low and it can therefore be used for mounting electrical parts accurately such as the diaphragm and magnet in telephony cases. It possesses hardness and toughness without brittleness, takes a smooth polished surface and is moisture, water and oil proof. It does not shrink or warp under ordinary conditions. A piece 12 inches by 12 inches and  $\frac{1}{4}$  inch thick arcs over at 75,000 volts but does not puncture between brass spheres  $\frac{1}{2}$  inch in diameter.

It can be moulded into a great variety of shapes. It is used extensively in all types of insulators, bushings and terminals, for railway work, power transmission, radio and telephone transmission over a wide range of frequencies and voltages.

**Empire Cloth** consists of a closely-woven cambric coated with two or more films of an oxidized oil, prepared by a special process. Canvas, duck, linen, silk and paper are also coated by the same process. (See *Varnished Cambric*.)

**Erinoid** is an English product made from solids of milk and is similar to Galalith and resembles horn in appearance. It is furnished in sheets, tubes, and rods in various colors including a striated appearance. Its insulating properties are good if not used in damp places. It can be shaped with tools and polished by rotating in a barrel with Erinoid shavings and pumice stone.

**Esvelite** is somewhat similar to Bakelite except that it is brittle and becomes flexible in boiling water. According to Butlemaann its specific gravity is 1.2 and its dielectric strength is 15 kv. per mm.

**Fiber** is pure cotton cellulose chemically treated to form a hard bone-like material. It is known by various trade names such as Fiber, Vulcanized Fiber, Hard Fiber, Horn Fiber. These fibers are all essentially the same and vary only in quality and uniformity with the skill and experience of the manufacturer. Fiber of best quality has its origin in old rags because the natural oil of the virgin cotton fiber is deleterious and cannot be removed by easy chemical process. This oil is removed in the wearing and washing of the garment. All dirt and grit must be removed from the rags. The quality also depends on the assortment of the rags.

"Vulcanized Fiber sheets are made by passing cotton rag paper through a strong-acid or chloride bath and rolling it up on a large drum where each layer of paper sticks to the layer beneath it. When the proper thickness is obtained the acid soaked material is cut from the drum and cut in half forming two sheets of raw fibre. These sheets are put through a soaking process in large wooden tubs, each subsequent tub containing a weaker solution, the last tub containing pure water." (Catalogue of The Continental Fiber Co.)

The soaking process requires from one week to one year depending on the thickness of the sheet. A very small amount of acid will remain in spite of all the soaking. The sheets are air dried and seasoned at a constant temperature. During the drying, they warp and shrink to one-half the original thickness. They are flattened in a steam heated hydraulic press and then calendered to exact thickness.

According to Almy the mechanical and physical properties of fiber varies between wide limits according to the manipulation of the chemical treatment and the varying quality of the original paper or rags. A fiber for a particular use should therefore be selected with great care.

Fiber is not waterproof. It will absorb water but is not injured beyond warping by either hot or cold water because it returns to its original dimensions and properties when dried. Dilute acids and alkalis cause no other effects than water, but concentrated acids cause disintegration. Organic solvents and oils have no effect whatever. At a sustained temperature of 80° to 100° C., it loses its water of condition and becomes brittle and chars in a short period of time at 200° C.

According to Eves, the dielectric strength is about the same for all colors of a given fiber. The tendency of the iron salts in the coloring matter to lower the dielectric strength is offset by the loading effect of the coloring matter which gives the fiber greater homogeneity. The dielectric strength of thin specimens of fiber increase with increase in temperature whereas it decreases with increase in temperature with thick specimens. The moisture is dispelled from the thin specimens at the higher temperatures but is retained in the thicker specimens. This difference in the retained moisture explains the variations in dielectric strength as the temperature is increased. Fig. 1 gives the average breakdown voltage for different thicknesses of fiber of all colors.

Fig. 1.

Fiber is used very extensively. One of the greatest uses of fiber, either for mechanical or electrical purposes, is for railway signal insulation. The Railway Signal Association's specification requires a specific gravity of 1.3 to 1.5; an absorption when immersed in water at 70° F. for twenty-four hours, not to exceed 45 per cent by weight for 3.18 mm. fiber, 30 per cent for 4.76 mm. and 26 per cent for 6.35 mm. fiber; a tensile strength of 5000 pounds per square inch; a dielectric strength of 1280 volts per millimeter for all thicknesses under an application of voltage for one minute between disc electrodes 2.54 cm. in diameter; withstand bending to a circle of a radius ten times the thickness without cracking or splitting.

Formica is furnished in three grades in the form of sheets, tubes and rods, and can be moulded. Its physical and chemical properties are claimed to be similar to those of redmanol. Its electrical and mechanical properties as given by the manufacturer are: dielectric strength, 39 kv. per mm. Resistivity,  $1.7 \times 10^{12}$  ohm-cm., tensile and compressive strength, averaging 20,000 pounds per square inch, specific gravity of 1.25 to 1.35 and a linear coefficient of expansion of .00002 per degree centigrade. It will withstand a temperature of 150° C. continuously.

**Fuller-Board.** — See section on *Pressboard*.

**Galalith** is a German product made by heating skimmed milk with caustic soda and precipitating the casein with acid. The casein plates after being dried are saturated with formaldehyde and dried again resulting in a translucent sheet of yellow-white color. It is rather hygroscopic but serves as a good insulator in dry places. It can be shaped cold after being softened with hot water. Its specific gravity is 1.34.

**Gilsonite.** — See section on *Asphalt*.

**Glass** is a silicate of soda or potash combined with certain metallic oxides usually lead oxide. Owing to the condensation of moisture upon its surface glass has a very large surface leakage. Rain water roughens its surface and the resulting accumulation of dirt reduces its insulating qualities. According to Gray and Dobbie the specific resistance of potash glass is higher than that of soda glass. Annealed glass has in general a higher specific resistance than unannealed glass. As compared with porcelain, glass is inferior in mechanical strength; whereas porcelain is only chipped by a blow, glass is easily cracked or shattered.

**G-E Sealing Compounds** are divided into two classes:

(1) For the protection of coils from the penetration of moisture and mineral oils. These compounds withstand rough handling, and possess uniform flow point under continued heat, a high degree of fluidity and high penetration at the treating temperature.

(2) For filling cavities to exclude moisture, dust and dirt. The first group in this class includes solid compound which are melted, poured in place and solidified by cooling. Some of the uses are, for filling cable end bells and joints and for filling over screw heads in receptacles, sockets and switches. The second group includes plastic compounds some of which set without the application of heat. They are used to fill in spaces between wires of armatures and of field coils.

The flow point varies from 65° to 250° C., depending upon the compound. The breakdown voltage of No. 227 joint compound is 75 kv. at 65° for a 0.25 inch gap, and of No. 239 filling compound is 40 kv. at 80° C. for a 0.2 inch gap.

**Gummon** is a coal tar product. It will withstand the flame of a Bunsen burner, remaining perfectly hard. It is not easily sawed or drilled as it takes the temper out of steel. Other insulating materials having similar properties are agalite and australite.

**Gutta-Percha.** — See article on *Gutta-Percha*.

**Hemit** is furnished in four grades. Grade A can be moulded accurately with metal inserts and is claimed to be less brittle than porcelain. It withstands a temperature of 318° C. continuously and sudden changes of temperature without cracking. It is non-hygroscopic and not affected by dilute acids. Grade B can be shaped with tools or moulded. It is hygroscopic and does not resist acid. It will withstand a temperature of 300° C. continuously and sudden changes of temperature. Grade C 1 is moulded in sheets and is non-hygroscopic, but does not resist acids. It withstands a continuous temperature of 425° C. and exposures to the electric arc and sudden changes of temperature. Grade C 2 is moulded in sheets and should not be exposed to moisture which reduces its dielectric strength. It is unaffected by the electric arc and withstands a continuous temperature of 1100° C. and sudden changes of temperature.

**Jute** is a fiber obtained from the inner bark of certain trees growing in India. Commercial jute is usually softened and rendered less brittle by impregnating it with paraffin or some similar mineral oil. It is used extensively as a filler in lead-covered cables and as a constituent of certain kinds of paper and press-board.

**Kalanite** is an English product furnished in three grades. (A) in sheets and rods which can be shaped with tools, (B) a moulding mixture and (E) in sheets which are fire resisting and used for arc shields and switch boxes.

**Lava** is a mineral talc, machined in its natural condition and then baked at a temperature of 1100° C. to a condition of extreme hardness. It is then unaffected by any subsequent temperature short of its baking temperature. It is slowly attacked by hydrochloric acid but is not affected by other acids or alkalis.

Its dimensions are unchanged by absorption of moisture and it has a negligible coefficient of expansion with temperature.

**Lavite.** — See section on *Lava*.

**Leatheroid.** — See section on *Fiber*.

**Litholite** is an insulating material resembling psychiloid in structure. It is made in sheets and is pressed into any form. It is softened by sulphuric acid and distilled water and is reduced to a pulp if immersed in caustic soda. It is tough but inflammable. It is used for commutator rings, bushings, washers, fuzers, bobbins and for square and round tubing.

**Marble** is the name given to any limestone which is sufficiently compact to admit of a polish. While pure marble is white, the presence of iron oxide or other impurities give it different colors. It is used principally for switchboard work and should not contain metallic veins, which reduce its insulating qualities. If used on circuits of 1000 volts or more, it should be saturated with an insulating varnish and baked. It shows oil spots and for that reason it is sometimes stained black and given a so-called marine finish.

**Mica** is an anhydrous silicate of aluminium and potash or sodium. It crystallizes in a laminated mass, some grades of which may be subdivided down to a thickness of 0.0008 millimeter. The ultimate thickness of cleavage layers is unknown and may be finally but one layer of the molecular structure. It is useful as an insulator because of its high insulating qualities and its ability to withstand high temperatures. Owing to its impurity, lack of flexibility and excessive surface leakage in the natural state, the laminae are separated and sorted into various grades of purity and are then cemented together to form plate or flexible reconstructed mica of any thickness or purity. Moulded mica is used in the manufacture of overhead line material and in the making of moulded pieces as a substitute for hard rubber. It softens at 136° F. Moulded mica is insoluble in water, but is affected by certain oils and all acids and alkalis to some extent. Mica loses its insulating qualities at a temperature of 1000° C., but recovers them after cooling. Andrews showed that the dielectric strength of mica is greatly reduced when immersed in or coated with oil.

**Micabond Cloth, Paper and Plate** are forms of reconstructed mica. Micabond cloth is India sheet mica faced on one side with muslin and on the other with Japanese insulating paper, bonded together with a special binder. It is furnished in three different grades varying in flexibility and in thicknesses from .05 inch to 0.125 inch. Among its uses is the insulation of field coils and transformer coils. Micabond paper is made in the same way as the cloth except that paper of different grades are used on both sides of the mica. It is furnished in three different grades in the form of sheets and tapes and in thickness from 10 to 25 mils. Micabond plate is made of mica sheets bonded with orange shellac. Grades 101 and 111 are furnished in sheets from .01 to 0.125 inch thick and are used for armature slots, spools for magnets and other similar purposes. These grades can be moulded. Grades 102 and 104 are also furnished in sheets which are very carefully milled to exact thickness varying from .01 to 0.125 inch and are intended especially for the insulation of commutator segments. These grades cannot be moulded. Grade 21 is made by a special process and is recommended for use in electric flat iron and ranges. Micabond is also furnished in the form of tubes, washers and commutator rings.

**Micanite** is also a reconstructed mica. White mica of India and amber mica of Canada are used. The mica films are very carefully inspected for purity and the bonding material is carefully selected to give the best results. It is furnished in the same forms and in the same grades and dimensions as micabond. Its uses are the same as those of micabond.

**Mineraliac** is furnished in four grades all of which are impervious and show no alkali or acid reactions. Grade No. 1 is an impregnating of the consistency of molasses with a flash point of 230° C. Grade semi-solid compound used in cable end bells and potheads or for impregnating coils, fiber and wood for use on high voltage. Grades No. 2-A is used of No. 2 in warm climates because of its higher flow point. Grade No. 2 is semi-solid compound for use on voltages below 2000 volts. Grade No. 3 is a mineral insulating compound for use in high voltage cable joints. Its coefficient of expansion is low and its dielectric energy loss is low.

	No. 2	No. 2-A	No. 20	No. 3
Flow point, °C.....	48	59	75	68
Drip point, °C.....	63	85	127	91
Flash point, °C.....	200	243	348	182

**Oil.** — See article on *Oil, Transformer*.

**Paper** (See article on *Paper, Impregnated*.) The various kinds used for insulation may be divided into two classes according to the method of manufacture:

(a) Fiber or pulp compressed into paper, examples of which are Kraft and Fuller board. This class of paper may receive a sizing treatment with a solution to harden the surface.

(b) Fiber specially digested or parchmentized to give a close grained texture, an example of which is fish paper. This class of paper must be fully washed out in the manufacturing process to remove all digesting solution otherwise the product becomes very brittle and disintegrates with age.

The following list gives the name, origin and method of manufacture of well-known papers in use:

Name	Origin	Method of manufacture
Linen paper	Linen rags	Compressed and sized
Kraft paper	Wood pulp	Sulphate treatment used
Rope paper	Old rope	Compressed and unsized
Press board	Cotton rags	Compressed and sized
Fuller board	Cotton rags	Compressed and unsized
Fish paper	Cotton rags	Digested with sulphuric acid
Fiber	Cotton rags	Digested with zinc chloride
Asbestos paper	Asbestos and cotton	Compressed and unsized

Paper is very hygroscopic and should not be used for insulation unless it is impregnated or sealed. It is used extensively in telephone cables and in lead sheath. Paraffined paper is used as a dielectric in electric cables. Impregnated with oils, it is used in power cables in which it is also used with a lead sheath. Many other uses might be listed but these are the most important.

**Paraffin** is a product obtained by the destructive distillation of shale. The dielectric strength of cloth, wood and paper is increased by impregnation with paraffin and the materials are rendered less hygroscopic.

is acidproof but is very inflammable and has a melting point depending upon the grade. The commercial grades of paraffin have melting points varying from  $47^{\circ}$  to  $52^{\circ}$  C. Its insulating properties are excellent. The surface leakage is very low and is practically constant up to 90 per cent relative humidity. A special grade of paraffin has such high electric resistance that it cannot be measured by any methods yet conceived. Its melting point is  $38^{\circ}$  C.

**Parolite** is an English trade name for an insulation which is similar to bakelite mica.

**Pitch** is a residue from vegetable oils. Examples are cottonseed pitch and wood pitch. Coal tar residues are often referred to as pitches. Pitch is used mainly as a binder in moulded insulations.

**Porcelain** (See article on *Insulation for Overhead Lines*.) Porcelain is distinguished from other forms of earthenware by a vitrified and non-porous structure. It is composed of china clay, ball clay, flint and felspar. China clay, sometimes called kaolin, is slightly plastic whereas ball clay is very tough and plastic. By a proper combination of the two the desired plasticity is obtained. Flint is in the form of pure sand or quartz ground so finely as to be entirely free from any gritty feeling. Feldspar is a natural rock and is ground as fine as the flint. These four ingredients are mixed in proper proportions and passed through the manufacturing processes which require very skillful care and experience upon which depends the quality of the product. Such articles as knobs, cleats and lamp sockets are made by a dry process and are not suitable for high voltage because of their porosity. Insulators are made by a wet process and are non-porous which is necessary for high voltage use. The glaze is provided to protect the porcelain from dust and deterioration in the weather and should have the same temperature coefficient of expansion as the porcelain.

In the dry process the great variety of forms of the product is obtained by pressing the material into a steel mold. Articles made with this process shrink  $\frac{1}{2}$  inch per inch in firing. The shape of the insulator made by the wet process is obtained by turning it down with machine tools before firing. It shrinks about  $\frac{3}{16}$  inch per inch in the firing process. The shrinkage is caused by the material fusing at the high temperature attained and filling the voids between the finely divided particles.

The mechanical strength depends upon the flint content, the heat resistance upon the clay and the dielectric strength upon the felspar which unfortunately also adds brittleness. In a special type of porcelain for spark plugs, magnesia is used which adds mechanical strength at high temperatures. Porcelain, because of its low tensile strength, should be used under a compressive strain. It is comparatively inexpensive, chemically inert and not sensitive to changes of temperature. The fracture of good porcelain is conchoidal, fine grained, white and bright.

**Pressboard** is similar to paper in its construction, except that it is thicker and less flexible. It is usually hygroscopic unless impregnated with some moisture repellent. It is pressed into many useful forms, and is used as an insulator, principally in connection with low voltages. See sections on *Fiber, Paper, etc.*, for other properties.

The dielectric strength of oiled pressboard is not very definite. It depends a great deal upon the time of application of the stress. The dielectric strength of varnished pressboard is low but uniform and depends largely on the varnish film.

**Presspahn** is a type of pressboard made in Germany. It is strong and can be easily bent. It is usually impregnated and boiled in pure linseed oil, thinned with benzine. Other insulations which are similar to presspahn are terrinox, casta and repelite. These sometimes contain inserts of linen or cotton.

**Redmanol** is a synthetic resin or amber, made of phenol and anhydrous hexamethylenetetramine. It is chemically inert, non-corrosive and non-inflammable. Its physical and chemical properties remain unchanged with age, but its dielectric strength increases with age. It is manufactured in four forms: molded, laminated, transparent and paint.

Moulded Redmanol is furnished in a number of different grades and can be moulded very accurately with metal inserts. These grades do not warp and some of them with proper fillers can be used continuously in air at temperatures up to 260° C. and in super-heated steam up to 343° C. The properties vary with the different grades.

Laminated Redmanol is tough, strong and flexible and can be shaped with tools very accurately and takes a smooth polish. It does not warp or deteriorate with age or upon exposure to heat and weather. It is recommended as an insulator to withstand the effect of salt sea air. It is available in sheets, tubes and rods in different grades with different properties.

Transparent Redmanol has a refractive index of 1.66 and therefore possesses brilliancy and lustre when polished.

Redmanol paint is used for coating electrolytic baths and vats containing solutions of not over 50 per cent of nitric acid, and as a protective coating against ammonia and sulphur dioxide fumes. These coatings withstand indefinitely a temperature of 230° C. and are not affected by boiling water or strong salt solutions.

**Resin** is the oxidized exudation of certain trees or plants and may be of recent origin or exist as a fossil. Some of the common resins which are used for insulating purposes are mastic, shellac, jalap, colophony, storax, amber, copal, kauri gum, gutta-percha, gum arabic, chicle and dammar. Most resins are insoluble in water but dissolve in alcohol, ether, etc., forming varnishes of high dielectric strength. The resin varnishes are limited in their use by the fact that they become brittle at low temperatures, and will disintegrate if under vibration. Resins are hygroscopic and in general possess undesirable acid properties.

**Rubber.**—(See article on *Rubber*.) Hard rubber is frequently referred to as ebonite or vulcanite. According to Paterson, Rayner and Kinnes, the best grade of hard rubber is composed of 65 per cent of para rubber and 35 per cent of sulphur. They made up a number of specimens accordingly and also a number with 15 per cent of various adulterants and in addition obtained one specimen in the open market. Their results show that a good grade can generally be identified by the specific gravity and yield point. The specific gravity of the specimens made up without adulterants was 1.2 and that of the open market was 1.5. The yield point of the former was 75° C. and the latter 56° C. Adulterants will usually increase the specific gravity.

The yield point was obtained by supporting a specimen 25 mm. wide and 10 mm. thick as a cantilever beam with a one pound weight fixed at 15 cm. from the support in an oven and observing the yield after two hours heating at each temperature. The temperature at which the specimen yields and takes a permanent set is the yield point. A high grade will yield not more than 20 mm. in two hours at 70° C.

The dielectric strength test should be applied under oil and by imbedding snugly two spheres 51 mm. in diameter in a specimen 10 cm. thick until the spheres are 0.5 mm. apart. The best grade of hard rubber should show a dielectric strength of 110 kv. per mm.

French chalk or stearite as an adulterant will not materially affect the dielectric strength but the product will be spotty and will not take a good polish.

The surface resistivity of rubber decreases upon exposure to light. Curtis

found that a high surface resistivity could be restored by washing the surface with a dilute solution of ammonia and rinsing it thoroughly with water. The surface should be thoroughly wiped with a cloth until it is dry. The appearance of the surface can be improved by rubbing it, after it is dry, with waste oiled with a light lubricating oil.

**Sindanyo** is an English product made of asbestos with a special binder. It is manufactured in the form of sheets under pressure and then afterwards impregnated with an insulating compound. The sheets are furnished in two grades and of dimensions 3 feet by 4 feet or 3.5 feet by 8 feet and 0.125 inch to 2 inches thick. The Ebony grade is a substitute for slate and marble. Its dielectric properties are better than marble or slate as it is non-hygroscopic and free of metallic veins. As its mechanical strength is greater than that of either marble or slate it can be used in thinner slabs for the same purpose. It will not swell or warp under severe conditions and withstands temperature up to 200° C.

The plain grade is fire resisting and has good mechanical strength but unstable dielectric properties. It will withstand 900° C. without disintegration, warping or diminution of mechanical strength. It is used for arc deflectors and insulation in heating units.

**Slate** is any rock having a fissile structure, the common variety being composed principally of silica, alumina, and oxides of iron. It is hygroscopic and should be boiled in paraffin. It is often permeated by metallic veins, making it unfit for use unless the electrical connections are insulated by bushings. It is useful for switchboard and switch-base work owing to its desirable mechanical and fireproof qualities. Its dielectric strength decreases rapidly as the temperature increases, and at a high temperature slate becomes a conductor. When a high voltage is impressed upon a piece of slate for some time, the slate usually is not punctured but, due to the consequent rise in temperature, the slate acts as a short-circuit to the impressed voltage. The breakdown is thus only apparent as the specimens regain their dielectric properties after cooling.

**Stamol** is an English product made of asbestos and a rubber compound. It is furnished in sheets 1/4 inch thick and 50 inches by 60 inches. It is flexible and is used for lining controller cases and switch boxes. Its dielectric strength is 3.9 kv. per mm.

**Varnished Cambric.** — See article on *Cambric, Varnished*.

**Varnishes, Insulating,** are made in two classes: (1) baking varnishes, which harden by oxidation when subjected to artificial heat and (2) air-drying varnishes and similar compounds, which harden or set by evaporation of the solvent. Varnishes and similar compounds are manufactured in a number of grades adapted for use in armature, field and transformer coils, magnet and arc lamp coils, transformer bushings, insulating cloth, paper and fiber, armature and transformer stampings, asbestos and magnesia board, cut-out boxes, switch and panel boards, mica plate, flexible mica, mica cloth and paper, storage batteries, weatherproof wire, iron and metal fittings, moulding, pot-heads, taped connections, etc. Some of the trade designations are P. and B., S. P. C., S. V. K., G. P., H. R., Voltalac, W. P., Glinolac, Benolite, Dolph's, Ohmlac, Mineralac, Nico, M. C., Insullac, Enamelac, Armalac, Chatterton, Linolac, M. I. C., etc.

**Vulcabeston** is an English product often called "J. P. Bakelite" and is furnished in the form of sheets or special moulded forms. One grade is made of asbestos fiber and rubber as a binder. It is slightly elastic and has a tensile strength of 3600 pounds per square inch. It is claimed to withstand a temperature of 145° C. without physical changes. When immersed in cold water for 48 hours it absorbs 1.75 per cent of its weight of water. Grade No. 201 is

made of asbestos fiber with a special phenolic gum as a binder. It has a tensile strength of 9000 pounds per square inch and will withstand a temperature of  $260^{\circ}$  C. without undergoing physical changes. It absorbs 0.6 per cent of its weight of water when immersed in cold water for 48 hours.

**Vulcanite.** — See article on *Rubber*.

**Wood.** — Thoroughly dried hard wood, if impregnated with an insulating material, makes a good insulator. The woods commonly used are maple, cherry, ash and yellow pine. For use in transformers, wood is usually impregnated with transformer oil, and when used in air, the wood is impregnated with paraffin or rosin.

**Other Insulations** which are in very general use but not described in published literature are: Carvanite, Faturan, Kalanite, Pilit, Solidite, Stabelite and Tegit.

Information on the various insulating materials described were obtained from the authorities cited in the bibliography, from the following manufacturers: American Lava Corporation, American Vulcanized Fiber Company, Chicago Mica Company, Condensite Company of America, Continental Fiber Company, Delaware Hard Fiber Company, Diamond State Fiber Company, Formica Insulation Company, General Bakelite Company, General Electric Company, M. Kirchberger & Co., Mica Insulator Company, Minerallac Electric Co., National Fiber and Insulation Company, Redmanol Chemical Products Company, J. Spaulding & Sons Company, D. M. Steward Manufacturing Company, R. Thomas & Sons Company, and Westinghouse Electric and Manufacturing Company.

**INSULATING MATERIALS, TESTING OF.** — (See also *Insulating Materials, Properties of*.) The most important electrical properties of an insulating material are its dielectric strength, specific inductive capacity, resistivity, dielectric loss, and power factor. Some of the more common methods of measuring these quantities are described below.

**DIELECTRIC STRENGTH.** — The dielectric strength of an insulating material is defined as the puncturing voltage per unit thickness, the thickness usually being measured in centimeters. The voltage required is in general higher than can be conveniently obtained with direct-current sources of e.m.f. Alternating e.m.f.'s are therefore used in such tests. The materials to be tested are placed between electrodes connected to the high-tension terminals of a transformer, which receives power from a low-voltage alternator.

**Testing Transformers and Alternators.** — Transformers for such use are made to deliver voltages up to 500,000 volts. For the purpose of comparison and computation of the maximum e.m.f. from the effective value, it is essential that the alternator should give a sine-wave voltage at all loads. Both transformer and alternator should be large enough to operate with good voltage regulation at all testing loads, so that no distortion of the wave-form will be produced by the charging current. Skinner suggests the following ratings of testing transformers:

Max. test voltage	Cap. of trans. in kw.*	Max. test voltage	Cap. of trans. in kw.
2,000	1	50,000	50
6,000	3	100,000	100
10,000	5	150,000	150
30,000	30	250,000	250

\* Testing transformers are usually rated by their four-hour capacity.

The alternator should have a distributed field winding and in order that the combination of alternator and transformer may respond to any instantaneous change, the impedance of each should be low; that is, the speed of the alternator should be high and the e.m.f. induced per turn in the transformer should be high.

**Form of Electrodes.** — Many investigators have demonstrated that the form and size of the electrodes used are important factors of the test. If the corners of the electrodes are rounded, the resulting brush discharge heats the specimen so that it breaks down at a low voltage. If the edges of the electrodes are not rounded, the increased flux density at the edges produces an excessive strain on the dielectric under the edges of the electrodes. Most authorities favor the use of flat electrodes with slightly rounded edges. Hendricks suggests flat electrodes with corners rounded to a radius equal to one-tenth of the diameter of the flat face. Kinzbrunner has discussed in detail the effects of various shapes of electrodes.

For testing oils or other liquids two standards composed of definitely shaped terminals supported in a liquid container are commonly used. In one the test terminals consists of brass balls  $\frac{1}{4}$  inch in diameter fastened to rods  $\frac{3}{16}$  inch in diameter and placed vertically in a glass tube. The distance between the balls

is adjustable, a distance of 0.15 inch, however, being considered standard. In the other standard the terminals consist of brass disks 1 inch in diameter mounted on rods  $\frac{3}{8}$  inch in diameter and placed horizontally in a block made of Bakelite or some other insulating material. The spacing between the disks in this case is also adjustable, although 0.1 inch is adopted as standard. Average dry oil should not break down in the ball electrode standard at more than 60,000 volts and in the disk electrode standard at more than 30,000 volts.

**Time of Electrification.** — Materials may be tested by impregnating with puncturing voltage, 1. instantaneously, 2. in steps of one-minute duration, 3. in several instantaneous applications of decreasing voltage and increasing time of electrification. The question of the proper time of electrification is present undecided, although many investigators favor the one-minute standard. For arguments against this standard, see paper by Kinzbrunn in Bibliography at end of this article).

**Control of Voltage.** — The voltage impressed between the test terminals may be controlled 1. by varying the excitation of the alternator, 2. by inserting resistance in series with the low-voltage terminals of the transformer, 3. by varying the number of active turns on the low-tension side of the transformer, 4. by an induction regulator in series with the transformer primary. A combination of the first and third methods is very commonly used. In the second method the voltage wave is made more peaked as resistance is introduced. In the third method, if used alone, the circuit must be broken as connections are made to the tap leads. By varying the field excitation of the alternator and changing the tap connections between tests, the shape of the voltage wave may be kept constant and the variation of field saturation in the alternator may be kept to a minimum. The last method is probably the most commonly used and gives entirely satisfactory results.

**Measurement of Voltage.** — The voltage impressed upon the material under test may be determined by 1. a variable spark gap shunted across the test terminals, 2. by a voltmeter and an extension coil or multiplier connected across the electrodes, 3. by an electrostatic voltmeter connected across the test terminals, 4. by a voltmeter connected across the low-tension terminals of the transformer, the reading of which is to be multiplied by the ratio of transformation of the transformer, 5. by a potential transformer and a voltmeter connected across the terminals and 6. by a special voltmeter winding placed in the middle of the high-tension winding of the power transformer. The needle spark-gap method, while convenient because of its indication of the maximum rather than the average value of the voltage, is tedious in use, and its readings are dependent upon the time of electrification, circulation of air, the condition of the needle, etc. The sphere spark gap is preferable; see *Spark Gap*. The use of the extension coil and extension coil, while flexible and convenient, is not recommended because of the load which is placed upon the transformer and the possibility of overheating in the extension coil. The use of an electrostatic voltmeter is desirable but at high voltages the moving element must be immersed in oil, the instrument sluggish in action, and may frequently break down. In all methods involving the ratio of transformation of the transformer, the results are not reliable owing to the assumption of a constant ratio of transformation at all voltages. The use of the potential transformer and voltmeter is prohibited in the standard because of the cost of the instrument transformer and the excessive distortion introduced by such an arrangement.

A voltmeter winding in the power transformer furnishes as a rule the most accurate and efficient method of measurement, the chief source of error being due to leakage flux and impedance drop in the transformer.

**in Results.**—The puncturing voltage of an insulating material depends on its previous history, precise condition when tested, size, shape, intensity of electrostatic field, temperature, time of electrification, and nature of the surrounding medium. The puncturing voltage is generally a function of the temperature rather than any other factor, and since the temperature varies greatly under the action of the corona discharge (see article on Corona Discharge) should be eliminated. To prevent corona, 1. guard rings may be supplied, as described by article on Corona Discharge; 2. the electrodes may be imbedded in the dielectric in the "oil drop" method described by Walter may be used; 3. the electrodes and test specimen may be immersed in oil or varnish. In the last case materials easily permeated by air should be coated with a varnish before testing. While the temperature may range from  $-25^{\circ}\text{C.}$  to  $+125^{\circ}\text{C.}$ , tests between these limits should suffice to indicate average working conditions.

**INDUCTIVE CAPACITY OR DIELECTRIC CONDUCTIVITY**

(*Condensers.*) The specific inductive capacity of any substance is the ratio of the capacity of a condenser, in which the substance is placed between the plates, to the capacity of the same condenser when the plates is filled with air. This ratio, designated  $K$ , varies with the temperature of the substance, the time of electrification, and the frequency, when tested with alternating currents. The capacity of most substances decreases as the temperature rises, the case of a few substances. The specific inductive capacity increases with the time of electrification and decreases as the frequency increases.

The determination of the specific inductive capacity of a substance by the determination of the capacity of a condenser of known capacity when filled with the substance is commonly used for solid material and for liquids. Having determined the capacity of any condenser from test, the specific inductive capacity of the substance is obtained by substituting the known constants in the formula given in the article on *Capacity and Charging Current*. The methods of measuring capacity are given in the article on *Condensers*.

The American Institute of Electrical Engineers recommend that measurements be made with alternating current. The specific inductive capacity with alternating current, therefore, is of such a nature that a detailed description of the method is given below.

In the case of a liquid a standard condenser  $C_s$  is first obtained on the container with air as a dielectric, and then the same container with the unknown liquid as a dielectric. The specific inductive capacity is

$$K = \frac{R_a}{R_x}$$

where  $R_a$  is the resistance with air in the container and  $R_x$  is the corresponding resistance with the dielectric.

**Wheatstone Bridge Method.**—A Wheatstone bridge as shown in figure 1 is used.  $R_1$  is a mica or an air condenser,  $R$  and  $R_2$  are resistances,  $L$  is a variable inductance and  $I_2$  may be a fixed inductance. The galvanometer may be either a telephone or a vibration galvanometer, and is used for 60-cycle work. As the capacity to be measured is small, the method should be used by inserting, first the unknown condenser  $C$  and varying  $R$  and  $L$  until a balance is obtained, and

then a standard condenser  $C_2$  in the same arm and obtaining a balance again by varying  $R$  and  $L$ , but leaving  $C_1$ ,  $L_1$  and  $R_2$  undisturbed. Then

$$C_2 = \frac{R_2}{R_1} C_1,$$

where  $R_1$  and  $R_2$  are corresponding readings obtained on  $R$  with  $C_1$  and  $C_2$ .

The power factor is equal to  $\sin \theta_2$  or  $\tan \theta_2$  when  $\theta_2$  is small, and may be computed from the following equation:

$$\tan (\theta_2 - \theta_1) = \tau \left( \frac{L_2}{R_2} - \frac{L_1}{R_1} \right),$$

where  $\theta_1$  is the angle by which the current falls short of being  $90^\circ$  ahead of the e.m.f. impressed on the standard condenser, and is zero for an air condenser and seldom more than  $5'$  for a good mica condenser.  $L_1$  and  $L_2$  are readings obtained on  $L$  with  $C_1$  and  $C_2$  respectively.

If only an approximate value of the specific inductive capacity is desired, the inductances  $L$  and  $L_2$  may be omitted in Fig. 1. In this case the current in the detector will not be zero when the bridge is balanced but will be a minimum.

Where a telephone detector is used and high degree of accuracy is required, the bridge should be shielded so that the observer will be at the same potential as the telephone. Also a guard ring should be provided in the condenser under test, the ring being on the side nearer the detector and connected to the junction of  $L$  and  $L_2$ .

Fig. 1.

**INSULATION RESISTANCE.**—The method commonly employed is one of substitution. A standard resistance  $R_0$  (usually  $\frac{1}{10}$  megohm) connected in series with a D'Arsonval galvanometer is connected across a direct-current source of e.m.f. of about 500 volts and the deflection  $D_0$  of the galvanometer noted. The galvanometer must have a sensitiveness of about  $1 \times 10^6$  and the deflection should be directly proportional to the current. If the galvanometer is shunted, an Ayrton universal shunt should be used (*see Shunts*) so that the damping of the galvanometer will be independent of the multiplying power. The deflection  $D_x$  is then noted when the unknown resistance  $R_x$  is connected in place of the standard resistance. Then

$$R_x = \frac{D_0}{D_x} R_0.$$

The usual errors of this method are due to leakage and absorption. Leakage may be reduced considerably by the use of a guard ring, so connected as to shunt the leakage current around the galvanometer. The deflection of the galvanometer will vary with time due to absorption, and the resistance of the material will apparently vary with the time of electrification. To facilitate comparison of the insulation resistance of dielectrics, it has become common practice to take the resistance obtained after one minute's electrification. Owing to the large negative resistivity temperature coefficient of most dielectrics, it is essential that the temperature of the material be noted when tested.

**ENERGY LOSS IN THE DIELECTRIC—EFFECTIVE CONDUCTANCE.**—Energy loss in dielectrics is difficult to measure on account of both the small amount to be measured and the low power factor. The compensated

method and the electrostatic wattmeter method have sometimes the dielectric loss is expressed as the effective loss is equal to the watts lost divided by the square of

### DYNAMOMETER, WATTMETER METHOD.—

is subjected to a high voltage from a test transformer by it is measured by means of a delicate, mirror type

Fig. 2.

of the potential transformer and wattmeter is neutralized by means of a condenser  $C$ . The effective voltage may be varied by changing the value of the shunting capacitor. When making a test a zero-loss air condenser is substituted for the capacitor  $C$ . The value of the shunting capacitor  $r$  is varied until the wattmeter shows zero. The test sample is then substituted for the air condenser and the wattmeter is used in indicating the power lost in the sample.

The potential coil of the wattmeter is connected across the variable resistance  $R_w$ . This puts the current in the instrument will read as an ammeter.

The instrument is calibrated by direct-current, using a potentiometer and a standard resistor separately calibrated if used as an ammeter.

**INSULATOR PINS.** — (See also *Cross Arms; Insulators for Overhead Lines*.) Insulator pins are made of wood, iron and various combinations of wood and porcelain.

**WOODEN PINS.** — Wooden pins are usually made of locust but also of oak, birch, maple or eucalyptus.

The forest service reports: "Black locust is admitted to be the best woods used for insulator pins, but of late years other woods are being introduced into use. Among those which will probably prove satisfactory as substitutes for the black locust are Osage orange, various oaks, yellow birch, gum, hickory, elm, etc." Also: "The value of eucalyptus, particularly blue gum, for insulator pins has been thoroughly demonstrated. After fifteen years' service, eucalyptus pins are still in use."

**Standard Distribution Pins** (Fig. 1). — The standard wooden pin for use on distribution lines is of locust, 9 inches long,  $1\frac{1}{2}$ -inch diameter shank, and  $\frac{1}{2}$ -inch diameter thread, as shown in Fig. 1. It is often described simply as by 9-in. pin." It is standard for use with double-petticoat deep-groove insulators and is also used for some insulators designed for higher voltages.

Fig. 1. Standard Locust Pin

Fig. 2. Insulator Pin for 13,000

**High-voltage Distribution Pins** (Fig. 2). — For voltages above 13,000 not exceeding 13,200 it is desirable to have pins with  $1\frac{1}{2}$  inches diameter to fit standard cross arms, but with larger threads, as shown in Fig. 2.

**High-voltage Transmission Pins.** — For voltages above 13,200 exceeding 25,000 wooden pins are used to a considerable extent. They are special and their length must be sufficient to give the clearance between insulator to cross arm required by the design of insulator used. The shape of the pins are larger than those of standard pins.

On high voltages wooden pins are too weak for the high stress imposed by the great pin leverage of large insulators and present practice is toward the use of iron pins to secure the required strength. The use of paraffined wood pins has been practically discontinued.

**IRON DISTRIBUTION PINS.** — Iron pins (malleable iron or forged iron) are made with  $1\frac{1}{2}$  inch shanks and 1-inch threads so as to be interchangeable with standard wooden pins. They are used at points of heavy loading.

Pins with Iron Shanks consisting of  $\frac{3}{4}$ -inch,  $\frac{5}{8}$ -inch or  $\frac{3}{4}$ -inch diameter are also used. These have a nut and washer on the lower end used to secure the pin to the cross arm.

the base of the pin firmly into contact with the top of the arm. This type of pin has the advantage that the smaller hole removes less wood from the arm. For heavy stresses the shank of the pin should be stiff, or the base of the pin broad to prevent local crushing of wooden cross arms due to the pin leverage.

**ATTACHMENT OF INSULATORS TO PINS.** — Insulators are usually attached to wooden pins by a screw thread having a pitch of 4 threads per inch. The threaded portion of the pin is tapered, the diameter increasing downward from the top about  $\frac{1}{16}$ -inch per inch of length. Standard thread diameters are 1 inch for distribution insulators and  $1\frac{1}{4}$  inches for high-tension insulators measured at the small end over the thread. Good fit in the thread between pins and insulators is not commonly attained because: (1) the threads are often imperfectly cut on the pins, (2) the wood of the pin shrinks so that it ceases to be circular or warps so that the axis of the pin is not truly straight, (3) the porcelain of the insulator warps in manufacture so that the hole ceases to be circular or the surface of the thread may not be smooth. Where a pin does not screw into the insulator to full depth intended, or where it is loose or bears unequally, the strength of the attachment is much reduced. The weakest point is usually at the root of the bottom thread.

**Attachment of Insulators to Iron Pins.** — Insulators are sometimes attached to iron pins by a screw thread similar to that used for wooden pins. The thread on the iron pin is often made of lead to get a more uniform bearing.

In later types the thread is made in the form of a coiled spring to better distribute the load stresses.

High-tension insulators are frequently cemented to iron pins. The pin hole of the insulator may be threaded as usual. The end of the pin is usually corrugated or fluted instead of being threaded. The pin is grouted to insulator with neat Portland cement.

**ATTACHMENT OF PINS TO ARMS.** — The standard wooden distribution pin has a shank of  $1\frac{1}{2}$ -inch nominal diameter. The actual diameter at the top is the same as the nominal diameter, the shank tapering so that the bottom is about  $\frac{1}{16}$  inch smaller. The pin hole in the cross arm is bored to the nominal diameter but often becomes smaller (across the grain) due to shrinkage of the wood, so that a standard pin, although smaller than nominal size of the pin hole except at extreme top, will often make a good driving fit. Pins which are too small (or pin holes which are too large) will make a loose fit and should not be used. Pins are often made considerably oversize at the top and undersize at the bottom to allow for inaccuracy of workmanship. Such pins will not drive completely in, and they weaken the construction by increasing the pin leverage and decreasing the bearing surface between the pin and cross arm. At the top of the shank a shoulder should be provided to limit the distance the pin can be driven in. For maximum strength the shank should be long enough to go completely through the arm and the taper should be small enough so that it will bear against the arm for the full depth without leaning far to one side. The standard  $1\frac{1}{2}$ -inch by 9-inch pin has a  $4\frac{1}{2}$ -inch shank length corresponding to the old "standard" depth of cross arm, and, therefore, does not develop the full strength of the later standard arms which are  $4\frac{1}{2}$  inches or  $4\frac{3}{4}$  inches deep.

Pins are prevented from pulling out of the arm (especially where the wire exerts an uplift on the insulator and pin) by driving a nail (usually six-penny) through arm and pin.

Wooden pins for high-tension insulators are made with larger diameter shanks, 2 inch,  $2\frac{1}{4}$  inch and  $2\frac{1}{2}$  inch being used.

**Comparative Strength of Some Special High-tension Pins.**—The following are the results of tests made on pins fitted into wooden cross arms. The pins broke at the top of the shank.

Material	Dimensions of shank, inches		Pin leverage, inches from center of stress to top of arm	Break strength, pound
	Diameter	Length		
Oak.....	2¼	6	12	140
Oak.....	2¼	6	16	120
Oak.....	2½	6	12	305
Oak.....	2½	6	16	120
Eucalyptus.....	2¼	6	about 10	260
Red oak.....	2½	7¼	12½	495
White oak.....	2½	7¼	12½	738
Locust.....	2½	7¼	12½	1121

**COSTS.**—The following figures, giving the cost, are rough approximations.

Material	Dimensions in inches			Approximate cost per rod
	Diam., Shank	Overall length	Diam., Top	
Standard Oak (Fig. 1).....	1½	9	1	\$ 7.50
Standard Locust (Fig. 1).....	1½	9	1	14.00
Special Locust.....	1½	10¾	1¾	22.00
Solid Drop-forged Galvanized Iron.....	1½	9	1¾	500.00

Y., 1912; *Forest Service Circular, No. 179*; Ohio Brass Co., *Catalog No. 12*; Western Electric Co., *Catalog Bulletin No. 74*; Westinghouse General Supply Catalog.

**INSULATORS FOR OVERHEAD LINES.** — (See also *Distribution Lines; Insulator Pins; Transmission Lines.*) Insulators for overhead lines may be classified as insulators for distribution lines, pin insulators for transmission lines and suspension insulators for transmission lines. The general features of design common to all classes of line insulators will first be considered.

**DESIGN OF LINE INSULATORS.** — Glass is commonly used for making small low-voltage insulators and porcelain for large insulators. Porcelain has greater mechanical strength, condenses less moisture on its surface and parts may be cemented together, but faults cannot be as readily detected as in glass. Glass insulators are often completely shattered by a blow while porcelain insulators usually are only chipped under similar circumstances. Various compositions are also used to a limited extent for line insulators.

**Properties of Porcelain and Glass.** — Following are some of the more important characteristics of porcelain and glass:

Property	Glass	Porcelain
Tensile strength, lb. per sq. in. ....	2,500-9,000	1,500-2,200
Crushing strength, lb. per sq. in. ....	6,000-10,000	14,000-16,000
Elastic limit, lb. per sq. in. ....	3,200 approx.	.....
Modulus of elasticity, lbs. per sq. in. ....	8,000,000	2,500,000 (b)
Coeff. of expansion per °F. ....	0.0000046	0.00000585 (b)
Coeff. of expansion per °C. ....	.....	0.00000413 (a)
Weight per cubic foot in lbs. ....	160	155
Puncturing strength in volts per inch for very thin samples. ....	300,000	400,000
for commercial sizes and quantities ...	150,000	125,000
Specific inductive capacity (air = 1) ....	5 to 10 (a)	4.35 (a)

(a) Smithsonian Physical Tables. (b) Austin, A. O., Proc. N.E.I.A., 1913.

In American practice porcelain parts are made from  $\frac{1}{4}$  inch to  $2\frac{1}{2}$  inches in thickness. In European practice porcelain is used in thicknesses up to 1 inch. The working voltage usually averages from 10,000 to 20,000 volts for each thickness of porcelain used. 15,000 volts is about an average figure, so that a 30,000-volt insulator usually has two parts, a 40,000-volt insulator 3 parts and a 50,000-volt insulator 4 parts.

An insulator must be designed to stand extreme and sudden temperature changes, sleet and rain, as well as smoke, dust, and often special conditions such as salt fogs, salt water sprays, and chemical fumes, without deterioration from chemical action, breakage from mechanical stresses or electrical failure. The design of high-tension insulators is a process of compromise between requirements often antagonistic in nature.

Some of the principal points in the electrical design of high-voltage insulators are:

**Shape.** — The insulating surfaces should conform to the flow lines of the electrostatic field, the surfaces of the rain sheds or petticoats should conform to equipotential surfaces, the leakage resistance per shell should be about equal, the plane of mechanical rupture should not coincide with the plane of electrical stress, and the unit should have approximately equal capacitances per shell.

**Thickness to Resist Puncture.** — The porcelain must be thick enough to resist puncture by the combined working voltage of the line and any probable

transients whose time lag to spark over is great. If this thickness is greater than desirable from a manufacturing standpoint, two or more pieces are used to give the proper aggregate thickness.

**Arcing Distance; Free Arcing.** — The porcelain must extend beyond the charged conducting connections (i.e., the wire or cap at the top and pin at the bottom) sufficiently so that the distance between the connections through the air around the porcelain is greater than the arcing distance of the maximum voltage to be carried. The arcing distance required for a given voltage may be determined roughly (but only very roughly) from the tables of arcing distances between needle points; see article on *Spark Gap*. The greater radius of curvature (compared with needle points) of such metal parts as the insulator pin decreases the potential gradient at the terminals. Also the porcelain has a much greater specific inductive capacity than the air and its proximity to the arcing path disturbs the electrostatic field through the air. Surface charges on the porcelain because of surface leakage or corona also modify the field.

Free arcing is the property of arcing over along a line which does not touch the porcelain body from the point where the arc leaves the metal cap to where it strikes the metal pin. Where the arc touches any part of the porcelain the great heat fractures the porcelain in a few seconds; hence the desirability of designing the insulator so that it is free arcing. A properly designed insulator will arc over as a whole before any individual part (i.e., shell or unit) arcs over. In many defective designs the insulator will fail by some parts arcing over, thereby increasing the voltage on others which then fail by puncture or arcing over.

**Factor of Safety Against Puncture.** — The thickness of a porcelain part must be so related to the distance around it that it will arc over before it will puncture. The ratio of puncture strength to arc over-voltage is the factor of safety of the part, or of the insulator, against puncture.

This ratio should be high to give sufficient margin to protect the insulator from puncture by the transients before mentioned.

**Guard Rings and Rods.** — Where an insulator is not naturally "free arcing" from cap to pin, properly located rings or rods will divert the arc so as to accomplish an equivalent result. Rings used for this purpose are known as Nicholson guard rings. Where a pin insulator is improperly designed so that it is liable to puncture before flashing over, a Nicholson ring around the base may be used to redistribute the potential or to reduce the arcing distance so as to reduce trouble from puncture. Such rings and rods are also sometimes used in connection with suspension insulators.

**Leakage Surface.** — Leakage surface is ordinarily measured as the number of (linear) inches from cap (or equivalent) to pin taken radially along the surface; see Fig. 4. This, however, is only a rough measure as it neglects the varying width of leakage path. The figures in the accompanying table on pin insulators from a manufacturers' catalog give approximately the total amount of leakage surface used in practice. The amount of surface allowed varies considerably between different designs and makes.

Rated voltage	Length of leakage surface, inches
5,000	4
6,600	5½
10,000	6¾
23,000	12
44,000	29
66,000	53

**Spread of Petticoats of Pin Insulators.** — In two concentric shells the two surfaces which lie opposite to each other are at different potentials

except where they are cemented together. The difference in potential between two points on opposite surfaces is greater the further they are removed from the joint. Unless the shells diverge correspondingly so as to increase the distance between the shells as the potential increases the air will break down and part of the leakage surface will be short-circuited by a corona discharge. This divergence is shown in Fig. 4, where the top is a disc made slightly convex to shed water and the inner shells are a series of cones which radiate from the top of the pin.

**Color and Glazing.** — Brown, slate and white are the common colors used in glazing porcelain. Brown is the most common color since it is more of a aid in determining faults. Slate-colored glazing of the same color as galvanizing on towers makes insulators a less conspicuous target for malicious destruction.

**Cementing of Insulators.** — Insulator parts are cemented together with neat freshly burned and finely ground Portland cement which is usually allowed to set under water from ten to fourteen days before testing mechanically. The more freshly burned and finely ground the cement and the higher the temperature, the less time required for setting. The cemented surfaces of porcelain are unglazed and corrugated to obtain good bond.

**Faults in Insulators.** — The more common faults in porcelain are porosity, folds and flaws in moulding and the development of checks and hair cracks in process of drying, incomplete and non-uniform glazing, warping, air bubbles, conducting impurities, under- and over-firing and chipping of edges. Only 50 to 75 per cent of moulded shapes ordinarily pass final test and even a less number of the more difficult shapes. Inspection and testing are essential to eliminate faults in both design and manufacture.

**DISTRIBUTION-LINE INSULATORS, STANDARD (Fig. 1).** — For ordinary distribution circuits, including constant-potential circuits up to 2200 volts nominal and series-arc circuits of all voltages, the double-petticoat deep-groove (D.P.D.G.) insulator, of the type shown in Fig. 1, is standard.\* Such insulators are usually of glass, though occasionally of porcelain, and in cases where there are heavy stresses, as at dead ends where iron pins are required, the insulators are made of moulded mica. The dimensions vary with different manufacturers.

Fig. 1.

These insulators are used with the standard pin shown in Fig. 1 in the article on *Insulator Pins*.

**Pony Insulators.** — These are small insulators used for telegraph and telephone wires. They are unsuitable for electric light and power wires. The groove is too small (sometimes only  $\frac{1}{8}$  in.) to properly support the larger wires used in lighting and the leakage surface is insufficient for proper insulation.

**Insulators with Top Groove.** — The standard distribution insulator has a groove in the side to which the wire is tied. For very heavy cables special insulators with groove in top are used. Insulators for higher voltage usually have both side and top groove. The former used where there is horizontal stress due to angle in line, and the latter on straight parts of line where the weight is the principal force.

**DISTRIBUTION-LINE INSULATORS, HIGH-VOLTAGE (Fig. 2).** — For circuits exceeding 2200 volts but not exceeding 13,200 volts nominal, it is convenient to have insulators which can be used on the standard distribution

\*The same size insulator is used for 110-volt and 2200-volt circuit. This has the advantage that only one kind of insulator is kept in stock, and a wire can be transferred from use on a low-voltage circuit to one of higher voltage without reinsulating it.

pins. A number of insulators are made with 1-in. threads to fit the standard  $1\frac{1}{2}$  in. by 9-in. pin. It is better, however, to use stronger special pins with  $1\frac{3}{8}$ -in. top; see article on *Insulator Pins*. Fig. 2 shows an insulator which has been used on these voltages. It is used with the pin shown in Fig. 2 in the article on *Insulator Pins*. The manufacturer rates this insulator at 23,000 volts with a factor of safety (wet) of 2.

**TRANSMISSION-LINE INSULATORS, PIN-TYPE** (Figs. 3 and 4).—The pin-type insulators are similar in mechanical construction to the low-voltage insulators used for distribution lines, but are larger and designed for heavier mechanical stresses as well as higher voltages. The conductor is supported on a top groove except where an angle in the line causes a lateral pressure, in which case the side groove is used. For

Fig. 2.

voltages up to about 10,000 volts the insulator usually consists of but a single porcelain part. For higher voltages from two to five parts are cemented together. The size and expense of pin-type insulators increase rapidly with the voltage so that while they may be used for operating potentials of 70,000 and even more, their

Fig. 3.

Fig. 4.

use is generally restricted to potentials of not over 50,000. Typical three-part insulators are shown in Figs. 3 and 4. The separate parts are called

Fig. 5.

Fig. 6.

parts, shells or cones and are numbered in order beginning with the top.

On a cost per mile basis, the suspension insulator construction is often less

than the pin type for pressures above 44,000 volts, due to the longer spans thus made possible.

**Tie Wires and Clamps.** — Tie wires consisting of the same material as conductors are commonly used for fastening conductor to insulator. Two common types of ties are shown in Figs. 5 (single tie wire) and 6 (double tie wire). For copper conductors the tie wires are usually soft-copper wires which are three sizes on the A.W.G. (B. & S. gage) smaller than the conductor. Metal caps carrying clamps for the conductor are cemented to tops of insulators when more strength is required than can be obtained by tie wires.

**TRANSMISSION-LINE INSULATORS, SUSPENSION TYPE** (Figs. 7 to 10). — The suspension type insulator is always used in tension, the con-

Fig. 7.

Fig. 8.

Fig. 9.

nections at the two ends being made so that the insulator is free to swing in any direction; the insulator takes such a position that its axis coincides with the direction of the mechanical stress.

This type is used hanging below the cross arm with axis vertical as a suspension insulator for sustaining the weight of cable at points where there is little horizontal force, and also with axis approximately horizontal as a "strain" or "dead-end" insulator at points where the horizontal force predominates.

The suspension type consists of one or more complete insulators, called "units," connected in a string. Each unit consists of one or more insulating parts usually with a metal cap above and a metal pin below, all cemented together. Three typical designs now in general use are shown, Figs. 7 to 9.

**Relation Between Electrical Strength of Single Unit and a String of Units.** — The potential per unit required to flash-over a suspension insulator composed of units of the same design decreases with an increasing number of units as shown in Fig. 10. This is due to an unequal potential gradient. See Bibliography.

**Connections Between Suspension Units.** — The caps and pins of suspension insulators are commonly made of galvanized malleable iron castings, but where strength is required the pins are steel drop forgings, and pressed steel for these fittings is coming into general use.

Fig. 10.

The common types of connection between the pin of one insulator and the cap of the one next below are ball and socket, clevis and pin (Figs. 7 and 8) and hook and eye. The hook and eye is the simplest type, but there is danger of its becoming unhooked and, in order to obtain strength, the design requires more space between units than other types of connection. The clevis and pin has the disadvantage of loose parts. The ball-and-socket connection requires special terminal fittings and a rigid connection to prevent the clamp from turning when used on deadend insulators for conductors which tend to untwist. It can, however, be designed with less space between units than other types.

A type of suspension insulator which does not require caps and pins is shown in Fig. 9. These units are connected together by cable loops. This was one of the first types of suspension insulators. It is not commonly used on account of cost of manufacturing. A very close inspection is often required to find punctured units that are not shattered by the failure.

**Conductor Clamps for Suspension Insulators.**—A common form of insulator clamp is shown in Fig. 8 in the article on *Wires and Cables, Bare*.

Other forms are in use (see Manufacturers' catalogues). They are usually made of malleable castings or pressed steel. A requirement to be remembered when using steel cored cables is provision for clamping the steel core independently of the aluminum or copper wires in strain clamps. Strain clamps should have an ultimate strength at least equal to that of the cable supported.

**TESTS OF INSULATORS.**—Tests of insulators may be classified as (1) design tests, made on a very few insulators to determine the characteristics of new designs, and (2) routine tests made on each insulator manufactured to detect defects of material or workmanship.

**Design Tests.**—Design tests are quite expensive for very high-voltage insulators because of the difficulty of securing suitable testing apparatus.

**Mechanical Tests** should be made to determine the strength. With pin-type insulators the important point is the strength of pin and insulator combined against a force (representing a horizontal wire pull) applied at the wire groove in a direction at right angles to the axis of the pin. For suspension-type insulators the tensile strength is the important mechanical consideration. These tests should be carried to the point of destruction of a number of samples.

Combined dry flashover and tension tests are important to determine the load under which a unit will fail electrically. Proper design should produce an insulator good electrically up to its maximum mechanical strength.

**Electrical Tests** should be made for puncture strength, arc-over voltage dry and wet, free arcing properties and corona formation. The electrodes used should conform in shape to the cap and pin used in practice so that all surface exposed to puncture when the insulator is in use will be tested. Design tests of the electrical properties of suspension insulators should be made on complete strings of insulators as well as on single units, assembled under field conditions as to proximity of towers, etc.

**Puncture Test.**—As the air surrounding a properly designed insulator acts as a safety valve, it is necessary to immerse the insulator in oil in order to test the material of which the insulator is composed up to its puncture strength at normal frequency. Such a test may be used to ascertain the margin by which the puncture strength exceeds the flash-over voltage and to verify the dielectric strength of the porcelain. Tests in air made with high frequencies, however, are found to puncture insulators which arc over at normal operating frequencies. The frequencies used for normal tests include all commercial frequencies or say

from 25 to 125 cycles per second with 60 cycles the most common. For high-frequency testing a 100,000 cycle oscillator is found suitable.

**Arcing Tests.**—Arcing tests, both dry and wet, are made to determine the voltage at which an insulator will arc over when the voltage is raised with the insulator in its normally dry condition and when wet as in rainy weather. The dry arcing test is the most common one made because of its simplicity, the voltage merely being raised on cap and pin until arc over occurs. Wet test in new designs is very important as there is danger of puncture or arc over of individual parts which appear safe on dry test. The standard precipitation for a wet test is  $\frac{1}{4}$  inch of distilled water per minute inclined at an angle of  $45^\circ$  with the axis of the insulator. The wet arcing test usually gives a lower arc-over voltage and hence gives a measure of the electrical factor of safety of the ice (ratio of voltage at which failure occurs to working voltage) under the weather conditions when the factor is usually the lowest.

**Free Arcing Tests.**—In order to test the free-arcing properties the testing transformer must be large enough so that the flash at time of arc over will continue as a true power arc; even then the phenomena of fracture will rarely occur, even if the insulator is not free-arcing, because of the comparative feebleness of the power used in testing.

**Corona Formation** is indicated by the emission of a sound (i.e., the insulator is not "quiet") and may be still more accurately detected by the light from the corona when insulator is tested in the dark. Corona is considered an evidence of defective design and it is considered desirable that the voltage of corona formation should not be much below the arc-over voltage and certainly not below working voltage. However, many and perhaps most, high-voltage insulators show some corona at working voltage, though the amount is so small that it is difficult to detect.

**Routine Tests.**—No high-voltage insulator should be used without having been tested at the factory. Mechanical tests, except on a few selected samples, are not ordinarily made on pin-type insulators. On suspension insulators a tension test on each unit is desirable, but should not exceed about one-half the expected ultimate strength, for this is sufficient to eliminate defective ones, and most insulators are permanently injured electrically at a point below this ultimate strength.

Flash-over or arcing tests should be made on each porcelain part before assembly (so that no poor part will get into any insulator) and on the whole insulator when assembled. Each part should be tested to flash-over potential for five minutes, on normal frequency, or two minutes at 200,000 cycles.

The cup-shaped parts (also complete pin-type insulators) may be tested by setting them inverted in a pan of water used as one electrode, and partly filling the cup with water for the other. A large number of similar parts are ordinarily tested simultaneously in this way. Assembled suspension units are tested by using pin and cap as electrodes. The string of units forming a complete suspension insulator is not tested, except for a few selected samples (design tests). Factory tests of parts can be made at the factory with a transformer which will give a moderately high voltage, and no special measuring instruments are necessary, as the fact that parts are tested to arc-over voltage is evidenced by the fact that the arc-over is visible. A certain number of all units fired should be submitted to a test for porosity by immersing broken units in fuchsine dye under pressure of about 200 pounds per square inch for about two hours.

**Testing on the Line.**—Periodic testing of insulators on the line should be carried out to eliminate deteriorating units before they fail and interrupt service.

**SPECIFICATIONS FOR INSULATORS.** — (See also Article on Specifications.) Several specifications for high-voltage insulators have been suggested as suitable for "Standard Specifications"; see papers by Peek, Sanford and Thomas in *Transactions of A.I.E.E.*, 1913, Vol. 32-2, pp. 1457-1508. Specifications covering the inspection and tests of porcelain high-tension line insulators for over 25,000 volts, which had been prepared by the High Tension Transmission Committee of the A.I.E.E., were presented at the 1914 annual convention of the Institute. The reader is referred to the above-mentioned papers for details.

**INSTALLATION OF INSULATORS.** — See the articles on *Distribution Lines and Transmission Lines*.

**INTEGRALS.** — (See also *Derivatives; Equations, Differential.*) If the function  $y = f(x)$  be plotted as a curve (see Fig. 1) and the axis of  $x$  be divided into a number of very small sections, each of width  $dx$ , the area between the curve and the axis of  $x$  may be conceived as the sum of the products obtained by multiplying each length  $dx$  by the corresponding altitude or ordinate  $y$ . Then

$$\text{Area} = \int y \, dx,$$

where  $\int$  stands for "sum."

Fig. 1.

**The Definite Integral.** — The area between the values  $x_1$  and  $x_2$  is written

$$\int_{x_1}^{x_2} y \, dx.$$

Such an expression is called a "definite integral."

It is evident from the figure that the area of the curve between  $x_1$  and  $x_2$  is equal to the difference between the area from 0 to  $x_2$  and the area from 0 to  $x_1$ . Hence calling the former area  $F(x_2)$  and the latter area  $F(x_1)$ , we have

$$\int_{x_1}^{x_2} y \cdot dx = F(x_2) - F(x_1).$$

This equation is the general expression for any definite integral.

**Indefinite Integrals.** — The above equation may also be written

$$F(x_2) = \int_{x_1}^{x_2} y \, dx + F(x_1)$$

and if  $x_1$  is considered a variable, the subscripts are omitted, as follows:

$$F(x) = \int y \, dx + A,$$

where  $A$  is a constant for any given reference point  $x_1$ . This constant  $A$  is an arbitrary constant, since any point  $x_1$  may be chosen as the reference point, but when a point is once chosen,  $A$  is fixed. The expression  $\int y \, dx$  is called an "indefinite integral" and  $A$  is called the "integration constant."

From the definition of a derivative (see *Derivatives*), the derivative of  $F(x)$  is

$$\frac{dF(x)}{dx} = \frac{\int_{x_1}^{x+dx} y \, dx - \int_{x_1}^x y \, dx}{dx}$$

and from the figure, it is evident that the difference between the area from  $x_1$  to  $x + dx$  and the area from  $x_1$  to  $x$  is simply  $y \, dx$ . Hence

$$\frac{dF(x)}{dx} = y,$$

that is, the integral  $F(x)$  of any function  $y$ , with respect to  $x$ , must be such a function that when differentiated with respect to  $x$ , the result is the function  $y$ .

**Formulas for Integration.** —  $a$ ,  $m$ ,  $s$  and  $s$  are variables;  $a$ ,  $m$  and  $n$  are constants.

$$\int (u+v) dx = \int u dx + \int v dx$$

$$\int y dx = \int y \frac{dx}{dx} dx$$

$$\int u dv = uv - \int v du$$

$$\int \frac{F'(x)}{F(x)} = \log F(x)$$

where  $F'(x)$  stands for  $\frac{dF(x)}{dx}$ .

TABLE OF INTEGRALS

Function $f(x)$	Integral $\int f(x) dx$	Function $f(x)$	Integral $\int f(x) dx$
$x^m$	$\frac{1}{m+1} x^{m+1}$	$\frac{1}{\sqrt{a^2 - b^2 x^2}}$	$\frac{1}{b} \sin^{-1} \frac{b}{a} x$
$\frac{1}{ax}$	$\frac{1}{a} \log_e ax$	$\frac{1}{\sqrt{a^2 + b^2 x^2}}$	$\frac{1}{b} \sinh^{-1} \frac{b}{a} x$
$e^{ax}$	$\frac{1}{a} e^{ax}$	$\frac{1}{a^2 + b^2 x^2}$	$\frac{1}{ab} \tan^{-1} \frac{bx}{a}$
$a^{bx}$	$\frac{1}{b \log_e a} a^{bx}$	$\frac{1}{(a^2 - b^2 x^2)bx < a}$	$\frac{1}{ab} \tanh^{-1} \frac{bx}{a}$
$\cos ax$	$\frac{1}{a} \sin ax$	$\frac{1}{(a^2 - b^2 x^2)bx > a}$	$\frac{1}{ab} \tanh^{-1} \frac{a}{bx}$
$\sin ax$	$-\frac{1}{a} \cos ax$	$\frac{1}{(x-a)(x-b)}$	$\frac{1}{a-b} \log \frac{x-a}{x-b}$
$\tan ax$	$-\frac{1}{a} \log (\cos ax)$	$\frac{1}{\sqrt{2ax - x^2}}$	$\sin^{-1} \sqrt{\frac{x}{2a}}$
$\cosh ax$	$\frac{1}{a} \sinh ax$	$\frac{1}{x \sqrt{x^2 - a^2}}$	$-\frac{1}{a} \sin^{-1} \frac{a}{x}$
$\sinh ax$	$\frac{1}{a} \cosh ax$	$\frac{1}{x \sqrt{x^2 + a^2}}$	$\frac{1}{a} \cos^{-1} \frac{a}{x}$
$\tanh ax$	$\frac{1}{a} \log (\cosh ax)$	$\frac{1}{x \sqrt{a^2 + x^2}}$	$-\frac{1}{a} \sinh^{-1} \frac{a}{x}$
$\tan x \sec x$	$\sec x$	$\frac{1}{x \sqrt{a^2 - x^2}}$	$-\frac{1}{a} \cosh^{-1} \frac{a}{x}$
$\sec^2 ax$	$\frac{1}{a} \tan ax$	$\frac{x}{\sqrt{a^2 \pm x^2}}$	$\pm \sqrt{a^2 \pm x^2}$
$\frac{1}{\cos^2 ax}$	$\frac{1}{a} \tan ax$	$\frac{x}{\sqrt{x^2 - a^2}}$	$\sqrt{x^2 - a^2}$
$\frac{1}{\sin^2 ax}$	$-\frac{1}{a} \cot ax$		

Function $f(x)$	Integral $\int f(x) dx$
$\sqrt{a^2 - x^2}$	$\frac{1}{2} \left( x \sqrt{a^2 - x^2} + a^2 \sin^{-1} \frac{x}{a} \right)$
$\sqrt{x^2 + a^2}$	$\frac{1}{2} \left[ x \sqrt{x^2 + a^2} + a^2 \sinh^{-1} \frac{x}{a} \right]$
$\sqrt{x^2 - a^2}$	$\frac{1}{2} \left[ x \sqrt{x^2 - a^2} - a^2 \cosh^{-1} \frac{x}{a} \right]$
$\sin ax \sin bx$	$\frac{\sin(a-b)x}{2(a-b)} - \frac{\sin(a+b)x}{2(a+b)}$
$\cos ax \cos bx$	$\frac{\sin(a-b)x}{2(a-b)} + \frac{\sin(a+b)x}{2(a+b)}$
$\sin^2 ax$	$\frac{1}{2} x - \frac{1}{4a} \sin 2ax$
$\cos^2 ax$	$\frac{1}{2} x + \frac{1}{4a} \sin 2ax$
$\sinh ax \sinh bx$	$\frac{\sinh(a-b)x}{2(a-b)} - \frac{\sinh(a+b)x}{2(a+b)}$
$\cosh ax \cosh bx$	$\frac{\sinh(a-b)x}{2(a-b)} + \frac{\sinh(a+b)x}{2(a+b)}$
$\sinh^2 ax$	$\frac{1}{2} x - \frac{1}{4a} \sinh 2ax$
$\cosh^2 ax$	$\frac{1}{2} x + \frac{1}{4a} \sinh 2ax$
$e^{ax} \sin bx$	$\frac{e^{ax} (a \sin bx - b \cos bx)}{a^2 + b^2}$
$e^{ax} \cos bx$	$\frac{e^{ax} (a \cos bx + b \sin bx)}{a^2 + b^2}$
$\frac{e^{mx}}{x}$	$\log_e x + \frac{mx}{1} + \frac{m^2 x^2}{2!} + \frac{m^3 x^3}{3!} + \dots$
$\sin^m x \cos^n x$	$-\int \sin^{m-1} \cos^n x \, d \cos x$

**Double Integrals.**—Just as the area of a surface may be represented by the expression

$$\int y \cdot dx$$

so the volume of a solid may be represented by

$$\int \left[ \int y \cdot dx \right] ds$$

or adopting the usual notation, by

$$\int \int y \, dx \cdot ds$$

taken between limits determined by the data of the problem.

## INTEREST, ANNUITIES AND SINKING FUND. — Let

 $P$  = principal invested in dollars; $s$  = number of years principal is invested; $r$  = rate of interest, per cent per annum; $A$  = total amount of principal and interest at end of  $s$  years.

Note. — The following relations hold irrespective of the unit of time selected, provided  $r$  is taken as the interest earned per \$100 during that time.

Simple Interest. — If the principal is invested at simple interest, then

$$A = \left( r + \frac{nr}{100} \right) P.$$

Compound Interest. — If the principal is invested at compound interest, and if the interest earned each year is invested at the end of that year at the same rate as the original principal, then the total amount due at the end of  $s$  years is

$$A = PR^n,$$

where

$$R = 1 + \frac{r}{100}.$$

$R^n$  is the amount of the principal of 1 dollar and interest at the end of  $s$  years. The following table gives the value of  $R^n$  for  $s$  ranging from 1 to 50 years and from 3 to 6 per cent.

$$\text{VALUES OF } R^n = \left( 1 + \frac{r}{100} \right)^n.$$

Years	Per cent interest = $r$				Years	Per cent interest = $r$			
	3	4	5	6		3	4	5	6
1	1.03	1.04	1.05	1.06	16	1.6047	1.8730	2.1899	2.5403
2	1.0609	1.0816	1.1025	1.1236	17	1.6528	1.9479	2.2920	2.6928
3	1.0927	1.1249	1.1576	1.1910	18	1.7024	2.0258	2.4066	2.8543

8	1.2668	1.3686	1.4774	1.5936	23	1.9736	2.4647	3.0715	3.8197
9	1.3048	1.4233	1.5513	1.6895	24	2.0328	2.5633	3.2251	4.0487
10	1.3439	1.4802	1.6289	1.7908	25	2.0937	2.6658	3.3863	4.2919
11	1.3842	1.5394	1.7103	1.8983	30	2.4272	3.2433	4.3219	5.7435
12	1.4258	1.6010	1.7958	2.0122	35	2.8138	3.9460	5.5159	7.6862
13	1.4685	1.6651	1.8856	2.1329	40	3.2620	4.8009	7.0398	10.2858
14	1.5126	1.7317	1.9799	2.2609	45	3.7815	5.8410	8.9847	13.7648
15	1.5580	1.8009	2.0789	2.3965	50	4.3838	7.1064	11.4670	18.4204

The following table gives the number of years required for a given principal to double itself at compound interest.

Interest Rate	3	4	5	6
Years to Double	23.5	17.7	14.2	11.9

**Annuities.**—An annuity is a fixed sum of money paid yearly, or at other equal times agreed upon.

One dollar invested at interest at  $r$  per cent at the beginning of every year will at the end of  $n$  years amount to

$$R \cdot \frac{R^n - 1}{R - 1} \text{ dollars,}$$

where  $R = 1 + r/100$ , the interest being compounded at the end of each year.

One dollar invested at the beginning of a period of  $n$  years will yield at the end of each year an annuity of

$$\frac{R^n (R - 1)}{R^n - 1} \text{ dollars,}$$

where  $R = 1 + r/100$ , the interest being compounded at the end of each year.

**Sinking Fund.**—A sinking fund is a fund built up from fixed yearly payments or annuities. Sinking funds are usually provided to retire bonds, which are issued for a given number of years. The annuity required to retire a bond of \$1000 at the end of  $n$  years is

$$1000 \left( \frac{R - 1}{R^n - 1} \right).$$

Values of this annuity for various rates of interest and for various values of  $n$  are given in the following table.

ANNUITY REQUIRED TO REDEEM \$1000

At end of years	Rate of interest, per cent								
	2	2½	3	3½	4	4½	5	5½	6
1	495.05	493.78	492.69	491.42	490.20	489.00	487.80	486.62	485.43

**INTERNAL-COMBUSTION ENGINES.** — (See also *Gas; Gas Producers, Power Stations, Gas-Electric.*) An internal-combustion engine is an engine in which combustible gas, vapor, or oil is burned in a cylinder, generating high temperature and high pressure in the gases of combustion, which expand behind a piston driving it forward. (Rotary gas engines or gas turbines are still, in 1922, in the experimental stage.)

**Gas Engine.** — A gas engine in its simplest form is similar to a reciprocating single-acting steam engine, comprising a cylinder, a piston, crank, flywheel, etc. The pressure to move the piston is obtained by exploding or burning with great rapidity a compressed mixture of air and combustible gas.

**Oil and Gasoline Engines.** — The lighter distillates of petroleum, such as gasoline, are easily vaporized at moderate temperatures, and a gasoline engine differs from a gas engine only in having an atomizer attached, for spraying a fine jet of the liquid into the air-admission pipe. With kerosene and other heavier distillates, or crude oils, it is necessary to provide some method of atomizing and vaporizing the oil at a high temperature, such as injecting it into a hot vaporizing chamber at the end of the cylinder, or into a chamber heated by the exhaust gases.

**Diesel Oil Engine.** — The distinguishing features of the Diesel engine are: It compresses air only, to a predetermined temperature above the firing point of the fuel. This fuel is blown as a cloud of vapor (by air from a separate small compressor) into the cylinder when compression has been completed, ignites spontaneously without explosion, solely by reason of the heat of the air generated by the compression, and burns steadily with no essential rise in pressure. The temperature of gases, developed and rejected, is much lower than with engines of the explosive type. The engine uses crude oil and residual petroleum products.

Diesel engines sizes run from 6¾ by 8¾ inches, two-cycle, four cylinder, 110 b.h.p. for four cylinders to 33.2 × 39.4 inches, two-cycle, one cylinder, 1750 b.h.p. for one cylinder

The largest for land service are four-cylinder engines of approximately 2400 b.h.p. These engines are running for electric light service with admirable results on a guaranteed oil consumption not to exceed 0.4 pound of oil per brake horsepower-hour. They are of the two-cycle type. Four-cycle engines have an oil consumption of practically 90 per cent of this figure, or about 0.36 pound of oil per brake horsepower-hour.

The thermal efficiency of these engines is between 30 and 40 per cent. Twenty-five to 30 per cent of the heat is carried away in the cooling water and the rest in the exhaust gases.

The variation of economy with variation of load as shown by tests is reported to be:

Per cent rated load.....	30	50	75	100	120
Lb. oil per b.h.p. hour.....	0.71	0.55	0.46	0.43	0.44

**Alcohol Engines.** — Due to the relatively high cost of alcohol, even when "denatured," alcohol engines are not used extensively in this country.

**CLASSIFICATION OF INTERNAL-COMBUSTION ENGINES.** — Internal-combustion engines are classified as four-cycle and two-cycle engines, single- and double-acting engines, and single- and multi-cylinder engines.

**Four-cycle Engines.** — In what is known as a four-cycle engine of gas takes place in one end of the cylinder every two revolutions of the flywheel, or every two double strokes. The following sequence of events takes place during four consecutive strokes: (a) inspiration of gas and air during an entire stroke; (b) compression during the return stroke; (c) ignition at or near the dead-point and expansion during the third stroke; (d) expulsion of the burned gas during the fourth stroke.

Fig. 1 is an indicator diagram of a four-cycle engine. *AB*, shows the admission of the mixture, at a pressure slightly below the atmospheric pressure on account of the resistance of the inlet valve. *BC* is the compression line, the pressure increasing as the clearance space, ignition taking place at *C* and combustion with the pressure continuing from *C* to *D*. The gradual termination of the combustion is shown by the rounded corner at *D*. *DE* is the expansion line, *E* is the pressure drop as the exhaust valve opens, and *FA* the line of expansion of the burned gases, the pressure being slightly above the atmosphere on account of the resistance of the exhaust valve.

**Two-cycle Engine.** — In a two-cycle single-acting engine an explosion takes place with every revolution, or with each forward stroke of the piston. Referring to the diagram, Fig. 1, and beginning at *E*, when the exhaust port begins to open to allow the burned gases to escape, the pressure drops rapidly to *F*. Before the end of the stroke is reached an inlet port opens, admitting a mixture of gas and air from a reservoir in which it has been compressed. This mixture being under pressure assists in driving the piston out through the exhaust port. The inlet port and the exhaust port close early in the return stroke and during the remainder of the stroke the mixture, which may include some of the burned gas, is compressed. Ignition takes place at *C*, as in the four-cycle engine.

In one form of the two-cycle engine only compressed air is admitted and the exhaust port is open, the fuel gas being admitted under pressure when the exhaust port is closed. By this means a greater proportion of the burned gas is swept out of the cylinder. This operation is known as "scavenging."

**Single- and Double-acting Engines.** — These terms have the same significance as in the case of steam engines (q.v.). Comparatively few internal-combustion engines are single-acting.

**Multi-cylinder Engines.** — In small multi-cylinder engines the cylinders are in "parallel," i.e., each has a separate piston connected to the crankshaft. In large engines two cylinders are frequently arranged in tandem. "Twin cylinder" is used to designate two cylinders operating in parallel, as contrasted with the "two-cylinder tandem" arrangement, in which the two cylinders are in "series." A "twin-tandem" engine has four cylinders or two pairs of tandem cylinders.

**RATING.** — In contrast to steam prime movers the gas engine has a wide limit of power with the usual methods of governing and its economy is maintained until this limit is almost reached. This characteristic makes a maximum rating more significant than a normal rating with overload capacity. Ordinarily rated, however, engines can develop 20 per cent overload for long periods and will care for momentary swings much greater. Due to their low efficiency (75 to 85 per cent) gas engines are preferably rated in terms of brake horse-power instead of indicated horse-power.

Fig. 1. Indicator diagram of a four-cycle engine.

**Rating of Automobile Engines.**—Automobile engines are sing as a rule multi-cylinder, the cylinders all being in parallel. The used Automobile Manufacturers Association have adopted the rary formula for the rating of automobile engines

$$\text{Brake horse-power} = \frac{D^2 N}{2.5},$$

where  $D$  = diameter of each cylinder in inches,  $N$  = number of rating is usually referred to as the A.L.A.M. rating. It approximately to the actual brake horse-power when the piston speed per minute and the mean effective pressure is 55 pounds per square inch. The following ratings are derived from the formula:

dia. in.....	2½	3	3½	4	4½	5	5½
dia. mm.....	64	76	89	100	114	127	140
horse-power, 1 cylinder....	2½	3.6	4.9	6.4	8.1	10	12.
horse-power, 2 cylinders...	5	7.2	9.8	12.8	16.2	20	24.
horse-power, 4 cylinders...	10	14.4	19.6	25.6	32.4	40	48.
horse-power, 6 cylinders...	15	21.6	29.4	38.4	48.6	60	72.

**DESIGN AND CONSTRUCTION.**—Only a few of the more important features in the design and construction of internal-combustion engines are mentioned here. See *Bibliography* at end of this article for references to treatises on the subject.

**Arrangement of Cylinders in Large Engines.**—The number and arrangement of cylinders depends upon the space, the power required and the form of rotation to be produced. Vertical-cylinder engines are used for sizes up to 750 horse-power. They require less floor space than horizontal types but the superior mechanical properties of the latter warrant their use when space economy is not important. The tandem double-acting arrangement is standard in horizontal engines. As it is not practical to develop more than 1500 horse-power in a single cylinder, engines of this size are twin, tandem, double-acting.

**Cooling** is one of the most important problems of gas-engine design. For all sizes provision for air cooling or a simple water jacket about the cylinders suffices, but the large sizes require the cooling of the piston, pistons and valve stems. The superficial area of the cylinders increases less than their cubical contents and this fact tends to aggravate the cooling problem as the size of the cylinders is increased. Cooling is more difficult for horizontal engines than with lean. One practical result of these difficulties is found in that engines of large capacity are little if any cheaper per horsepower than small ones and that maintenance is apt to be proportionately large. The amount of cooling water required per horse-power-hour is stated by investigators to be from 0.75 to 1.00 cubic foot. Figures for a large commercial plants average 2.4 cubic feet. This high average is due to the fact that water cost little in most of these plants.

**Ignition.**—The "hot-tube" method of igniting the compressed gas and air in the cylinder is practically obsolete, and electric systems are used instead. Of these the "make-and-break" and the "jump-spark" systems are in common use. In the former two insulated contact pieces are placed at the end of the cylinder, and through them an electric current passes. A spark coil is included in the circuit, and when it is suddenly broken at the proper time for ignition, by mechanism oper-

the valve-gear shaft, a spark is made at the contacts, which ignites the "jump-spark" system two insulated terminals separated about an inch apart are located in the cylinder, and the secondary or high-tension of an induction coil causes a spark to jump across the space between them. The circuit of the primary current is closed by mechanism operated by the cam. See article on *Ignition, Electric*.

In some oil engines the mixture of air and oil vapor is ignited at the beginning of the temperature generated by compression of the vapor, in a chamber at the end of the cylinder, called the vaporizer, which is not water-jacketed and therefore is kept hot by the repeated ignitions. Before starting the vaporizer is heated by a Bunsen burner or other means.

**Timing.** — By adjusting the cam or other mechanism operated by the valve-gear shaft for causing ignition, the time at which the ignition takes place, with reference to the end of the compression stroke, can be regulated. In some engines the mixture is usually ignited before the end of the stroke, the advance depending on the inflammability of the mixture and on the speed of the engine.

**Governing.** — Two methods of governing the speed of an engine are in common use, the "hit-and-miss" and the throttling methods. In the hit-and-miss engine receives its usual charge of air and gas only when the engine is running at or below its normal speed; at higher speeds the admission of the mixture is suspended until the engine regains its normal speed. One method of governing is to interpose between the valve rod and its cam or other operating mechanism, a push rod, or other piece, the position of which with reference to the end of the valve rod is controlled by a centrifugal governor so that it will open the valve rod if the speed is at or below normal and misses it if the speed is above normal.

The throttling method of regulating is similar to that used in steam engines; the quantity of mixture admitted at each charge is regulated by varying the position of a butterfly valve in the inlet pipe. Cut-off governing is also used, such as varying the time of closing the valve during the suction stroke, or varying the time of admission of the mixture alone, or "quality regulation."

**Lubrication** of cylinders is best provided by a time force-feed system, injecting oil between the piston rings at dead-center positions. The lubrication should be closely regulated, as an excess carbonizes on the cylinder walls and becomes a source of trouble. Bearings are commonly ring-oiled or oiled.

Owing to the high temperatures that prevail in the cylinder of a combustion engine, the question of proper lubrication is a serious one. The oil should be exceedingly pure, free from acids, and composed of hydrocarbons that leave no residue after combustion. Only mineral oils, therefore, are suitable for the purpose. The ignition point of good cylinder oil should be at least lower than 535° F. The losses in power due to poor lubrication of cylinders may amount to 10 or 15 per cent.

The amount of oil required per horsepower-hour varies with the type of the installation and the method of operation. For full load 24-hour operation the proportion per horsepower-hour is, of course, greater than for a part load, or under a light load for a 9 or 10-hour day. The average of several engines is given by the engine manufacturers for the amount of engine oil required per 1000 horsepower-hour. The operators of commercial plants require, however, that average about double this amount, and an equal quantity of cylinder oil.

**Starting Devices.** — In large engines starting is now universally accomplished by compressed air. In some small stationary engines a starting cartridge is inserted into the cylinder head and set off by percussion.

are now almost universally used for automobile engines  
(*Starting and Lighting Systems for Automobiles*).

Gasoline engines are usually designed for speeds of from  
100 to 3000 revolutions per minute. Large gas engines, for central-station ser-  
vices, run at about as follows:

.....	275 rev. per min.
.....	200 rev. per min.
.....	150 rev. per min.
.....	100 rev. per min.

#### DEVELOPED BY AN INTERNAL COMBUSTION EN-

gines. To calculate the power developed by an internal-combustion engine, it is necessary to know the mean effective pressure in the engine cylinder, the diameter of the cylinder and either (1) the length of stroke and the number of revolutions per minute, or (2) the piston speed and number of explo-

sions per minute. — The mean effective pressure can be obtained from a test diagram (see *Steam Engines*), or if a test diagram is not available, the mean effective pressure either has to be assumed from a knowledge of the mean effective pressures of engines of the same type and working under the same conditions, or it may be calculated from the ideal air diagram by the use of a coefficient or diagram factor depending on the ratio of the initial to the compression pressure.

Values of mean effective pressure are given by C. P. Poole as a rough approximate guide for four-cycle engines. The pressures obtained with different fuels in a four-cycle engine are given in the following table. The mean effective pressure of the pump diagram is usually from 4 to 8 pounds per square inch above the atmosphere, and the corresponding mean effective pressure of the engine is about 3.8 to 7.

#### MEAN EFFECTIVE PRESSURE, POUNDS PER SQUARE INCH, FOUR-CYCLE ENGINES

Compression pressure	Engine horse-power						
	5	10	25	50	100	250	500
100	..	55	60	65	70	75	80
130	..	65	70	75	80	85	90
160	..	..	..	80	85	90	90
100	..	..	60	65	65	70	75
130	..	65	65	70	75	80	85
160	..	..	75	80	85	90	90
65	..	60	65	70	80	85	..
100	..	75	80	90	90	95	100
130	..	..	..	..	100	105	110
65	70	75	80	85	..	..	..
100	85	90	90	95	..	..	..
65	50	55	60	65	..	..	..
115	70	75	80	85	..	..	..

**Number of Explosions per Revolution.**—The number of explosions per revolution depends upon the type of engine as given in the accompanying table.

**Formulas for Horse-power Output.**—(See also *Lemp, H.; B.H.F. for Internal Combustion Engines, G. E. Rev. 22, p. 808, Oct., 1919.*)

$p$  = mean effective pressure, lb. per sq. in.

$d$  = diameter of cylinder bore, inches,

$N$  = number of revolutions per minute,

$e$  = total number of explosions per revolution,

$S$  = piston speed, feet per minute,

$L$  = length of stroke, feet,

$\epsilon$  = mechanical efficiency, as a fraction,

$P_i$  = indicated horse-power.

Then

$$P_i = \frac{pLd^2eN}{42,000} = \frac{pd^2eS}{84,000}$$

The brake horse-power is

$$\text{Brake h.p.} = \epsilon P_i$$

The brake horse-power is frequently expressed by the formula

$$\text{Brake h.p.} = Cd^2,$$

where  $C = \epsilon p e S / 84,000$  is called the "engine constant." For  $\epsilon = 0.8$  explosions per revolution the values of  $C$  for various mean effective pressures are as follows:

VALUES OF  $C$  FOR 2 EXPLOSIONS PER REVOLUTION

M.E.P., lb. per sq. in.	Piston speed, feet per minute				
	500	600	700	800	900
50	0.50	0.60	0.70	0.80	0.90
60	0.60	0.72	0.84	0.96	1.08
70	0.70	0.84	0.98	1.12	1.26
80	0.80	0.96	1.12	1.28	1.44
90	0.90	1.08	1.26	1.44	1.62
100	1.00	1.20	1.40	1.60	1.80
110	1.10	1.32	1.54	1.76	1.98

These values of  $C$  apply to 4-cylinders, 4-cycle, single-acting, to 2-cylinders, 2-cycle, single-acting, and to 1-cylinder, 2-cycle, double-acting. For 4-cylinders, 4-cycle, single-acting, divide by 4; for single cylinders, 4-cycle, double-acting, or 2-cycle, single-acting, divide by 2.

**TESTING INTERNAL-COMBUSTION ENGINES.**—The power of a gas or oil engine includes the measurement of its power by a friction dynamometer. The number of cubic feet of gas or pounds of oil used per brake horse

specific value of the gas or oil. In connection with the tests may be taken, the air supply and the jacket cooling water exhaust gas analyzed, the temperatures of air, water and heat balance calculated showing the thermal efficiency and the loss of energy. For details see *Code of 1922 of the*

**FUEL CONSUMPTION.** — The thermal efficiency of an internal combustion engine is considerably higher than that of the best steam turbine. It is probable that the maximum efficiency of such engines under the most favorable operating conditions is based on the indicated horse-power or 30 per cent, based on brake horse-power. The mechanical efficiency of an internal combustion engine is that of a reciprocating engine, ranging from 70 to 85 per cent for a high-class reciprocating engine and 92 to 95 per cent for turbines.

**Operating Conditions.** — The conditions which appear to give the highest efficiency for gas and oil engines are: (1) high temperature of cooling water; (2) high pressure at the end of compression; (3) lean fuel mixture; (4) timing of the ignition; (5) maximum load. The higher efficiency may be due to the fact that high compressions may give a lean mixture, while with rich mixtures high-compression pressures are a danger of preignition. For equal temperatures, the hotter the walls of the cylinder the less heat is lost from the hot gases, and therefore the higher the efficiency. The allowance for higher compression without preignition, and high efficiency of high efficiency. Cool walls also tend to give the higher efficiency, since with hot walls the fuel mixture expands more on cooling, thus reducing the weight of charge admitted in the suction stroke.

**Heat Losses.** — The heat losses are: (1) the heat carried away by the cooling water, (2) that carried away in the waste gases, and (3) that lost by radiation. The relative amounts of these three losses vary greatly, depending on the design of the engine and on the amount of water used for cooling. The following tables quote the following:

P., per cent	Ratio air to gas	Heat- ing value of charge, B.t.u.	Work done by 1 ft. lb.	Ex- haust temp., deg. F.	Distribution of heat losses, per cent		
					Work	Jacket water	Ex- haust
30	7.11	18.5	140	1022	18.0	51.2	30.8
35	7.35	17.4	141	1137	18.1	45.6	36.3
40	7.43	17.0	190	867	24.4	53.8	21.8
45	7.40	16.8	184	992	23.7	49.5	26.8

The distribution of the heat losses varies with the rate of compression.

**Efficiency and Fuel per Brake Horse-Power.** — The over-all

efficiency of internal-combustion engines is the product of the thermal efficiency by the mechanical efficiency. A more convenient expression is

$$\text{Over-all efficiency} = \frac{2546}{HQ} \quad \text{as decimal fraction}$$

where  $H$  = heat of combustion, B.t.u. in one cubic foot, and  $Q$  = number cubic feet of gas supplied per brake horse-power hour. In the case of a liquid fuel it is more convenient to take  $H$  = heat of combustion, B.t.u. per pound and  $Q$  = pounds of liquid supplied per brake horse-power hour. See articles *Gas and Fuels*. The product  $HQ$  in either case is the number of B.t.u. brake horse-power.

In Fig. 2 are given the results of tests on several internal-combustion engines using different kinds of fuels, and also, for comparison, the performance of three steam turbines. These curves were supplied by Prof. W. E. Wickend

These curves bring out very strikingly the relatively poor performance

Fig. 2. Fuel Consumption of Gas and Oil Engines

of internal-combustion engines at light loads. Under working conditions gas engines are expected to produce a brake horse-power hour for every 9000 to 12,000 B.t.u. in the fuel. The average of several quotations from different manufacturers is as follows:

Per cent rated load.....	100	75	50	25
B.t.u. per b.h.p.-hr.....	10,500	12,000	14,700	20,000

**Coal per Brake Horse-power Hour.**— Figures giving the coal consumption of a producer per brake horse-power hour of the gas engine supplied

unless the type of producer and type of engine as well as the conditions are stated. Let  $H$  = B.t.u. per pound coal,  $e_1$  = efficiency of producer,  $e_2$  = over-all efficiency of gas engine. Then

$$\text{coal per brake horse-power hour} = \frac{2546}{H e_1 e_2}$$

If the heating value of the coal used is 14,000, the over-all efficiency is 30 per cent and the efficiency of the producer 80 per cent,  $0.3 \times 0.8 = 0.24$  pound coal will be required per brake horse-power hour. Figures as low as 0.7 pound coal per brake horse-power hour are exceptional, but they are exceptional.

Examples are:

Fuel	Lb. per b.h.p.-hr.	
	As fired	Dry
Anthracite.....	1.3	1.3
Bituminous coal.....	1.3	1.2
.....	2.0	1.6
.....	2.6	2.0
.....	3.3	...

**ENGINE TROUBLES.** — Among the causes of troubles are: poor position of the fuel; too much or too little air supplied; wrong timing for the kind of fuel; ignition timer set too late or too early; backfiring; electrical and mechanical troubles with the engine; carbon deposits in the cylinder and on the igniting contacts.

**ENGINE COSTS (Pre-war figures).** — Differences in the ratings and the development of the art and the close competition of the market make the cost quite variable. The following methods of estimating are for typical installations and probably represent average conditions.

1. Let  $P$  = brake horse-power rating; then

Gas Engines, cost in dollars.....	$36 \times P$
Gas engines, cost in dollars.....	$400 + 40 \times P$
Gas engines, cost in dollars.....	$2500 + 24 \times P$
Gas engines, cost in dollars.....	$34 \times P - 2500$
Gas engines, cost in dollars.....	$3000 + 47 \times P$
Gas engines, cost in dollars.....	$3000 + 45 \times P$

2. For engines less than four-cycle for the larger sizes.

Dieterichs. For practical application of gas and oil engines, see *The Gas Engine*, by F. R. Jones, and *Engine Handbook*, by E. W. Roberts. For descriptions of large gas engines using blast-furnace gas, see papers in *Proc. Iron and Steel Inst.*, and *A.S.M.E.* See also Fernald and Orrok, *Engineering of Power Plants*, W. H., *The Diesel Engine and its Applications in So. California*, *Trans.*, Vol. 37, p. 447; Goldingham, A. H., *The Heavy Oil Engine*, *Trans.*, Vol. 37, p. 477.

**IRON, PIG AND CAST.**—(See also *Iron, Wrought; Castings, Iron and Steel; Magnetic Properties of Iron; Steel.*) Chemically pure iron is not a commercial product. Iron of a very high degree of purity may be obtained, however, by electrolytic deposition. The microscopical constituent of pure iron is called ferrite, and pure iron is said by metallographists to be composed of polyhedral crystalline grains of ferrite. Commercial products are pig iron, cast iron, malleable cast iron, wrought iron and steel.

**PIG IRON.**—Pig iron is the crude product obtained from iron ore by melting in a blast furnace. The name is applied either to the molten material or to rough castings varying in length from 30 inches to 36 inches and in cross-section from about 10 sq. in. to 30 sq. in. A mass of piled pig iron 6 by 12 ft. weighs approximately 100 tons. Pig iron is made by burning a mixture of iron ore, coke or other fuel and limestone in a high furnace through which a blast of heated air is forced under pressure. The liquid iron when drawn from the furnace is either run into sand molds formed on the ground near the furnace, or into cast-iron molds forming a part of a conveyor chain which receives the molten iron, chills it by contact, and delivers it at the car. A pig is the bar of iron formed in either of these types of molds. The molten iron is also occasionally conveyed to the steel furnace without being allowed to cool.

**Classification.**—Pig iron may be classified as follows:

- a. Gray, white or mottled as determined by the color of its fracture and its chemical composition.
- b. Coke, anthracite or charcoal iron as determined by the fuel used in reducing the ore.
- c. Foundry iron, Bessemer iron, etc., according to the use to which it is to be put.

**Use of Pig Iron.**—The product of the blast furnace is irregular in composition and physical properties and is not used directly. By forming it into pigs it is possible to grade it, and also transport it to foundries and iron and steel furnaces. Pig iron is sometimes used by engineers because of its great weight to form counterweights in unbalanced structures such as movable bridges, but concrete is more economical for this purpose.

**Strength.**—See below in the section on *Cast Iron*.

**Specifications for Pig Iron.**—See *Standard Specifications for Foundry Pig Iron in American Society for Testing Materials Standards*.

**Cost.**—The cost of pig iron is an important factor in commerce. Quotations are given weekly in *The Iron Age* and in the first issue of each month of the *Engineering News-Record*. The fluctuations in price are very considerable, even in normal times, Bessemer pig at Pittsburg varying during 1912 from \$1.90 to \$18.15 per long ton of 2240 pounds. Since the World War the increase has been great. Bessemer pig was quoted at \$50.46; Pittsburg, Aug. 31, 1920, at \$26.96, May 16, 1922.

**CAST IRON.**—Cast iron may be defined as iron containing so much carbon that it is not malleable at any temperature, specifically, iron cast into articles of specific form and purpose as distinguished from pig iron. Except for special cases castings are made of gray iron. Cast iron is made from pig iron by melting the latter and casting in sand or iron (chill) molds. The furnace commonly used is a cupola furnace although reverberatory furnaces are sometimes employed.

**Composition of Cast Iron.**—The composition of an iron casting is identical with that of the pig iron from which it is made and usually consists of metallic

iron (ferrite) accompanied by from 2.5 per cent to 4 per cent (by weight) carbon, together with silicon, phosphorus, manganese and other impurities. The carbon may be chemically combined with the iron, giving homogeneous white iron, or some of it may be precipitated in cooling in the form of graphite, making gray iron or mottled iron. The influence of carbon upon the properties of the cast iron is of great importance and may be summed up as follows:

**Uncombined Carbon or Graphite.** — Porosity and workability, ductility and shrinkage decreases, with an increase in the percentage of graphite. Strength also generally decreases with an increase in graphite, although it is noted that an iron may be weak by having too much combined carbon. That treatment which changes some of this combined carbon to graphite increases its strength.

**Combined Carbon.** — In slowly-cooled white iron all the carbon is in the form of an alloy, called cementite, which forms in cooling, and partakes of the characteristics of cementite, being hard and brittle. Its strength characteristic increasing with an increase in the percentage of the combined carbon. The carbon in this condition is called combined carbon.

**Silicon.** — This acts as a precipitant of carbon, drawing it out of solution into graphitic form. The maximum precipitation occurs with about 2.5 per cent to 3.5 per cent of silicon. Beyond this percentage the effect is noted. Increase of silicon up to 3.5 per cent therefore softens iron, decreases shrinkage, imparts fluidity and reduces the strength. The maximum density of gray iron occurs with about 1 per cent of silicon. More than 2 per cent causes porous iron.

**Sulphur.** — Sulphur increases the amount of combined carbon, the effect in this direction being far greater than that of silicon in reducing combined carbon, it being generally considered that 0.01 per cent S is equivalent to 0.15 per cent Si. The amount of sulphur should be restricted to a low percentage. In the Standard Specifications of the A.S.T.M. the sulphur content is limited to not over 0.08 per cent for light castings, not over 0.12 per cent for medium castings and not over 0.12 per cent for heavy castings.

**Manganese.** — This increases the total carbon and the proportion of carbon in combined form, although by combining with sulphur and the effect of the latter, the net result may be a decrease in the combined carbon. It strengthens the iron if below 1 per cent, strengthens but increases brittleness if between 1 per cent and 1.5 per cent, and if over 1.5 per cent increases strength and toughness and increases hardness and shrinkage.

**Phosphorus.** — This causes expansion after solidification, making the iron useful for very thin castings. It, however, tends to make the iron weak and brittle and should be kept below the following values:

	Per cent
Chilled castings.....	0.3
Malleable castings.....	0.2
Gray castings.....	0.7

**Use of Cast Iron.** — Cast iron should in general not be used where high tensile or bending strength is required. Its cheapness and high crushing strength make it useful for heavy parts of machinery, and for pieces where patterns not easily made by tools are needed. It is frequently used for pipes, despite its low tensile strength, and often for columns in buildings, although cast-iron columns have been superseded to a considerable extent by steel columns, except for the simplest forms of construction. Cast iron with the outer surface chilled by iron molds are much used.

length. — The ultimate compressive strength of cast iron is 60,000 lb. per sq. in. A safe working value for cases where eccentricity occurs is 16,000 lb. per sq. in. For columns the following formula is used if the applied load is not eccentric.\*

$$\frac{P}{A} = 6100 - 32 \frac{l}{d}$$

$P$  = load in pounds,  
 $A$  = area in square inches,  
 $l$  = length of column restrained against lateral deflection in inches,  
 $d$  = diameter or shortest side of rectangular column, in inches.

— Ultimate strength may vary from 15,000 to 35,000 lb. per sq. in. Ordinarily from 18,000 to 22,000 lb. per sq. in. For cast-iron columns it is usual to specify 3,300 lb. per sq. in. or  $\frac{1}{3}$  of the tensile strength of the latter to be 16,500 lb. per sq. in.

Modulus of elasticity varies from 10,000,000 to 30,000,000 lb. per sq. in. For gray cast-iron the modulus of elasticity may be taken as 16,000,000 lb. per sq. in.

Cast iron has no well-defined elastic limit.

**Cast Iron.** — See *American Society for Testing Materials*

**Cast Iron.** — See *Castings, Iron and Steel*.

**CAST IRON.** — This is the name given to cast iron which has had the combined carbon changed to graphitic carbon in the matrix by reheating white iron to a temperature somewhat above the eutectic point. The process used in the United States generally involves a core of white iron entirely from the outer layer. Malleable cast iron is used for all kinds of cultural machinery, pipe fittings which have to be threaded, and for all kinds of castings which require a much higher tensile strength (from 40,000 to 50,000 lb. per sq. in.) than ordinary cast iron and is more ductile. It is frequently referred to as malleable iron, and should be carefully guarded against by its name. Articles such as bevel gears, hammers and automobile drop

**Malleable Cast Iron.** — See Standard Specifications in *American Society for Testing Materials Standards*.

**Iron Castings.** — See *Castings, Iron and Steel*.

**Iron Castings.** — See *Bibliography* in article on *Steel*.

**Columns, Simple.** for effect of eccentricity on building columns. The allowable loads on cast-iron columns as given in the building code are summarized in the article on *Buildings, Allowable Unit Stresses* and are too high for conservative practice.

**IRON, WROUGHT.** — (See also *Iron, Pig and Cast; Magnetic of Iron; Steel.*) If commercial iron is mechanically mixed with amount of slag (see *article on Steel*) there results a malleable wrought iron which does not harden when suddenly cooled. It melts white heat, but becomes pasty at a lower temperature, in which case it can be readily welded. It is ductile when cold.

**PROCESS OF MANUFACTURE.** — Practically all wrought iron is produced from pig iron by indirect processes although direct processes also exist. These indirect processes may be divided into two general classes based upon the type of furnace used: (a) reverberating furnaces; and (b) charcoal hearths. The best iron is made upon the latter but puddling furnaces produce the larger quantity. The essential difference between the two processes is that in hearths the chief source of oxygen is atmospheric air, and the fuel is burned in contact with the iron, while in puddling furnaces the chief source of oxygen is magnetic oxide of iron, which is burned in a chamber separate from that containing the iron. The details of these processes follows.

**Puddling.** — This method consists of melting pig iron in a reverberatory furnace heated either by coal or natural gas. The furnace is lined with oxide of iron. The pig is exposed for about two hours to the continuous action of a flame hot enough to melt it and to remove its impurities, but not hot enough to keep pure iron in a molten state. At the termination of the flame the molten iron becomes less fusible and finally solidifies. After reaching this condition it is puddled by being worked into balls by manual labor. It is then taken from the furnace and squeezed or hammered into blooms, and then rolled into small bars about  $\frac{3}{4}$  inch thick and from 6 to 12 inches wide, called "muck bars." After cooling, these muck bars are cut into short pieces about 2 feet in length, piled into bundles, fastened by wire, reheated to welding heat and re-rolled into merchant bars. If they are further subjected to a second piling, heating and re-rolling, it is called "finer iron."

**Charcoal Hearths.** — The following are the more important processes.

1. **Finery Process.** — Charcoal fineries produce "knobbed" iron of a high degree of softness which is much used for boiler tubes.

In the finery process the pig iron is first melted down in a charcoal refinery to remove the silicon, phosphorus, and sulphur, and is then transferred in a molten condition to a charcoal hearth which is still hot from the previous charge. Damp charcoal is thrown in, a low-pressure, unheated blast is turned on and the metal agitated to keep it in contact with the blast. After an hour or more the metal is collected into a ball and hammered. Some of the slag, cut up and reheated in piles. Gray iron may be produced in this process.

2. **Walloon Process.** — The Walloon process is used in Sweden for producing wrought iron from Dannemora pig iron, the resulting product being shipped to England, particularly to Sheffield, for conversion into blooms for use in fine toolmaking.

In the Walloon process long pigs are melted gradually by being pushed forward into a charcoal fire. The molten iron drops through the blast and is decarburized, and collects in a pasty mass at the bottom of the furnace. The partially refined iron is then raised to the top of the charcoal fire and melted down with the addition of rich slag and hammer scale. It is then balled, reheated and hammered.

**Process.** — The Lancashire process is used principally in the United States.

This process somewhat resembles the Walloon process. Pig iron is melted in two layers of charcoal, the liquid dropping down through the charcoal being oxidized. The molten metal collects in a pasty mass of slag where it is allowed to remain for twenty or twenty-five minutes, then mixed with decarburizing slag and remelted in a similar furnace. The pasty mass is removed from the hearth and hammered.

"Busheled iron" is made of scrap instead of pig iron. The scrap is melted in a furnace, squeezed and rolled into bars. The resulting product is of high purity.

— Wrought iron consists of a mass of ferrite interspersed with small particles of slag. Commercial shapes of wrought iron, such as plates, are made from piles of muck bars, and have a fibrous character consisting of a series of welds.

Wrought iron has been gradually replaced by steel for most structural purposes. The quality of iron, however, is still in demand where toughness is necessary, and where welding or other blacksmith work of a high degree of purity is sometimes specified for use where the best material is needed.

Wrought iron is on sale in the eastern states under the following grades:

**Swedish Iron.** — Best grade; used for fine wrought work. It is particularly fibrous.

**Double Refined.** — This is the best domestic iron. It is used for welding or machine work.

**Single Refined.** — This is the cheapest grade. Used for nails, horseshoes, and other work as readily as other grades.

**TENSILE STRENGTH; WEIGHT.** — The values stated in the following table indicate the tensile strength of wrought iron of the various grades. The following values are from tests made upon merchant bars by the Massachusetts Institute of Technology, and show the variations that may be expected in the various grades bought in the market without specifications which follow show the strength which may be expected of the grades specified therein.

**TENSILE STRENGTH, MODULUS OF ELASTICITY, ELONGATION, ETC., OF WROUGHT IRON**

(M.I.T. Tests)

	Single Refined	Double Refined	Swedish
Tensile strength, per sq. in. ....	47,000	51,700	40,600
.....	32,000	25,800	20,900
.....	35,000		
.....	27,700,000	29,700,000	29,100,000
Elongation in 10 inches ..	.....	22.7	26.4
.....	20.6	37.5	75.0

**Compressive Strength.** — For all practical purposes this may be taken as the yield point, or from 3000 lb. to 4000 lb. above the elastic limit.

**Weight.** — Wrought iron weighs 480 lb. per cu. ft. A bar 1 yard in length and 1 sq. in. in cross-section weighs 10 lb.

**STANDARD SPECIFICATIONS FOR WROUGHT IRON.** — *American Society for Testing Materials Standards.*

**COST.** — In the *Iron Age* for May 18, 1922, refined iron bars were quoted at 2.10 cents per pound, f.o.b. Pittsburgh.

**BIBLIOGRAPHY.** — See *Bibliography* in article on *Steel*.

**LAMPS, ARC.**—(See also *Arc, Electric; Distribution and Transmission Systems; Lamps, Incandescent; Illumination, Street; Photometric Quantities; Radiometry; Rectifiers.*) The theory of the electric arc is discussed in detail in the article on *Arc, Electric*. Arc rectifiers are discussed in the article on *Rectifiers*. This article deals with the use of the electric arc as a source of illumination.

The positive and negative electrodes are termed respectively anode and cathode. The active conducting medium of the arc is supplied by the electro-vaporization of the cathode. The wasting of the anode is due only to its oxidation and can be prevented without interrupting the arc by cooling or by isolation from air. With the exception of the carbon arc, it is more difficult to maintain an arc with alternating than with direct current.

**Voltage Drop Across an Arc.**—The voltage drop across an arc comprises three elements, (1) a sensibly constant drop at the anode, (2) a similar but much smaller drop at the cathode and (3) a variable drop in the arc stream. The electrode drops depend only on the nature of the electrodes. The drop in the arc stream varies with the current according to Ohm's law, but the relation is greatly complicated by the changes in the resistance of the arc stream. Steinmetz (*Radiation, Light and Illumination*, p. 139) proposes the following general expression for arc conduction in air:

$$E = E_0 + \frac{k(l+h)}{\sqrt{I}}$$

where  $E$  is the total voltage,  $E_0$  the electrode drop,  $l$  the arc length in inches,  $I$  the current, and  $k$  and  $h$  constants depending on the cathode material.

For carbon electrodes,  $E_0 = 36$ ,  $k = 130$ ,  $h = 0.33$ .

For magnetite-copper electrodes,  $E_0 = 30$ ,  $k = 123$ ,  $h = 0.05$ .

**Steadying Resistance.**—When the arc is employed in a series circuit its instability is overcome by supplying it with a constant current. Arcs in multiple on constant-potential circuits must each be compensated by a considerable ballast of stable series resistance or reactance; see article on *Arc, Electric*.

**Power Factor.**—Due to the distortion of the current wave by the varying resistance of the arc, the alternating-current carbon arc has a power factor of about 85 per cent, although the current and voltage pass through their zero values simultaneously; see *Alternating Currents*. Reactive ballast coils used in constant-potential lamps reduce the over-all power factor to values between 60 and 75 per cent.

**Sources of Luminosity.**—There are three distinct modes of light production by electric arcs, viz., (1) by incandescence of the electrodes due to their high temperature, (2) by the luminescence in the arc of salts derived from mineralized carbon electrodes, and (3) by the luminescence in the arc of the conducting vapors from the cathode. The first is exemplified by the ordinary carbon arc. The second mode is exemplified by the flame arc. The color of the light and its efficiency depend on the nature of the luminescent salts and the temperature attained in the arc. Carbon electrodes heavily mineralized with calcium salts yield a yellow light of high efficiency. Barium salts yield white light and strontium red, but the efficiencies are lower than those attained with yellow light. The third mode is exemplified in the metallic arcs, the chief practical representatives being the magnetite and the mercury arcs. Here the color of the light depends solely on the natural spectrum of the cathode vapor and the efficiency depends on the richness of that spectrum in highly luminous components.

**Steadiness of Light.**—Light from arc lamps is inferior to that from incandescent lamps in the matter of steadiness. The conditions requisite for

steady light are constant arc length, constant current, fixity of arc position, uniform feed, homogeneous electrodes and complete protection from draft. When well ballasted the mercury arc in the vacuum tube best meets these conditions. The alternating-current arc displays instantaneous variations in intensity which are very annoying at low frequencies. Arcs should not be operated at less than 40 cycles per second where considerations of hygiene are important. The three-phase arc is free from this defect.

**CARBON ARC LAMPS.**— Unless used for indirect light the upper electrode of a direct-current carbon arc should be the anode in order to gain the fullest advantage of downward light distribution from the crater. In the alternating-current arc semi-craters of lower temperature are formed on both electrodes, resulting in lower efficiency of light production than in the direct-current arc. The performance of typical carbon arc lamps is given in Table I and Fig. 1.

#### Open Carbon Arcs.

— The open arc is characterized by the rapid oxidation of the electrodes due to the free access of air. The anode of a direct-current open arc wastes at a rate between 1 and 2 inches per hour and the cathode at about half the rate of the anode. The electrodes of open alternating-current arcs burn from 1 to 1.5 inches per hour. A life per trim sufficient for all-night operation may be obtained by the use of a single pair of very long, heavy carbons or by providing two sets for successive consumption. The open arc is very sensitive to drafts. It is operated with short arc length, low voltage, usually 45 to 55, and heavy current, usually 6.6 to 10 amperes, to improve the steadiness of the light. The short arc length impedes downward light distribution and the intense crater casts harsh shadows. The erratic travel of the arc about the electrodes makes the light very unsteady. The use of the open arc is now confined to series circuits.

**Inclosed Carbon Arcs.**— The inclosed carbon arc with closely restricted air supply affords a greatly increased electrode life over the open type. It is also much less liable to extinction by wind, and hence can effectively employ greater arc length, higher voltage and lower current than the open arc. The crater of the inclosed arc is less pronounced, entailing some loss of efficiency compared with the open arc, but the greater length of the arc reduces the interference of the lower carbon with downward distribution. The light is much steadier than

that from the open arc. It is bluer in color, due to the greater proportion of light derived from the arc proper. Electrodes of moderate length afford a trim of from 80 to 100 hours in alternating-current lamps and of 100 to 200 hours in direct-current lamps. The range of currents in common use is from 3 to 7.5 amperes.

**Intensified Carbon Arc.**—The intensified carbon arc, used in direct-current circuits, employs a short, thick vertical lower carbon as cathode and two long, thin, inclined carbons as anode. The upper carbons are positioned above the cathode and feed downward at the rate of consumption to the aid of any regulating mechanism. The lower carbon is controlled by a solenoid and tends to maintain an arc of constant length at a fixed level. The high current density in the positives produces a very intense dual crater which emits light of somewhat whiter quality and of higher efficiency than that of the ordinary enclosed arc. The fixed level of the arc and the absence of crater travel aid in the effective use of reflectors and diffusing globes and in the maintenance of a definite form of light distribution. Under standard conditions of use the 5-ampere arc has a life per trim of from 80 to 100 hours.

#### FLAME ARC LAMPS.

The flame arc depends for light production on the luminescence of salts impregnated in carbon electrodes. In its electrical characteristics it is essentially a carbon arc. The evolution of this type of lamp has been along two structural lines, one having vertical electrodes, introduced by Blondel, and the other having inclined electrodes, introduced by Bremer. In both types both electrodes are enclosed in a glass globe, the regulating mechanism and the arc is maintained at a fixed level by a vitreous canopy or economizer which serves to conserve the heat of the arc, deflect the fumes to the ports at the periphery of the housing, and assist in the downward reflection of light. Flame arcs may be open or enclosed. The performance of typical flame arcs is given in Table 2, Fig. 2.

**Open-flame Arcs.**—The open type provides positive ventilation to remove the fumes of the arc from the arc inclosure and to prevent their deposit on the inner surface of the enclosing globe. The unrestricted air supply causes a rapid wasting of the electrodes. To obtain a practicable life per trim the electrodes are r

great cross-section. The co-axial arrangement of very  
 previously impracticable; hence the converging arrangement.  
 afford additional advantages through the high current  
 absence of arc travel and low heat loss by conduction. A  
 employed to hold the arc in its proper position below the  
 of this type have a maximum luminous intensity in the  
 and hence must be hung very high to produce uniform illumina-  
 flame arc with converging electrodes has a life per trim of  
 The open type with vertical electrodes has a life per  
 hours, but produces a less steady light than the converging  
 el.

The ventilating system of open-flame arcs requires very careful design. Unless the fumes are positively removed from the inclosing globe, the accumulation of powder on the globe during the life of a single pair of electrodes reduces the light transmitted by as much as 40 per cent.

Lamps of the open type are greatly handicapped by the high cost of maintenance and electrodes.

**Inclosed Flame Arcs.**—The inclosed type of flame arc is provided with a condensing chamber into which the fumes of the arc are carried by convection, as shown in Fig. 3. The gases are thus cooled and freed from their solids without rapid ingress of air. The life of the electrodes is thus prolonged about ten times, giving a life per trim of from 100 to 150 hours. The electrodes used in inclosed flame arcs are less highly mineralized than those used in open arcs and the gain in life is accompanied by some loss in efficiency. The diverging carbon type of flame arc has not been developed in the inclosed type.

Fig. 3. Method of Condensing Gas in Inclosed Flame Arc

**MAGNETITE ARC LAMPS.**—The magnetite arc depends for its production solely on the luminescence of the conducting vapors produced at the cathode. The cathode consists of a thin iron tube closely packed with a fine powdered mixture of magnetite, oxide of titanium and oxide of chromium. The positive electrode is a block of copper of large heat-radiating surface. The magnetite produces an arc of excellent conductivity, but of relatively low luminous spectrum. The titanium oxide enriches the spectrum of the arc, improving its color and efficiency. The oxide of chromium serves to restrain the rapid vaporization of the active elements and so prolong their life. The light is of excellently balanced white color. The copper anode is consumed and requires infrequent replacement. The cathode has a life of from 100 to 250 hours depending on the current and arc length. It is possible to operate the magnetite arc in an inclosure with limited air access, but the need of ventilation to remove the copious brown fumes. The magnetite arc is relatively unsteady, a feature which is aggravated by the intermittent method of feeding.

The two commercial types of magnetite arc lamps differ principally in the electrode arrangement. In the General Electric type the positive is the upper; in the Westinghouse type the negative is the upper. The advantages claimed for each type conflict sharply.

Unlike other types of arc lamps the magnetite arc is poorly adapted to interior use on constant potential circuits. Its field is therefore largely limited to street lighting on constant-current circuits. While the magnetite arc is solely a direct-current device, it is readily adapted to use in connection

Fig. 4. Light Distribution of Magnetic Arc Lamps in Clear Globes

supply by the use of the mercury arc rectifier combined with a transformer; see *Rectifiers*.

per lamp on series circuits is from 75 to 80. The standard is 6.6 amperes. The performance of typical magnetite arcs is shown in Table III and Fig. 4.

#### EFFICIENCY OF POWER OF CARBON AND FLAME ARCS. —

The efficiency of all types of arc lamps falls off gradually during the life of the lamp, due to the accumulation of ash and fumes on the glass. The amount of this loss varies greatly with the conditions. Matthews (*Electricity*, 1901, p. 296) reported tests of inclosed carbon arcs of various types. The results are typical, viz., reduction of light output in 100 hours: high-grade carbons 5 per cent, low-grade carbons 30 per cent. This loss depends chiefly on the purity of the carbons employed. The amount of loss also depends on the scheme of ventilation and the extent to which the lamp is mineralized. Composite results of many tests on inclosed arcs are reported in *Good Lighting*, Vol. 7, p. 515, show a loss in 100 hours of 15 per cent of the initial mean lower hemispherical candlepower. Tests of General Electric inclosed white flame arcs made at the Massachusetts Institute of Technology (*Wright and Sprouts*, 1912) showed the light in 150 hours burning to be 18 per cent. The loss of light in these tests is relatively small, due to the positive character of the maintenance and the importance of very careful cleaning of glassware of arc lamps as is apparent from the above data.

#### DIFFUSING GLOBES. —

The intrinsic brilliancy of all types of arc lamps is high to seriously interfere with good vision when in the open. Diffusing globes reduce the light by from 25 to 40 per cent but generally serve to increase the effectiveness of vision by a factor which fully compensates for the loss of light. Diffusing globes also serve to distribute the light toward greater uniformity at various vertical angles. A uniform side-wise distribution must be attained by a properly designed globe.

#### MECHANISMS FOR CARBON AND FLAME ARCS.

The mechanism of an arc lamp serves the following functions: (1) to start the arc upon lighting, (2) to feed one or both electrodes at the proper rate, and (3) to maintain approximately constant the arc length.

Feeding systems are of two general classes. In the first type the electrode is fed by gravity upon the releasing of a clutch controlled by the lamp. In the second type the electrode is fed by a series of feeding steps are small and frequent the process approaches a continuous feed. In the second type the arc is retracted at each step to maintain a magnetite arc.

**Gravity-feed Mechanism for Multiple Carbon Arcs.**—The most common type of constant-potential lamps are practically all of the gravity-feed type. The most common type has a ballast of resistance or reactance in series with a solenoid and with the arc itself; see Fig. 5. When the arc is not lighted the carbons are in contact. When the switch is closed the solenoid is energized and draws its plunger, tightens the clutch and strikes the arc by drawing the carbons apart. As the arc lengthens the current falls until the forces on the plunger are balanced. As the arc lengthens by burning away, the current tends to fall, releasing the clutch and permitting the carbon to feed until checked by the rising of the plunger. In a well-adjusted lamp this process is practically continuous. In alternating-current mechanisms of this type the plungers are laminated ballast consists of a reactive coil.

Fig. 5. Multiple Carbon Arc Lamp

Fig. 6. Carbon Arc Lamp

**Gravity-feed Mechanism for Series Carbon Arcs.**—The type of mechanism for gravity-feed lamps of the series class employs the differential action of two solenoids to control the feeding clutch. Fig. 6 shows a type of mechanism as applied to the inclosed carbon arc. It provides a solenoid  $S_1$  in series with the arc, a solenoid  $S_2$  and resistance coil in parallel with the arc, and a short-circuiting cut-out. The solenoids act differentially on the clutch. The shunt solenoid when strengthened tends to release the clutch, the series solenoid to lift it.

When the lamp is idle the carbons are normally in contact. When current is switched on, the series solenoid is energized and draws out the arc. The cut-out opens,  $S_2$  is energized and tends to oppose the drawing action of  $S_1$ , equilibrium being attained when the arc has the proper length. As the carbons burn apart  $S_2$  is strengthened and releases the clutch momentarily, allowing the upper carbon to feed by gravity. If the circuit through the arc is accidentally broken,  $S_2$  alone is energized and the cut-out is immediately closed, preventing the interruption of the circuit. Alternating-current mechanisms have laminated plungers, but differ in no essentials from direct-current lamps.

Fig. 7. Mechanism and Circuit of a 4-amp. Arc Lamp

**Intermittent Feed Mechanism.**—The intermittent type of feeding mechanism for series lamps is shown in Fig. 7. When the current is switched on, starting magnets are energized, bring the electrodes together and cause them to strike. As the electrode burns away the arc gradually increases

il the shunt coil is sufficiently energized to momentarily and cause the striking process to be repeated. As the er with considerable force the accumulated slag is broken thode.

**for Flame Arcs.** — The mechanisms of flame arcs with only in details from those of carbon arcs of analogous n that the feeding device is dual and acts on both carbons, e arc at a fixed level. Mechanisms for converging car- a great variety. The most generally-used type for con- on has a series coil whose plunger acts laterally on one he arc and gravity feed. In many cases an escapement shunt solenoid is used to regulate the rate of feed. In of feed is controlled by a metal fin attached to each elec- s fin rests against a refractory lug. The fin is vaporized e arc at a rate exactly corresponding to the required rate

**ARC LAMPS.** — (See also *Rectifiers*.) The luminous ele- mp is a luminescent arc, in a highly evacuated tube of between a mercury cathode and an anode of mercury or ed by it. The voltage required to sustain such an arc, tive electrode) is mercury, consists of a constant drop at 13 volts and an arc stream voltage which is directly pro- a. The arc voltage per inch increases with the vapor or pressures the arc is an unstable conductor and the ills with a rising current. At high pressures, as in the arc voltage rises very rapidly with the current.

actinic radiation from mercury-arc lamps gives them the fields of photography and blue-printing. The large rom quartz-tube lamps not inclosed in glass may be uti- of processes for bleaching, sterilization, etc.

**Mercury-arc Lamps.** — The mercury arc can be sus- tages only when the mercury electrode is the cathode; l in the mercury-arc rectifier (see *Rectifiers*).

y-arc lamp with alternating current the tube is provided are attached to the respective terminals of a reactance

The cathode is attached to the middle point of this e power factor of this type of arrangement, including d the lag produced by the reactance coil, is from 50 to cent types have power factors from 50 to 85 per cent, egulation of the line. In other words, when the line ay great extent, say from 10 to 15 volts from normal, the mp is used. When the line voltage is kept within say er factor lamp can be used as less regulation inductance

**Mercury-arc Lamps.** — The glass-tube type of lamp operates and temperature. Its spectrum is that characteristic of is entirely deficient in red lines and has a great prepon- n and violet.

ic brilliancy of this type of lamp renders diffusing glass- simple color composition tends to enhance the acuity of e the spectrum is perceptibly improved by combining ic reflector coated with rhodamine enamel, which by part of the blue and violet radiation incident upon it to

**Methods of Starting.**—The mercury arc is started either the tube until mercury from the cathodes makes metallic contact with the anode and strikes the arc or by breaking down the gap by a high-voltage spark discharge. As installed for general lighting the mechanism usually is an automatic starter operating on one of the two methods referred to. The tilting mechanism is operated by a solenoid which is cut out as the arc is struck. The spark-discharge device is essentially an automatic quick-break switch which opens the circuit of an induction coil so as to cause it to discharge through the tube. The tube is mounted in an inclined or vertical position. The mercury vapor condenses at the top in a condensing chamber and is returned to the cathode by gravity.

**Performance of Mercury-arc Lamps.**—Performance data for typical lamps of this class are given in Table IV.

TABLE IV.—CANDLE-POWER CHARACTERISTICS OF HEWITT MERCURY VAPOR LAMPS

Lamps for Alternating-current Circuits

Rating of lamp in average watts	Voltage	Type	Length of tube in inches	Mean lower hemispherical c.p.	Watts per mean lower hemispherical c.p.	Total lumens

Quartz Lamps for Direct-current Circuits						
726	200-240	Z	4	2400	0.3	18,839

**Life of Glass Tubes.**—Tubes fail ultimately through vacuum through deterioration of vacuum. The life per tube varies considerably, usually several thousand hours of operation.

**Loss of Candle Power with Age.**—The light output of lamps deteriorates quite rapidly during the early portion of tube life. The data reported by Harrison (*Trans. Ill. Eng. Soc., Vol. 6, p. 545*) give the average value on two type H tubes operated at 3.3 amperes;

Per cent initial candle power...	100	83	80	77	73	70.5	67
Hours burning.....	0	250	500	1000	2000	3000	4000

**Quartz-tube Mercury-arc Lamps.** — The quartz-tube lamp operates at a high temperature and pressure. Its luminescent spectrum is richer than that of the low-pressure lamp and has superposed upon it a continuous spectrum of incandescence including all luminous elements. The light of the high-pressure lamp is therefore much nearer white than that of the low-pressure lamp. On account of the high pressure of the arc in the quartz tube the length required in circuits of commercial voltage is very much less than the length of glass-tube arcs. The quartz-tube lamp emits a considerable amount of invisible ultra-violet radiation which is capable of doing serious injury to the eye. Ample protection is afforded by surrounding the tube by an envelope of clear glass. Quartz tubes are nominally indestructible, but may require occasional repumping.

**COST OF ARC LAMPS (Pre-war prices).** — Open carbon-arc lamps are no longer sold. Magnetite and metallic oxide arc lamps cost from \$23 to \$27. The first cost of flame-arc lamps is from \$33 to \$45. Glass-tube mercury-arc lamps cost complete, including reactance coil, from \$27 to \$35. The renewal cost of short glass tubes is approximately \$9, that of long glass tubes \$12; the average cost per lamp per year will run around \$3 per lamp.

**Annual Costs.** — The following comparative costs of arc-lamp operation under street lighting conditions for a total of 4000 hours (one year, all night service) are given by Friedman (*Elec. World*, Vol. 55, p. 1071).

#### ANNUAL COST OF OPERATING ARC LAMPS

D., *Electric Arc Phenomena*, N. Y.; Numerous papers in annual conventions, reports of *Nat. El. Light Assoc.*, *Trans. Ill. Eng. Soc.* and other technical papers; 1916 Lectures I.E.S.-U.P. *Illuminating Engineering Practice*. See also *Bibliography* in article on *Illumination, Interior*.

**LAMPS, INCANDESCENT ELECTRIC.**—(See also *Illumination, Lamps of; Illumination, Interior; Illumination, Street.*) Incandescence denotes the emission of light by a solid or liquid body due to its temperature elevation. The performance of incandescent bodies is referred to a standard *black body* or one which, at any temperature, emits the maximum possible intensity of radiation at each wave-length of the spectrum. The percentage of luminous radiation from incandescence is low, but increases markedly with the temperature. Hyde computes the luminous radiation from a black body as 1.9 per cent at 2000° C. Abs., 8.8 per cent at 2500° C., 16.9 per cent at 3000° C., 32.5 per cent at 4000° C., 44 per cent at 5000° C. and a maximum of 50 per cent at 6500° C. Certain materials excel the black body in relative light radiation due to *selectivity* or the relative depression of heat radiation as compared with light.

The efficiency of the incandescent lamp depends on: (a) the temperature which its filament can sustain without an undue rate of decay; (b) the degree of selectivity manifested; and (c) the prevention of thermal leakage by conduction and convection. These conditions require a filament of the highest obtainable melting point and lowest vapor tension, which must be supported by a system of low thermal conductivity. So fully are the two latter conditions met that the thermal leakage of modern lamps is less than 5 per cent.

**Electrical and Mechanical Properties of Lamps.**—The specific resistance of the filament material should be relatively high to insure favorable dimensions in units of low power and high voltage. A relatively large positive temperature coefficient of resistance is desirable as this tends to lessen the variations in performance caused by voltage fluctuations. The filament should be of great mechanical strength, especially in its resistance to fracture. The material required should be obtainable in ample quantities, readily workable and uniform in its finished state. Experience indicates that alloys are distinctly inferior to pure metals and metalloids in all essential features.

**Vacuum.**—Incandescent lamps require the highest practicable vacuum for the chemical and thermal protection of the filament. In the manufacture of lamps the first stage of evacuation is mechanically produced. Final exhaustion is produced chemically by burning within the inclosure a small amount of phosphorus compound. During the latter stage the filament is raised to incandescence to drive off residual gases. To prevent the loss of vacuum through the unequal expansion of the glass and the leading-in wires the latter are made of a copper-steel alloy.

**TYPES OF LAMPS.**—There are described in the following paragraphs the types of incandescent lamps which have become of commercial importance. Of the several types the tungsten filament is the most widely used.

**Carbon Lamps.**—Carbon vaporizes at about 3900° C. and exists in a variety of forms which vary greatly in other physical properties. *Base carbon*, prepared as lamp filaments by carbonizing squirted threads of dissolved cellulose, is of low conductivity, high vapor tension and of negative temperature coefficient of resistance. *Graphitic carbon*, which is deposited from hydrocarbon vapors on incandescent filaments of base carbon, has a high conductivity, low vapor tension and a small positive temperature coefficient. *Metallized carbon*, prepared from the two preceding types by heat treatment in an electric furnace, has a greatly increased conductivity, a small positive temperature coefficient, low vapor tension and a fair degree of selectivity. The common carbon lamp has a core of base carbon on which a shell of graphitic carbon has been deposited by the process of flashing. The hot resistance of this type is

approximately half the value cold. The chief advantage of this type is its low cost and great ruggedness.

**Gem Lamps.**—These have filaments of metallized carbon prepared from one or two preceding forms by heat treatment in an electric furnace. Such a filament has a greatly increased conductivity, a pronounced positive temperature coefficient, low vapor tension and a fair degree of selectivity. These features give the gem lamp a higher efficiency and a better color of light than the carbon lamps. The hot resistance of the gem lamp is 2.6 times its value cold.

**Tungsten Lamps.**—Tungsten melts at about 3200 deg. C.; has a low vapor tension, its atomic weight being 184; has a conductivity of 6.2 microhms per cu. cm. at 25° C. for the hard-drawn variety and 5 microhms for the annealed; has a mean temperature coefficient of +0.0051 between 0° and 170° C. and is selective in radiation to a valuable degree. The hot resistance of the filament is from 10.8 to 13 times the cold resistance, depending on the type of lamp. Tungsten is exceedingly hard and is worked with difficulty. Early filaments were produced by sintering finely divided tungsten reduced from tungstic oxide; they were extremely fragile and were uncertain in performance.

Drawn wire filaments superseded the former pressed filaments and revolutionized lamp manufacture, simplifying the processes very considerably and reducing the cost. It is possible to draw filaments exactly to size, which increases the practical efficiency by eliminating weak points and also makes it possible for the first time in lamp manufacture to produce all lamps of a lot for a predetermined voltage. Some early difficulties with erratic blackening of bulbs have been eliminated by the introduction of special chemicals known as "getters" in the bulb. The tungsten lamps made by the principal American manufacturers are commonly known as "Mazda B" lamps.

**Non-Vacuum Tungsten Filament Lamps.**—This type of lamp has a closely coiled helical filament of drawn tungsten wire mounted in a glass chamber filled with nitrogen or other inert gas. The pressure of the gas retards the decay of the filament so that it may be operated with a satisfactory life at a higher temperature than is practicable in a vacuum. The gain in radiant efficiency so obtained is offset in part by the convection of heat from the filament by the gas. When the diameter of the filament is minute there is little or no net gain in efficiency. When the filament is relatively heavy the net efficiency may be doubled. The helical coiling of the filament increases its effective diameter as a radiant and simplifies the problem of its support, for the filament is distinctly soft when incandescent. The gas-filled lamp has an elongated bulb, the upper portion of which serves as a cooling chamber. The walls of this chamber receive the black deposit from the filament, but are so placed that they absorb but little of the useful light. The larger sizes of gas-filled lamps are standard for operation in a pendent position only. If it is desired to operate these at some other angle, they should be ordered for up-right or universal burning, the lamps in such cases being supplied with slightly modified filament supports. Such lamps are much more brilliant than vacuum lamps and should be fully shaded. The light of the gas-filled lamp is decidedly whiter than that of the vacuum tungsten lamp. The gas-filled tungsten filament lamps manufactured by the principal American firms are commercially known as "Mazda C" lamps.

**Use of Various Types of Lamps.**—The following table shows the relative use of the various types of lamps produced for domestic sale in recent years, as secured from various sources. It will be noted that the inefficient types have been rapidly superseded by the more efficient "Mazda" lamps. For 1919, the total sales of incandescent lamps, excluding miniature lamps, amounted, accord-

ing to Schroeder, to 183,000,000 for domestic use, 190,000,000 of these being the tungsten filament type.

RELATIVE USE OF VARIOUS TYPES OF LAMPS

Type of lamp	1907	1910	1913	1916	1919
	per cent	per cent	per cent	per cent	per cent

Mazda.....	0.10	18.47	55.65	83.68	93.0

**TYPES OF BULBS AND FILAMENTS.** — The more common forms of bulbs and filaments are illustrated in Fig. 1. In the bulb designation, suc

Fig. 1. Bulb Classification (Lamps Illustrated  $\frac{1}{8}$  Scale)

as S-19, the letter indicates the type of bulb, and the number the diameter of the bulb in eighths of an inch. "S" indicates a straight side bulb, "G" a round, or globular, bulb, "T" a tubular bulb, and "PS" a pear-shaped bulb.

**Coiled Filaments.** — One of the results of the use of ductile tungsten in the manufacture of Mazda lamps, has been the possibility of winding the tungsten wire around a mandrel, thereby producing a helically coiled filament. The first application of this was the so-called "focus" type of lamp, in which the filament was concentrated into a small space, more or less approximating a point source. In this way the automobile and the locomotive headlight lamps became available, also a more effective stereopticon lamp.

The advantages of the concentrated light source in connection with lenses and reflectors is illustrated in the following table, according to Stickney, which shows the maximum beam candle-power obtained with a 16-in. parabolic

of approximately 100 watts, but with widely varying filaments. In these tests the lamps were focussed so as to give maximum power and operated at 100 mean spherical candle-power.

#### MEAN SPHERICAL CANDLE-POWERS (G. H. Stickney)

Bulb used	Type	Light source dimensions mm.		Beam candle power
		Dia.	Length	
30	C headlight	2.0	6.5	462,000
30	C headlight	5.0	5.0	223,000
25	C stereopticon	6.5	6.5	142,000
30	B stereopticon	8.0	8.0	32,600
25	C regular	25	0.5	12,700
35	B regular	30	68	3,800

The filament, however, is most pronounced in gas-filled

**Lenses.** — Lamps of this type are designed for use with lenses and are employed with stereopticons, small moving picture projectors, and for spotlighting, floodlighting, headlighting, and

**Flashlights.** — This term covers a wide variety of small lamps used for flashlight purposes. Such lamps are usually operated at low voltage and are mounted in small size bases. Important uses of miniature lamps are in Christmas tree ornaments like the Christmas tree and in "flashlights."

**Daylight Lamps.** — For color matching, photography and other special purposes, various colored lamps are available. Colors are obtained either by dipping the bulbs or by the use of colored glass in the envelope. The former is less expensive but the latter is more permanent. A lamp known as "Mazda C-2" or "Daylight" is standard. These are of the same construction, but the filament is operated at a higher voltage to produce whiter light, and a specially determined blue filter is used. The light from these lamps is approximately daylight in color.

**RATINGS AND PERFORMANCE.** — Constant potential lamps are rated in watts and voltage at which they are designed to operate. Constant current lamps are rated by candle-power. Secondary ratings are given in lumens per watt and in lumens per candle-power. From these values the light output in lumens and the mean spherical candle-power can readily be determined. The rating of street-series or constant-current lamps is nominal candle-power per 10 lumens output; thus, an 80 candle-power lamp is a 800 lumen lamp, while a 600 candle-power lamp is a 6000 lumen lamp.

Lamps are made in the following sizes: 75, 100, 150, 200, 250, 300, 350, 400, 450, 500, 550, 600, 650, 700, 750, 800, 850, 900, 950, 1000, 1100, 1200, 1300, 1400, 1500, 1600, 1700, 1800, 1900, 2000, 2100, 2200, 2300, 2400, 2500, 2600, 2700, 2800, 2900, 3000, 3100, 3200, 3300, 3400, 3500, 3600, 3700, 3800, 3900, 4000, 4100, 4200, 4300, 4400, 4500, 4600, 4700, 4800, 4900, 5000, 5100, 5200, 5300, 5400, 5500, 5600, 5700, 5800, 5900, 6000, 6100, 6200, 6300, 6400, 6500, 6600, 6700, 6800, 6900, 7000, 7100, 7200, 7300, 7400, 7500, 7600, 7700, 7800, 7900, 8000, 8100, 8200, 8300, 8400, 8500, 8600, 8700, 8800, 8900, 9000, 9100, 9200, 9300, 9400, 9500, 9600, 9700, 9800, 9900, 10000 lumens. These lamps having the following lumen ratings respectively: 750, 1000, 1500, 2000, 2500, 3000, 3500, 4000, 4500, 5000, 5500, 6000, 6500, 7000, 7500, 8000, 8500, 9000, 9500, 10000 lumens.

lamps had the same distribution of candle-power, thus causing horizontal candle-power to bear practically a fixed relation to spherical candle-power and to the total light output. In re-

Fig. 2.

various forms of filaments are used so that the mean horizontal candle-power is now no longer a representative measure of the light output of the lamp. This feature is illustrated in the following diagram (Fig. 2), of Stickney.

**Performance with Voltage Variations.** — The very high rate of light produced and of filament life with temperature causes modern lamps to be extremely sensitive to variations in voltage. A high temperature coefficient of resistance, as in the tungsten filament lamp, affords partial compensation to voltage variations and increases the stability of the lamp's performance. The relations of candle-power, watts, wattage, and life to voltage are shown for modern types of lamps in Fig. 3. Increasing the voltage increases the candle-power and efficiency, but greatly reduces the life of the lamp. Operating conditions are always a compromise between these conflicting factors. Under ordinary conditions circuit voltage and lamp voltage agree closely. The effect of low voltage on candle-power is marked. For factory service requires that the voltage be maintained within 3% of the rated value for the lamp. The sensitiveness of life to voltage makes the utter futility of life tests with imperfect voltage regulation.

The relations between lamp performance and voltage may be very simply expressed by a series of simple proportions and exponents:

$$\frac{I_1}{I_2} = \left[ \frac{V_1}{V_2} \right]^a; \quad \frac{W_1}{W_2} = \left[ \frac{V_1}{V_2} \right]^b; \quad \frac{E_1}{E_2} = \left[ \frac{V_2}{V_1} \right]^c; \quad \frac{L_1}{L_2} = \left[ \frac{V_1}{V_2} \right]^d$$

where  $V$  = voltage,  $I$  = candle-power,  $W$  = watts,  $E$  = watts per candle-power.

The values of the exponents in the above expressions, as determined by the Nat. El. Lamp Assoc., are as follows:

	a	b	c	d
Carbon.....	5.55	2.05	3.51	20.5
Gem.....	4.80	1.75	3.06	17.6
Tungsten.....	3.68	1.50	2.10	13.8

These exponents apply to variations within a moderately limited range and it should be kept in mind that an extreme variation in voltage would not follow the same law.

Fig. 2. Characteristic Curves of Incandescent Electric Lamps

**Life Performance.**—The rated life of incandescent lamps applies to the average of a very large number and not to individual performance. All lamps deteriorate with continued burning in candle-power, efficiency and strength. This decay is partly due to the slow vaporization of the filament and partly to

growing light absorption in a black deposit on the inner side of the bulb. The frosting of bulbs, while not accelerating filament decay, hastens the decline of candle-power and efficiency due to the added absorption by the bulb deposit of internally reflected light and the greater tendency of the lamp to accumulate exterior dirt. The effect of bowl frosting is practically negligible. The life curves of Fig. 4 are typical of present-day lamps.

**Effect of Frequency.** — Incandescent lamps operated by alternating current of low frequency produce a flickering light due to cyclic variations of temperature. The flicker is greatest in filaments of small diameter and low thermal capacity, and increases in magnitude as the frequency is reduced. 110-volt carbon lamps of low efficiency have been successfully used with a frequency of 25 cycles. Tungsten street series lamps are satisfactory at 25 cycles. On account of the low heat capacity of slender filaments, 110-volt Mazda lamps of 25 watts or less and 220-volt lamps of 60 Watts or less, show perceptible flicker on 25 cycle circuits. Lamps made for higher amperage avoid this effect. See reference in *Bibliography* at the end of this article.

Fig. 4. Life Curves of Typical Incandescent Lamps

#### COST OF LIGHT BY INCANDESCENT LAMPS (Pre-war figures). —

The main factors in the cost of light are the renewals of lamps and the cost of energy. Minor factors are the labor of inspection, the cost of renewals and the interest on investment in lamps and fixtures. The longer the lamp remains in service the less is the renewal cost chargeable to each lumen-hour and the greater the energy cost. Operating the lamp at better efficiency increases the renewal cost and reduces the energy cost per lumen-hour; at poorer efficiency the reverse is true.

The most economical voltage at which to operate a lamp which is rated at a definite voltage  $V$  is  $RV$ , where  $R$  is a factor which is a function of the ratio of the cost of energy per kilowatt-hour to the cost of renewing the lamp. This factor  $R$  may be calculated from the following formula,

$$R = \sqrt[0.25]{\frac{0.000208 E I D_e L}{D_r}}$$

$$= 0.139 \sqrt[0.25]{\frac{E I D_e L}{D_r}}$$

in which

- $E$  = watts per candle at rated voltage,
- $I$  = candle-power at rated voltage,
- $D_e$  = cost of energy per kilowatt-hour in dollars,
- $D_r$  = cost of lamp renewal in dollars,
- $L$  = life of lamp in hours at rated voltage.

**DIFFUSERS FOR INCANDESCENT LAMPS.** — Diffusers soften light and reduce its brilliancy by the increase in the area of its apparent source. This is at the expense of considerable absorption (see table on *Absorption of*

in article on Illumination, Laws of). The chief diffusing glass, produced by sand-blasting or acid etching; translucent glasses, such as alabaster, opaline, opal, milk, etc., which has finely-divided mineral oxides; and prismatic glass. These coated bulbs, globes and bowl reflectors partially covering emission from ground glass is inferior to that from other media, is partially visible as a bright spot in high contrast to the opaline and alabaster transmit a subdued image of the filament-considerable portion of the light very effectively. Opal and diffusing, but may be highly absorbing if the glass is very developments have enabled glass manufacturers to blow this which is a combination that gives excellent diffusion with low tatic globes transmit by refraction innumerable images of the filament distributed over the entire surface of the globe. by the diffusion is imperfect, but to averted vision the effect refracting prisms enable the light distribution to be modified erable range. Other diffusing globes tend to equalize light tions.

partially and to produce artistic effects. The chief reflect-  
shined metal, silvered glass, prismatic glass, opal glass, enam-

elled metal and aluminum paint. Polished metals, silvered glass and prismatic glass afford a wide latitude in the distribution of light, depending on the contour and depth of the bowl. Diffusely-reflecting surfaces afford less range of control and are not capable of producing strong downward concentration. Prismatic and opal glass reflectors transmit a moderate amount of diffused light and afford some direct illumination for surfaces not receiving the directed beams from the unit. Practically all reflectors are designed for mounting at a definite position with reference to the luminous center of the filament and produce their normal distribution only in this position. The table below gives data on the mean performance of representative groups of reflectors for incandescent lamps.

The curves shown in Fig. 5 indicate the distribution of light from various forms of equipment when used with Mazda C lamps, according to G. H. Stickney

**LIGHTING PLANTS.** — (See also *Distribution and Transmission Systems; Illumination, Interior; Illumination, Street; Lamps, Arc; Lamps, Incandescent; Power Stations; Substations.*) Electric lighting systems divide broadly into two classes, viz., series or constant-current, and parallel or constant-potential. The former system is appropriate where a large number of similar lamps in scattered locations are to be controlled simultaneously and where a high voltage can be safely applied to the circuit, as in street lighting. The parallel system is extremely flexible, is adapted only to low voltages and permits the independent control of single lamps and groups.

More recently there has been a tendency in street lighting to adopt a scheme possessing characteristics of both the series and the constant-potential systems. These combination systems have been termed "constant-potential series" systems by Dr. Steinmetz in their relation to street lighting distribution problems.

**LOAD CONDITIONS.** — The load of a lighting plant varies greatly with the season and with the hours of the day. There is usually a sharply-defined

peak load in the early evening which reaches its annual maximum in mid-winter. Storms attended by darkness often give rise to sudden and heavy increases of load. Such conditions demand generating equipment of great flexibility in operation. Sufficient generating capacity must be available to carry the maximum peak load and to provide an ample reserve against accidents. The brief duration of the peak load in many plants makes desirable the selection of types of equipment having large temporary overload capacity in order to decrease the reserve needed. Typical load curves are shown in Figs. 1 and 2.

**Load Factor and Diversity Factor.** —

(See also *Standardisation Rules of the A.I.E.E.*) The load factor of a machine, plant or system is the ratio of the average power to the maximum power during a certain period of time. The diversity factor is the ratio of the sum of the maximum power demands of the subdivisions of any system or part of a system

Fig. 1. Load Curves of Lighting Plants

to the maximum demand of the whole system or the part of the system under consideration, measured at the point of supply. The investment in a lighting system is largely determined by the peak load to be provided for. The annual charges on this investment are practically independent of the output; hence the investment expense per kilowatt-hour varies in nearly inverse ratio to the annual load factor. The average annual load factors of lighting installations, of various types, as given by E. W. Lloyd (*Nat. El. Li. Assoc., 1900, Vol. 2, p. 586*) range from 5 to 29 per cent, with the general average of complete systems less than 20 per cent. The economic advantages of high load factor can be secured in lighting service only by combining it with loads having non-coincident peaks, as commercial power and railway systems. Fig. 2 shows typical load curves and load factors for a typical winter and a typical summer day of (a) a city system of lighting and power, (b) a city street and elevated railway system and (c) the combined load of (a) and (b) (*Trans. A.I.E.E., 1912, Vol. 11, p. 230.*) The advantage of the diversity factor of these loads is apparent.

In a general sense an appropriate scale of charges for electric energy should be graded according to the degree, to which the load contributes to the system's peak as well as according to the energy consumed. Off-peak loads may appropriately receive low rates. The gain in load factor from diversity often makes it possible for a lighting station to sell energy at wholesale to a railroad system at a cost less than that at which the latter system could generate it independently.

Diversity factors exist between the various subdivisions of a lighting system and have an important influence on the rated capacity and investment required in the several elements of a system. H. B. Gear (*Trans. A.I.E.E., 1910, Vol. 29, p. 375*) reports the diversity factors of various classes of service and branches of the system of the Commonwealth Edison Company of Chicago to be:

#### DIVERSITY FACTORS OF A LIGHTING SYSTEM

Subdivision of the System	Residence lighting	Commercial power	Scattered power	Large users
Substation to feeders.....	1.15	1.15	1.15	1.15
Feeders to transformers.....	1.6	1.25	2.0	1.25
Transformers to meters.....	3.0	1.6	1.1	1.0
Total diversity factor.....	6.20	2.30	2.53	1.44

Fig. 2. Load Curves of Composite System on Winter Day. Daily Load Factor: Light and Power 53.8%, Electric Railways, 53.6%, Combined Load 56.3%, Diversity Factor, 1.658

Although these data are ten years old, they represent present conditions quite accurately. For a rediscussion of the question, see an article by H. B. Gear on "Increasing Demand Factor of Residence Consumers" on page 9 of the *Electrical World* for July 6, 1918.

**DIRECT- VS. ALTERNATING-CURRENT SYSTEMS.** — (See also *Distribution and Transmission Systems*.) Direct current has the following advantages for lighting: (1) safety, since the lines are in no way associated with high-voltage conductors; (2) freedom from power factor, reactance and skin effect, which results in superior voltage regulation in heavily loaded low-voltage circuits; (3) the direct availability of the storage battery as a reserve and a load regulator; (4) the self-exciting and self-regulating features of direct-current generators; (5) the superiority of direct-current motors for adjustable speed service and for the operation of elevators and cranes; and (6) the marked superiority of direct-current arc lamps. Direct current is generally used in isolated plants and in congested city districts because of the greater ease with which good voltage regulation is maintained.

The advantages of alternating current are chiefly those incidental to its flexibility of voltage transformation and control, which makes possible an extended range of economical transmission and the independent regulation of separate feeders and lines. Alternating-current generators are less expensive than direct-current machines, being free from commutator limitations and adaptable to much higher speeds.

**Voltage.** — The range of voltage from 100 to 125 is standard for electric lighting in America. In England and to some extent on the continent the 200- to 250-volt range has been extensively used. The higher range lends itself to more economical distribution of power, the lower range to the superior construction of incandescent and arc lamps. The Edison 3-wire system of distribution is largely used in direct-current systems. The voltage generated for alternating-current systems is usually the same as that used for primary distribution when the latter is below 15,000 volts, although steam turbo-alternators are often provided with raising compensators having a ratio of 1 to 2 when the line voltage supplied is in the range from 6000 to 15,000. In most systems of small and medium capacity the a-c. line voltage is 2300. The secondary distribution system is supplied by transformers and is usually at 110 to 115 volts between lines.

Small self-contained lighting outfits for train-lighting and similar service where a storage battery is used for regulating purposes are usually designed for a voltage range from 25 to 35 or from 50 to 65, and use lamps of the train-lighting and compensator type. See also *Lighting of Trains by Electricity*.

**Phases.** — The polyphase system affords distinct advantages in the first cost and voltage regulation of both generating equipment and lines. Primary distribution in all modern a-c. systems is either 2-phase or 3-phase, the latter predominating largely. Secondary distribution from transformers is either single-phase, 2-wire or 3-wire; 2-phase, 3-wire or 4-wire; or 3-phase, 3-wire or 4-wire. 6-phase connections are used only as a link between high voltage systems and synchronous converters. See also *Converters, Synchronous; Transformers*.

**Frequency.** — The standard lighting frequency in America is 60 cycles, and that in Europe 50 cycles. A frequency of 25 cycles has many advantages for overhead transmission and for conversion to direct current by synchronous converters. Power transmitted at 25 cycles is frequently converted to 60 cycles for lighting purposes by the use of frequency changing motor generators. In a few cases where a large load of induction motors is associated with a lighting system the compromise frequency of 40 cycles is employed.

performance of electric lamps for interior lighting is not on 25 cycles, due to flicker in the light, certain incandescents have been operated with a fair degree of satisfaction. It is obvious that a higher frequency for interior lighting is

3. — (See also *Gas Engines; Steam Engines; Steam Turbines*.) Prime movers for lighting plants should provide approximately constant angular velocity during each revolution. The turbine has a great advantage over the reciprocating engine due to its lower first cost and superior operating economy. Other advantages due to lighter foundations, smaller space requirements, ease of attendance, and lower cost of maintenance. The turbine engine is preferred for the driving of direct-current generators at its more appropriate speed.

Gas engines surpass steam power in thermal efficiency, but have a higher first cost and small range of overload capacity. The cost of steam power may be large when the cost of coal is high, but where a supply of natural or by-product gas is available at low cost the cost of the system is unusually good. Internal combustion engines are successfully used with steam units in plants furnishing both steam and electricity where a supply of exhaust steam has large value. The turbine engine involves a high investment and heavy maintenance. It is an excellent type of motive power where oil is a cheap fuel. Gas from a public source of supply and gasoline engines are used in very small lighting plants to operate internal combustion engines. Gas engines are relatively expensive fuels, but may afford a saving in producing plant on the premises. Gas-engines in lighting plants should be controlled by close-regulating governors and should be supplied with a considerable inertia.

Turbine types are well adapted to the driving of lighting generators and should be provided with close-regulating governors.

4. — Steam prime movers are capable of carrying overloads of 50 per cent or more whereas gas engines and turbines are limited in this respect. A large overload capacity enables the plant to carry reserve equipment for emergencies. Current practice is to design boiler or gas producer capacity to carry the average load and resort is had to forcing during peaks of short duration. A large number of modern stations of medium capacity provide a reserve of 50 per cent for each kilowatt of generating capacity.

5. — (See also *separate articles on Generators*.) Direct-current generators are compound-wound and are operated at the voltage of the system. A heavy direct current can usually be more economically generated by direct generation than by direct generation. It is an economic necessity when the direct-current load is more than 50 per cent of the station. Edison 3-wire systems may be supplied by direct-current generators in series, by special 3-wire generators or by alternating-current generators operated in conjunction with voltage balancing sets. Direct-current generators are chosen for low cost and good efficiency. Direct-current generators are usually provided with individual shafts, but large alternators are supplied with exciting systems comprising several exciters in parallel.

6. — Direct-current generators are now practically obsolete. Power for direct-current is most economically obtained from constant-potential a-c. generators through constant-current transformers. Direct current for

series circuits is obtained by operating the mercury arc rectifier in the secondary circuit of the constant-current transformer.

**DISTRIBUTION.** — (See also *Distribution and Transmission*) Distribution systems are designed with a view to the greatest possible of service and the closest regulation of voltage consistent with reasonment. The 3-wire system is standard for local d-c. service. An inter network of mains is used in extensive 3-wire systems and is fed at main feeders from stations or substations. Alternating current is distributed in 110 volts or more, 3-phase, to transformers, from which secondary distribution is made to consumers by 2-wire and 3-wire systems. To obtain good voltage regulation on polyphase systems it is necessary to maintain a close balance.

**SUBSTATIONS.** — (See also *Substations, Lighting*.) Substations are used for the following purposes: (a) to receive alternating current from high-voltage transmission lines or feeders and reduce it in voltage for local distribution; (b) to convert alternating current from feeders into direct current for adjacent territory; (c) to convert alternating current received from high-voltage transmission lines to 25 cycles to 60 cycles for distribution by local lighting circuits; (d) to convert alternating current from constant potential sources to constant current direct or alternating, for the supply of arc lighting circuits; (e) to hold up batteries used as load regulators or reserves on d-c. systems; and (f) to act as feeder regulators for the control of voltage on lighting circuits. Conversion of direct current is accomplished either by motor-generator sets or by synchronous converters. Motor-generator sets may be either of the synchronous or induction type and are usually operated without step-down transformers. Synchronous converters are usually 3-phase or 6-phase and are always operated with voltage-lowering transformers. Converters may be of the split-pole, the synchronous booster type or the compound type to provide automatic control of d-c. voltage, or may be operated in conjunction with voltage regulators similar to those used on a-c. feeders.

**Motor Generators versus Synchronous Converters.** — (See also *Generators; Converters, Synchronous*.) Motor-generator equipment is expensive and less efficient than converter equipment, but occupies less space, affords more synchronous condenser capacity for power factor correction, and is more reliable in its operation, especially at an a-c. frequency of 25 cycles. Synchronous converters are used almost exclusively for 25-cycle service and are gaining in use at 60 cycles. Each converter is usually supplied with its own bank of lowering transformers. Converters of larger capacity than 1000 kw. are usually operated 6-phase. Converters supplying 3-wire d-c. service are adjusted to give from 220 to 250 volts, d-c., and the neutral wire is connected to the neutral connection of the transformers.

**Storage Batteries.** — (See also *articles on Batteries, Storage*.) Storage batteries are extensively used in stations and substations as a reserve source in case of failure of the primary source of direct current. It is difficult to operate a battery as a load regulator on constant-voltage systems, especially by a step-down connection. A booster or end-cell arrangement is required to compensate for the sloping volt-ampere characteristic. The substation battery commonly consists of the bus bars fully charged and assumes the load if the voltage of the bus bars falls a certain amount. The battery falls in voltage as its discharge proceeds, and additional cells must be added in series to sustain the line voltage. A cell switch for this purpose may be either hand-operated or automatic; if automatic, it is controlled by a relay switch operated by a solenoid connected to the main bus bars.

\* This comparison is on the basis of converter and transformer versus motor-generator set without transformers.

**EQUIPMENT.**—(See also *Switchgear Equipment for Power protectors.*) As lighting systems are required to render practical service the protective appliances are intended to disconnect circuits only in extreme emergencies and then only those in generators and exciters are not as a rule provided with auto-circuit breakers. Radial feeders and transmission lines have circuit breakers with extreme overloads, often with inverse time elements. Circuit breakers operated in parallel at both ends are provided with interlocking to open the circuit breakers at both ends in case of trouble, to avoid disturbance of other circuits.

**REGULATION.**— Aside from the condition in which the system is installed and maintained, the quality of lighting service is almost entirely dependent on the continuity of service and close regulation of voltage. The standards require that the variation of voltage at the lamps shall not exceed 5 per cent on either side of the mean. Service with less than 3.5 per cent variation may be considered fair and with more than 5 per cent de-

viations the voltage at the loads may be obtained fairly constant by means of regulators properly over-compounded. A much more sensitive regulation is afforded by the Tirrill regulator (see *Regulators*), which compensates for all but the most transient voltage fluctuations of the system. Synchronous converters have fixed ratios of voltage conversion, and are used to provide approximately constant voltage at load centers as discussed in the paragraph on *Substations*. A plan of voltage regulation is used in 3-wire networks is to provide in the station or substation bus bars differing somewhat in voltage. All feeders terminate at the bus bars, by which they may be connected with either set of bus bars. The more heavily loaded feeders are connected to the higher voltage bus, the lower bus, with the result of nearly uniform voltage at the load centers of the network of mains.

Three methods are employed in a-c. systems: (1) to regulate the voltage by hand or by Tirrill regulators to constant voltage or to constant voltage in proportion to the load; (2) to provide not only approximate regulation but to equip each outgoing line with feeder regulators of the Tirrill type, to be automatically controlled if desired, so that the voltage at the load centers to supply approximately constant voltage at its center of gravity. This method is the more flexible and economical for extensive distances where each feeder is independently regulated and may be provided with a separate voltage regulator with regard to economy rather than inherent voltage regulation. Synchronous regulators are preferred for close control if the loads are not too heavy.

For voltage regulation at load centers voltmeters should be provided at the load centers to indicate conditions at these centers. The voltmeters are connected to the feeders at the distributing centers by small wires. The voltmeters at the feeders at the station through compensators which allow for the drop in the feeders. When a power load of low power factor is connected to a d-c. lighting system, voltage regulation and economy may be assisted by the use of the synchronous condenser to correct the power factor; see *Converters, Synchronous*.

Articles on this subject will be found in *Trans. A.I.E.E.* and in the trade papers. See also *Bibliography* in articles

**LIGHTING OF TRAINS BY ELECTRICITY.** — Electricity is used almost exclusively by the railroads of the United States for the lighting of trains.

At the present time there are over 20,000 cars lighted by electricity. The gas cars are being converted to electricity as quickly as conditions permit.

**Systems Used.** — The following systems are used for the purpose of lighting:

- a. Axle Generator System.
- b. Head End System.
- c. Straight Storage System.

**Axle Generator System.** — This method of lighting is the most common. The principal parts of the axle generator system are:

(1) *An axle generator* mounted either on the truck or under the car body and driven by means of a belt from a pulley on the truck axle.

The generator is usually wound for 40 volts and delivers current to a lead storage battery through suitable regulating devices. The capacity of the generators vary from 1 kw. to 4 kw., depending upon the service required. A 1 kw. machine is found to be of sufficient capacity for a baggage car. A 2 kw. machine is required for a baggage car and a 2 kw. machine while the additional load on a passenger coach often requires a generator of 4 kw. capacity.

(2) *A storage battery*, usually of 16 cells, of from 100 to 300 ampere-hour capacity.

The battery is installed in a suitable ventilated box hung under the car. The amount of charge is regulated by an automatic device mounted on a control panel inside the car. When the car reaches a predetermined point the automatic switch cuts in and connects the generator to the battery. The battery automatically disconnects the generator from the battery when the current drops below a predetermined limit.

(3) *A regulator panel* on which are mounted the apparatus controlling the output of the generator and a lamp regulator which holds a constant current through the lamps.

(4) *A drive* which consists of a belt connecting properly proportioned pulleys on the generator and on the car axle.

The development of a suitable shaft drive is at present occupying the attention of axle generator manufacturers. This would obviate the use of belts and eliminate one of the sources of trouble especially in winter weather.

(5) *A suspension.* — The former general practice of suspending the generator from the truck is being rapidly superseded by the body suspension.

By mounting the generator under the car body a much lighter form of suspension can be used. The machine is also better protected from shock on the track, crossing switches, etc., than when mounted on the truck.

**Head End System.** — The so-called Head End Systems may be divided into three classes, viz.:

- a. A Straight Generator System.
- b. A Steam Generator Set with Batteries.
- c. An Axle Driven Generator Set with Batteries.

(a) *The straight generator system* consists of a direct connected generator usually installed in a baggage car next to the locomotive, steam being supplied through a reducing valve at 90 pounds pressure. Current is furnished at 40 volts. A loop system of wiring is used in order to give uniform lighting. This system is applicable only when trains run solid between terminals.

of this system is that the train is without light as soon as disconnected, or the set becomes inoperative.

*Generator set with storage batteries* is used to good advantage on long and solid trains.

of the turbo generator type—80 volt and a capacity of

to have three or four cars in the train each equipped with a 24 hour battery. The batteries ensure the lighting of all cars at all times.

*Generator set with batteries* has a generator mounted in the car, driven by means of a chain drive through the car floor from

100 volts, 20 kw. capacity. The battery equipment and other accessories are generally used in the axle generator system.

**System.**—This is the most simple method of lighting by

each car with one or two sets of 16 cell storage batteries suspended in the car and arranged for convenient charging at terminal yards.

requires elaborate charging facilities at terminals where it is used. The cars and either hold them long enough to give the battery a full charge or to have spare batteries fully charged to replace the discharged ones.

This system appears inexpensive to operate. However, when the maintenance charges, together with fixed charges of the charging plant are taken into account, perhaps the most expensive method of lighting cars.

Considerable study has been given to car illumination in recent years. When cars were first lighted electrically no shades were used to protect the eyes from the glare of the lamp filament from the eye. Now great attention is given to protect against objectionable glare and give as far as possible uniform illumination on the reading plane.

Attention is also given upon the style of fixtures employed, and their location in the car, ranging from 15 to 100 watts. The Mazda B type of lamp is used

Types in use are:

End and head end systems.....	60-64 volt
Intermediate system.....	30-32 volt

Great improvements in the manufacture of lamps since the early 1900s have made possible the use of Mazda lamps for car lighting. The old type carbon filament operated at 100 watts per candle power has been replaced by Mazda lamps which operate at approximately 1 watt per candle power.

In ordinary lighting three standard types of fixtures are used: semi-indirect, and indirect. Fixtures are in some cases mounted on the center deck while in other cases side deck mounting is used.

The U. S. Department of the U. S. Government after many exhaustive tests and specification for the lighting of railway mail cars. This has determined the location of light units, limits for illuminating values, and requirements, etc.

From an operating standpoint the axle generator system is more desirable than the battery system. A car so equipped may be operated on any division of track without the need of charging facilities at the division terminal points or train line junctions. It may also be cut out of one train at a junction

point for connection to another train without special arrangements to supply light from an outside source.

**COSTS.** — The approximate first costs of the various sizes of equipments are shown below together with the approximate average costs. In this connection it should be noted that the costs given are (1921) figures and may be subject to considerable modification due to changes in local and market conditions.

**First Costs:**

Type of car	Kw. rating of generator	First cost including
Baggage	1	\$900
Coach	2	1200
Diner	4	1900

**Maintenance Costs:**

Type of car	Per 1000 miles	Per car per year
Average	\$4.00-\$5.00	\$17.00

The above figures do not include interest or depreciation on investment in equipment or maintenance facilities.

**LIGHTNING PROTECTORS: GROUND WIRES, ARRESTERS, CHOKE COILS.** — (See also *Distribution Lines; Ground Connections; Power Stations; Substations; Switch Gear Equipment for Power Stations; Transmission Lines.*) Abnormal rises of voltage in transmission and distribution circuits may be set up either by lightning discharges or by electrical oscillations caused by switching loads on and off the lines. The latter type of disturbances have been called "internal lightning." High-frequency oscillations are usually of small power and are generally called "statics." The term "surge" is used for any kind of oscillation.

A "ground wire" is a grounded wire which is run above and parallel to the main wires of an aerial line. A "lightning arrester" is any device shunted between wires or from wire to ground, which device under normal voltage permits practically no current to flow, but which becomes a fairly good conductor, usually by the formation of an arc, when the voltage rises a given amount above normal. A "choke coil" is a coil of wire of comparatively low resistance and small inductance, which is placed in series with the line. The coil has a very small impedance to normal line frequencies, but a high impedance to high-frequency oscillations.

**GROUND WIRES.** — A line completely inclosed in a grounded metallic sheath, as, for example, a lead-covered cable, is completely protected from induced electrostatic charges (see *Electricity and Magnetism, Principles of*). The ground wire used over aerial transmission lines acts as a partial screen and is one of the best means of protecting aerial lines against lightning. The protection is not perfect, however, since the wire forms only a partial screen.

Where systems operate with a thoroughly grounded neutral this neutral wire can form the overhead grounded conductor, and the system becomes practically a three-phase four-wire system allowing the use of single-phase transformers of 58 per cent normal line voltage to be connected between any phase wire and the neutral. See articles on *Distribution Circuits; Transmission Lines.*

**LIGHTNING ARRESTERS.** — A lightning arrester consists essentially of a spark gap so set that excess voltage will cause the gap to arc over, allowing the charge due to this voltage to pass to ground. There is combined with the gap some means of suppressing the power arc which follows and which tends to continue after the abnormal voltage has ceased.

An ideal lightning arrester should take no current at the ordinary operating potential, but at any potential much higher than ordinary there should pass enough current to limit the abnormal potential to some fixed value. When the abnormal potential ceases the arrester should stop taking current from the line. The closer an arrester approaches these ideal conditions the better the arrester.

This arrester shown consists essentially of two horn gaps in series with a resistance to ground. One side of one of the horn gaps is made up into the form of a triangular choke coil and the sharp bend in this coil increases the tendency of the lightning to jump across the first air gap rather than to pass around the choke coil and thence to the apparatus to be protected. For 70,000 volt ser-

Fig. 1. Horn-gap Arrester

vice there is an air gap of approximately two inches between the horn formed by the choke coil and the intermediate horn, and a further air gap of approximately five inches between the intermediate horn and the horn connecting through the resistors to the ground. For lower voltages the intermediate horn is omitted and the distance between the knees of the horn depends largely upon the voltage between line and ground, and has been based principally on actual test. It varies between about  $\frac{1}{2}$  inch to  $\frac{3}{4}$  inch for 2200 volts to about  $6\frac{1}{2}$  to 10 inches for 110,000 volts.

The resistor in the ground circuit can be made either in the form of a resistance rod or in the form of a water resistor, the latter being the type usually employed in Europe. These water resistors usually are made of earthenware tubes containing a mixture of about 70 per cent glycerin and 30 per cent water, and the resistance is usually selected to allow approximately 1 ampere to flow to ground at the time of a lightning discharge.

The operation of the horn gap is based on the fact that a short-circuit once started at the base travels upward due to the heated gases and to the force exerted on the arc by the magnetic field of the current until the arc is ruptured by attenuation. On circuits of high voltage this rupture sometimes takes a second or two, but seems to act with but little disturbance of the line. The angle between the horizontal and the straight portion of the knee ranges from 55 to 60 degrees. The curvature of the knee should have a radius of from 3 to 5 inches.

**Multipath Arresters** have been developed for a-c. and d-c. service for voltages not exceeding 1000 by the use of a carborundum block fastened between two terminal plates, thus allowing the static discharge to spread itself over a number of minute discharge paths. The normal voltage between the line and the ground is divided into so many minute gaps that the voltage across each gap is too small to maintain an arc after the discharge has passed.

**Nonarcing Arresters** (Fig. 2) based on the discovery of "nonarcing metal" by Mr. A. J. Wurts, formed the first successful high-voltage arresters. The peculiar property of this metal is that an alternating current will not maintain an arc between adjacent cylinders of the metal provided the voltage is not too high and that the power current which follows the lightning discharge does not vaporize too much of the metal. The first condition is met by having a fairly large number of very small gaps in series, and the second condition gives no trouble where the amount of power current is comparatively small as was the case on the early high-voltage installations. For large amounts of power it becomes necessary to use resistors in series with the spark gaps to limit the current, and these resistors reduce the effectiveness of the arresters. For very high voltages different schemes are used to reduce the number of gaps required. It has been found that by shunting a certain number of these gaps by a non-inductive resistor the effectiveness of the arrester is increased.

Fig. 2 shows an arrester of this design intended for service on 6600-volt lines where the capacity does not exceed 2000 kv-a. The nonarcing cylinders are

Fig. 2. Nonarcing Lightning Arrester

in insulators in such a way that there is an air gap of adjacent cylinders in each one of the four sets of seven. The slab forming the base of the arrester also has mounted resistance rods shunting some of the gaps. Modifications used for the "low equivalent," "multigap," "multiphase" gap" arresters that were installed before the electrolytic came out and are still giving good satisfaction in many plants as high as 88,000 volts.

Arresters (Fig. 3) have been found after experimental research and experience of many years to be the best suited for high voltages in actual service. See also *Power Stations, Hydroelectric*.

The arrester consists essentially of a series of nested aluminum trays filled with electrolyte, arranged and supported in a steel tank. Fig. 3 and 4 show a cross-section of the steel tank. The electrolyte forms an insulating film on the trays. The film is broken down by a small current at abnormal voltage, and the resistance of the film is reduced to a capacity per current to frequency, but the current to frequency. Thus the arrester is both high frequency. The mica covering and prevents the electrolyte. The film is sufficient due to a long life. The heating of the elements, these are provided with insulation to protect from the

Fig. 3. Electrolytic Arrester

film on the trays it is necessary periodically to charge the arrester by closing the gaps and permitting current to flow into the gap. The gap is so arranged that it not only acts as a convenient disconnecting switch for the arrester, but also serves as a disconnecting switch by opening the gaps.

In general types of gaps in use, the horn or sphere gap is used at high voltages, and the horn or sphere gap when used at lower voltages.

diameter, discharge high frequency surges at values nearly the same cycle discharge value of a plain horn.

The most improved gap known to the art at this time is the improved sphere gap. This gap in addition to the advantages of the sphere gaps, selects the frequency surges and discharges them at voltages of about 0.6 of the cycle discharge value of the gap. This property is obtained by an arrangement of resistors and condensers. In the commercial form the condensers take the form of line insulators.

Owing to the use of the liquid electrolyte, the necessity for periodic cleaning and the comparatively high price of the aluminum cell electrolytic other types of arrester such as the oxide film have been developed. The film arrester depends for its functioning on the fact that certain dry compounds such as lead peroxide can be readily changed from a very good conductor to an almost perfect nonconductor (litharge) by the application of a degree of heat, such as would be caused by the passage of a lightning discharge.

**CHOKE COILS** (Fig. 4) are an important element in the protection of circuits against static disturbances, in addition to the lightning arrester.

The inductance of the choke coil acts as a reflector to high-frequency waves and prevents the potential to which the leads of the generator or transformer coil are subjected from undergoing excessive or abrupt changes. As at the operating frequency the value of volts per turn in a choke coil is very small, a surge may cause a spark to pass momentarily between turns but no arc will be formed. This is not usually true of a generator or transformer. Although extra insulation for the end turns of generators and transformers is desirable, it cannot entirely take the place of choke coils but permits the use of coils of a smaller choking power.

Fig. 4 shows a type of choke coil built in normal capacities up to 1000 farads and in voltage ratings up to 132,000 volts. Modifications of this type can be supplied for heavier currents and for higher voltages. They are made of copper or aluminum rod in the form of a cylinder 6 inches or 15 inches in diameter wound into about 20 turns. These are supported on insulators, or for suspension in the line circuits and are suitable for indoor or for outdoor service.

**INSTALLATION OF ARRESTERS** is dependent on their design. The electrolytic type is usually arranged for outdoor service, as is the sphere gap type. The other types are usually mounted indoors and are connected to the circuit at the point where the lines pass from the building. Nearly all types of arresters can be furnished for outdoor service, if desired.

**Ground Connection.** — (See also article on *Ground Connections*.) The most important feature of a lightning-arrester installation is the satisfactory ground connection to enable the static electricity to pass into the earth. With a poor ground connection the value of lightning surges is greatly reduced.

Fig. 2 shows an arrester where the capacity due

Fig. 4. Choke Coil

A common method of securing a ground connection is to solder or rivet the ground wire to a large tinned copper plate which is buried in several layers of crushed coke or charcoal in permanently damp earth. Wrought-iron pipes driven deep into the moist earth will also make a good ground. In hydraulic plants the ground should include a connection to the penstock or some other portion of the piping system.

**SPECIFICATION FOR LIGHTNING ARRESTERS.** — (See also article on Specifications.) As the services to which lightning arresters are subjected are not capable of reproduction for testing purposes, lightning arresters cannot be specified in terms of performance. Hence it is necessary for the engineer to specify the type and essential features of construction after an examination of the various types. When calling for proposals, the following details should be stated: station or out-of-door service, voltage and frequency of circuit; details as to where arresters are to be located.

**DIMENSIONS, WEIGHTS AND COSTS** vary so much for the different voltages, class of service, whether grounded or ungrounded neutral, indoors or outdoors, that it is impossible to tabulate this information in the limited space available.

Lightning protection in a power house is almost independent of its capacity but depends on the voltage and number of feeders to be protected. A 200 ampere, 2300 volt, 3 phase feeder would require lightning protection costing about \$12, while a 200 ampere, 110,000 volt feeder would require lightning protection costing about \$5700.

**LOCOMOTIVES, ELECTRIC.** — (See also *Cars, Electric; Collectors, Current; Locomotives, Steam; Railways, Energy Requirements and Motor Capacity* for.) For many years a new type of electric locomotive was designed for nearly every new proposition. However, with the very numerous applications of electric locomotives of from 30 to 50 tons weight for slow freight and switching service on interurban roads and in terminals, the double-truck bogie type finally demonstrated its superior fitness and came to be adopted almost universally in America for all work involving speeds less than 45 m.p.h. For higher speeds special provision must be made for guiding the locomotive around curves by the addition of guiding trucks or axles, for placing as much of the weight of the motors as possible on springs and for raising the center of gravity to a reasonable height (five feet or over). With a low center of gravity every side-wise movement of the mass of the locomotive strikes a blow side-wise on the track, but with a high center of gravity a side swaying is transformed into a downward thrust on the track. As the track is not usually designed to withstand great side thrusts it is better to avoid a low center of gravity in high-speed locomotives.

The coefficient of adhesion for electric locomotives has usual and safe values of from 18 to 22 per cent. It is higher for electric than for steam locomotives on account of the uniform torque of the electric motor. With clean dry rails the coefficient for electric locomotives may be as high as from 30 to 40 per cent.

**CLASSIFICATION.** — Locomotives are usually classified by the arrangement of their wheels and the subdivision of the wheels into driving wheels and guiding wheels. A series of numerals is used, each numeral representing a group of wheels of one form usually on one truck. Thus 4-4-0 designates a locomotive having four wheels on a guiding truck, four driving wheels connected and no trailing wheels or truck. This is the common "American" type of steam passenger locomotive. An ordinary double-truck four-motor freight locomotive or motor car would be designated as 4-0-4. (See also *Locomotives, Steam*.)

**TYPES OF MOTORS.** — Locomotives are built with various types of motors and operate from various systems of electrical distribution, e. g.,

a. *Direct-current Motors* at 600, 1200, 1500 or 2400 volts; for the higher voltages two motors are operated in series.

b. *Single-phase Motors* for 250 volts and 15 or 25 cycles, connected to the secondary of a transformer which receives its power from a 6000- or 11,000-volt trolley line.

c. *Three-phase Induction Motors* operating at about 500 volts supplied by the secondary of a transformer whose primary is connected to a 6000- or 11,000-volt three-phase trolley.

**CONTROL SYSTEMS.** — The control of all modern electric locomotives is by the multiple-unit system (q.v.), as the currents required are too large or the voltage too high for a drum control (q.v.). The possibility of one motorman operating and controlling two or three locomotive units at the same time is also advantageous.

**TYPES OF ELECTRIC LOCOMOTIVES.** — The simplest form of electric locomotive is a box car with a motor geared to each of the four axles on two bogie trucks. Such a locomotive would be geared for a very low speed and hence high tractive effort. To prevent slipping of the wheels the car would be weighted down with ballast or a load of freight.

The most common type of electric locomotive consists of a cab and framing carried on two heavy four-wheel trucks, each axle carrying a geared motor. Extra strength is provided in the cab framing to transmit the tractive effort of

the motors to the couplers. The complete locomotive may weigh from 30 to 50 tons and is equipped with motors having an aggregate capacity of approximately 500 horse-power. It will haul trains of about 20 cars, weighing about 500 tons, at speeds from 20 to 30 miles per hour. The usual tractive effort at the one-hour rating of the motors is from 10,000 to 15,000 lb. Such locomotives are well adapted for switching purposes in terminal freight yards and for hauling freight trains on interurban electric railways.

**Detroit River Tunnel Locomotives.** — A further development of this type of locomotive is exemplified in the large locomotive used for pusher and grade service in the Detroit River Tunnel of the Michigan Central R.R. and other similar installations. Each of these locomotives weighs from 100 to 120 tons, all on drivers, and consists of two four-wheel trucks carrying geared motors of from 300 to 500 horse-power each. The two trucks are coupled together by a pin or hinge which causes them to guide each other. This is called the "Articulated" type. The cab, containing all the control and auxiliary apparatus, is mounted on the trucks. The Detroit River Tunnel locomotives operate on 600 volts d-c. Locomotives of this type are now in operation also on 2400 volts d-c. and on 6000 volts three-phase a-c. They are limited in speed to about 40 miles per hr. on account of their lack of guiding trucks.

**New York Central R.R. Locomotives.** — The locomotives constructed in 1910 have a leading and a trailing two-axle guiding truck and in the middle four driving axles with gearless motors. The armature of each motor is mounted directly on the driving axle and the bi-polar field of the motor forms a part of the mechanical frame work of the locomotive. The magnetic flux passes through all four motors in series and returns by the side frames. The motors are wound for 600 volts d-c. and have very large air gaps to allow for the play between the armature and the field as the wheels pass over irregularities in the tracks. The field structure is spring borne but the armatures are not.

The locomotives constructed in 1913 consist of two sections articulated, with two two-axle trucks on each section. One truck on each section is rigid and the other is a bogie or guiding truck. Every axle carries a motor and all wheels are of the same size. The single cab is carried on a king pin on each section.

**New Haven R.R. Locomotives.** — The type of electric locomotive adopted by the N. Y., N. H., & H. R.R. in 1911 has four gearless single-phase series motors, the armatures being mounted on quills concentric with the driving axles and driving the wheels by means of springs. The locomotive has two trucks, each having four large driving wheels and two smaller guiding wheels. The motors are designed to operate at from 250 to 300 volts either a-c. or d-c., two in series on the line for d-c. and on the secondary of a transformer for a-c. The line voltage is 11,000 at 25 cycles.

**Pennsylvania R.R. Locomotives.** — The locomotives of the Pennsylvania R.R. consist of two similar units coupled back to back. Each unit has a two-axle guiding truck and has two driving axles rigid with the body frame. There is one large motor per unit, mounted in the cab and driving the wheels by means of an inclined connecting rod from the motor to a jack shaft and horizontal side rods from the jack shaft to the drivers. The connecting rods on opposite sides are placed at right angles to avoid dead centers.

**Chicago, Milwaukee & St. Paul Locomotives.** — The freight locomotives delivered in 1916 (see table) consist of two similar units coupled together, each unit having a leading bogie truck of idle axles for guiding, and two four-wheel trucks with all axles driving. A motor is geared to each of the four driving axles of each unit. The motors are designed to operate with 1500 volts d-c. and 10 motors are permanently connected in series for 3000 volts, the line

\* One hour rating.

potential. Special arrangements are provided for regenerative braking on downgrades by using the main motors as separately excited generators. The passenger locomotives of that date are similar except as to gear ratio. In 1920 two new types of passenger locomotives were installed, one using gearless motors like the New York Central and the other using twin motors geared to each driving axle (see *Bibliography*).

**SPECIFICATION FOR ELECTRIC LOCOMOTIVE.**—The following memoranda are intended to assist in writing specifications. See also article on *Specifications*.

On important high-speed systems it is usual for the design of the locomotive to be worked out by the purchaser and manufacturer working in collaboration, and in such cases, the design is usually specified in detail. In other cases, it is more usual to specify the operating characteristics and leave the design to the manufacturer. The following memoranda are to assist in the preparation of a specification of the latter type.

**General Description of Service.**—Whether for direct- or alternating-current, single-phase or three-phase, freight or passenger hauling, overhead trolley or third rail. Line voltage, etc.

**Specific Details of Work to be Performed by Locomotive.**—Weight of cars loaded and empty. Maximum train weight. Average train weight. Time to make typical run of stated length. Number and duration of stops in typical run. Ton miles per day per locomotive. Maximum speed on level with average load. Maximum speed on maximum grade with maximum load. Acceleration (miles per hour per second), with maximum load. Hours per day in regular service. Amount of time in shifting and yard service.

**Profile and Plan of Line.**—Grades and curves.

**Clearances and Limiting Dimensions.**—Gauge of track, clearance diagram of right-of-way. Maximum and minimum height of trolley wire or third-rail location. Height of coupler. Wheels, tread and flange (M.C.B. or special). Weight of rail. Minimum radius of curve. Wheel diameter. Maximum permissible weight per running foot of right-of-way.

**Operating Characteristics.**—Absence of nosing or lateral swing. Absence of rail pounding. Temperature-rise limitations. Efficiency.

**Control.**—See specifications under *Control Systems for Railway Motors*.

**Motors.**—See specifications in articles on *Motors*.

**Air Brake.**—Straight, automatic or combined. General characteristics.

**COST, WEIGHT AND DIMENSIONS.**—Electric locomotives cost about \$800 per ton weight, which is considerably more than steam locomotives, but they are cheaper to operate and maintain as they can make more mileage per day. It costs, roughly, between 5 and 10 cents per locomotive mile to operate electric locomotives.

The characteristics of the most prominent types of electric locomotives are given in the table, page 938.

**BIBLIOGRAPHY.**—Anon., *Electric Locomotives for C. M. & St. P. Ry.*, E. R. J., 1916, Vol. 48, p. 888; Burch, E. P., *Electric Traction for Railway Trains*, N. Y., 1911; *Locomotive Dictionary*, A.R.M.M.A., N. Y. 1906; Carter, F. W., *The Electric Locomotive*, Proc I.C.E., 1916, Vol. 201-2, p. 221; Murray, W. S., *Maintenance of New Haven Locomotives*, Trans. A.I.E.E., Jan. and Nov., 1907; New York R. R. Club, *Symposium on Electric Locomotives*, E. R. J., 1918, Vol. 51, p. 556-564; Reagan, H. C., *Locomotives, Simple, Compound and Electric*, New York.

**LOCOMOTIVES, STEAM.** — (*See also Locomotives, Electric; Railways, Energy Requirements and Motor Capacity for.*) Locomotives are classified broadly by the number of truck and driving wheels. Each arrangement of wheels has a definite name, but the various wheel arrangements are so numerous that the "Whyte classification" has come into extensive use.

**Whyte Classification.** — According to this scheme of classification three numbers are used; the first indicates the total number of leading or truck wheels in front of the drivers, the second indicates the total number of drivers, and the third indicates the total number of wheels behind the drivers and under the locomotive proper. Tender wheels are not included. This classification may be extended, by the use of more than three numbers, to cover engines of the articulated, or Mallet, type. The classification and names of some of the more important types are given in the table on the next page, the weights being in short tons. The tabular values are for comparatively recent engines of the largest size. Each type of engine has been made in a wide variety of sizes, ranging mainly downwards from the given weights to approximately half these values for standard gauge track, and much lower for narrow gauge or industrial tracks. The weight of the tender loaded ranges approximately from 60 to 100 per cent of the weight of the engine.

**DESIGN AND PERFORMANCE.** — A steam locomotive is essentially a moving power plant and as such it must transport its fuel and water with it. Its limitations as to size and weight are determined by roadway clearances, the curves upon which it must run, and the strength of the track supporting it.

Locomotive engines may be either simple or compound, but compound locomotives are not as extensively used now as formerly, except in the case of the articulated types.

The load upon a driving axle is generally limited to 30 tons, but this weight has been exceeded in a number of recent engines of large size.

**Maximum Power.** — The limit of power of a steam locomotive is measured by the size and steam-producing capacity of its boiler (*see Boilers*). Owing to the necessarily small grate area, coal must be burned very rapidly under an induced draft. The rate of combustion is quite commonly as high as 100 pounds and sometimes exceeds 200 pounds per square foot of grate area per hour. The use of brick arches and superheaters largely increases the power, adding from 30 to 40 per cent in some cases. On account of difficulties of lubrication, wear of valves, etc., piston valves must be used with superheaters. The use of superheaters is practically universal in modern high-powered engines.

The maximum horse-power which can be exerted by a steam locomotive is in some cases 4000, although this is unusual; from 2000 to 2500 is a fairer maximum figure for ordinary cases. The largest tenders have a capacity of 20,000 gallons of water and 20 tons of coal.

**Tractive Effort.** — The tractive effort of a single-expansion steam locomotive at slow speed is computed from the following formula:

$$\text{Tractive effort} = \frac{P \times D^2 \times S}{d}$$

where  $P$  = mean effective pressure in cylinders, in lbs. per sq. in. (usually taken as 0.85 of boiler pressure),

$D$  = diameter of the piston, in inches,

$S$  = stroke, in inches,

$d$  = diameter of driving wheels, in inches.

**Tonnage Rating.**—By the tonnage rating of a locomotive is commonly meant the weight, in tons, of the train which it can pull, exclusive of the weight of the locomotive, but including the weight of the tender. Short tons (2000 lb.) are used. Let:

$F$  = maximum tractive effort, usually taken as the tractive effort corresponding to a mean effective pressure equal to 0.85 of boiler pressure,

$G$  = maximum grade, per cent.

$L$  = weight of locomotive, in tons,

$R$  = locomotive resistance, lbs. per ton,

$r$  = train resistance, lbs. per ton,

$T$  = "tonnage rating," i.e., weight behind locomotive.

Then

$$T = \frac{F - (R + 20G)L}{r + 20G}$$

See article on *Railways, Energy Requirements and Motor Capacity for*, for values of  $r$  and  $R$ . On heavy grades this value of the tonnage rating will be limited by the ability of the fireman to keep up full steam pressure. This difficulty has been very satisfactorily overcome in recent years by equipping the engines with mechanical stokers.

Empty or partially loaded cars have a larger resistance per ton than fully loaded cars. With all empty cars on a straight track the capacity of an engine may be reduced as much as 47 per cent on a level stretch, 15 per cent on a 1 per cent grade, and 8.6 per cent on a 2 per cent grade. The corresponding figures with half loading would be 18, 4, and 2.3 per cent.

According to an extended series of experiments reported in a paper read before the American Society of Civil Engineers in December, 1902, by Mr. A. C. Dennis, freight train resistance is practically constant between 7 and 35 miles per hour, and may be regarded as made up of two parts—the dead load tonnage (cars) multiplied by the normal grade and curve resistance in pounds per ton plus 8.9, and the live load tonnage (freight) multiplied by the normal grade and curve resistance in pounds per ton plus 2.6, for any degree of loading. This is equivalent to regarding one ton of dead load as having a greater resistance than one ton of live load, with a variable ratio depending on grade and curvature. It is often convenient to consider the combined value of the live load and the product of the dead load by this ratio. This result is known as the tonnage rating of the train, with the understanding that a rating ton is a live load ton or its equivalent in the above sense.

The tonnage rating of a locomotive when used in connection with the above method of computation means its capacity in rating tons under the proposed conditions, a quantity which changes with grade and curvature, but remains constant under any condition of loading. The locomotive and tender are considered as dead load tonnage in computing their tractive resistance.

**Reduction of Tonnage Rating in Stormy Weather.**—Weather conditions also affect the steam locomotive's capacity. The worst condition is cold weather with a heavy wind at right angles to the track. This side wind always makes engines steam badly and increases flange friction against the rails. It is a common cause of delays.

Tonnage ratings are reduced a variable amount under severe weather conditions. Some roads have fixed rules and some have not. The maximum reduction, taken from a table published in Bulletin No. 59 of the University of Illinois Engineering Experiment Station, is 30 per cent for temperatures around 15 degrees below zero. On lines having heavy grades the grade resistance is

such a large proportion of the total work to be done that the train resistance becomes a very small factor. Consequently the tonnage ratings for roads having very heavy grades are practically the same for all seasons and weather conditions.

**Unbalanced Forces.**—The necessity of partially balancing the heavy reciprocating parts by weights located on the wheels produces unbalanced vertical forces which are hard on roadbed and bridges.

**Center of Gravity and Stability.**—The boiler is necessarily placed almost wholly above the wheels and the center of gravity of the whole engine is therefore a considerable distance above the rails. Careful tests have shown this to be a positive advantage so far as ease of maintenance of track is concerned. By proper elevation of outer rails on curves, the overturning tendency of the centrifugal force may be wholly or sufficiently neutralized. This overturning tendency is much less than most engineers suppose. It is safe to state that it is impossible to *overturn* a locomotive at any practicable speed upon any ordinary curve by the action of centrifugal force unless the conditions are such (as in a cross-over, for instance) as to set up a rolling or oscillatory motion of the engine about its longitudinal axis. Generally speaking, the tender is the part of the train most likely to leave the rails. This is due to its varying and shifting load of coal and water.

**Typical Large Locomotives.**—The locomotives listed on the following page are typical of modern locomotive development. The information for the first three engines was kindly furnished by the Baldwin Locomotive Works, and for the last two was obtained from Bulletin No. 7 of the Locomotive Superheater Company. The first two engines were built by the Baldwin Company, the Pacific type for the Lehigh Valley Railroad, and the Mountain type for the A. T. and S. F. Railway. The Consolidation engine is now under construction by the Baldwin Company for the Western Maryland Railway, and is a very large engine for this type. The fourth engine is the heavy Mikado and the fifth the heavy Santa Fe of the United States Railroad Administration Standard Locomotives. All five engines are equipped with superheaters, piston valves and Walschaert valve gear. The first engine burns a mixture of hard and soft coal while the remaining four are soft coal burners. In computing the tractive effort of these engines the mean effective pressure is taken as 0.85 of boiler pressure. The total effective heating surface is taken as the total boiler heating surface plus 1.5 times the superheater heating surface.

**OPERATION OF STEAM LOCOMOTIVES.**—Below are given some of the more important facts in regard to steam locomotive operation.

**Location of Coal and Water Stations.**—Coal and water stations for replenishing the tender are required at intervals, depending upon the topography of the line and volume of traffic. On fairly level roads coaling stations are required at intervals of 50 or 60 miles for freight engines and 120 miles for passenger engines. Water stations are needed at about 50-mile intervals for passenger and 25-mile intervals for freight service. These distances may be much reduced on heavy grades. The location of water stations is also a matter of available water supply. Where possible water should be taken at regular stops.

**Fuel and Water Consumption.**—This is very variable depending upon topography and alignment of road, kind of service, frequency of stops, whether single or double track, climatic conditions, weight of trains, etc. The number of pounds of coal burned per locomotive mile averages about 104 for passenger, 208 for freight, 150 for mixed, 108 for switching and 150 for all types of service. The actual water evaporated varies from 4.5 to 6.5 lbs. per pound of coal burned. The first figure is for a coal consumption of 200 lbs. and the last for 65 lbs. per sq. ft. of grate per hour.

## TYPICAL STEAM LOCOMOTIVES

The United States oil is used for fuel on account of the results in a greater expense for upkeep of boilers on heat, but in the far west and southwest is economical

**Kinds of Coal.** — Exhaust nozzles and draft appliances any one of various kinds of coal, and arrangements should be made for the kind of coal for which the engine is "drafted," as other kinds are less efficient and consequently at what is probably a higher cost though the cost per ton of the improper coal is less.

Whenever a locomotive is standing idle under steam, coal is wasted during this idle time should be reduced to a minimum by avoiding idling while before an engine is needed, and by keeping trains moving on the road. Roads having traffic largely of one kind can be made more particular than those having a mixed traffic composed of many kinds.

The friction in a locomotive is large, ranging from about 20 per cent of the power of the engine to a maximum of 50 per cent or more in the case of passenger service. Probably 35 per cent is a fair average. An appreciable economy can be instituted by increasing the draft allowed for an engine. Most motive power officials are in favor of this respect. Generally oil consumption is kept at a minimum, and is used to overcome the resulting friction. The proper draft is the ratio of oil to coal that the total expense for the two

boilers must be blown off and washed out at intervals depending on the amount of water used.

**Figures.** — The first cost of a steam locomotive is from 60 to 70 per cent of weight, including tender.

The cost of maintenance and repairs ranges from \$2000 to \$3000 per year, an average figure being \$2600.

The life of a locomotive is about 20 years; hence in addition to the cost of maintenance and repairs an annual depreciation of 5 per cent of the first cost should be allowed against the locomotive. In addition, an interest charge on the first cost should be included.

The following are as follows, the figures being for ordinary mixed service on moderate grades:

Coal	10.6 cents per loco.-mile
Oil	18.9 cents per loco.-mile
Water	0.3 cent per loco.-mile
Electricity	0.5 cent per loco.-mile
Depreciation	11.3 cents per loco.-mile
Maintenance and repairs	41.6 cents per loco.-mile

The cost of operation of a locomotive, including wages of conductor and fireman, is \$50 per day, on the basis of 100 miles being a day's work. The total cost of a locomotive costing initially \$20,000 and covering the above expenses per day would then be roughly:

Initial cost	\$10,000
Depreciation	2,600
Maintenance and repairs	1,000
Interest	1,000
<hr/>	<hr/>
Total	\$14,600

**LOGARITHMS.** — The logarithm of a number  $A$ , to a given base  $b$ , is the power  $n$  to which that base  $b$  must be raised in order to equal the number  $A$ . Thus, if  $b^n = A$ , then  $n$  is the logarithm of  $A$  to the base  $b$ , which may be written  $n = \log_b A$ . From this definition the following properties are readily deduced, where  $A$  and  $B$  are any two numbers.

$$\log AB = \log A + \log B.$$

$$\log \frac{A}{B} = \log A - \log B.$$

$$\log A^n = n \log A.$$

**Characteristic and Mantissa.** — These three equations hold irrespective of what is chosen as the base of the logarithms, provided the same base is used for each logarithm. In the common or Brigg's system of logarithms the number 10 is chosen as the base. In such a system the logarithm of any number may be expressed directly in terms of the logarithm of a number (including decimal fractions as numbers) between 1 and 10. For example:

$$\begin{aligned} \log_{10} 376.42 &= \log (100 \times 3.7642) \\ &= \log 100 + \log 3.7642 \\ &= 2 + \log 3.7642, \end{aligned}$$

since the power to which 10 must be raised to give 100 is 2. Similarly,  $\log_{10} 3764.2 = 3 + \log 3.7642$ . The logarithms of all numbers between 1 and 10 are less than unity. The whole number or integer part of a logarithm is called its "characteristic" and the fractional part its "mantissa." The characteristic of the logarithm of a number less than unity is negative. For example:

$$\begin{aligned} \log 0.037642 &= \log \left( \frac{1}{100} \times 3.7642 \right) \\ &= \log 1 - \log 100 + \log 3.7642 \\ &= -2 + \log 3.7642. \end{aligned}$$

In general, the characteristic of a number greater than unity is positive and is one less than the number of figures to the left of the decimal, while the characteristic of a number less than unity is negative and is one greater than the number of ciphers between the decimal and the first significant figure. A table of logarithms gives the mantissas only, the characteristics being determined by the above rule. Such a table is given below.

**Antilogarithms.** — If  $n = \log A$ , then  $A$  is the number whose logarithm is  $n$ . This may be written symbolically

$$A = \log^{-1} n.$$

$A$  is then called the antilogarithm or inverse logarithm of  $n$ . The antilogarithm of a number (i.e., the number which has the given number for its logarithm) is found from a table of logarithms by finding the number in the margin corresponding to the decimal point of the given number in the table, and fixing the decimal point by the rule given above. Example:

$$\log^{-1} 1.6464 = 44.3.$$

**Use of Logarithms.** — Logarithms are used in the processes of multiplication, division, raising to powers and taking roots. For example, to find the product of two numbers take from the table the logarithms of the two numbers,

add these logarithms, and then from the table find the number of which this is the logarithm. The position of the decimal point is fixed by the value of the mantissa in the sum of the two logarithms. By adding a whole number to a mantissa and subtracting the same number from the characteristic the mantissa of the final result can always be kept positive.

**Examples.** — Multiply 376.2 by 0.587:

$$\begin{array}{r} \log 376.2 = 2 + .57541 \\ \log 0.587 = -1 + .76863 \end{array}$$

$$\text{Adding gives } 1 + 1.34404 = 2.34404.$$

therefore  $376.2 \times 0.587 = 220.8$ .

Divide 37.62 by 587:

$$\begin{array}{r} \log 37.62 = 1 + .57541 = 1.57541 \\ \log 587 = 2 + .76863 = 2.76863 \end{array}$$

$$\text{Subtracting gives } -1 + .80678$$

therefore  $\frac{37.62}{587} = 0.06409$ .

**NATURAL LOGARITHMS.** — (*See also Roots and Powers.*) The base of the so-called natural system of logarithms is the value of the expression  $\left(1 + \frac{1}{n}\right)^n$  when  $n$  is taken equal to infinity. The numerical value of this expression is found by expanding  $\left(1 + \frac{1}{n}\right)^n$  by the binomial theorem (*see Series*), and is equal to 2.718282 +. This number is usually represented by the symbol  $e$ , that is,

$$e = 2.718282 +, \text{ or } 2.718 \text{ approximately.}$$

Logarithms to this base are readily calculated by means of Taylor's series (*see Series*); also this number  $e$  enters in a very simple manner into various mathematical and physical relations (*see Equations, Differential; Transient Electric Phenomena; Hyperbolic Functions; Trigonometric Functions*).

The relation between a logarithm of any number  $A$  to any base  $b$  and the logarithm of  $A$  to any other base  $a$  is

$$\log_b A = \frac{\log_a A}{\log_a b}.$$

Hence  $\log_e A = 2.30259 \log_{10} A$ .

From this last relation the natural logarithm of any number may be found directly from the table of common logarithms.

**Example.** —

$$\log_e 376.2 = 2.3026 \times 2.57541 = 5.930.$$

The natural logarithm may also be taken directly from the table of exponential functions (q.v.), remembering that  $\log_e A$  is the number in the margin of the table corresponding to the number equal to  $A$  in the columns of the table.

The symbol "ln" is frequently used for the natural logarithm and the symbol "log" without a subscript is usually employed as an abbreviation for the logarithm to the base 10.

**LUBRICANTS AND LUBRICATION.** — (See also *Bearings; Friction.*)

Ordinary lubricants may be classified as follows:

**Vegetable Oils.** — Commonly employed vegetable oils are linseed, cottonseed, rape and castor. Vegetable oils decompose at comparatively low temperatures. They are used chiefly for compounding with mineral oils.

**Animal Fats.** — Animal fats ordinarily employed for lubrication are tallow, seal's-foot, lard, sperm, wool grease and fish oil. Like vegetable oils they decompose at comparatively low temperatures and are used chiefly for compounding with mineral oils.

**Mineral Oils.** — These are all petroleum products, and form the whole or the greater part of most of the lubricants employed.

**Solid Lubricants.** — Dry graphite, soapstone and mica are sometimes used as lubricants for slow-speed work when the bearing surface is restricted in area and the load to be carried is very large.

**"Deflocculated" Graphites.** — In 1906 E. G. Acheson discovered a process of producing a fine, pure, unctuous graphite, which when heated with a solution of tannin would remain suspended in water for months. The graphite thus suspended in water, known as "aquedag" has been successfully used as a lubricant (*Trans. A.I.E.E., 1907*). Acheson's "deflocculated" graphite, as the graphite in the finely divided form is called, has also been suspended in oil, the oil emulsion being known as "oildag," making an excellent lubricant.

**Greases.** — Compounds of oils and fats containing sufficient soap to form a more or less solid mass at ordinary temperatures are called greases. Lime soda or lead soaps are used in these compounds. For very high pressures graphite, soapstone and mica are sometimes added to the grease.

**QUALIFICATIONS OF A GOOD LUBRICANT.** — The generally accepted conditions of a good lubricant are as follows:

1. "Body" (i.e., viscosity) enough to prevent the surfaces to which it is applied from coming in contact with each other.
2. Freedom from corrosive acid, of either mineral or animal origin.
3. As fluid as possible consistent with sufficient "body."
4. Low coefficient of friction (as determined in a standard bearing).
5. High "flash" and burning points.
6. Freedom from all materials liable to produce oxidation or "gumming."

The examinations to be made to verify the above are both chemical and mechanical, and are usually arranged in the following order:

1. Identification of the oil, whether a simple mineral oil, or animal oil, or a mixture.
2. Density.
3. Viscosity.
4. Flash point.
5. Burning point.
6. Acidity.
7. Coefficient of friction.
8. Cold test.

**Test for Fats.** — Heat a small quantity of the oil in a small test tube 15 minutes with small pieces of metallic sodium or caustic potash. If fatty oil is present, a soapy mass will form at the top. (*Gebhardt.*)

**Test for Tarry Matter.** — Dissolve a small quantity of the oil in from 10 to 20 times its bulk of gasoline; tar and other insoluble matter will be precipitated. (*Gebhardt.*)

**Specific Gravity.** — This is usually made with a hydrometer, graduated according to the Baumé scale. At 60° F.

$$\text{Specific gravity} = \frac{140}{130 + \text{degrees Baumé}}$$

**Viscosity.** — Viscosity, or internal friction, is usually determined by observing the time required for a given amount of oil to flow through a standard orifice. By "specific viscosity" is meant the ratio of the time for the oil to run out to that required for an equal volume of water at 60° F. The temperature of the oil should always be observed and stated. Engine oils are usually tested for viscosity at 70° F. and cylinder oils at 212° F. (*Gebhardt.*)

**Flash Point.** — The flash point is determined by heating a sample of oil in a cup at the rate of 15° F. per minute until a spark will ignite the vapor; the corresponding temperature is the flash point. The flash point as thus determined depends to some extent upon the surface exposed, the size of the spark, the distance between spark and surface of oil and the dimensions of the cup. (*Gebhardt.*)

**Burning Point or Fire Test.** — By continuing the application of heat and noting the temperature at which the oil itself takes fire and continues to burn, the burning point is determined.

**Acidity.** — The presence of free acid is determined by shaking up equal quantities of oil and water and testing with litmus paper.

**Cold Test.** — The cold test is the temperature at which the oil will just flow.

**Friction Test.** — The coefficient of friction as determined from friction-testing machines gives but little information concerning the action of the oil under the widely different conditions found in practice. (*Gebhardt.*)

**Properties of Vegetable and Animal Oils.** — The following data are taken from *Gebhardt's Steam Power Plant Engineering.*

Kind of oil	Specific gravity		Flash test, ° F.
	Water as 1.00	Baumé	
Lard.....	0.9175	23	305
Sperm.....	0.8815	29	478
Tallow.....	0.9080	24.5	540
Cottonseed.....	0.9210	22	518
Linseed.....	0.9299	19	505
Castor.....	0.9639	15	...
Palm.....	0.9046	25	405
Rape-seed.....	0.9155	23	...

Properties of mineral oils as compounded for ordinary use are given below.

**Grease Lubricants.** — Tests made on an Olsen lubricant testing machine at Cornell University are reported in *Power*, Nov. 9, 1909. It was found that some of the commercial greases stood much higher pressures than the oils tested, and that the coefficients of friction at moderate loads were often as low as those of the oils. The journal of the testing machine was 3¼ inches diameter, 3¼ inches long, and the habbitt bearing shoe had a projected area of 5.8 square inches. The speed was 240 revolutions per minute and each test lasted one hour, except when the bearing showed overheating. The following are the coefficients of friction obtained in the tests:

## RELATIVE VALUES OF FRICTION COEFFICIENT WITH GREASES AND OILS

Lb. per sq. in.	Mineral grease	Animal grease	Graphite grease	Mineral grease	Engine oil	Engine oil	Grease	Grease
86.2	0.024	0.023	0.04	0.023	0.019	0.015	0.020	0.025
172.4	0.021	0.023	0.05	0.018	0.04	0.022	0.015	0.022
258.6	0.021	0.023	....	0.018	0.06	0.037	0.014	0.020
344.8	0.035	0.025	....	0.019	....	....	0.017	0.020
431.0	0.050	0.035	....	0.028	....	....	0.026	0.019

**APPLICATIONS OF VARIOUS TYPES OF LUBRICANTS.** — The type of lubricant to use in any case depends upon:

1. The cost due to consumption of lubricant.
2. The saving in annual cost due to lessening of wear of bearings, guides and other rubbing surfaces.
3. The cost of the energy saved (as the result of decreased friction losses) due to the use of the lubricant.

For minimum annual cost the sum of the last two items should equal the first. Estimates of this kind are difficult to make, and the result is that the kind of lubricant used in any specific case is usually determined by experience.

The following table, from a paper in *Power*, December, 1905, p. 750, gives the kind of lubricant ordinarily employed for various purposes, together with their approximate characteristics. The cold test of all these oils, except oil for refrigerating machinery, is given as 30° F. Refrigerating-machinery oil should not solidify above 0° F.

**METHODS OF LUBRICATION.** — The commonest type of "lubricator" on engines or dynamos is the simple oil cup with sides of glass, so that the level of the oil in the cup can be seen. Any type of lubricator in which the flow of oil can be seen is known as a "sight feed." The flow of oil is regulated by a needle valve in the base of the cup.

**Lubrication of Crossheads, Crank Pins, etc.** — In applying oil to rubbing surfaces, both of which are in motion, various devices are used by means of which the oil cup can be kept at rest. A stationary oil cup may be used with a "wiper" on the moving member, or a "telescopic," "pendulum" or "centrifugal" oiler may be employed. Sometimes the crank, connecting rod and crossheads are inclosed in a casing the bottom of which is filled with oil so that at each revolution the end of the connecting rod splashes oil over all the parts.

**Oil Rings and Chains.** — The bearings of small high-speed engines and dynamos are frequently provided with rings or chains running loosely over the journal and dipping into an oil bath in the pedestal below the bearing. The rotation of the journal gives enough motion to the rings to enable them to carry up sufficient oil from the bath to keep the bearing surfaces bathed in oil.

**Cylinder Lubrication.** — The oil must be forced into steam cylinders against the steam pressure. This is usually accomplished by means of specially constructed cylinder cups, hydrostatic lubricators or force pumps. A brief description of the more common forms of these devices will be found in Gebhardt's *Steam Power Plant Engineering*.

## APPLICATIONS AND CHARACTERISTICS OF VARIOUS OILS

Kind of oil and application	Specific gravity, Baumé	Flash test, ° F.	Fire test, ° F.	Viscosity at 70° F. (Water = 1)
<i>High-pressure cylinder oils:</i> For cylinders using dry steam at from 110 to 210 lb.	25-24.5	600-610	645-660	175-205
<i>General cylinder oil:</i> For cylinders using dry steam at from 75 to 100 lb. Also for air compressor cylinders when the oil is made from steam-refined mineral stock and has a viscosity of 200.	26-25.5	550-585	600-630	180-190
<i>Wet cylinder oil*</i> For cylinders using moist steam, especially in compound- and triple-expansion engines.	25.8-25.3	560-585	600-630	150-185
<i>Gas-engine cylinder oil</i> †	26.5	320	350	300
<i>Automobile gas-engine oil</i> ‡	29.5	430	485	195
<i>Heavy engine and machinery oils:</i> For heavy slides and bearings, shafting and horizontal surfaces.	30.5-29.5	400	440-450	170-195
<i>General engine and machinery oils:</i> For high-speed dynamos and other comparatively heavy machines.	30.8-30	400-420	450-470	175-190
<i>Fine and light machine oils:</i> For fine work, such as printing presses, sewing machines, typewriters, spindles, etc.	32.5-30.2	400	440	110-160
<i>Cutting oils:</i> For cutting tools, screws, etc.	27-23	410-420	475-480	210-175
<i>Refrigerating machine oil</i> §	30.2	200	225	165
<i>Wet service and marine oils</i> ¶	28	430	475	230
<i>Greases:</i> Various kinds, used in special work requiring high pressures and low velocities.	.....	.....	.....	.....

\* May contain not over 2 to 6 per cent of refined acidless tallow oil in the high-pressure oils and not over 6 to 12 per cent in the low-pressure oils.

† Neutral mineral oil compounded with soap. The soap will not decompose at high heat, and although not a lubricant serves as a vehicle for carrying some oil.

‡ Owing to lack of body this oil will not deposit carbon on the sparking points.

§ May contain 30 to 40 per cent of pure strained lard oil.

**Oil-feed Systems.**—In power plants oil is supplied continuously to the bearing surfaces of the various engines and generators by means of an oil-feed system, comprising essentially a supply tank, pump and the necessary piping. Oil filters and purifiers are also used in connection with the oiling system, to eliminate the impurities which collect in it due to dust, wear of bearings, exposure to the heat and to the atmosphere. See article on *Power Stations*.

**AMOUNT OF OIL REQUIRED FOR ENGINES.**—J. H. Spoor, in *Power*, Jan. 4, 1910, has made a study of a great number of records of the amount of oil used for lubricating cylinders of different engines, and has reduced them to a systematic basis, i. e., the number of pints of oil used in a 10-hour day for different areas of surface lubricated. The surface is determined in square inches by multiplying the circumference of the cylinder by the length of stroke. The results are plotted in a series of curves for different types of engines, and approximate average figures taken from these curves are given below:

PINTS OF CYLINDER OIL IN 10 HOURS

Type of Engine	Square inches lubricated									
	1000	2000	3000	4000	5000	6000	8000	10,000	12,000	18,000
Automatic highspeed	2	....	....	....	....	....	....	....	....	....
Simple slide valve...	0.5	....	....	....	....	....	....	....	....	....
Compound.....	....	2	....	3.5	4.3	5	5.5	6	6.5	....
Corliss:										
Average.....	0.9	1.65	2.25	3.75	....	....	....	....	....	....
Maximum.....	1.2	2.25	....	....	....	....	....	....	....	....
Minimum.....	....	1.00	....	....	....	....	....	....	....	....

As shown in the figures under 2000, Corliss, a certain engine may take 2½ times as much oil as another engine of the same size. The difference may be due to smoothness of cylinder surface, kind and pressure of piston rings, quality of oil, method of introducing the lubricant, etc. Variations in speed of a given type of engine and in steam pressure do not appear to make much difference, but the small automatic high-speed engine takes more oil than any other type. Vertical marine engines are commonly run without any cylinder oil, except that used occasionally to swab the piston rods.

The amount of engine oil required will of course depend upon the number of cups on the engine and the size of the various bearings. For a 1000-h.p. Corliss engine the Vacuum Oil Company state that the amount of engine oil would not exceed twice the amount of cylinder oil required.

R., *Lubricating Engineers' Handbook*.

**MACHINE TOOLS, ELECTRICAL OPERATION OF.** — (See also *Motors, Industrial Applications of.*) When the work of equipping a machine tool with motor drive is undertaken, there are certain features which should be taken into account and properly analyzed, as the conditions of operation generally vary greatly with the product manufactured. If a tool is intended for a certain specialized kind of work, information on the following points should be given:

1. The exact class of work which the tool is to accomplish.
2. If the power required to remove the metal is not known, then a statement should be made as to the approximate feed and cutting speeds to be taken.
3. Careful analysis should be made of the time required to load and unload the machine, to determine the feasibility of employing auxiliary means other than manual labor for loading the tools.

From this information an approximate determination can be made as to the intermittency of operation of the tool, in order to decide whether an intermittently rated motor or a continuously rated motor will be required. From a knowledge of the physical shape of the work, a determination can be made as to whether an adjustable-speed motor will result in economy of time, if used on this particular class of tool. The tool builder can then decide upon the proper type of controller, and its most desirable location from an operating point of view for the workman.

If a special type of tool is not desired and it is preferable to purchase one with such characteristics that it can be used for general manufacturing, one should determine as nearly as possible the range of material or work for which it will be used in straight manufacturing operations.

**TYPE OF MOTOR.** — The following table will aid in the choice of the proper motor for machine tool application.

It must be kept in mind that various circumstances, such as size or roughness of work, flywheel capacity, etc., may call for radical departures in choice of motors, this list being compiled to meet average conditions.

**Shunt Motors** are used in the following cases: when the work is of a fairly steady nature; when considerable range of adjustment of speed is required, as on lathes and boring mills, and on group and line-shaft drives, etc.

**Compound-wound Motors** are used where there are sudden calls for excessive power of short duration, as on belt driven planers, punch presses, etc. When a 50 per cent shunt, 50 per cent series, field is used, a motor is obtained which will develop nearly as much torque per ampere as a series motor with the advantage that light load speed will not be greater than 150 per cent full load speed.

**Series Motors** should be used where speed regulation is not essential and where excessive starting torque and slow starting speeds are required, as, for instance, in moving carriages of large lathes, in raising and lowering the cross rails of planers and boring mills, and for operating cranes.

When in doubt as to the choice of compound or series motors of small horsepower, the choice might be determined by the simplicity of control in favor of the series motor. Series motors, however, should never be used when the motor can run without load, as the speed would accelerate beyond the point of safety.

**Induction Motor.** — The alternating-current motor of the squirrel-cage rotor type corresponds to the constant-speed, shunt, direct-current motor, but with a high-resistance rotor it approaches more closely the characteristics of a compound direct-current motor. It is understood that the variable-speed machines, checked in this list under the alternating-current squirrel-cage rotor column, have the necessary mechanical speed changes.

Motor. # Squirrel-cage rotor — high starting torque.

Reaction motor with external rotor resistance.

For tire lathes as it allows slowing down when cutting hard spots.

Presses running at high speed can be driven by shunt motors.

The slip-ring induction motor with external rotor resistance would be used for variable speed, but this must not be construed to mean that it corresponds to a direct-current, adjustable-speed motor, as it has the characteristics of a direct-current shunt motor with armature control.

The self-contained, rotor-resistance type would be used for line-shaft drives and for groups when of sufficient size.

**Multi-speed Alternating-current Motors** are those giving a number of definite speeds, usually 600 and 1200 or 600, 900, 1200 and 1800 r.p.m., and are made for both constant horse-power and constant torque. These motors would be used where alternating current only was available, or direct current limited, and the speed range of the motor, together with one or two change gears, would give the required speeds.

**Shaft Couplings.**—In connection with the selection of motors, standard shafts and shaft extensions should be chosen so that spare parts and interchanges may be made with the least cost and time. A number of standard shafts and shaft extensions are shown in the sketches in Fig. 1.

**CONTROL EQUIPMENT.**—The choice of control, whether it be for old or new tools, in the majority of cases is fully as important as that of the motor. In selecting the control it is necessary to consider the nature of the work, the accessibility of the controller to the operator, the method of attaching it to the tool and in some cases its relative position to other tools; for instance, an open-type starting rheostat should not be exposed to danger of short-circuit from flying chips.

When installing controllers, accessibility in case of accident should be kept in mind, even though of little importance as far as starting up is concerned. The starting apparatus should be placed where the motor or some of the moving parts can be seen by the operator. On individual motor-driven tools, where the motor is started and stopped many times a day or where the starting conditions are of a severe nature, or where tools are edged along, drum-type controllers with extra heavy starting resistance should be used. For adjustable speed motors, using the drum-type control, the field control should be through fingers making contact on segments of the controller drum and not by sliding contacts on a dial. Motors above 40 or 50 horse-power under these severe conditions are best operated by a master controller which operates contactors for cutting out steps of starting resistance, and if adjustable speed, the field control should be taken care of by fingers making contact on segments of the drum. This class of starting apparatus will stand any quantity of abuse and, by the addition of a simple current limit relay device, becomes practically a fool-proof protection for the motor. There are cases where it might be advantageous to use master controllers and contactors even with smaller motors. The controlling apparatus as well as the motor in the case of individual drives should be attached directly to the tool when possible. This arrangement allows moving the tool by simply disconnecting the leads and connecting them in the new position. In case of portable tools this, of course, is an absolute necessity.

Upon the convenient arrangement of the control depends to a considerable degree, the output of the tool. The importance of the arrangement from the standpoint of the operator cannot be ignored, since the output of a tool will be

Fig. 1. Standard Shaft Couplings

materially increased when an operator can start and stop the tool and obtain at all times maximum cutting speeds by simply turning a handle. The controller must be placed in a safe position and should be accessible for repairs, which very often means that some arrangement is necessary to bring the operating handle within easy access of the operator.

The convenience of control, which bears directly on production, is ignored in the majority of tools where the control is of the greatest importance. A familiar illustration of the convenience of control is the arrangement so commonly seen on lathes, whereby the operating handle travels with the tool carriage and allows the operator at all times a complete control of his tool.

**APPLICATION OF REVERSING MOTORS.**— One of the most interesting motor applications is the use of reversing motors for machine tools. The large increase in production due to this form of drive on planers is generally appreciated, but the application of the reversing motor drive in its various forms (which is almost unlimited) is not so well understood. This reversing drive is applicable not only to planers, new and old, but to screw, worm and rack-driven slotters, keyseaters, turret lathes, wire and tube drawing machinery, grinder tables, lapping machines and to boring mills, when machining projections which are short in comparison with the total travel of the mill or when machining surfaces where projections prevent a complete revolution.

The motors recommended for this service are of the commutating pole type with a speed range usually of from 300 to 1200 r.p.m. for the small sizes and 250 to 1000 r.p.m. for the larger sizes. Other speeds can be obtained when required. The speeds given allow the motor, in the majority of cases, to be coupled direct to the driving shaft of the machine.

Starting, stopping and reversing are accomplished in remarkably short periods of time. It is considered the best practice to bring the motor to rest by means of dynamic braking.

On all reversing motor equipments, an emergency brake must be provided so the motor will be brought to rest quickly, when the voltage fails. Under-voltage protection should always be used.

**Reversing Planers.**— These equipments should provide quick reversals, the motor being brought to rest before each reversal, preferably by dynamic braking. This method will insure the motor, and consequently, the planer, coming to rest at practically the same point, for the various conditions encountered. This is especially important when planing up to a shoulder or in a pocket, where any overtravel would damage the work or the machine.

It is advisable to use an equipment so interlocked that it is impossible to connect the panel to the power supply with the master switch in a running position. If this feature is not used, an unexpected start is liable to result. "Jogging" by means of a portable push button is desirable for setting up work.

The "cutting" and "returning" speeds should be independently adjustable, and thirty-five or more cutting speeds provided.

**Example.**— In Fig. 2 curves *A*, *B* and *C* are for motor No. 2 and show the ampere input of a 10 horse-power, 1250 r.p.m. motor driving a 36-inch modern type planer through shifting belts. *A* is the return stroke of the planer table at a speed of 68 feet per minute; *C*, the cutting stroke, without cut, at 33.3 feet per minute; *B*, the same cycle but with a cut slightly less than 10 horse-power. The lost time on the cutting stroke, due to the belt slipping, is plainly seen, the cutting speed falling off from 33.3 feet to 29.4 feet or 13 per cent. Curves *E*, *F* and *G* are made on the same machine when driven by motor No. 1, a 10-horse-power, 250 to 1000 r.p.m. reversing motor, direct connected. These curves are superimposed on the above curves for comparative purposes. No attempt was made in this set of curves to duplicate the slow cutting or return speeds of the

belt-driven machines as the comparison would have shown power only. *E* is the return stroke of the planer table at a speed of 88.7 feet

Fig. 2. Tests on 36 in. by 10 ft. Reversible Planer

*G*, the cutting stroke at 53.2 feet per minute; *F*, the same cycle but of approximately 13 horse-power. The speed drop in this case is down only. For comparison the speed of motor No. 1, curve *F*, was the most economical speed under the conditions which the test was made. The loss in time of the belt drive as compared with the direct-connected motor drive (the depth of cut and feed being the same in both cases) was 1.5 per cent.

## MAGNETIC PROPERTIES OF IRON AND OTHER METALS.

— (See also *Electricity and Magnetism, Principles of; Magnetic Testing.*) For the definitions of magnetizing force and flux density see *Electricity and Magnetism, Principles of*; for the relations of the various units in which these quantities are expressed see *Units and Conversion Factors.*

**Hysteresis Loop — Residual Magnetism and Coercive Force.** — When a magnetic substance which is not magnetized initially is placed in a magnetic field the intensity of which is increased from 0 to  $H_m$ , the flux density produced

Fig. 1.

Fig. 2.

in the magnetic substance increases in the manner shown by the curve  $OB_m$  in Fig. 1. If the magnetizing force is then decreased to a value  $H$  the flux density does not return to the value corresponding to this value of  $H$  on the ascending curve, but decreases less rapidly than it increased. This phenomenon is known as "magnetic hysteresis."

When the magnetizing force is reduced to zero the flux density in general has a considerable value ( $OR$  in Fig. 1); this value of  $B$  is called the "residual" or "residual" magnetism. To reduce the flux density to zero the magnetizing force must be reversed and increased in the reversed direction to a value  $OC$ , called the "coercive force." As the magnetizing force is still further increased in the reversed direction to a value numerically equal to the positive maximum, and then decreased to zero, reversed, and increased again to  $H_m$ , the flux density passes through the cycle of values represented by the closed loop. This closed loop is called the "hysteresis loop."

If the iron (or other magnetic substance) is not originally unmagnetized, this hysteresis loop will be shifted above or below the axis of  $H$ , but after a number of reversals of the magnetizing force between given positive and negative values, the loop will become practically symmetrical with this axis, particularly if the iron is continually jarred. In the armatures of electrical machines and the cores of transformers, in which the field intensity reverses a large number of times every second, and the iron is continually jarred, the relation between flux density and field intensity after a short interval of time is represented by a symmetrical loop of the form shown in Fig. 1.

The area inclosed by the hysteresis loop depends upon the maximum value of the flux density reached during the cycle, but the general shape remains

about the same. Fig. 2 shows a series of loops corresponding to various values of the maximum flux density. The area of the loop is also different for various kinds of iron or steel.  $\frac{1}{4\pi}$  times the area of this loop when  $B$  and  $H$  are plotted to scale is equal to the ergs of heat developed in the iron per cubic centimeter per cycle. (See section on *Hysteresis Loss*, below.)

**Permanent Magnets — Retentiveness.** — An examination of this hysteresis loop also makes clear how a bar of steel may be permanently magnetized by placing it in a magnetic field. For, when the bar is removed from the field it retains a flux density approximately equal to the residual magnetism  $OR$ . In the case of a cast-iron or steel bar, properly hardened, the bar thus magnetized may be handled with comparative roughness without reducing to any considerable extent the strength of its poles, but in the case of a soft-iron bar even the slightest jar will cause it to lose its magnetism almost entirely. The property possessed by a magnetic substance of retaining its magnetization is called its "retentiveness." See also article on *Magnets, Permanent*.

**B-H Curves.** — Starting with a sample of iron completely demagnetized, and gradually increasing the magnetizing force, the flux density increases in the manner indicated by the middle curve from  $O$  to  $B$  in Fig. 1. This curve is called the "rising  $B-H$  curve." The curve showing the relation between the maximum flux density and the maximum magnetizing force for successive hysteresis loops, i.e., the dotted curve in Fig. 2, is similar in shape to this rising  $B-H$  curve, and is called the "alternating  $B-H$  curve." Except for the lower values of the flux density the rising and alternating  $B-H$  curves are practically identical. For engineering purposes, the alternating characteristic is the more important, and may be conveniently referred to as the "normal"  $B-H$  curve.

**Permeability.** — The magnetic permeability  $\mu$  of a substance corresponding to any degree of magnetization is usually defined as the quotient of the flux density  $B$  by the magnetizing force  $H$ , that is

$$\mu = \frac{B}{H}.$$

On account of the hysteresis effect, however, this quotient may have any value within wide limits depending upon how the magnetization is produced. Consequently a more restricted definition of permeability is required in the case of highly magnetic substances like iron and steel. For such substances the normal permeability for any value of the flux density is taken as the ratio of  $\frac{B}{H}$  corresponding to this flux density on the normal  $B-H$  curve.

The relation between permeability and magnetizing force or flux density is a complex one. As the flux density increases,  $\mu$  reaches a maximum at a relatively low flux density and then decreases ultimately to unity when the magnetizing force reaches a value so large that the intensity of magnetization  $J$  is negligible in comparison with  $H$ . This limiting condition, however, is never reached in practice.

**Reluctivity.** — Magnetic reluctivity is defined as the reciprocal of magnetic permeability, viz.,

$$\text{Reluctivity} = \rho = \frac{1}{\mu} = \frac{H}{B}.$$

Typical reluctivity curves are given in Fig. 6, corresponding to the  $B-H$  curves in Figs. 3 to 5.

**Intensity of Magnetization.** — The difference between the flux density  $B$

is a magnetic substance corresponding to a given magnetizing force  $H$  and the flux density (numerically equal to  $H$ ) which this same magnetizing force  $H$  would produce in free space, divided by  $4\pi$ , is called the intensity of magnetization, viz.,

$$J = \frac{B - H}{4\pi}$$

**Susceptibility.** — The quotient of the intensity of magnetization  $J$  divided by the magnetizing force  $H$  is called the magnetic susceptibility  $\kappa$  corresponding to this magnetizing force; viz.,

$$\kappa = \frac{J}{H} \quad \text{whence} \quad \mu = 1 + 4\pi\kappa$$

**Magnetic Saturation.** — Experiment shows that up to the highest values of the magnetizing force which have yet been produced, the normal flux density  $B$  always increases with an increase in the magnetizing force  $H$ . However, such experiments indicate that the difference between the flux density  $B$  and the magnetizing force  $H$ , that is, the difference  $(B-H)$ , approaches a definite maximum limit, dependent solely upon the nature of the material under test. In other words, for any given magnetic substance there is a definite limit to the intensity of magnetization  $\left(J = \frac{B - H}{4\pi}\right)$  which can be established in it.

When this limiting value of the intensity of magnetization is reached, the substance is said to be "magnetically saturated."

The difference  $(B-H)$ , when  $B$  and  $H$  are both expressed in c.g.s. electromagnetic units, may be conveniently designated as the "metallic" component of the flux density corresponding to a given magnetizing force  $H$ , since it is equal to the excess of the resultant flux density over the flux density which this same magnetizing force would produce in free space. The maximum, or saturation, value of this metallic flux density is about 20,000 gausses for soft iron and steel, 15,000 gausses for cast iron, 12,000 gausses for cobalt, and 6000 gausses for nickel. To increase the flux density beyond these values requires an increase in the magnetizing force equal to the increase in flux density desired.

An inspection of the reluctivity curves in Fig. 6 shows that for values of the magnetizing force greater than about 40 ampere-turns per inch (or 20 gilberts per centimeter), the relation between reluctivity and magnetizing force is approximately a straight line one. Due to the fact that there is a definite magnetic saturation point, the reluctivity curves actually have a slight downward droop.

If instead of the reluctivity  $\rho = \frac{H}{B}$ , the ratio  $\frac{H}{B - H}$  is plotted against the magnetizing force, it is found that for very high values of  $H$ , this ratio bears an exact linear relation to the magnetizing force  $H$ , viz., that

$$\frac{H}{B - H} = \alpha + \sigma H \quad (5)$$

where  $\alpha$  and  $\sigma$  are constants for any given material. Steinmetz calls the constant  $\alpha$  the "coefficient of magnetic hardness" and the constant  $\sigma$  the "coefficient of magnetic saturation."

**FACTORS AFFECTING THE PERMEABILITY AND HYSTERESIS LOSS.** — The normal permeability and the hysteresis loss (the latter is proportional to the area of the hysteresis loop) depend to a very great extent upon the physical structure and chemical constitution of the sample and the heat treatment to which it has been subjected. It has also been recently discovered (Pender and Jones, *Phys. Rev.*, 1913) that when sheet steel is annealed in an alternating magnetic field, the permeability is increased in certain cases as much

as 50 per cent, but there is no appreciable change in the hysteresis loss. The *B-H* curves of two samples taken from the same lot of material may even differ considerably. The permeability and hysteresis loss also depend to a slight extent upon whether the sheets are magnetized in the direction of rolling, or transverse thereto, being higher in the latter case.

**Temperature and Aging.** — Permeability and hysteresis also depend upon the temperature of the sample at the time the observations are taken, though the variation due to ordinary changes of temperature is slight. For very high temperatures, however, all magnetic substances become practically non-magnetic. This temperature corresponds to the major recalcence point, which is about 750° C. for steel of the quality used in armature and transformer punchings. When steel is kept continuously at a moderately high temperature (100° C.), the hysteresis loop also gradually increases in size, and therefore the energy loss in the magnetic circuits of electric machines due to hysteresis increases with time. This effect is called "aging." There is practically no aging of silicon steel.

**Chemical Composition of "Electrical" Sheet Steel.** — Sheet-steel manufacturers make a special grade of sheet for electrical purposes, which they sell under various trade names. Such steel is always low in carbon content and, except silicon in the so-called silicon steels, all impurities are reduced to small amounts. Silicon steel, i.e., steel containing about 3 per cent silicon is also extensively used, particularly for the magnetic circuit of transformers. The permeability of this steel is somewhat lower, in the useful range of flux densities, than that of ordinary electrical steel, but the area of the hysteresis loop, and therefore the hysteresis loss, is from 40 per cent to 60 per cent less; the specific resistance of silicon steel is also about 3 times greater than that of ordinary electrical steel, resulting in a reduction of about 70 per cent in the eddy current loss (see curves below). Aluminium has much the same effect as silicon, but the aluminium alloy is not so easily rolled.

The following are typical chemical analyses of the two kinds of electrical steel, but it should be understood that considerable variations in the proportions of the various constituents occur in practice.

	Ordinary electrical steel *	Silicon steel
	Per cent	Per cent
Silicon.....	0.01	3.46
Phosphorus.....	0.06	0.04
Manganese.....	0.50	0.13
Sulphur.....	0.03	0.02
Carbon.....	0.06	0.06

\* Parshall & Hobart, Electric Machine Design.

Of a large number of electrical steels analyzed by the Bureau of Standards (Lloyd and Fisher, *Trans. A.I.E.E.*, 1909, Vol. 28, p. 463) none showed more than the slightest trace of vanadium.

**Annealing of Sheet Steel.** — Sheet steel as it comes from the rolling mill may be greatly improved in magnetic properties by proper annealing. The chief requirement seems to be that the steel be brought to a temperature about 100° C. above the major recalcence point, i.e., to a temperature of about

Fig. 4. Magnetization Curves for Soft Steel Castings (G. E. Co.).

NOTE.—Steel forgings have a permeability somewhat less than steel castings. For forgings use the curve marked "Minimum."

Fig. 5. Magnetization Curves of Cast Iron (G. E. Co.).

850° C., and then allowed to cool slowly down to a temperature of from 100 to 150° C., when it may then be removed from the annealing furnace and allowed to cool more rapidly. The time required for annealing is from 12 to 36 hours. The annealing is usually done after the punchings have been made, thus eliminating the hardening at the edges produced by the cutting; otherwise this hardening may produce a considerable increase in the hysteresis loss.

**TYPICAL B-H CURVES.**—In Figs. 3 to 5 are given the standard B-H curves used by one of the large manufacturing companies. The abscissas ( $H$ ) of these curves are plotted to a logarithmic scale, in order to increase the range of the curves. These curves represent results obtainable under ordinary commercial conditions (joints not included) on iron and steel of the composition found suitable for electrical purposes. Ordinary commercial iron or steel will not, as a rule, have a permeability as high as given by these curves.

The "maximum" and "minimum" curves in Figs. 3 to 5 do not refer to individual samples, but to the average of, say, the ten highest and ten lowest samples respectively in one hundred samples included in the "average" curve. Whether the maximum, average or minimum curve should be used is a matter of judgment on the part of the designer.

In Fig. 6 are given the reluctivity curves corresponding to Figs. 3 to 5, and also the reluctivity curves for nickel and cobalt as determined by Fleming, Ashton and Tomlinson (*Phil. Mag.*, 1899, Vol. 48, p. 271). Alloys of certain non-magnetic metals have been found to be magnetic to about the same extent as nickel; see paper on *Heusler Alloys* by E. B. Stephenson, *Bull.* 47 (1911), University of Illinois, Eng. Exp. Stat.

**Maximum Permeability.**—As indicated by the curves in Fig. 3, the maximum permeability of sheet steel occurs below the range of commercial flux

Fig. 6. Reluctivity and Permeability

densities. A number of tests by the author showed that this maximum occurs at from 6 to 10 kilolines per square inch, the permeability decreasing rapidly with flux densities less than these values, the complete curve being similar

ves shown in Fig. 6. The author has obtained a maximum out 9000 c.g.s. units with ordinary electrical sheet steel, and 1000 c.g.s. units with silicon steel carefully annealed in small magnetic field (*Pender and Jones, Phys. Rev., 1913*). A value as high as 72,000 has been obtained by Yensen for pure iron heat-treated (*Elec. Rev., London, 80, p. 539, 1917*). These exceptionally high values, however, are not obtained in practice under commercial conditions.

5. — When a varying magnetic field is established in a circuit, a certain amount of heat is developed due (1) to hysteresis and (2) to the electric currents induced in the conducting mass. The latter are called eddy currents, and the total amount of energy dissipated is the sum of hysteresis and eddy-current losses.

Core-loss = hysteresis loss + eddy-current loss.

6. — As already noted, the hysteresis loss is proportional to the area of the hysteresis loop. Steinmetz (*Elec. Eng., 1890; Trans. A.I.E.E., p. 3*) found from a series of tests on a large number of samples that the area of the hysteresis loop for a given sample is approximately 1.6 power of the maximum flux density corresponding to the maximum magnetizing force.

7. — If the magnetic field throughout the iron is uniform, and the hysteresis exponent is assumed constant and equal to 1.6, then the hysteresis loss is expressed by the formula

$$P_h = KVfB^{1.6} \quad \text{or} \quad P_h = KWfB^{1.6},$$

where  $P_h$  is the hysteresis loss in watts per pound of iron,  $V$  is the volume of iron in cubic centimeters,  $f$  is the frequency of alternating field, in cycles per second,  $B$  is the maximum flux density, in gauss, and  $W$  is the weight of iron in pounds.

8. — The factor  $K$  depends upon the units in which the other quantities are expressed. If  $V$  is in cubic centimeters,  $B$  in gauss,  $f$  in cycles per second the formula is usually written

$$P_h = \eta V f B^{1.6}.$$

9. — The hysteresis loss in ergs per cycle per cubic centimeter is  $\eta B^{1.6}$ . The factor  $\eta$  is Steinmetz's hysteresis coefficient and the quality of iron or steel is frequently expressed in terms of this constant.

10. — The coefficient  $\eta$  is not absolutely constant, even for a given sample, because of any heterogeneity in the material of the sample, as, for example, the grain size. The amount of scale on the sheets of which the sample may be composed also affects the value of  $\eta$ . In general, the greater the heterogeneity the value of  $\eta$  increases with the flux density, and the greater the degree of heterogeneity. See Ball, *Journal of Magnetic Laws for Steel and Other Materials, Journal of the A.I.E.E., April, 1916*.

11. — The hysteresis loss is also sometimes stated as the watts per pound at 10,000 cycles. Let  $w_1$  = hysteresis loss in watts per pound at 10,000 cycles. Then the corresponding value of  $\eta$  is:

$$\eta = \frac{w_1}{10,000} \quad \text{Specific Gravity} = 7.7 \quad \text{Specific Gravity} = 7.5$$

$$\eta = 0.0013 w_1 \quad \eta = 0.00110 w_1.$$

12. — The hysteresis loss only, excluding the eddy-current loss, which is given by the formula

13. — The following table gives the value of  $K$  in terms of  $\eta$  when the various quantities for hysteresis loss are in the units stated.

## FORMULA FOR CALCULATING HYSTERESIS LOSS

$$P_h = KVIB^{1.6}$$

Power, $P_h$	Volume, $V$	Frequency, $f$	Flux density, $B$
Ergs per sec.	Cu. cm.	Cycles per sec.	Gausses
Watts	Cu. cm.	Cycles per sec.	Kilogausses
Watts	Cu. in.	Cycles per sec.	Kilogausses
Watts	Cu. in.	Cycles per sec.	Kilolines per sq. in.

$$P_h = KWIB^{1.6}$$

Power, $P_h$	Weight, $W$	Frequency, $f$	Flux density, $B$
Ergs per sec.	Grams	Cycles per sec.	Gausses
Watts	Kilograms	Cycles per sec.	Kilogausses
Watts	Pounds	Cycles per sec.	Kilogausses
Watts	Pounds	Cycles per sec.	Kilolines per sq. in.

$d$  = specific gravity = 7.7 for ordinary electrical sheets = 7.5 for silicon

**Hysteresis Loss for Various Substances.** — The hysteresis loss for iron, steel and other magnetic metals depends to so great extent on their chemical composition, physical structure, heat treatment, etc., that

## VALUES OF HYSTERESIS COEFFICIENT

$\eta$  = ergs per cycle per cubic centimeter for  $B = 1$  gauss

$w_1$  = watts per pound at 60 cycles for  $B = 10,000$  gaussess

Metal	Values of $\eta$		Values
	From	To	From
Silicon steel, annealed sheets.....	0.0006	0.0015	0.55
Ordinary electrical sheets, annealed....	0.00095	0.004	0.84
Soft cast steel.....	0.003	0.012	2.7
Cast iron.....	0.011	0.016	10
Forged steel.....	0.015	0.025	13
Hard cast steel.....	.....	0.028	.....
Cobalt.....	0.012	.....	11
Nickel.....	0.013	0.040	12

values have no significance. The preceding table is intended to give the range of the value of the hysteresis coefficient for iron and steel used in electrical machinery; figures for nickel and cobalt are also included.

The extreme low values of  $\eta$  can seldom be uniformly realized in practice. One of the large manufacturing companies uses for design purposes the values  $\eta = 0.00145$  for silicon steel and  $\eta = 0.0033$  for ordinary electrical sheets, these values allowing a considerable margin for variations in the quality of the steel. For close design the particular quality of steel to be used should be carefully tested (*see Magnetic Testing*) and the test results used.

In Fig. 7 are plotted hysteresis loss curves for various values of  $\eta$  assuming the  $B^{1.6}$  law.

**Eddy-Current Loss.** — When an alternating magnetic field is established in a conducting material alternating currents are set up in it due to the alter-

Fig. 7. Hysteresis Loss

ating e.m.f. produced by the alternating field. Consider a sheet of iron, Fig. 8, subjected to a uniformly distributed alternating field parallel to its faces. The dots indicate the flux lines perpendicular to the page and the loops the induced currents. Let

$B$  = flux density, in gausses,

$x$  = thickness of plate, in centimeters,

$\rho$  = specific resistance of plate, in abohms per cm-cube,

$\frac{dB}{dt}$  = rate of change of flux density with time, gausses per second.

Then the instantaneous power loss per cubic centimeter of the sheet, when the thickness  $x$  is very small (1 per cent or less) compared with the width of the plate, is

$$p = \frac{x^3}{12\rho} \left( \frac{dB}{dt} \right)^2.$$

Fig. 8.

The average power loss per cubic centimeter for a complete cycle of variation of the flux, in ergs per second, is

$$P_e = \frac{x^2}{12\rho} \times \left( \text{root-mean-square value of } \frac{dB}{dt} \right)^2.$$

It should be noted that this average loss depends upon the form factor (see *Alternating Currents*) of the rate of change of flux density, the latter being proportional to the counter e.m.f. induced by the varying field of the magnetizing coil.

If the induced voltage and therefore the flux density varies according to a sine function of the time, i.e., if  $B = B_m \sin(2\pi ft)$ , where  $B_m$  is the maximum value of the flux density,  $f$  the frequency, and  $t$  the time, then the average power loss due to eddy currents per cubic centimeter is

$$P_e = \frac{(\pi x f B_m)^2}{6\rho}.$$

If the voltage wave has a form-factor  $h$ , the loss for the same  $B_m$  is greater than this by the factor  $\left(\frac{h}{1.11}\right)^2$ ; see below.

The corresponding formula for the eddy-current loss per unit volume in a wire or cylinder of radius  $r$ , magnetized parallel to its axis, to a uniform flux density over its cross section is

$$P_e = \frac{(\pi r f B_m)^2}{4\rho}.$$

**Eddy-current Coefficient.** — In practice the field in the sheets is seldom perfectly uniform, and eddy currents flow from one sheet to the other, unless they are insulated from each other; consequently the eddy-current loss in a core made up of a bunch of sheets is usually greater than that given by the above formula. The eddy-current loss in a laminated core is therefore usually expressed by the formula

$$P_e = K_1 V (x f B)^2,$$

or

$$P_e = K_1 W (x f B)^2,$$

where  $V$  and  $W$  are the volume and weight respectively of the core and  $B$  is the maximum flux density. The coefficient  $K_1$  is determined from actual tests on a suitable sample (see *Magnetic Testing*).

The coefficient  $K_1$  (aside from its dependence upon the units in which the various quantities are measured) depends upon the specific resistance of the iron, the wave shape of the induced voltage, the distribution of flux in the sheets, the degree to which the sheets are insulated from each other, and upon the shape of the magnetic circuit in so far as this affects the distribution of flux. The results of the tests by Lloyd and Fisher also indicate that  $K_1$  depends upon the value of  $B$ , or, in other words, that the eddy-current loss does not vary directly as the square of the maximum flux density, all other conditions being the same. At high frequencies, above 100 cycles per second, the loss also increases less rapidly than the square of the frequency, due to the increase in the effective resistance of the sheets as the result of an action similar to the skin effect (q.v.) in a wire carrying a rapidly alternating current.

When the loss  $P_e$  is expressed in watts,  $V$  in cubic centimeters,  $f$  in cycles per second,  $x$  in centimeters and  $B$  in gausscs, the coefficient  $K_1$  may be represented by the symbol  $e$ , and the formula for eddy-current loss becomes

$$P_e = eV (x f B)^2.$$

loss is frequently stated as the watts per pound at 10,000 cycles for a thickness of sheet corresponding to No. 29 on the scale (0.0141 inch = 0.358 centimeter). Let  $w_2$  = eddy-current

Fig. 9. Eddy-current Loss in Ordinary Electrical Sheet Steel

Fig. 10. Eddy-current Loss in Silicon Sheet Steel

loss per pound at 10,000 gaussers and 60 cycles for sheets 0.0141 inch thick. The corresponding value of  $\epsilon$  is:

$$w_2 = d^2 w_1$$

$$\text{Specific Gravity} = 7.6$$

$$\epsilon = 0.000368 w_2$$

$$\text{Specific Gravity} = 7.5$$

$$\epsilon = 0.000359 w_2$$

## FORMULA FOR CALCULATING EDDY-CURRENT LOSS

$$P_e = K_1 V (xfB)^2$$

Power, $P_e$	Volume, $V$	Thick-ness of sheets, $x$	Frequency, $f$	Flux density, $B$
Ergs per sec.	Cu. cm.	Cm.	Cycles per sec.	Gausses
Watts	Cu. cm.	Cm.	Cycles per sec.	Kilogausses
Watts	Cu. in.	In.	Cycles per sec.	Kilogausses
Watts	Cu. in.	In.	Cycles per sec.	Kilolines per sq. in.

$$P_e = K_1 W (xfB)^2$$

Power, $P_e$	Weight, $W$	Thick-ness of sheets, $x$	Frequency, $f$	Flux Density, $B$
Ergs per sec.	Grams	Cm.	Cycles per sec.	Gausses
Watts	Kilograms	Cm.	Cycles per sec.	Kilogausses
Watts	Pounds	In.	Cycles per sec.	Kilogausses
Watts	Pounds	In.	Cycles per sec.	Kilolines per sq. in.

$d$  = specific gravity = 7.7 for ordinary electrical sheets = 7.5 for silicon-steel.

**Eddy-current Loss in Sheet Steel.** — The eddy-current coefficient for various makes of ordinary electrical sheets is subject to much the same variation as the hysteresis coefficient, and the same is true for various makes of silicon steel. The values given in the following table are for uniform distribution of flux and sinusoidal time variation.

## VALUES OF EDDY-CURRENT COEFFICIENT †

$e$  = ergs per sec. per cu. cm. for 1 cycle per sec., thickness of 1 cm.

$B$  = 1 gauss.

$w_1$  = watts per lb. at 60 cycles, thickness of 0.0141 in., and  $B$  = 1 gauss.

Kinds of sheets	Values of $e$			Values of $w_1$		
	From	To	Average	From	To	Average
Silicon steel . . . . .	0.000043	0.000098	0.000065	0.12	0.27	0.19
Ordinary electrical . . . . .	0.00012	0.00025	0.00022	0.34	0.70	0.52

\* These formulas are based on the assumption that the flux-time wave is sinusoidal. When this is not the case the total eddy-current loss is the sum of the losses due to several harmonics (including the fundamental) in the flux-time wave would have to be calculated separately.

† From tests by L. T. Robinson, *Trans. A. I. E. E.*, 1911, Vol. 30, p. 741 and Fisher, *Bull. Bur. Stds.*, 1909, Vol. 5, p. 453. The "average" values given by Mr. Robinson for "standard" and "alloyed iron" respectively.

Eddy-current-loss curves for ordinary electrical sheets are plotted in Fig. 9, and for silicon steel in Fig. 10, these being based on Robinson's values of  $w_e$  and the formula given above, which assumes uniform distribution of flux in the sheets and a sine-wave variation with time. The numbers on the curves are the gage numbers of the sheets, viz.,

- No. 29 gage = 0.0141 inch thick,  
 No. 26 gage = 0.0188 inch thick,  
 No. 24 gage = 0.0250 inch thick,

See Gages, Sheet Metal.

**Effect of Wave Form on Core-Loss.**—Experiments by M. G. Lloyd (*Bull. Bur. Stds., 1908, Vol. 5, p. 381*) show that for a given maximum flux density in the core the hysteresis loss is practically independent of the wave form of the counter induced e.m.f. in the exciting coil, provided the voltage wave does not pass through zero more than twice per cycle. On the other hand, the eddy-current loss for a given maximum flux density depends upon the magnitudes of the harmonics which may be present in the voltage wave.

**Effect of Direction of Grain in Silicon Steel.**—According to Chubb and Spooner (*Elec. J., 13, p. 303, 1916*), whenever it is possible to avoid it, silicon sheet-steel should not be used with the lines of force perpendicular to the direction in which the sheets have been rolled, since the magnetic properties under these conditions are not at their best.

**EXCITING CURRENT ANGLE OF HYSTERETIC ADVANCE.**—For a given wave shape of the impressed e.m.f., the wave shape of the exciting current (neglecting eddy currents) is determined by the shape of the hysteresis loop, since the exciting current is proportional to the magnetizing force  $H$ . Curve  $I$  in Fig. 11 shows the wave shape of the exciting current for a sine wave impressed e.m.f. calculated from hysteresis loop in Fig. 2 for a maximum flux density of 10,000 gauss.

The sine curve  $I_0$  is the fundamental of this wave (see *Wave Analysis*), and the curve  $i$  is the difference between  $I$  and  $I_0$  and consists chiefly of the third harmonic.

The curve  $E$  is the sine wave of induced voltage. The flux curve would be a sine curve shifted  $90^\circ$  to the left (ahead of  $E$ ).

The angle  $\alpha$  by which the fundamental of the current wave leads the flux wave is called by Steinmetz the "angle of hysteretic advance of phase."

For flux densities below the knee of the  $B-H$  curve the effective value of the fundamental current wave  $I_0$  differs but slightly from the effective value of the actual current wave.

In the above discussion the effect of eddy currents is neglected. The effect of these is to increase the exciting current by a component of the same shape as, and in phase with, the impressed e.m.f., thus causing an increase in the effective value of the exciting current and an increase in the angle by which the exciting current leads the flux.

Fig. 11.

**Magnetizing and In-phase Components of Exciting Current.**—Let

$P_0$  = total core-loss,

$E$  = back e.m.f. induced in the exciting coil,

$I$  = exciting current,

$\cos \phi = P_0/EI$ .

Then  $I \sin \phi$  is called the magnetizing component of the exciting current, and  $I \cos \phi$  the in-phase (or energy) component. For magnetizations near the knee of the  $B$ - $H$  curve

$$\phi = 90 - \alpha',$$

where  $\alpha'$  is the total angle of advance of the exciting current ahead of the flux, due to both hysteresis and eddy-current losses.

**MAGNETIC TESTING.** — (See also *Electricity and Magnetism, Principles of; Magnetic Properties of Iron and Other Metals.*) The ordinary magnetic tests of iron and other substances are: (1) The determination of the normal  $B$ - $H$  curves and hysteresis loop, and (2) The determination of the core-losses, i.e., hysteresis and eddy-current losses. The following is a brief table of contents of this article:

**DETERMINATION OF THE NORMAL  $B$ - $H$  CURVES AND HYSTERESIS LOOP.** — Under certain conditions, noted below, the magnetizing force  $H$  may be calculated in terms of the number of turns per unit length and the current. The flux density  $B$  may be measured in any one of three ways: (1) By winding on the sample a secondary or "test" coil and connecting in series with it a ballistic galvanometer or equivalent device (e.g., a fluxmeter, q.v.) and noting the deflection of this instrument when the current in the primary or "magnetizing" coil is changed in value or reversed; (2) by measuring the mechanical force required to separate one end of the sample from a yoke which, with the sample, forms a closed magnetic circuit; and (3) by measuring the change in resistance of a spiral of bismuth inserted in an air gap between two parts of the sample or between the sample and a yoke. (4) In addition the permeability of two samples may be compared by a device known as a permeability bridge, in which the detector is a magnetometer or compass. These four methods may be designated respectively as the ballistic, traction, bismuth spiral and bridge methods respectively. The first is best suited for precision measurements, the last three for rapid shop tests where great accuracy is not demanded.

**Magnetic Circuit of Testing Apparatus.** — The simplest form of circuit is a straight bar, which is placed inside a solenoid or helix, the flux returning through the air. With this type of circuit, however, unless the bar and coil are very long, the demagnetizing action of the magnetic poles formed at the ends and along the sides of the bar render it impossible to calculate with accuracy the resultant magnetizing force in the bar. If the sample is made in the form of a closed iron ring, the mean magnetizing force over the cross-section of the metal may be calculated, but, unless the radial thickness of the metal is small compared with the radius of the ring, the magnetizing force will be appreciably greater near the inner edge than near the outer edge, and as the permeability is a function of the magnetizing force, an appreciable error may be introduced. Also, the difficulty of winding the coils on a ring makes its use objectionable.

**Bar and Yoke.** — As a compromise, the sample is usually made in the form of a rod (or bunch of straight strips, in the case of sheet steel) which is fitted into a massive yoke of low reluctance which completes the magnetic circuit. The magnetizing coil is wound on the sample only. As a first approximation, in case the joints between sample and yoke are well made, the reluctance of the yoke and joints may be neglected, and the magnetizing force per unit length of the sample taken as the total magneto-motive force divided by the length of the sample. Methods have been devised for correcting the effect of the yoke and joints as described below.

**Demagnetizing the Sample.** — After the sample has been mounted ready for test (inserted in the yoke, if a bar and yoke method is employed) the circuit is thoroughly demagnetized by an alternating magnetizing force, preferably of about 1 period per second, which is gradually reduced from an initial intensity which establishes an induction well beyond the point of maximum induction to be measured to a final value somewhat lower than the lowest induction to be measured.

**Ordinary Ballistic Method.** — The connections are shown in Fig. 1. A ring sample is here shown, but this may be replaced by a straight sample

Fig. 1. Connections for Ballistic Method of Measuring Permeability

or by a straight bar in a yoke, Fig. 2. The test coil on the sample, the ballistic galvanometer  $G$ , the secondary coil of the standard solenoid and a resistance  $r$  are all connected permanently in series. This

Fig. 2. Bar and Yoke

resistance is adjusted so that the galvanometer shows a suitable deflection when the current in the magnetizing coil of the test sample is reversed. The galvanometer is then calibrated (see *Galvanometers*), keeping this resistance unchanged. A double-pole double-throw switch is provided for connecting the battery circuit at will to the magnetizing coil on the test sample or to the primary coil of the standard solenoid. The sample should be in place when the galvanometer is checked, as the hysteresis and eddy-current losses due to the variable current in the primary during the test have the same effect as an increase in the resistance of the galvanometer circuit. (See *Burrows, C. W., Bull. Bur. Standards, 1909, Vol. 6, p. 31.*)

**Precautions.** — For a high degree of precision the sample should be placed with its axis perpendicular to the earth's field, the apparatus should be protected from mechanical vibration, and should be sufficiently remote from any strong magnets (such as the permanent magnets in ammeters and voltmeters) in order not to be affected by their magnetic fields.

**Calibration of Galvanometer.** — Let

$N_1$  = number of turns in primary of standard solenoid *per centimeter length* (axial),

$n_1$  = total number of turns in secondary coil of standard solenoid,

$n$  = total number of turns in secondary coil on test sample,

$A_1$  = mean cross-section, in square centimeters of primary coil of standard solenoid if secondary is on the outside; if the secondary is inside the primary  $A_1$  is the mean cross-section of the secondary,

$A$  = cross-section in square centimeters of the test sample,

$a$  = mean cross-section in square centimeters of the magnetizing coil on test sample if the test coil is on the outside; if the test coil is on the inside  $a$  is the mean cross-section of the test coil,

$I_1$  = current established through primary of solenoid,

$D$  = deflection of galvanometer when this current is reversed,

$B$  = flux density in test sample corresponding to a deflection  $D$  when the current through the magnetizing coil on the sample is reversed,

$H$  = magnetizing force in sample corresponding to the flux density  $B$ .

The flux in maxwells established by the current  $I_1$  through the primary of the solenoid is then  $0.4\pi N_1 I_1 A_1$ , and the number of linkages of this flux with the secondary of the standard solenoid, i.e., with the galvanometer circuit, is  $0.4\pi n_1 N_1 A_1 I_1$ . When the double-throw switch is thrown to connect the battery to the magnetizing coil on the test sample, establishing in this coil a current  $I$  and a flux density  $B$ , the number of linkages between the flux in the test sample

and the galvanometer circuit will be  $BnA + Hn(s - A)$ . If these two linkages are equal, as they will be if the galvanometer shows the same deflection  $D$  when  $I$  is reversed through the magnetizing coil on the test sample as when  $I_1$  is reversed in the primary of the solenoid, then

$$B = \frac{0.4\pi n_1 N_1 A_1}{nA} I_1 - \frac{s - A}{A} H. \quad (1)$$

Or, putting

$$K = \frac{0.4\pi n_1 N_1 A_1}{nA},$$

which is a constant for a given solenoid and sample, then

$$B = KI_1 - \frac{s - A}{A} H. \quad (2)$$

The correction term  $\left(\frac{s - A}{A}\right)H$  is usually negligible except for very low values of the flux density.

Hence, by sending various currents  $I_1$  through the primary of the solenoid, reversing these currents and noting the deflection  $D$ , a curve may be plotted showing the relation between  $B$  ( $= KI_1$ ) and  $D$ . Then, when a given current is reversed through the magnetizing coil on the test sample and the deflection  $D$  noted, the flux density corresponding to this current may be read directly from the curve. This curve will be practically a straight line unless the damping of the galvanometer is excessive.

The calibration curve holds only for a constant total resistance in the galvanometer circuit (see Galvanometers). If it is necessary to change this resistance in order to alter the sensibility of the galvanometer a new calibration curve must be obtained.

#### Calculation of Magnetizing Force. — Let

$N$  = number of magnetizing turns per centimeter of mean circumference (see Fig. 1); If a straight sample with or without a yoke is used,  $N$  is taken as the total number of magnetizing turns divided by the free length of the sample in inches.

$I$  = current in magnetizing coil in amperes.

Then the magnetizing force in gilberts per centimeter is

$$H = 0.4\pi NI. \quad (3)$$

This formula represents the average magnetizing force over the section of the ring, if a ring sample is used. If a straight sample is used, the formula is approximate only, due to the reluctance of the return circuit through the air or yoke.

#### Determination of Normal $B$ - $H$ Curve by Ballistic Method. —

The sample is first demagnetized as described above, then the lowest magnetizing force to be used is applied and reversed many times until the iron is brought to a cyclic magnetic state, that is, until the reversal of the magnetizing force reverses the direction of magnetization without changing its magnitude. The number of reversals required to establish a cyclic condition in soft steel ranges from about 10 at high flux densities to several hundred at low flux densities. In general the harder the steel the fewer the number of reversals required. The galvanometer deflection is then noted, and the corresponding value of  $B$  taken from the calibration curve and  $H$  calculated from the formula given above. As a check, it is well to carry the iron through the demagnetizing process again, reduce to a cyclic state, and redetermine the point.

Higher points on the curve may be obtained in a similar manner, but it is not necessary to demagnetize the sample between successive points unless it accidentally becomes magnetized above the point being determined.

**Determination of Hysteresis Loop by the Ballistic Method.** — The sample is first demagnetized and then the maximum magnetizing force (corresponding to the tip of the loop) is applied and a cyclic condition established as described in the preceding paragraph. By suddenly inserting an additional resistance in the magnetizing circuit, e.g., by moving the slider on the resistance  $R$  so that less of this resistance is short-circuited, the magnetizing force is reduced to any desired value, and the change in flux density corresponding to this change in magnetizing force is determined by noting the galvanometer deflection. If the calibration curve of the galvanometer has been obtained by the method of reversals, as described above, the change in flux density is twice the value of  $B$  as read from the calibration curve, since the actual change in flux corresponding to any ordinate of the calibration curve is twice this ordinate.

The next point on the hysteresis loop is determined in the same manner, first bringing the iron to a cyclic state under the maximum magnetizing force corresponding to the tip of the loop. Data with negative values of the magnetizing force are obtained by reversing the currents in addition to making the adjustments already described. The points on the hysteresis curve may be taken in any order.

In this method of obtaining hysteresis data, the measured quantity is the change in induction when the magnetization is changed at one step from a maximum to any other given point on the hysteresis loop. This method is comparatively free from the irregularities due to the slow creep that occurs when a magnetizing force is applied slowly or changed by small steps. It is also free from irregularities due to variations in the size of step in the "step-by-step" method, in which the magnetizing force is changed from one value to the next lower without restoring it each time to the maximum value. (*See Burrows, Bull. Bur. Standards, 1909, Vol. 6, p. 1.*)

**Zero Ballistic Methods for Determining Flux Density.** — By using an independent battery circuit to energize the primary of the standard solenoid and establishing the currents  $I_1$  and  $I$  at the same time and reversing them simultaneously, it is possible by having the relative directions of these currents right, so to adjust  $I_1$  that for a given value of  $I$  the net discharge through the galvanometer is zero, and no deflection occurs. Under this condition  $B$  may be calculated directly from equation (1) or (2) above.

Instead of using a standard solenoid with fixed coils, an adjustable mutual inductance, previously calibrated, may be used, and a constant current maintained through its primary, the adjustment being effected by moving the secondary. Let

- $M$  = mutual inductance of standard, in henries,
- $I$  = current in amperes, in primary of mutual inductance,
- $n$  = total number of turns in test coil on sample,
- $A$  = cross-section of sample in square centimeters,
- $B$  = flux density in sample for balance.

Then

$$B = 10^8 \frac{MI}{nA} = K_1 M,$$

where  $K_1 = \frac{10^8 I}{nA}$  = a constant for a given test coil and sample and given current in the primary of the mutual inductance.

The design of a standard mutual inductance suitable for this purpose is described in detail by Burrows, *Bull. Bur. Stds.*, 1909, Vol. 6, p. 31.

**Burrows' Compensated Double-Yoke Method.** — This method, described in detail in Vol. 6 of the Bulletins of the Bureau of Standards (*Reprint No. 117*), is the standard method used by the Bureau of Standards and has also been adopted as the standard method of testing permeability by the American Society for Testing Materials, see *Proc. Am. Soc. Test. Mat.*, 1912. The following description of the method is taken from Burrows' paper.

Fig. 3 shows the relative positions of the magnetizing and test coils when double yokes and double rods are used. The lower rod is the one under test.

Fig. 3. Double Yoke and Bars

The upper rod is an auxiliary rod of approximately the same magnetic properties as the test specimen. *T* and *A* are the two main magnetizing coils, one wound over each rod. Over the four joints are wound four short coils *J*, each about 1.5 centimeters long. These are connected in series and used as a single coil. *t* and *a* are the two test coils surrounding test and auxiliary specimen respectively. *j* is the end test coil distributed with one-half over each end of the test rod.

**Test Samples.** — When rods are to be tested these should preferably be of square cross-section,  $\frac{3}{8}$  by  $\frac{3}{8}$  inch (0.9525 cm.) and 30 cm. long. With rods of square cross-section it is possible to make a more perfect joint between the rods and yokes. Sheet steel is tested by making up two equal bundles of strips 3 centimeters wide by 50 centimeters in length, having a total weight of 5 kilograms (*Stand. Spec. of Am. Soc. Test. Mat.*, June, 1912). Each bundle will be about 2.25 centimeters thick. One bundle takes the place of the test rod, the other takes the place of the auxiliary rod.

**Yokes.** — The yokes are of soft iron, provided with suitable clamps for holding the sample firmly and making a good magnetic joint. When sheet steel is being tested, the yokes may be made of short strips of the material 3 centimeters wide, the magnetic circuit in this case being a rectangle made up of strips, the joints at the four corners being alternately butt and lap in successive layers.

**Magnetizing Coils.** — No. 18 A. W. G. double-cotton-covered copper wire is a convenient size. A coil made of ten layers of this wire will stand continuously a current of 1.7 amperes, corresponding to a magnetizing force of  $H = 171$  gilberts per centimeter. For short periods twice this current may be safely employed, giving a magnetizing force of about 350 gilberts per centimeter. The length and diameter of the coils will depend upon the dimensions of the test sample (see above). If the coils are made of round cross-section the hollow core on which they are wound should have a shallow screw thread, 8 threads to the centimeter, cut on the outside. The first layer is wound in this thread, and succeeding layers wound in the same direction between adjacent wires in the previous layer. The various layers are then connected in series. The mag-

magnetizing force at the center of such a coil of ten layers, assuming perfect compensation for the rest of the magnetic circuit, is

$$H = 0.4\pi \times 8 \times 10 I = 100.53 I,$$

where  $I$  is the current in the coil.

**Test Coils.**—The test coils are made of fine wire (enameled or silk covered) wound on thin cores of paper, cloth or slotted metal. Coils  $t$  and  $a$  are placed over the middle portions of the test rod and auxiliary rod, respectively. Over the two ends of the test rod are placed the two halves of a third test coil  $j$ . These three test coils have the same number of turns and are spread over a considerable length of rod, so as to prevent any irregularities which may exist in the iron from exerting a preponderating influence. If the test coils are placed inside the magnetizing coils the correction for the flux between the rod and the coil will be small.

**Connections for Permeability Test.**—Fig. 4 shows diagrammatically the full scheme of electric circuits both primary and secondary. The coils  $T$ ,  $J$ ,  $A$ ,  $t$ ,  $j$  and  $a$  are the same as those of the same letters in Fig. 3. The coils  $M$  and  $m$  are the primary and secondary of the variable mutual inductance (or standard solenoid) used to balance the e.m.f. induced in the test coil.

**Compensation.**—Compensation is secured when the flux across every section of the iron circuit is the same, i.e., when there is no leakage. This condition may be closely realized by adjusting the currents in the three magnetizing coils separately.

The switches  $ST$  and  $SJ$  are reversed repeatedly, and the resistance  $RA$  and  $RJ$  adjusted until the three test coils,  $t$ ,  $j$  and  $a$ , indicate the same change in flux when the magnetizing currents are simultaneously reversed, i.e., switches  $ST$  and  $SJ$  reversed simultaneously. With the key  $K$  on the point  $t-a$ , the equality of flux in the test and auxiliary rods is secured first by adjusting  $RA$  until the galvanometer shows no deflection on reversing  $ST$ . Then with the key  $K$  on the point  $t-j$  the flux near the magnetic joints is adjusted to uniformity.

**Measurement of Induction.**—To measure the induction  $K$  is moved to the point  $t-m$ . A reversal of the magnetizing forces produces an impulsive electromotive force acting on the galvanometer, which may be measured as a deflection or may be compensated for by reversing simultaneously a suitable current through a variable mutual inductance, or standard solenoid  $M$ .

**Measurement of Magnetizing Force.**—For accurate work the current should be measured by means of a potentiometer (see *Potentiometers*). If the shunt used for measuring the current has a resistance of 1.0053 ohms and the magnetizing coil  $T$  80 turns per centimeter, then

$$H = 100 V,$$

where  $V$  is the fall of potential across this shunt.

Fig. 4. Connections for Burrows' Method of Testing Permeability

**STANDARD INDUCTION TESTS OF THE A.S.T.M. (1901 Edition).**—The normal magnetic induction is the induction produced by a magnetizing force in a given piece of magnetic material which has been previously demagnetized and then subjected to many reversals of the given magnetizing force.

Both the induction  $B$  and the magnetizing force  $H$  shall be expressed in terms of the C. G. S. electromagnetic unit (gauss).

**Sheet Metal.**—The standard normal induction data for sheet material shall consist of the magnetizing forces corresponding to inductions of 2000, 4000, 6000, 8000, 10,000, 12,000, 14,000, 16,000, 18,000, 20,000 gauss, or such as may be obtained without exceeding a magnetizing force of 200 gauss.

The following details are to be observed:

The permeability sample for sheet material shall consist of an even number of strips cut parallel to the direction of rolling, and even number of strips cut perpendicular to that direction selected from material sampled as for core loss.

The sample shall weigh not less than 1 nor more than 2 kg.

The magnetic circuit shall be a rectangle having the test material for one pair of opposite sides, and the same or different material for the other pair, which may be shorter. The joints at each corner are alternately butt and lap, or may be clamped on the edges.

The magneto-motive force is applied in two sections. The main magnetizing coils shall consist of two equal uniformly-wound solenoids surrounding the test material. The compensating coils shall consist of four short coils, each having the same number of turns wound closely over the ends of the magnetizing coils.

The test coil surrounds the middle portion of each bundle of test material. Four other test coils each of half the number of turns are placed over the four positions of the test material, approximately midway between the yokes and the center. The two center test coils are joined in series and the four end test coils are joined in series. The corresponding ballistic deflections, due to these two sets of test coils, are measures of the magnetic fluxes through the underlying portions of the magnetic circuit. By connecting the two test coils so that the induced electromotive force opposes that of the four coils, and adjusting the current through the compensating magnetizing coils so that there is no resulting ballistic deflection, an approximate uniformity of flux is secured through the greater portion of the test material, and the induction may be measured ballistically in the regular manner. The magnetizing force when the flux is adjusted to uniformity is that calculated from the uniform winding of the main magnetizing solenoids.

The cross-section of the magnetic circuit is determined as in the standard core-loss test.

**Rods.**—The standard test for rods for use in electromagnets shall consist of the magnetizing forces corresponding to induction of 2000, 4000, 6000, 8000, 10,000, 12,000, 14,000, 16,000, 18,000, 20,000 gauss, or such as may be obtained without exceeding a magnetizing force of 200 gauss.

The standard data for material intended for permanent magnets shall consist of the normal induction ( $B$ ), the normal residual induction ( $B_r$ ), and the normal coercive force ( $H_c$ ) corresponding to a magnetizing force of 200 gauss.

Standard magnetic data shall be determined by the Burrows compensated double-yoke method. (For further details see *A.S.T.M. Standards*.)

**Permeability Bridge.**—A double-bar and yoke arrangement, such as shown in Fig. 3, may be used without compensating or test coils to obtain a fairly

accurate measure of the permeability of a sample, provided the  $B$ - $H$  curve of one of the rods is known. A small magnetic needle or compass placed in the air space between the two rods is used as a detector of magnetic leakage from one rod to the other. The currents in the two magnetizing coils are adjusted until the needle shows no deflection when the currents in the two coils are reversed. The total flux in each rod will then be the same. The magnetizing forces in the two rods are then calculated from the currents in the magnetizing coils (equation 3 above) and the flux from the  $B$ - $H$  curve of the standard sample.

**PERMEAMETERS FOR SHOP TESTS.** — A great number of approximate methods have been devised for the rapid testing of permeability in shop work, where a high degree of precision is not required. Some of these are briefly described below.

**Thompson Permeameter (Fig. 5).** — In this instrument the flux density is measured in terms of the force required to separate a rod  $S$  from a yoke  $A$ , when the magnetic circuit formed by the rod and yoke is magnetized by a current in the coil  $B$ . The handle  $E$  is turned until the sample is pulled away from the yoke and reading on the balance taken at the instant of break.

Let

$I$  = amperes in magnetizing coil,

$N$  = number of turns in magnetizing coil,

$l$  = "equivalent" length of magnetic circuit in inches = distance from  $a$  to  $D$  plus from 10 to 20 per cent to allow for reluctance of yoke and joints,

$P$  = pull in pounds as read by balance,

$A$  = cross-section of rod  $S$  in square inches.

Then the magnetizing force is

$$H = \frac{0.4 \pi NI}{2.54 l},$$

and the flux density is, within the accuracy of measurement by the instrument,

$$B = 1320 \sqrt{\frac{P}{A}}.$$

There are several errors in the instrument, however, notably the unavoidable air gap between the sample and the top of the yoke and the contact at  $D$ , which makes the instrument unsuitable for the accurate determination of the absolute values of the qualities of iron and steel. It is, however, extremely useful for the comparison of samples where exact absolute values are not required. More nearly absolute values can be obtained by properly calibrating the instrument by using a standard sample the permeability of which at various flux densities has been measured by a more accurate method.

**Faby Permeameter.** — This apparatus (Fig. 6) is H-shaped with test coils  $ST$  spanning the free ends of the  $H$  and a magnetizing coil  $M$  wound on the cross-piece.  $D$  and  $D'$  are also test coils.  $SDDT$  have the same number of turns and are connected in series and in such a manner that the integrated e.m.f.'s induced in  $S$  and  $D'$  when a magnetizing current is reversed in  $M$  are in the same direction but in opposition to those simultaneously induced in  $D$  and  $T$ . The permeameter is initially adjusted so that when the coils  $S$  and  $T$  encircle air the differential effect of the coils  $D$  and  $D'$  is zero. In use,  $S$  encircles a standard bar bridging the gap on the left and  $T$  the test-bar bridging the gap on the right. In the cross-bar is an air-gap  $J$ , designed to create a demagnetizing force within

Fig. 5. Thompson Permeameter

which is adjustable to suit requirements. Magnetomotive force is applied in the compensating coils  $C$  and the currents in  $M$  and  $C$  are equally adjustable. When current is flowing in both  $M$  and  $C$  the circuit has its m.m.f. increased and that of the other circuit is decreased by an equal amount.

By adjusting the current in the compensating coils the difference in fluxes between coils  $D$  and  $T$  can be made equal to the difference in fluxes between coils  $J$  and  $S$ . When these flux differences are equal, the leakage flux through the gap in parallel with the path of the coil  $T$  is equal to the leakage flux through the gap in parallel with  $S$ . Since these two paths are symmetrical, the leakage flux is the same. Hence the same difference of magnetic potential exists between the terminals of  $T$  as between the terminals of  $S$ . If  $T$  has a relatively large number of turns. It is wound on the core and may be used to measure the difference of magnetic potential between the terminals of  $S$ . Hence the mean magnetizing force, which will be that obtained from the current of  $T$  in which the test specimen lies.

The consistency of repetition, effect of length of test specimen, effect of iron in the vicinity, position of specimen on the core, and the strain effect the instrument represents a distinct advance on other instruments in common use. Normal induction measurements are made with errors no greater than 5 per cent of the magnetizing force for a given induction. Commercial materials are seldom uniform and do not give better precision than 5 per cent. The instrument is also suitable for the measurement of sheet materials. For a complete description of the instrument and its use see *Bull. Bur. Stands.*, 14, p 267, 1917.

Fahy's Permeameter

Fig. 7. Koepsel Permeameter

**Permeameter (Fig. 7).**—The magnetic circuit consists of the two heavy soft-iron pole pieces  $P$  and  $P_1$ , with a gap and soft-iron core in the voltmeter). A small coil  $h$  is placed in the gap and connected to an auxiliary current supply. The sample current passing through the magnetizing coil  $C$ . The flux through the magnetic circuit causes the coil  $h$  to deflect an amount proportional to the flux, for a constant strength of auxiliary current. The deflection is read by a pointer, attached to the coil  $h$ , swinging over a scale graduated to read directly in flux densities. The calibration of the instrument does not hold for wide variations in the permeability of the samples tested. It depends upon this permeability. Also the magnetizing force is not known only approximately. These difficulties can be overcome by placing compensating coils on the yokes  $P$  and  $P_1$  and sending

sufficient current through these to compensate for the leakage. For detailed description see *Bull. Bur. Stands.*, 11, p. 101, 1914.

**Esterline Permeameter.**— This instrument is similar to the Koepsel apparatus except that the moving coil and core ( $h$  and  $A$  in Fig. 7) are replaced by a small direct-current armature. The apparatus then becomes a small separately-excited dynamo. The armature is driven by an auxiliary motor at a constant speed. The voltage across the armature is then directly proportional to the total flux cutting the armature conductors. Leakage is avoided by the use of compensating coils on the pole pieces. The current in these compensating coils is adjusted until a small compass placed near the magnetic circuit of the apparatus shows no deflection when the magnetizing and compensating currents are simultaneously reversed. The apparatus is described in detail in *Proc. Am. Soc. Test. Mat.*, 1906, Vol. 6, p. 320.

Fig. 8. Drilled Hole for Drysdale Permeameter

Fig. 9. Drysdale Permeameter

**Drysdale Permeameter** (Fig. 9).— This device is particularly useful in determining the permeability of large generator frame castings or other large masses of metal without the preparation of samples. A hole is drilled in the casting at any point desired with a special drill that will leave a hole with a core in the center similar to that shown at  $C$  in Fig. 8.

A magnetizing coil  $A$  and a test coil  $B$  are wound on a soft-iron plug and inserted into this hole as shown. The terminals of both these coils are brought out through small holes in the plug. Measurements are made by the ordinary ballistic method.

**Bismuth Spiral.**— Bismuth has the property of changing in electrical resistance when put in a magnetic field. The per cent increase in resistance in bismuth when in a magnetic field is nearly proportional to the magnetic density of the field. For measuring permeability, a flat spiral of bismuth wire non-inductively wound is fastened between two plates of mica, the terminals of the coil being brought out through a long insulated handle.

The sample is made in two pieces and held in a yoke such as shown in Fig. 2. The two rods are inserted through the holes in the ends of the yoke and are pushed in until only a small air gap is left between their opposing ends. The bismuth spiral is inserted in this gap. The resistance of the spiral is measured with a Wheatstone's bridge and the flux density determined from a curve furnished with the spiral giving the variation in resistance with varying density. The calculated value of the magnetizing force must be corrected for the reluctance of the yoke and air gap.

**CORE-LOSS MEASUREMENTS.**— A great number of methods have been suggested for determining the core-loss in a sample of iron or steel when subjected to an alternating field. These methods may be classified as: (1) hysteresis loop method; (2) wattmeter method; (3) mechanical torque methods. Of these the wattmeter method, when a properly constructed magnetic circuit is employed, gives the most reliable results. The hysteresis loop method is tedious and gives no knowledge of the eddy-current loss. The mechanical torque methods necessitate an air gap in the magnetic circuit with a resulting induction in the specimen which is far from uniform; these latter methods, however, are frequently used where high degree of accuracy may be sacrificed

to speed in testing, e.g., in comparative shop tests.

**Hysteresis Loss from Hysteresis Loop.**—The hysteresis loop may be determined by any of the methods described above. The loop is plotted on cross-section paper and integrated. Plot the magnetizing force, in gilberts per centimeter, to a scale of  $k$  gilberts per centimeter equal to 1 inch and the flux density to a scale of  $b$  gauss equal to 1 inch. Then if  $A$  is the area of the loop in square inches, the hysteresis loss, in ergs per cycle per cubic centimeter of iron, is

$$W = \frac{AbA}{4\pi}$$

Fig. 10. Connections for Core-loss Tests

**Principle of Wattmeter Method of Determining Core-Loss.**— Fig. 10 is a complete diagram of connections. The principle of this method is as follows: The sample to be tested is inserted in a magnetizing coil of a known number of turns, under<sup>o</sup> which is wound a secondary coil having either the same number of turns or a multiple thereof. The primary coil is connected in series with a source of alternating e.m.f. (which can be adjusted without changing its wave form) and the current coil of a wattmeter. The potential coil of the wattmeter is connected to the secondary coil on the test sample. A voltmeter is also connected across this secondary coil.

Let

$N_1$  = number of primary turns,

$N_2$  = number of secondary turns,

$A$  = cross-section of sample in square centimeters,

$f$  = frequency in cycles per second,

$k$  = form factor of secondary voltage,

$B$  = maximum flux density in sample, assumed constant throughout its length,

$V$  = reading of voltmeter,

$P$  = reading of wattmeter,

$R = r + \frac{R_1 R_2}{R_1 + R_2}$ , where  $r$  is the resistance of the secondary coil,  $R_1$  the resistance of the voltmeter and  $R_2$  the resistance of the potential coil of wattmeter.

The resistance  $R$  should be sufficiently large so that the heat developed ( $V^2/R$ ) in the secondary circuit is small compared to the core-loss, and the resistance  $r$  of the secondary coil should also be small compared with  $R$ . Then if the instruments are calibrated to read correctly and  $P$  and  $V$  are read simultaneously, the total core-loss is, assuming  $r$  negligible compared with  $R$ ,

$$P_c = \frac{N_1}{N_2} P - \frac{V^2}{R}$$

and the maximum flux density is

$$B = \frac{10^8 V}{4 k f A N_2}$$

<sup>o</sup> The two windings may also be "cross-wound."

**Test Specimen with Single Coil.**—The core-loss test can also be made with a single coil (the magnetizing coil) on the sample with the voltmeter and potential circuit of the wattmeter connected to the terminals of this coil. In this case, however, the voltage read by the voltmeter must be corrected for the resistance drop in the magnetizing coil, and the wattmeter reading for the  $rI^2$  loss in this coil. The two-coil method also has the advantage that the wattmeter reading can be made any multiple of the actual loss by using a proper ratio of  $N_2/N_1$ , thus enabling one to measure small losses with greater accuracy.

**Control of Impressed E.M.F.**—The e.m.f. impressed across the terminals of the magnetizing coil should have a sine wave form for all values of the maximum flux density at which tests are to be made. To secure this condition it is necessary that the e.m.f. of the generator supplying the current have a sine wave form, and that the resistance and reactance of both the generator and the circuit between the generator and the test sample be as small as possible, as the magnetizing current, having a distorted wave form due to hysteresis (see *Magnetic Properties of Iron*), will introduce a voltage drop having a non-sine form, thus distorting the impressed voltage wave.

The impressed voltage should therefore be controlled through the field of a generator having a large capacity compared to the power taken by the test sample, or instead of varying the field a transformer with suitable taps may be used, provided the resistance and leakage reactance of the transformer are small. In either case, the generator should give a sine wave at all field excitations within the range used. If this condition cannot be realized the hysteresis and eddy-current losses should be separated by measuring the total loss at two frequencies and the total loss then corrected for form factor (see below).

**Form of Specimen for Wattmeter Test.**—The specimen may have one of three forms: (1) It may be in the form of straight strips, the flux lines returning through the air; (2) straight strips may be used with a yoke; and (3) the specimen may be arranged to form a closed magnetic circuit in itself.

The first form gives a distribution of flux which is far from uniform. It is possible, however, by determining the flux distribution in the sample by means of an exploring coil to correct the observed losses for this flux variation (see *Robinson, L. T., Trans. A.I.E.E., 1911, Vol. 30, p. 742*).

The second form gives a more uniform flux, but it is necessary to distinguish between the energy supplied to the specimen and that supplied to the yoke. This can only be done satisfactorily by knowing the constants of the yoke, and only then by having the distribution of flux uniform, a condition difficult to secure.

Consequently, for accurate measurements the third form is the most reliable, although for factory use the first or second may prove more convenient where accuracy can be sacrificed for other considerations. The material used should be cut in a form such that only a small part of it is contiguous to a cut edge since all methods of cutting have a hardening effect upon the material bordering upon the cut. This means that the strip, whether straight or in ring form, should not be too narrow. This condition may be dispensed with if all specimens are annealed under definite conditions after cutting to size, and prior to testing.

Two general forms of magnetic circuit are available. The material may be stamped into rings (as in the Esterline apparatus), or the circuit may be built up from straight strips as in the Epstein apparatus. Leakage is most effectually avoided by using rings. With this form of specimen, however, the flux density will not be uniform unless rings of very great diameter are employed, and in the latter case there is a very great waste of material. The non-uniformity of flux existing in rings of small diameter, even when uniformly wound, and the errors resulting therefrom, are discussed by Loyd, M. G., *Bull. Bur. Stds., 1909, Vol. 5, p. 435*. The use of rings is thus restricted to cases where the

and after stamping, and the radial width of the ring should be in comparison to its diameter. When rings are employed, the test on each specimen separately with a magnetizing coil may be made by use of the apparatus of Esterline (*see p. 925*) or Möllinger (*ibid.*, p. 379).

**Method.**—This method has been adopted as the standard in the American Society for Testing Materials in this country. Commercial testing by both the General Electric and Westing-

The method is clearly described in the standard specifications for core-loss tests given in the following paragraph.

**Standard Core-loss Tests. (1931 Edition.)**—The power loss in electrical sheet steel when subjected to an alternating magnetic field is the core-loss. The standard core-loss is the total power in watts per kilogram of material at a temperature of 25° C., when subjected to a sinusoidally-varying induction having a maximum of 10,000 gauss and a frequency of 60 cycles per second, when measured as specified and denoted by the symbol  $W_{10,000}$ .

The coefficient is the percentage change in the standard core-loss after 100° C. for 600 hours.

Core-loss shall be measured under the following conditions:

The test circuit consists of 10 kilograms (22 pounds) of the test material, cut up into strips 50 centimeters (19 $\frac{1}{4}$  inches) long and 3 centimeters wide, half parallel and half at right angles to the direction of rolling, and divided up into four equal bundles, two containing material parallel to the direction of rolling, and two containing material at right angles to the direction of rolling, and finally the ends of the strips are joined into a square with butt joints and opposite sides consisting of the same material. No insulation other than the natural oxide film on the material (except in the case of scale-free material) shall be used between the strips, but the corner joints shall be separated by tough paper (0.004 inch) thick.\*

The test winding shall consist of four solenoids surrounding the magnetic circuit and joined in series. A secondary coil shall be wound around the primary coil carrying the voltmeter and the potential coil of the wattmeter. The primary coil shall be wound on a form of any non-magnetic non-conducting material having the following dimensions:

Section.....	4 by 4 cm.
Wall.....	not over 0.3 cm.
Height.....	42 cm.

The winding on each solenoid shall consist of 150 turns of copper wire having a diameter of 0.25 mm. over the 42-centimeter length. The total resistance of the primary winding shall be between 0.3 and 0.5 ohm. The secondary wind-

The purpose of this paper is to prevent the exposed end of the laminations being shorted together between those in the adjacent side of the other part of the sample, thus forming eddy currents at the corners which may not be confined to the laminations if the paper is not used. The certainty of the measurements is improved by a small but definite amount over the results which are obtained without the paper in the joints. This improvement is of course accomplished at the expense of an increase of leakage flux at the corners and consequently greater non-uniformity of flux distribution along the length of the sample. The errors imposed upon wattmeter are more severe as the general power factor of the test is less. The distribution over a section of the sample is more uniform with the use of the paper and is a definite gain in accuracy.

(L. T. Robinson.)

ing of 150 turns of copper wire on each solenoid shall be similarly wound beneath the primary winding. Its resistance shall not exceed 1 ohm.

A voltmeter and the voltage coil of a wattmeter shall be connected in parallel to the terminals of the secondary winding of the apparatus. The current coil of the wattmeter shall be connected in series with the primary winding.

A sine-wave electromotive force shall be applied to the primary winding and adjusted until the voltage of the secondary circuit is given by the equation,

$$E = \frac{4\sqrt{Nn}BM}{4\pi D 10^8}$$

in which

$f$ = form factor of primary e.m.f.	= 1.11 for sine wave,
$N$ = number of secondary turns	= 600,
$n$ = number of cycles per second	= 60,
$B$ = maximum induction	= 10,000
$M$ = total mass in grams	= 10,000,
$l$ = length of strips in centimeters	= 50,
$D$ = specific gravity	= 7.5 for high-resistance steel = 7.7 for low-resistance steel,
$E$ = 106.6 volts for high-resistance steel for sine voltage	
	= 103.8 volts for low-resistance steel for sine voltage.

A specific gravity of 7.5 is assumed for all steels having a resistance of over 2 ohms per metergram, and 7.7 for all steels having a resistance of less than 2 ohms per metergram. These steels are designated as high- and low-resistance steels, respectively.

The wattmeter gives the power consumed in the iron and the secondary circuit. The loss in the secondary circuit is given in terms of the total resistance and voltage. Subtracting this correction term from the total power gives the net power consumed in the steel as hysteresis and eddy-current loss. Dividing this value by ten gives the core-loss in watts per kilogram.

*Sampling.* — The core loss material shall be cut from two or more sheets taken at random from the shipment. The strips should be distributed symmetrically over the sheet, as nearly as may be practicable. It is recommended that a test sample shall represent not more than 5000 kg. (11,000 pounds).

*The Procedure.* — 1. Cut the test material into strips 3 by 50 centimeters as indicated under *Sampling*.

2. Place on the balance a pile of strips weighing 2.5 kilograms. Add a second pile of the same kind, bringing the weight up to 5 kilograms. In each case the weight is taken to the nearest strip. Add in succession two piles of 2.5 kilograms each, of the other kind of strips, bringing the weight up to 7.5 kilograms and 10 kilograms respectively.

3. Secure each bundle by string or tape (not wire) and insert in the apparatus as indicated.

4. Apply the alternating voltage to the primary coil and tap the joints together until the current has a minimum value, as shown by an ammeter in series. Then clamp the corners firmly by some suitable device.

5. Shunt the ammeter and adjust the primary current until the voltmeter indicates the proper value. This adjustment may be made by an auto-transformer by varying the field of the alternator, or by both, but not by the insertion of resistance or inductance in the primary circuit. Simultaneously the frequency must be adjusted to 60 cycles.

6. Read the wattmeter.

7. Calculations. Subtract from the wattmeter reading the instrument losses, which will be constant for any set of instruments and voltage, and divide by 10. The result is the standard core-loss.

**Bureau of Standards' Method.**— (*Bull. Bur. Stds., 1909, Vol. 5, p. 453; Trans. A.I.E.E., 1909, Vol. 28, p. 439.*) This is a modification of the Epstein method. It differs from the latter in the use of a smaller test specimen, from 1.5 to 2 kilograms (about 4 pounds) of strips 25.4 by 5 centimeters (10 by 2 inches), and in the use of a different form of joint between the four bundles of strips. In other respects it is essentially the same as the Epstein method.

Fig. 11 shows the arrangement of the joint. At the corners of the square, short pieces of test material are bent at right angles and interleaved between the strips of adjacent bundles, as shown in the figure. There are as many of

Fig. 11. Detail of Joint Used by N. B. S.

Fig. 12. Esterline Apparatus

these corner pieces as there are test pieces, and they are graduated in length so as to give a uniform lap of about 2 millimeters. A special clamp is tightened over these laps, so as to give a good magnetic joint. The object of these corner pieces is to reduce the leakage and thereby obtain a more nearly uniform flux throughout the sample. The loss in these corner pieces is small and can be calculated to a sufficient degree of accuracy and allowed for.

**Esterline Apparatus For Testing Iron Rings** (Fig. 12).— This apparatus is designed for testing rings made up of punchings from sheet steel. It is essentially a solenoid made in the form of a doughnut, but divided into two halves. The sample is inserted by lifting off the top half; the top half is then replaced and the teeth formed by the projecting ends of each upper half-turn fit into little sockets formed at the ends of the corresponding lower half-turn. (*Esterline, J. W., Proc. Am. Soc. Test. Mat., 1906, Vol. 6, p. 320.*)

**Ewing Hysteresis Tester.**— Strips  $\frac{3}{8}$  by 3 inches are cut from the sheets to be tested and a bundle of about 7 is used in each test. This sample is rotated at a relatively low speed (to avoid eddy currents) between the poles of a permanent magnet, the magnet being pivoted at the center of rotation and carrying a pointer that deflects over a scale, the deflection depending on the hysteresis loss in the sample. Two standard samples of known hysteresis properties are furnished with the instrument, so that the scale may be calibrated from time to time.

**The Blondel Hysteresis Tester.**— This apparatus is similar in principle to the Ewing hysteresis tester, but the magnet is revolved instead of the sample. The samples are made in the form of rings which are mounted on a pivoted spindle between the poles of a U-shaped permanent magnet. When the magnet is revolved the sample tends to follow it but is restrained by a spiral spring, and therefore it turns only through an angle such that the torque due to the hysteresis loss is balanced by the opposing torque of the spring.

**The Holden-Esterline Core-loss Tester.**— This instrument is similar to the Blondel hysteresis tester previously described but an electromagnet is substituted for the permanent magnet and this magnet is driven by a motor at the required frequency. The spring is arranged with a torsion head and pointer that is set to zero when the instrument is not in use.

The angle of torsion necessary to bring the sample back to its zero position

when the instrument is operating is read on a scale calibrated directly in watts loss. The speed of rotation being high the eddy-current losses are appreciable, and therefore the instrument reads the combined loss due to hysteresis and eddy currents at the frequency corresponding to the speed of rotation.

#### SEPARATION OF HYSTERESIS AND EDDY-CURRENT LOSSES.

—When the counter e.m.f. induced in the winding on any magnetic core is sinusoidal, the eddy-current and hysteresis losses may be separated by making measurements of the total loss at two frequencies  $f_1$  and  $f_2$ , at voltages  $E_1$  and  $E_2$ , respectively proportional to these frequencies. Let the values of the total core-loss at these two frequencies be  $P_1$  and  $P_2$ . Since the voltages are taken proportional to the frequencies and the voltage is sinusoidal, the maximum flux density will be the same in the two measurements. Let  $P_e$  be the eddy-current loss at the frequency  $f_1$  and  $P_h$  the hysteresis loss at this frequency. Then the following relations hold:

$$P_1 = P_e + P_h, \quad P_2 = \left(\frac{f_2}{f_1}\right)^2 P_e + \left(\frac{f_2}{f_1}\right) P_h.$$

Putting  $a = \frac{f_2}{f_1}$  and solving for  $P_e$  and  $P_h$ , gives

$$P_e = \frac{a P_1 - P_2}{a(1-a)}, \quad P_h = \frac{P_2 - a^2 P_1}{a(1-a)}.$$

**IRON-LOSS VOLTMETER.** — As pointed out in the article on *Magnetic Properties of Iron*, the core-loss depends upon the form of the impressed voltage wave. The dotted curves A, B and C in Fig. 13 show the variation in core-loss with form factor when the eddy-current loss is 14 per cent, 20 per cent and 30 per cent of the total loss. The loss corresponding to a sine-wave voltage (form factor 1.11) is taken as 100 per cent.

In making commercial tests on transformers it is frequently inconvenient to obtain a sine-wave voltage, and it is also equally inconvenient to obtain the form factor of the actual voltage available and the relative value of the eddy-current loss. Yet, for comparative purposes, the core-loss should be referred to a standard sine-wave form. The iron-loss voltmeter, devised by L. W. Chubb (*Trans. A.I.E.E.*, 1909, Vol. 28, p. 417) is an instrument designed to read,

when connected to a circuit in which the voltage has any wave form whatever, the value of the sine-wave voltage which would produce the same total loss as produced by the actual voltage. The meter is calibrated for one frequency only, usually 60 cycles per second. When such an instrument is connected across the transformer and the voltage adjusted until the instrument reads the rated voltage of the transformer, the core-loss read by a wattmeter connected in the usual manner will be the core-loss corresponding to a sine-wave voltage having an effective value equal to the voltage

Fig. 13.

is voltmeter, irrespective of what the reading of an ordinary  
d across the line may be.

a voltmeter is essentially an ordinary wattmeter, the current  
connected in series with a winding on a small laminated iron  
nents in series being connected directly across the line. The  
the wattmeter is also connected across the line to the same  
he first or series circuit. The meter therefore has but two  
eflection of the moving element of such a meter, when con-  
upply mains, is proportional to the total power absorbed by  
e iron core. Neglecting the small resistance loss in the series  
e, by adjusting the resistance in the potential circuit and the  
n the iron ring, to make the equivalent eddy-current loss in  
cluding the resistance loss in the potential circuit as an  
since it depends on the effective value of the voltage in the  
dy-current loss in the sample) any desired proportion of the  
adjustments are so made that at about 0.6 full-scale deflection  
y-current loss on a pure sine-wave voltage at 60 cycles is  
total, this being the average proportion of the hysteresis loss  
mercial 60-cycle transformers.

is then calibrated to read directly in volts by connecting it  
ordinary alternating-current voltmeter on a pure sine-wave  
ired frequency.

e hysteresis loss in the transformer under test is different  
on-loss voltmeter, a slight error will be introduced. Curves  
show the error when the eddy-current loss in the transformer  
0 per cent respectively, instead of 20 per cent.

eed only approximate the normal values; the final core loss  
voltage indicated by the iron-loss voltmeter will be the same  
ed on a sine wave of normal frequency and voltage.

**Form Factor.** — Chubb also gives a method of obtaining  
T from a wave of any shape. This is shown in Fig. 14. T

under test,

in the text.

**MAGNETS, PERMANENT.** — (See also *Magnetic Properties of Iron and Other Metals; Magnetic Testing.*) A permanent magnet is a piece of iron or steel which has been magnetized and which retains a relatively large part of its magnetism when the external magnetizing force is removed. The simplest form of permanent magnet is the bar magnet, used principally for experimental and instructional purposes and in the compass and certain types of galvanometers, etc. U-type permanent magnets are largely used in electrical measuring instruments and in the construction of magnetos.

The materials used for permanent magnets are (1) cast iron, (2) carbon-steel (0.15 to 0.3 per cent carbon), and (3) alloy steel containing carbon together with tungsten, molybdenum, chromium, or vanadium.

Cast iron magnets are used principally where weight is not objectionable.

Prior to 1914 high grade permanent magnets were made almost universally of alloy steel containing principally carbon, tungsten and chromium, and in which the percentage of manganese, sulphur and phosphorus was kept within the lowest practical limits. Since that date, chromium alloys have been produced from which it is possible to make magnets equal to those made of tungsten steel.

While the chromium alloys do not permit of as wide a range in manufacturing and heat-treating conditions as tungsten-steels, with proper and uniform conditions the product shows greater uniformity than that made of tungsten steel.

Carbon-steel magnets have about 75 per cent of the strength of tungsten steel magnets of the same size.

Permanent magnets are usually made by cutting and forming the raw material, and hardening it by heating to a temperature, dependent upon the nature of the steel, usually in the neighborhood of 900° C., and cooling quickly by plunging into cold water or brine, and magnetizing.

**Residual Induction and Coercive Force.** — The two magnetic qualities of fundamental importance in a permanent magnet are (1) the residual induction of magnet and (2) its coercive force or retentivity. By residual induction is meant the flux density which exists in the material when the external magnetizing force is reduced to zero. By the coercive force or retentivity is meant the external magnetizing force required to reduce the induction to zero.

The total magnetic strength of a magnet having a given residual flux per unit area is proportional to its cross-sectional area, and the ability of a magnet of given retentivity to hold its magnetism is proportional to its length; that is, the length of the bar from which it is made. For any magnetic circuit considered there is a cross-section and length of permanent magnet which will give the maximum flux with the requisite stability, using a minimum of magnet steel.

**Values of Residual Induction and Coercive Force.** — In the *Physical Review* for Dec., 1920 (p. 496), Honda and Saito give data on "K.S." magnet steel, a cobalt-tungsten-chromium steel having the composition:

C.....	0.4 to 0.8 per cent
Co.....	30 to 40 per cent
W.....	5 to 9 per cent
Cr.....	1.5 to 3 per cent

For samples 20 cm. long and 0.5 cm. diameter (dimensional ratio of 40), heated to 950° C. and quenched in heavy oil, and then magnetized in a field of 1500 gilberts per centimeter, the residual induction ranged from 7800 to 11,500, depending upon the composition of the sample. The coercive force ranged from 257 to 226 gilberts per centimeter. This coercive force is stated by Honda and Saito to be about three times greater than that of the best tungsten steel, and the residual induction to be also greater than that of tungsten steel.

The data given by Honda and Saito also show that for dimensional ratios greater than about 18, the residual induction is independent of the value of the dimensional ratio, whereas for smaller dimensional ratios the residual induction is approximately proportional to this ratio, the relation being

$$B = 650 \frac{l}{d},$$

where  $B$  is the residual induction,  $l$  the length, and  $d$  the diameter of the specimen. For a dimensional ratio of 15, K. S. magnet steel is about 1.8 times stronger than that of tungsten steel.

**Effect of Air Gap.**—The useful flux of a permanent magnet operating across an air-gap is always less than the flux which the magnet would give with no air-gap between its poles, or when magnetically "short circuited." On account of the very high reluctance, or magnetic resistance, of air the residual magnetism of a magnet of a given length is lessened as the air path between the poles is increased. This must be given careful consideration in the design of apparatus embodying the use of permanent magnets.

Since the introduction of an air gap between the poles of a permanent magnet has the effect of partially demagnetizing it, and the extent of the demagnetizing depends upon the relative length of the magnet and the air gap, it is important that the ratio of length of the magnet to the length of the air gap be such that the magnet will not be demagnetized by the air gap to the point where magnetization becomes unstable.

In some types of apparatus, such as magnetos, the magnet is opposed by a coil of wire carrying current. In designing permanent magnets for machines of this type it is important to take into account the effects of both air gap and coil.

**Magnetization.**—The process of magnetizing should be such as to fully saturate the magnet uniformly throughout its entire length. This can best be done by having the proper shaped and size coils to slip over each leg of the magnet, in the case of U-shaped magnets, completing the magnetic circuit by placing a keeper over the magnet gap and passing current through the coils.

The magnetizing apparatus should be so arranged that the magnet can be slipped out of the magnetizing coils and a soft iron keeper put on it before removing the keeper that was put on to complete the magnetic circuit while magnetizing.

U-shaped magnets magnetized by a very common but incorrect method, that of placing the magnets on the poles of a large electromagnet, will have large losses due to a large portion of the flux circulating around the magnet in paths that are not useful.

**Aging and Magnetic Treatment.**—One of the main conditions to be met by permanent magnets used in most electrical measuring instruments is that the magnet be stable and not subject to change with time, otherwise the instrument will go out of calibration. To secure this condition requires (1) a physical treatment of the steel after quenching, which makes further changes in its structure, molecular condition or magnetic qualities improbable, and (2) a magnetic treatment which will make changes in its magnetization under the condition of ordinary operation improbable.

When a magnet is hardened it undergoes rapid structural changes and for a time after quenching there is a change in condition taking place, rapid at first, and gradually decreasing until the physical properties become stable. This stability of the structural state of the steel can be hastened by physical treatment which usually consists in boiling the magnet in water for about 40 hours. This is called aging or maturing.

The magnetic treatment of the permanent magnet is usually carried out as follows: After the magnetic circuit on which the permanent magnet is to operate is completely assembled, a demagnetizing force is applied which removes a portion of the flux. It is next subjected to a magnetizing force and then to a demagnetizing force. This has the effect of reducing the residual induction somewhat, but makes the magnet more stable.

**Magnet Meter.**—The magnet meter provides a simple and effective method for the commercial testing of permanent magnets. This instrument consists of an ordinary millivoltmeter with the permanent magnet removed and having soft iron extensions which are attached to the pole pieces of the meter and extend through the meter case. The moving coil of this meter is connected in series with a battery, rheostat and milliammeter.

A magnet of standard strength is placed against the soft iron extensions of the meter pole pieces and the current through the magnet meter coil adjusted, by means of the rheostat, until the pointer of the instrument deflects to some arbitrary point on the scale. The standard magnet is now replaced with the magnet to be tested. With the current kept the same as in the first test the deflection of the instrument is noted.

**BIBLIOGRAPHY.**—A considerable portion of the material in this article is taken from a pamphlet on *Permanent Magnets* published by the Esterline Co., Indianapolis. See also Kelly, F. C., *Permanent Magnets*, G. E. Rev., 20, p. 569, 1917; Thompson, S. P., *Magnetism of Permanent Magnets*, Inst. Elec. Eng. J. 50, p. 80, 1913 (contains complete bibliography up to 1913); Honda and Saito, *Phys. Rev.*, Dec., 1920; Morgan, J. D., *Testing Magneto Magnets*, Engin., 103, p. 589, 1917.

**D MINIMA.** — (See also *Derivatives; Series, Mathematical.*)  
 tion of a variable  $x$ , then  $y$  will be a maximum or minimum  
 which satisfies

$$\frac{dy}{dx} = 0 \quad (1)$$

zero. If the second derivative  $\frac{d^2y}{dx^2}$  is positive for this value  
 corresponding value of  $y$  is a minimum; if this second derivative  
 corresponding value of  $y$  is a maximum.

zero for the value of  $x$  which satisfies (1), the corresponding

maximum or minimum unless  $\frac{d^3y}{dx^3}$  is also zero and  $\frac{d^4y}{dx^4}$  is not

zero,  $y$  is a minimum if  $\frac{d^4y}{dx^4}$  is positive and a maximum if  $\frac{d^4y}{dx^4}$  is

negative. If  $\frac{d^4y}{dx^4}$  is also zero, similar relations must hold for the fifth and  
 etc.

— Find the maximum and minimum values of

$$y = 2x^3 - 9x^2 + 12x - 3,$$

$$\frac{dy}{dx} = 6x^2 - 18x + 12 = 0,$$

$$\frac{d^2y}{dx^2} = 12x - 18,$$

maximum or minimum for  $x^2 - 3x + 2 = 0$ , that is, for  $x = 2$ , or

$\frac{d^2y}{dx^2}$  is positive; for  $x = 1$ ,  $\frac{d^2y}{dx^2}$  is negative; hence the maxi-

mum occurs for  $x = 2$ , while the minimum value of  $y$  is 1 and

[W. A. DEL MAR.]

**MECHANICS, PRINCIPLES OF.** — (See also *Structures, Simple; Units and Conversion Factors.*) In this article are given the definitions of the more commonly-used mechanical quantities together with a statement of the quantitative laws in accord with which displacements and motion of matter (including deformations) take place. The interrelations of the various units employed for measuring any particular quantity are given in the article on *Units and Conversion Factors.*

**DEFINITIONS.** — The various terms relating to the displacement and motion of matter and to forces producing these displacements and motions are the following:

**Scalar and Vector Quantities.** — A mechanical quantity which is not directed in space, e.g., mass, energy, etc., is called a scalar quantity. A mechanical quantity which has a space direction as well as magnitude, e.g., velocity, force, etc., is called a vector quantity. A scalar quantity may be positive or negative, that is, has two "senses," but to specify a vector quantity like force it is necessary to specify not only its magnitude but its direction with respect to one or more fixed lines of reference or axes. Scalar quantities may be treated as ordinary algebraic quantities, and added and subtracted in the usual way. Vector quantities must be added and subtracted *vectorially*, as described in the article on *Vectors.*

**Linear Displacement ( $l$ ).** — When a particle  $P$  moves from a point  $A$  to any other point  $B$ , the distance, measured along a straight line, from  $A$  to  $B$  is called the linear displacement of the point  $P$ .<sup>\*</sup> Any unit of length may be used as a unit of displacement; see *Units and Conversion Factors.*

**Angular Displacement ( $\theta$ ).** — Let a particle  $P$  move from a point  $A$  to some other point  $B$ , and let  $OX$  be any arbitrarily-chosen line, or axis. Draw planes through  $A$  and  $OX$  and through  $B$  and  $OX$ . Then the angle between the planes  $AOX$  and  $BOX$  is called the angular displacement of  $P$  about  $OX$ .<sup>\*</sup> Angular displacement may be measured in degrees, radians or turns; see *Angles and Units and Conversion Factors.*

**Linear Velocity ( $v$ ) and Speed ( $s$ ).** — The linear velocity or speed of a particle  $P$  is the rate of increase with time of the linear displacement of  $P$ , i.e.

$$v = \frac{dl}{dt} \quad \text{or} \quad s = \frac{dl}{dt}, \quad (1)$$

where  $dl$  is the linear displacement in time  $dt$ .

Any unit of length per any unit of time may be used as a unit of velocity or speed; see *Units and Conversion Factors.*

**Angular Velocity or Speed ( $\omega$ ).** — The angular velocity or speed of a particle about a given axis  $X$  is the rate of increase with time of its angular displacement about this axis, i.e.

$$\omega = \frac{d\theta}{dt}, \quad (2)$$

where  $d\theta$  is the angular displacement in time  $dt$ . Any unit of angle per any unit of time may be used as a unit of angular speed; see *Units and Conversion Factors.*

<sup>\*</sup> The positions of  $A$  and  $B$  (and of  $OX$  also in the case of angular displacement) must be referred to some system of coordinates; when the system of coordinates moves, the displacement as above defined is the displacement *relative* to this system of coordinates.

**Linear Acceleration ( $a$ ).** — The linear acceleration of a particle  $P$  is the rate of increase with time of the linear velocity of  $P$ , i.e.,

$$a = \frac{dv}{dt} = \frac{d^2s}{dt^2}, \quad (3)$$

where  $dv$  is the increase of linear velocity in time  $dt$ . Any unit of velocity per any unit of time may be used as a unit of acceleration, e.g., centimeters per second per second, miles per hour per hour, etc.; see *Units and Conversion Factors*.

**Acceleration Due to Gravity ( $g$ ).** Gravitational Acceleration Constant ( $g_0$ ). — At any given place on the earth a body falling freely in a vacuum has a constant linear acceleration, independent of its size, shape or material. This acceleration is called the acceleration due to gravity ( $g$ ), and the particular value of this acceleration at 45 degrees latitude and sea level is called the gravitational acceleration constant ( $g_0$ ). The value of  $g_0$  as adopted by international agreement\* is

$$g_0 = 980.665 \text{ cm. per sec. per sec.}$$

$$g_0 = 32.1739 \text{ ft. per sec. per sec.}$$

The value of  $g$  for any other location varies but slightly from this value, being at sea level approximately 0.3 per cent less at the equator, 0.3 per cent greater at the poles, and decreasing at the rate of about 0.01 per cent per 1000 feet increase in elevation. See *Landolt-Bornstein's Tables*.

**Angular Acceleration ( $\alpha$ ).** — The angular acceleration of a particle  $P$  about an axis  $X$  is the rate of increase with time of the angular velocity of  $P$  about  $X$ , i.e.,

$$\alpha = \frac{d\omega}{dt} = \frac{d^2\theta}{dt^2}, \quad (4)$$

where  $d\omega$  is the increase in angular velocity in time  $dt$ . Any unit of angular velocity per any unit of time may be used as a unit of acceleration, e.g., degrees per second per second, turns per second per second, etc.; see *Units and Conversion Factors*.

**Mass or Weight.\*** — Two bodies are said to have equal masses or weights,† irrespective of their volume, shape or chemical composition, if, when they are suspended simultaneously in a vacuum, one from each end of an equal-armed balance, there is no tipping of the beam of the balance from its original position. This criterion for the equality of two masses holds only in case the bodies and the balance are neither electrically charged nor magnetized, both bodies are supported at the same distance from the earth, and the equilibrium of the balance is not affected by the presence of any other bodies (except the earth) in the vicinity. This is an entirely arbitrary definition, but mass as thus defined is found to be a fundamental property of a body irrespective of its shape, physical state or relation to other bodies. The units of mass or weight and their interrelations are given in the article on *Units and Conversion Factors*.

**Density ( $\delta$ ) and Specific Gravity.** — The density of a uniform substance is defined as the mass of the substance per unit volume. When the substance

\* *Traité des Poids et Mesures*, 1901, p. 66. See Note 5, p. 3 of this book.

† The term weight is also used for the force exerted by the earth on a portion of matter; in this sense weight is not independent of the relation of the given portion of matter to other bodies, and the term mass is therefore preferable when referring to quantity of matter, since it has not acquired a double meaning. However, engineers almost invariably use the word weight instead of mass for quantity of matter. See the article on *Units and Conversion Factors* for a further discussion of this point.

is not uniform, its density at any point is defined as the mass of an infinitesimally small volume taken about the point divided by this volume; i.e., calling  $\delta v$  the volume and  $\delta m$  the mass of this volume, the density is

$$\delta = \frac{\delta m}{\delta v}. \quad (5)$$

In the c.g.s. system the standard unit of density is the gram per cubic centimeter, but any other unit of mass per any unit of volume may be used in either the metric or English system; see *Units and Conversion Factors*. For values of the density of various materials see article on *Weights of Materials*.

The specific gravity of a substance is defined as the ratio of the weight of a given volume of that substance to the weight of an equal volume of water or air. Water is used as the standard of reference for solids and liquids, and air at  $0^\circ$  C. and 760 mm. mercury pressure as the standard of reference for gases. Strictly, the temperature of the water also should be specified, but this is not always done. The variation in the weight of a given volume of water with temperature is slight and for many purposes negligible. When  $4^\circ$  C. is taken as the standard water temperature the specific gravity of a substance is numerically equal to its density in grams per cubic centimeter to within 25 parts in 1,000,000, a difference which is very much less than the degree of precision of ordinary measurements of density.

**Surface and Lineal Densities.** — Density as defined above is the *volume* density of a body. It is sometimes convenient to use factors which represent the mass or weight of a substance (or other physical quantity) per unit of surface or per unit of length, e.g., the weight per square foot of a plate or the weight per foot of a wire.

**Center of Mass, Center of Gravity, or Center of Inertia.** — A body of mass  $M$  which has any size or shape may be considered as made up of a number of small particles of masses  $m_1, m_2, m_3$ , etc., such that  $m_1 + m_2 + m_3 + \dots = M$ . These particles may be considered as small as desired, that is, each particle may be considered so small that it occupies but a point in space. Choose any three mutually perpendicular planes, fixed with respect to one another, and represent by  $x_1, y_1$  and  $z_1$  the perpendicular distances of the particle  $m_1$  from these planes respectively, and by  $x_2, y_2$  and  $z_2$  the perpendicular distances of the particle  $m_2$  from these three planes respectively, and so on for the other particles. Then the point whose distances from these three planes are respectively

$$\begin{aligned} X &= \frac{m_1 x_1 + m_2 x_2 + m_3 x_3 + \dots}{M} \\ Y &= \frac{m_1 y_1 + m_2 y_2 + m_3 y_3 + \dots}{M} \\ Z &= \frac{m_1 z_1 + m_2 z_2 + m_3 z_3 + \dots}{M} \end{aligned} \quad (6)$$

is defined as the center of mass, or center of gravity, or center of inertia, of the body. The name center of gravity arises from the fact that the vertical forces acting on all the various particles of a body, due to the pull of the earth, may be considered equivalent to a single force, equal to the sum of these individual forces, applied to the body at this point. The center of mass of a perfectly rigid body is a fixed point with respect to every point in the body; it may, however, lie either within or without the body.

Equations (6) may also be written in terms of the calculus, thus:

$$X = \int \frac{\delta x \delta v}{M}, \quad Y = \int \frac{\delta y \delta v}{M}, \quad Z = \int \frac{\delta z \delta v}{M}. \quad (6a)$$

where  $d\sigma$  represents an elementary volume of the body at any point,  $x$ ,  $y$  and  $z$  the distances of this point from the three planes of reference,  $\delta$  the density of the body at this point, and  $M$  the total mass of the body. When the density is uniform throughout,

$$X = \int \frac{x d\sigma}{V}, \quad Y = \int \frac{y d\sigma}{V}, \quad Z = \int \frac{z d\sigma}{V},$$

where  $V$  is the total volume of the body.

**Centroid or Center of Gravity of a Plane Section.** — This is defined as the point whose coördinates in the plane of the section are

$$X = \int \frac{x dA}{A} \quad \text{and} \quad Y = \int \frac{y dA}{A} \quad (6b)$$

referred to any two fixed mutually perpendicular lines in this plane,  $A$  being the total area of the section and  $dA$  any elementary area of the section. Physically, the center of gravity of a plane section may be defined as the center of gravity of a thin plate having the same shape as that of the section and of uniform thickness and specific gravity. See article on *Structures, Simple*, for the position of center of gravity for various plane sections.

**Center of Gravity of Cylinders and Prisms.** — The center of gravity of a cylinder or prism with parallel end surfaces and of any shaped cross-section, solid or hollow, is the centroid of that cross-section of the cylinder or prism which is halfway between the two ends, provided the cylinder has a uniform density throughout.

**Moment of Inertia ( $I$ ).** — Consider any axis of reference  $X$  and any particle of mass  $m$  at a distance  $r$  from this axis; then the product  $mr^2$  is called the moment of inertia of the particle  $m$  about the axis  $X$ . The moment of inertia of an extended body or system of bodies about any axis is

$$I = m_1 r_1^2 + m_2 r_2^2 + m_3 r_3^2 + \dots \quad (7)$$

the summation including products  $mr^2$  for all the particles of the body or system of bodies,  $r$  being the distance of the particle from the axis. This may also be written in the notation of the calculus as

$$I = \int r^2 dm, \quad (7a)$$

where  $dm$  represents the mass of any particle and  $r$  is the distance from the axis. In case the body has a uniform density  $\delta$  throughout this may also be written

$$I = \delta \int r^2 d\sigma, \quad (7b)$$

where  $d\sigma$  represents an elementary volume of the body.

**Units of Moment of Inertia of Bodies.** — The moment of inertia of a body is of the nature of, or has the "dimensions" of, (length)<sup>2</sup>  $\times$  (mass). When the mass is expressed in pounds and the distance  $r$  in feet then the moment of inertia may be said to be expressed in (foot)<sup>2</sup>-pounds, and similarly for any other units of mass and length. In applying the formulæ below the same set of units must be used throughout. See *Units and Conversion Factors*.

**Moment of Inertia of a Plane Section.** — The moment of inertia of a plane section about any axis is defined by the relation

$$I = \int r^2 dA, \quad (7c)$$

where  $dA$  represents any elementary area of this section and  $r$  the distance of this elementary area from the axis. When the axis is chosen *perpendicular* to the plane of the section *through its center of gravity* the moment of inertia about this axis is called the "polar" moment of inertia. Physically, the moment of inertia of a plane section about any axis may be defined as the moment of inertia about this same axis of a thin plate having the same shape as that of the section and having unit mass per unit of area.

The unit of moment of inertia of a plane surface has the dimensions of length to the fourth power.

Let  $X$  and  $Y$  be two mutually perpendicular axes in the plane of the section *passing through its center of gravity* and let  $Z$  be the axis through the center of gravity perpendicular to this plane and therefore also perpendicular to  $X$  and  $Y$ ; let  $I_x$  and  $I_y$  be the moments of inertia of the plane section about  $X$  and  $Y$  respectively, and  $I_z$  be the polar moment of inertia of the section. Then

$$I_z = I_x + I_y. \quad (7d)$$

Values of  $I_x$  and  $I_y$  for various plane figures are given in the article on *Structures, Simple*.

Let  $X$  be any axis in the plane of a section,  $X_0$  an axis through the center of gravity of the section parallel to  $X$ ,  $s$  the distance between the two parallel axes  $X$  and  $X_0$ ,  $I_0$  the moment of inertia of the section about  $X_0$ , and  $A$  the area of the section. Then the moment of inertia of the section about  $X$  is

$$I_x = I_0 + s^2 A. \quad (7c)$$

**Principal Axes and Principal Moments of a Plane Section.** — For every plane surface there are two rectangular axes passing through its center of gravity and lying in the surface, such that about one of these axes the moment of inertia is less, and about the other greater, than that about any other axis in the given surface. These two axes are called the *principal axes* and the moments the *principal moments of inertia*. If the plane figure has an axis of symmetry, this axis is one of the principal axes; e.g., a rectangle has two axes of symmetry, one parallel to each side, hence each of these axes is a principal axis. In the case of a circle any axis may be considered a principal axis. The principal axes for various sections are given in the article on *Structures, Simple*.

**Moment of Inertia of Cylinders and Prisms.** — Let the cylinder or prism be of any cross-section whatever, solid or hollow; let its density be  $\delta$  constant throughout; let the length of its own axis between the parallel end surfaces be  $l$ ; and let  $I_s$  be the moment of inertia of the cross-section of the cylinder or prism about any axis  $X$  parallel to the length  $l$ ; then the moment of inertia of the entire cylinder or prism about this axis  $X$  is

$$I_c = \delta I_s l. \quad (7f)$$

The density  $\delta$  must be referred to a volume unit based upon the same unit of length as that in which the dimensions of the cylinder or prism are expressed. For example, if  $I_s$  is expressed in centimeters-to-the-fourth-power,  $\delta$  must be expressed in mass per cubic centimeter, and  $l$  must be expressed in centimeters; if  $\delta$  is in grams per cubic centimeter, then the moment of inertia is in (centimeter)<sup>2</sup>-grams.

**Radius of Gyration ( $\rho$ ).** — The radius of gyration of a body about any axis is defined by the relation

$$I = M\rho^2 \quad \text{or} \quad \rho = \sqrt{\frac{I}{M}} \quad (8)$$

where  $M$  is the mass of the body and  $I$  its moment of inertia about the given axis. When the body has a uniform density throughout the radius of gyration may also be written

$$\rho = \sqrt{\frac{\int r^2 dv}{V}}, \quad (8a)$$

where  $V$  is the volume of the body. Radius of gyration is of the same nature as length and is therefore expressed in the same units as length.

**Radius of Gyration of Plane Section.** — The radius of gyration of a plane section about any axis is defined by the relation

$$\rho = \sqrt{\frac{\int r^2 dA}{A}}, \quad (8b)$$

where  $A$  is the total area of the section,  $dA$  an elementary area of this section and  $r$  the distance of  $dA$  from the axis. Values of  $\rho_x$  and  $\rho_y$  for various sections are given in the article on *Structures, Simple*.

From formula (7d) it follows that if  $\rho_x$  and  $\rho_y$  represent the radii of gyration of a plane section about two mutually perpendicular axes passing through the center of gravity of the section, then the radius of gyration  $\rho_z$  of this section about an axis through its center of gravity perpendicular to the plane of the section is

$$\rho_z = \sqrt{\rho_x^2 + \rho_y^2}. \quad (8c)$$

For example, for a circular section  $\rho_x = \rho_y = \frac{d}{4}$ , where  $d$  is the diameter of the section. Hence the polar radius of gyration about a perpendicular axis through the center of the circle is  $\rho_z = \frac{\sqrt{2}}{4}d$ .

From formula (7c) it also follows that if  $\rho_0$  is the radius of gyration about any axis  $X_0$ , then the radius of gyration about a parallel axis  $X$  at a distance  $x$  from  $X_0$  is

$$\rho_x = \sqrt{\rho_0^2 + x^2}. \quad (8d)$$

**Radius of Gyration of Cylinders and Prisms.** — The radius of gyration of a cylinder or prism about any axis  $X$  parallel to its own axis is the same as the radius of gyration about the axis  $X$  of any plane section of the cylinder or prism, provided the end surfaces are parallel and the density is uniform throughout. This relation holds for a prism or cylinder of any shape of cross-section, whether solid or hollow.

**Linear Momentum ( $mv$ ).** — When the center of mass of a body of mass  $m$  is moving with a linear velocity  $v$  with respect to any point  $P$ , the product  $mv$  is called the linear momentum of the body with respect to this point. Units of linear momentum are of the same nature or dimensions as the units of power; see *Units and Conversion Factors*.

Experience shows that in any system of bodies composed of two bodies or groups of bodies  $A$  and  $B$ , any change in the linear momentum of the first body or group of bodies  $A$  with respect to the center of mass of the system is accompanied by an equal and opposite change in the linear momentum of the second body or group of bodies  $B$  with respect to the center of mass of the system, and vice versa. This fact of experience is known as the *Principle of the Conservation of Linear Momentum*.

**Angular Momentum ( $I\omega$ ).**—When a body has a moment of inertia  $I$  about any axis  $X$  and is rotating about this axis with an angular velocity  $\omega$  with respect to any point  $P$ , the product  $I\omega$  is called the angular momentum of the body about this axis with respect to the given point. Units of angular momentum are of the same nature or dimensions as those of linear momentum and of power; see *Units and Conversion Factors*.

Experience shows that in any system of bodies composed of two bodies or groups of bodies  $A$  and  $B$ , any change in the angular momentum of the first body or group of bodies  $A$  about any axis  $X$  is accompanied by an equal and opposite change in the angular momentum of the second body or group of bodies  $B$  about this same axis, and vice versa. This fact of experience is known as the *Principle of the Conservation of Angular Momentum*.

**Force ( $f$ ).**—In general terms a force is that which produces or tends to produce a change in the state of rest or motion of a body, or "a force is pull or a push." The nature of force is not thoroughly understood, but the effects of a force, e.g., change in motion, the extension or compression of a spring, etc., are readily measured. From the principle of the conservation of linear momentum stated above it follows that any change in the motion of a body or portion of a body  $A$  is always accompanied by a change in the motion of some other body or portion of the same or of some other body  $B$ . Hence the body  $A$  is said to exert a force on the body  $B$ , and vice versa.

In a system composed of but two bodies  $A$  and  $B$ , uninfluenced by the presence of any other bodies, the measure of the force produced on the body  $A$  by the body  $B$  may be taken as the rate of change with time of the linear momentum of  $A$  with respect to the center of mass of the system formed by  $A$  and  $B$ . The measure of the force produced on  $B$  by  $A$  is similarly defined. From the principle of the conservation of linear momentum it then follows that the force produced on  $A$  by  $B$  is equal and opposite to the force produced on  $B$  by  $A$ , or "action and reaction are equal and opposite."

Stated in a formula the above definition is that the mutual force between any two bodies  $A$  and  $B$  whose motion is uninfluenced by any other forces is

$$f = m_1 a_1 = -m_2 a_2 \quad (9)$$

where  $m_1$  and  $m_2$  are the masses of  $A$  and  $B$  respectively, and  $a_1$  and  $a_2$  are the accelerations of the centers of mass of  $A$  and  $B$  respectively with respect to the center of mass of the system formed by  $A$  and  $B$  together.

**Force of Gravitation.**—For example, consider the case of a mass  $m$  at any point above the earth. The earth exerts a force on  $m$  and  $m$  exerts an equal and opposite force on the earth, and if there are no other forces acting  $m$  will move toward the joint center of mass of the earth and the body  $m$ , and similarly the earth will move toward this same point. However, as the earth has a mass many times that of any body at or near its surface, the center of mass of the system formed by  $m$  and the earth is practically that of the earth itself, and the motion of the earth with respect to this point is inappreciable. Hence the force exerted by the earth on the mass  $m$  is, within the limits of error of observation,

$$f = mg, \quad (9a)$$

where  $g$  is the acceleration of the center of mass of  $m$  with respect to the center of the earth, or with respect to any point fixed with respect to the surface of the earth in the vertical line through the center of mass of  $m$ .

**Units of Force.**—The rational unit of force is that force which will give unit linear acceleration to unit mass; this unit of force is called the "absolute" unit of force. When the mass is expressed in grams and the acceleration in centimeters per second per second, the corresponding absolute unit

of force is called the "dyne;" when the mass is expressed in pounds and the acceleration in feet per second per second, the corresponding absolute unit of force is called the "poundal."

The relation expressed by equation (9a), however, suggests another unit of force which for many purposes is very convenient, and in fact is the unit ordinarily used by engineers. This unit, called the "gravitational" unit of force, is the force exerted by the earth on unit mass; since the value of this force in terms of the absolute unit varies with latitude and elevation, it is also necessary to specify a definite place of measurement of this unit force, or better a definite value of the acceleration  $g$ , which shall be used in evaluating this force in terms of the absolute unit. The value of  $g$  adopted by international agreement is  $g = 980.665$  cm. per sec. per sec. = 32.1739 ft. per sec. per sec., which (see Note 5 at top of p. 3 of this book) is equal to the acceleration due to gravity at 45 degrees latitude and sea-level; see also above under *Acceleration*. Unfortunately the gravitational units of force are given the same names as the units of mass to which they refer; for example a force of 1 pound is the pull exerted by the earth on a mass of 1 pound at 45 degrees latitude and sea-level. This double use of names often leads to confusion unless one keeps clearly in mind the definitions of unit mass and unit force. See *Units and Conversion Factors*.

When the force acting on a body is expressed in absolute units, the relation between force, mass and linear acceleration is

$$f = ma \quad \text{absolute units.} \quad (9b)$$

When the force is expressed in gravitational units, the relation between force, mass and linear acceleration is

$$f = \frac{m}{g_0} \cdot a \quad \text{gravitational units,} \quad (9c)$$

where  $g_0$  stands for the numerical factor 32.1739 when  $f$  is in pounds,  $m$  in pounds and  $a$  in feet per second per second; similarly when  $f$  is expressed in grams,  $m$  in grams and  $a$  in centimeters per second per second  $g_0$  stands for 980.665.

**Measurements of Force.** — One seldom has to deal with a simple system of but two bodies, and consequently the above definitions of the measure of a force can seldom be applied to an actual measurement. The value of these definitions is that they fix the unit of force. Forces are measured by balancing the pull of an unknown force against a known force (e.g., gravity or the reacting force of a spring), the principles involved being deduced from the fundamental principle of the conservation of linear and angular momentum when applied to bodies in equilibrium; see the section on *Conditions for Equilibrium* below.

**Weight and Force.** — The word weight, as already noted, is used to designate both mass and force. A weight of 10 pounds, say, as ordinarily used in reference to "how much" of a substance, means that the piece of matter in question has a mass of 10 pounds. A weight of 10 pounds used in reference to the pull produced by the earth on a piece of matter means that this pull is a force of 10 pounds. From the above definitions it follows that, neglecting the slight variation with latitude and elevation, the numerical values of weight used in the two senses are equal, provided mass is expressed in absolute units and force in gravitational units, i.e., a mass of 10 pounds also weighs 10 pounds, but weighs 321.739 poundals; see above under *Units of Force*.

**Point of Application and Line of Action of a Force.** — Any particle, or point of a body which is acted upon directly by some external force (e.g.,

a string attached to the body at this point) is said to be the point of application of this external force. A line drawn through this point in the direction of the force is called the line of action of the force. In general, whenever a solid body is acted upon by any number of external forces applied at various points the motion produced is the same as that which could be produced by *not more than two* single external forces. When the points of application of these two resultant forces coincide, then the actual motion produced is the same as that which would be produced by a *single* force acting at that point.

**Impulse of a Force.** — The impulse of a force is defined as the time integral of the force, i.e., if a force  $f$  is applied for a time  $t$ , then the impulse is

$\int_0^t f dt$ , account being taken of both the variation of the magnitude and direction of the force during the given time interval. The total change in the linear momentum of a body in any time  $t$  is equal to the impulse of the resultant force acting on it during this time. The conception of the impulse of a force is useful in dealing with suddenly applied forces which continue but a short time.

**Concurrent and Coplanar Forces.** — When the lines of action of all the external forces acting on a body meet in a point these forces are said to form a concurrent system of forces. When all the external forces acting on a body lie in the same plane they are said to form a coplanar system of forces.

**Pressure ( $p$ ).** — The perpendicular component of the force per unit area exerted on any surface is called the pressure on that surface. Let  $df$  be the perpendicular or normal component of the force acting on an area  $dA$ , then the pressure at  $dA$  is

$$p = \frac{df}{dA} \quad (10)$$

The term pressure is sometimes used as a synonym for force and what is here defined as pressure is called the "intensity of pressure." The rational unit of pressure is force per unit area, e.g., dynes per sq. cm. or pounds per sq. in., but a number of other arbitrary units are employed, such as, one inch of water column, one millimeter of mercury column, one atmosphere, etc. A dyne per square inch is also a barie. A standard atmosphere is the pressure that will support a column of mercury 76 centimeters = 29.9212 inches high at  $0^\circ$  C. at a place where  $g = 980.665$  centimeters per second per second; using Thiesen and Schöel's determination of the density of mercury at  $0^\circ$  C. as 13.59545 grams per cubic centimeter (*Zeitsch. f. Instrkde.*, 1898, Vol. 18, p. 138) a standard atmosphere is equivalent to 14.6964 pounds per square inch. See *Units and Conversion Factors*.

**Absolute Pressure.** — The atmosphere exerts a pressure (ranging from about 29 to 30 inches of mercury, depending upon the weather conditions and elevation) upon every surface with which it is in contact. The total pressure on a surface including that applied by any artificial means and that of the atmosphere is called the absolute pressure on the surface.

**Torque or Moment of a Force ( $T$ ).** — Consider any axis  $X$  and any force acting at a point  $P$  at a perpendicular distance  $r$  from this axis; let  $f$  be the component of this force perpendicular to the plane through  $X$  and  $P$ . Then the product

$$T = rf \quad (11)$$

is called the moment of the force, or the torque due to this force, about the axis  $X$ . The distance  $r$  is called the "lever arm" or simply the "arm" of the force about this axis. Both absolute and gravitational units of torque are

used, the units being of the same nature or dimensions as the units of energy (see below), but the two words in the compound names of the energy units are usually reversed. For example the foot-pound is an energy unit but the corresponding unit of torque is called the pound-foot. The conversion factors, however, are identical; see *Units and Conversion Factors*. Torque is also frequently expressed as "torque at unit radius," e.g., a torque of so-many pounds at 1 foot radius is a common expression; a more exact expression for the measure of torque would be "force at unit radius."

Torques about the same axis can be added algebraically, and torques about several axes meeting in a point can be added vectorially.

**Couples.** — Two equal and opposite parallel forces which are not concurrent (i.e., do not act along the same line) are said to form a couple, and the strength of the couple is defined as the product of either force by the perpendicular distance between their lines of action. The torque produced by a couple about any axis perpendicular to the plane of the two forces is equal to the strength of the couple.

**Torque and Angular Acceleration.** — The relation between torque, moment of inertia and angular acceleration is the same as that between force, mass and linear acceleration, i.e.,

$$T = I\alpha, \quad \text{absolute units,} \quad (12)$$

where  $T$  is the torque in absolute units,  $I$  the moment of inertia and  $\alpha$  the angular acceleration, all about the same axis. When the torque is expressed in gravitational units the relation is

$$T = \frac{I}{g_0} \alpha, \quad \text{gravitational units,} \quad (12a)$$

where  $g_0$  is a number numerically equal to 32.1739 when  $T$  is expressed in pound-feet,  $I$  in (foot)<sup>2</sup>-pounds and  $\alpha$  in radians per second per second; similarly for the centimeter-gram-second units  $g_0 = 980.665$ .

**Work and Energy.** — When the point at which a force is applied to a body  $A$  moves\* with respect to the agent producing the force, in such a manner that the force has a component in the direction of the displacement of its application point, the force is said to do work; the body  $B$  exerting the force on  $A$  is also said to do mechanical work on the body  $A$ . As a measure of the mechanical work  $dW$  done by the force  $f$ , when its point of application moves a distance  $dl$  with respect to the body producing the force, is taken the product of the displacement  $dl$  by the component of the force  $f$  in the direction of this displacement, i.e.,

$$dW = (f \cos \theta) dl, \quad (13)$$

where  $\theta$  is the angle between the direction of the force and the direction of the displacement. For a finite displacement the mechanical work done is

$$W = \int_0^l f (\cos \theta) dl. \quad (13a)$$

When mechanical work is done on a body a change in the state of motion or in some other condition of the body is always produced. Like changes can also be produced by other means. For example, when two bodies are rubbed together rapidly, mechanical work is done on them by the agent which produces the force which moves one over the other against the opposing force due to friction. As a result, the temperature of the bodies is raised. The

\* Either as a result of the motion of the body  $A$  as a whole or in consequence of the motion of that part of  $A$  to which the force is applied.

temperature of the two bodies may also be raised by placing them near or in contact with a hotter body, without there being any appreciable amount of *mechanical* work done. In general, any change produced in a body or system of bodies by any means whatever, which change can also be produced directly by doing mechanical work on that body or system, or indirectly by doing mechanical work on some other body or system, is said to be due to a transfer of "energy" to that body or system; or work \* is said to be done on that body or system, irrespective of the means whereby the change is produced.

As a measure of the gain in energy corresponding to any change in a body or system of bodies is taken the amount of mechanical work which would have to be done by a mechanical force to produce this change and no other. For example, water can be heated by stirring it rapidly with a paddle driven by some external force; the total mechanical work done by this force can be expressed in terms of the value of the force, the number of revolutions of the paddle and the diameter of the pulley attached to the paddle, and the mass of the water and the resultant temperature rise can be measured. By making proper corrections for the work done against the various frictional forces other than the opposing force due to the stirring of the water itself and for the loss of energy by radiation, the amount of work required to raise the temperature of a pound of water, say, one degree Fahrenheit can be determined. By this means a very convenient secondary unit of energy can be expressed in terms of the unit of mechanical work, and the secondary unit can be used for expressing the amount of energy involved in various heat effects. See *Heat and Thermal Properties*.

Whenever a change takes place in a body or system of bodies which is the *reverse* of the change which can be produced in it by doing work on it, the body or system is said to *lose* energy, or energy is said to be transferred *from* it, or it is said to *do* work. As a measure of the amount of energy lost by the body or system when a given change takes place in it is taken the amount of work which would have to be done on it to restore it to its original condition.

**Units of Work and Energy.** — The fundamental unit of mechanical work in the c.g.s. system is the work done by a force of 1 dyne when its point of application is displaced (with respect to the agent producing the force) a distance of 1 centimeter in the direction of the force; this unit is called the "erg." The "joule" is equal to  $10^7$  ergs, by definition. The fundamental unit of mechanical work in the English gravitational system is the foot-pound, which is the work done by a force of 1 pound when its point of application is displaced a distance of 1 foot in the direction of the force; or 1 foot-pound is the work required to raise a mass of 1 pound a distance of 1 foot at a place where the acceleration due to gravity is 980.665 cm. per sec. per sec. or 32.1739 ft. per sec. per sec. Energy is expressed in the same units as mechanical work and in addition various heat units, such as the British thermal unit, the large and small calories, etc., are used; see *Heat and Thermal Properties*. For the relations among the various units see *Units and Conversion Factors*.

**Principle of the Conservation of Energy.** — Experience indicates that the amount of energy, as above defined, which can be transferred from a body or system of bodies to which no energy is added, is limited; i.e., the energy "possessed by" or "associated with" any body or system of bodies is *finite* in amount. As a rule, only a relatively small portion of the energy

\* The word "work" is used by some writers to signify mechanical work only, but the term is a very convenient one to use in referring to the transfer of energy by other means as well, i.e., any change resulting in a transfer of energy to a body may be said to result from the doing of "work" on the body, whether the change is produced by mechanical, electrical or other means.

associated with a body or system can be transferred to another body or system. Experience also justifies the assumption that whenever one body or system of bodies gains energy, some other body or system loses an exactly equal amount of energy. In every instance where this assumption can be tested directly it is found to hold, and every deduction from it has been found to be in accord with experimental fact. Hence this assumption is accepted as a fundamental principle of nature.

**Kinetic Energy.** — Work is required to set a body in motion, for while its motion is changing it is accelerating and therefore a force must be exerted upon it. From the definitions of acceleration, force and work given above it follows immediately that the work required to change the linear velocity of a body from  $v_0$  to  $v_1$  is

$$W_t = \frac{1}{2} m (v_1^2 - v_0^2) \quad \text{absolute units,}$$

$$\text{or} \quad W_t = \frac{1}{2} \frac{m}{g_0} (v_1^2 - v_0^2) \quad \text{gravitational units,}$$

where  $m$  is the mass of the body and  $g_0$  is the gravitational constant. Similarly, the work required to change the angular velocity of a rigid body about a given axis from  $\omega_0$  to  $\omega_1$  is

$$W_r = \frac{1}{2} I (\omega_1^2 - \omega_0^2) \quad \text{absolute units,}$$

$$\text{or} \quad W_r = \frac{1}{2} \frac{I}{g_0} (\omega_1^2 - \omega_0^2) \quad \text{gravitational units,}$$

where  $I$  is the moment of inertia of the body about this axis and  $g_0$  the gravitational constant. The expression

$$\frac{1}{2} m v^2 \quad \text{or} \quad \frac{1}{2} \frac{m}{g_0} v^2 \quad (14)$$

is called the "kinetic energy of translation" of the body, and the expression

$$\frac{1}{2} I \omega^2 \quad \text{or} \quad \frac{1}{2} \frac{I}{g_0} \omega^2 \quad (14a)$$

is called the "kinetic energy of rotation" of the body, both referred to the point with respect to which the velocities are measured.

**Total Kinetic Energy of a System of Bodies.** — The total kinetic energy of a moving system of bodies is equal to (1) the kinetic energy of the entire system moving with a velocity equal to the velocity of the center of mass of the system plus (2) the sum of the kinetic energies, rotational and translational, of each constituent body of the system due to the relative motion of this constituent body with respect to the center of mass of the whole system. For example, the total kinetic energy of a railway car is

$$W = \frac{1}{2} M v^2 + \frac{1}{2} \Sigma I \omega^2 \quad \text{absolute units,} \quad (14b)$$

$$W = \frac{1}{2} \frac{M}{g_0} v^2 + \frac{1}{2} \frac{\Sigma I \omega^2}{g_0} \quad \text{gravitational units,} \quad (14c)$$

where  $M$  is the entire mass of the car with full equipment,  $I$  the moment of inertia,  $\omega$  the angular velocity of any rotating part and the summation sign  $\Sigma$  indicates the sum of the products  $I\omega^2$  for all the rotating parts. See also *Railways, Energy Requirements for*.

**Potential Energy.** — The energy possessed by a body in virtue of its position with respect to the earth is usually called potential energy. More generally the term potential energy is used to designate any form of energy other than kinetic energy. In absolute units the increase in the potential energy of a body when it is raised a vertical distance  $h$  is  $mgh$ ; in gravitational units the increase in potential energy is  $msh$ .

**Power.** — By power is meant the time rate of doing work or the time rate of change of energy. Let  $dW$  be the work done in time  $dt$ , then the power is

$$P = \frac{dW}{dt} \quad (15)$$

The power produced by a force  $f$  or a torque  $T$  can also be expressed as

$$P = fv \quad \text{or} \quad P = T\omega, \quad (15a)$$

where  $v$  is the linear velocity of the point of application of the force and  $\omega$  is the angular velocity of the point of application of the torque. The rational unit of power is the unit of work done or of energy transferred per unit time, such as 1 erg per second, 1 joule per second, 1 foot-pound per second, 1 British thermal unit per second, and the like. 1 joule per second is called the watt, which is also equal to the power corresponding to 1 ampere and a potential difference of 1 volt (see *Units, Practical Electrical*). The horse-power (English and American) is defined\* as the power corresponding to 550 foot-pounds per second or 33,000 foot-pounds per minute. The metric horse-power, also called cheval-vapeur, force de cheval, Pferde-kraft, is defined as 75 kilogram-meters per second. The boiler horse-power is defined in the article on *Boilers, Steam*. The interrelations of the various units of power are given in the article on *Units and Conversion Factors*.

**CONDITIONS FOR EQUILIBRIUM.** — A body or system of bodies is said to be in equilibrium with respect to any external body (e.g., the earth) when (1) there is no change in the motion of the center of mass of the system with respect to this external body and (2) when there is no change in the total angular momentum of the body or system about any axis fixed with respect to this external body. These two conditions require (1) that the resultant of all the external forces † acting on the body or system be zero and (2) that the resultant of all the moments of these external forces, or torques, about any axis acting on the body or system be zero. These two conditions are most conveniently expressed by choosing three mutually perpendicular axes fixed with reference to the body of reference (e.g., the earth) and resolving all the forces into components  $F_x$ ,  $F_y$  and  $F_z$  parallel to these three axes and calculating the moments or torques  $T_x$ ,  $T_y$  and  $T_z$  of each of these forces about these three axes; then, using the symbol  $\Sigma$  to indicate the algebraic summation of the individual  $x$ ,  $y$  or  $z$  components,

$$\left. \begin{aligned} \Sigma F_x &= 0 & \Sigma T_x &= 0 \\ \Sigma F_y &= 0 & \Sigma T_y &= 0 \\ \Sigma F_z &= 0 & \Sigma T_z &= 0 \end{aligned} \right\} \quad (16)$$

\* The Bureau of Standards recommends the adoption of 746 watts as the definition of a horse-power. The older definition given above makes a horse-power 745.701 watts, using the standard value of  $g_0$  given above, namely, 980.665 cm. per sec. per sec. and the legal values of the foot and the pound (see *Units and Conversion Factors*). As this older definition is the one generally employed by all classes of engineers, it seems preferable to the author to retain it. See *Circular No. 34 of the Bureau of Standards and discussions in the various technical journals during 1912 and 1915*.

† i.e., forces any one of which would, if acting alone, produce a motion of the body or system or of some part of it with respect to the reference body.

These two sets of conditions constitute the basis of the entire subject of statics. Certain elementary applications are given in the article on *Structures, Simple*.

**Stability.** — When a body or system of bodies is in equilibrium and the state is such that when the body or system is displaced slightly it returns of itself to its original condition, the equilibrium is said to be stable; if when displaced slightly the body or system moves farther from its original condition, the equilibrium is said to be unstable; if when displaced slightly it remains in that condition, the equilibrium is said to be stable. The condition for stability may be expressed in a number of ways, viz.: (1) when the potential energy of the system with respect to the body of reference (e.g., the earth) is a minimum the equilibrium is stable; (2) when the forces acting are all gravitational the equilibrium is stable when the center of mass is in the lowest possible position; or (3) when the body or system rests on a number of points, the equilibrium is stable only when the resultant of all the forces acting on the body including its own weight, but excluding the supporting forces, cuts the smallest polygon which can be drawn including all the points of support.

**MOTION OF A PARTICLE.** — By a particle of matter is meant a portion of matter so small that it may be considered as occupying but a point in space. Let  $m$  be the mass of the particle,  $v$  its linear velocity at any instant with respect to any arbitrarily chosen set of axes of reference,  $dv$  the increase in its velocity in time  $dt$  (including both change in direction as well as in magnitude), and let  $F$  be the resultant of all the external forces, in absolute units,\* acting on the particle. Then the motion of the particle is completely specified by the equation

$$F = m \frac{dv}{dt},$$

where  $dv$  is taken to include the change in *direction* as well as the magnitude of the velocity. To take into account the variation of the direction of  $v$  as well as the variation in its magnitude, the resultant force  $F$  and the velocities may be resolved into components along the three axes, in which case this equation breaks up into the three equations

$$F_x = m \frac{dv_x}{dt}, \quad F_y = m \frac{dv_y}{dt}, \quad F_z = m \frac{dv_z}{dt}.$$

Since the velocity along any axis is equal to the time rate of displacement along that axis,  $v_x = \frac{dx}{dt}$ ,  $v_y = \frac{dy}{dt}$ , and  $v_z = \frac{dz}{dt}$ , whence these equations may also be written

$$\frac{d^2x}{dt^2} = \frac{F_x}{m}, \quad \frac{d^2y}{dt^2} = \frac{F_y}{m}, \quad \frac{d^2z}{dt^2} = \frac{F_z}{m}. \quad (17)$$

Hence when the forces can be expressed in terms of the coordinates of the point which the particle occupies at each instant, the displacements and velocities can be determined by solving these equations. Note that  $\frac{F_x}{m}$ ,  $\frac{F_y}{m}$  and  $\frac{F_z}{m}$  are the accelerations  $a_x$ ,  $a_y$  and  $a_z$  along the three axes.

**Rectilinear Motion.** — The simplest case is that of a particle acted upon by a force  $F$  which remains constant in direction. One of the axes, say the

\* When  $F$  is expressed in gravitational units replace  $m$  by  $\frac{m}{g_0}$ , where  $g_0$  is the gravitational constant.

$X$  axis, may be taken parallel to the line of action of the force, in which case equations (17) reduce to the single equation

$$\frac{d^2x}{dt^2} = \frac{F}{m}, \quad (17a)$$

and there is no acceleration along either of the other axes; i.e., the particle moves along the line of action of the force. If the force is also constant in magnitude,  $\frac{F}{m} = a$ , a constant. In this case the solution of (17a) is (see Equations):

$$\left. \begin{aligned} x - x_0 &= \frac{1}{2} a (t - t_0)^2 + v_0 (t - t_0), \\ v - v_0 &= a (t - t_0), \end{aligned} \right\} \quad (17b)$$

where  $t - t_0$  represents any interval of time,  $x - x_0$  the displacement of the particle during this interval and  $v - v_0$  the change in velocity of the particle during this interval. The displacement  $x - x_0$  may also be written

$$x - x_0 = \frac{v^2 - v_0^2}{2a}. \quad (17c)$$

**Curvilinear Motion; Motion in a Circle.** — Consider the special case of a particle moving in a circle of radius  $r$  with a constant tangential or peripheral velocity  $v$ . Choose the  $Z$  axis perpendicular to the plane of the circle. Let  $\theta$  be the angle (measured counter-clockwise) which a line drawn from the center of the circle to the particle makes at any instant with the  $X$  axis, then  $(90 - \theta)$  is the angle which this line makes with the  $Y$  axis at this instant. At any instant, then,

$$v_x = -v \sin \theta \quad \text{and} \quad v_y = v \cos \theta$$

and these components are not constant since  $\theta$  changes with time. The corresponding accelerations along the two axes are

$$a_x = -v \cos \theta \frac{d\theta}{dt} \quad \text{and} \quad a_y = -v \sin \theta \frac{d\theta}{dt},$$

both of which components are *toward* the center of the circle. But  $\frac{d\theta}{dt}$  is the angular velocity of the particle about the  $Z$  axis, and this is equal to the peripheral velocity divided by the radius, or  $\frac{d\theta}{dt} = \frac{v}{r}$ . Whence

$$a_x = -\frac{v^2}{r} \cos \theta \quad \text{and} \quad a_y = -\frac{v^2}{r} \sin \theta,$$

and therefore the resultant acceleration has the numerical value

$$a = \sqrt{a_x^2 + a_y^2} = \frac{v^2}{r} \quad (17d)$$

and is *toward* the center of the circle. Hence to cause a particle to rotate in a circle a force equal to  $\frac{mv^2}{r}$  must be applied to it in the direction *toward* the center, and the particle in turn pulls away from the center with an equal and opposite force which produces a tension outward along the radius in whatever (e.g., a string) holds the particle to the center. The tendency of the particle to pull outward from the center is called the centrifugal force, and its value

is  $\frac{mv^2}{r}$ ; the equal inward pull required to make the particle move in the circular orbit is called the centripetal force.

**Simple Harmonic Motion.**—(See also *Wave Analysis*.) By simple harmonic motion is meant a motion such that the acceleration of the moving particle or point at each instant is proportional to, but in the opposite direction from, the displacement. Such motion may be either rectilinear or a rotation about a fixed axis. Rectilinear simple harmonic motion may also be defined, see Fig. 1, as the motion of the projection  $P$  on a given diameter  $YY'$ , of a point  $Q$  which moves with a constant angular velocity  $\omega$  around a circle of radius  $A$ . The motion of the bob of a simple pendulum, the position of the end of a piston rod, etc., are examples of simple rectilinear harmonic motion (very nearly).

Referring to the circle diagram in Fig. 1,  $P_0$  represents the projection of the moving point  $Q$  at time  $t = 0$ . The angle made by  $OQ$  at any instant with

Fig. 1. Harmonic Motion

$OX$  is then  $(\omega t + \theta)$ . The linear velocity of  $Q$  is  $A\omega$ , and the component of this velocity at any instant along  $OY$ , i.e., the velocity of  $P$ , is

$$v = \frac{dy}{dt} = A\omega \cos(\omega t + \theta). \quad (18)$$

Whence the displacement  $y$  of  $P$  from  $O$  is, by integration,

$$y = A \sin(\omega t + \theta), \quad (18a)$$

and the acceleration along  $OP$  is, by differentiation,

$$a = \frac{d^2y}{dt^2} = -\omega^2 A \sin(\omega t + \theta), \quad (18b)$$

whence  $a = -\omega^2 y$ , which agrees with the first definition of harmonic motion.

**Period and Frequency.**—The period of any kind of an oscillation is defined as the time (usually in seconds) taken for the oscillating point to pass through a complete cycle of values back again to the starting point. The frequency is the number of complete cycles per unit time (usually per second). In the case of a harmonic oscillation the period is

$$T = \frac{2\pi}{\omega} \quad (18c)$$

and the frequency is

$$f = \frac{\omega}{2\pi}. \quad (18d)$$

**Amplitude.**—The “sine curves” to the right of the circle diagram show the variation with time of the displacement and the velocity (along  $OY$ ) of the projected point  $P$ . Displacement and velocity are plotted along the  $Y$  axis and  $\omega t$ , which is proportional to time, is plotted along the  $X$  axis. These curves bear a definite relation to each other and to the “origin” of time, i.e., to the point  $O$ . The maximum ordinate of each curve is called the “amplitude” of the curve. The amplitude of the displacement curve is  $A$ , the radius of the circle; the amplitude of the velocity curve is  $\omega A$ .

**Phase.**—The distance expressed in angular measure, from the origin to the point at which the curve first crosses the  $X$  axis in the *rising* direction is called the “phase angle” of the curve. The phase angle is taken positive when it is measured to the *left* from the origin, and negative when measured to the right.\* The phase angle of the displacement curve is  $\theta$ , and the phase angle of the velocity curve in the above case is  $\frac{\pi}{2} + \theta$ .

**Difference in Phase.**—The difference in the phase angles of two sine curves of the same frequency is called the “difference in phase” between the two curves; the difference in phase between the displacement curve and the velocity curve in the above case is  $\frac{\pi}{2}$  radians or 90 degrees. The curve which has the larger (algebraically) phase angle is said to “lead” the other curve, and the one with smaller (algebraically) phase angle is said to “lag behind” the other one. In the above example the velocity curve leads the displacement curve. Note that the curve to the left is the leading curve.

**ROTATION OF A SOLID BODY.**—When a solid body moves in such a manner that one straight line through the body remains fixed with respect to any given set of axes of reference, its motion is called simple rotation with respect to these axes. For such motion the external forces must be equivalent to two equal and opposite forces which have a moment only about the axis of rotation. Let  $T$  be the value of this moment or torque,  $I$  the moment of inertia of the body about this axis and  $d\omega$  the increase in the angular velocity about this axis in time  $dt$  (the same for each point of the body), then the motion is completely specified by the equation

$$\left. \begin{aligned} T &= I \frac{d\omega}{dt} && \text{(for } T \text{ in absolute units)} \\ \text{or } T &= \frac{I}{g_0} \frac{d\omega}{dt} && \text{(for } T \text{ in gravitational units).} \end{aligned} \right\} \quad (19)$$

For constant torque and therefore constant angular acceleration, i.e., for  $\frac{d\omega}{dt} = \alpha = \text{constant}$ , the change in angular velocity in the interval of time  $(t_2 - t_1)$  is

$$\omega_2 - \omega_1 = \alpha (t_2 - t_1), \quad (19a)$$

and the angle turned through in the interval  $(t_2 - t_1)$  is

$$\theta_2 - \theta_1 = \frac{1}{2} (\omega_2 + \omega_1) (t_2 - t_1) = \frac{\omega_2^2 - \omega_1^2}{2\alpha}. \quad (19b)$$

**THREE-DIMENSIONAL MOTION.**—The motion of a solid body may in the most general case be expressed in terms of a translation of its center and a rotation of the body around an axis through its center of mass. The motion

\* The opposite convention is used by some writers, in which case the equation for the sine curve is  $y = A \sin (\omega t - \theta)$ .

of the center of mass produced by any number of external forces is the same as would be produced by a single force, equal to the vector sum of the actual forces, acting on a single particle occupying the position of the center of mass in the actual body and having a mass equal to the entire mass of this body. The rotation can be determined by considering the center of mass as fixed and the actual forces then applied. That is, the translation of the center of mass and the rotation about the axis through it can be considered independently of each other; the actual motion is then the resultant of these two types of motion. See *American Civil Engineers' Pocket Book* for a brief treatment of this subject.

**MENSURATION.**—(See also *Angles; Equations; Trigonometry*.) The term mensuration is used in this article to include the relations between areas and volumes of geometric figures and their linear dimensions.

**Triangle.**—

$$\begin{aligned} \text{Area} &= \frac{1}{2} (\text{base}) \times (\text{perpendicular height}) \\ &= \sqrt{s(s-a)(s-b)(s-c)}, \end{aligned}$$

where  $a$ ,  $b$  and  $c$  are the lengths of the three sides respectively, and  $s = \frac{1}{2}(a+b+c)$ .

**Trapezoid.**—

$$\text{Area} = \left( \frac{a+b}{2} \right) d,$$

where  $a$  and  $b$  are the lengths of the parallel sides respectively, and  $d$  the distance apart.

**Parallelogram.**—

$$\text{Area} = (\text{base}) \times (\text{perpendicular height}).$$

**Parabola.**—

$$\text{Area} = \frac{3}{8} (\text{area of circumscribing triangle}).$$

**Cycloid.**—

$$\text{Area} = \frac{3}{8} \pi \times (\text{altitude})^2,$$

the altitude being the diameter of the rolling circle.

**Circle.**—

$$\text{Circumference} = 2\pi r = \pi d,$$

$$\text{Area} = \pi r^2 = \frac{\pi}{4} d^2,$$

where  $r$  is the radius and  $d$  the diameter.

$$\text{Area of segment} = \frac{r^2}{2} (\theta - \sin \theta),$$

where  $\theta$  is the angle in radians (see *Angles*) subtended by the arc of the segment. If  $n$  is the height of the segment, measured along the radius perpendicular to the chord,

$$\text{Area of segment} = \pi r^2 M - A (r - n),$$

where

$$A = \sqrt{n(2r-n)} \quad \text{and} \quad M = \frac{1}{180} \sin^{-1} \left( \frac{A}{r} \right).$$

**Ellipse.**—

$$\text{Area} = \pi ab,$$

where  $a$  and  $b$  are the principal semi-axes.

**Prism with Parallel Sides and Parallel Ends.**—

$$\text{Volume} = (\text{area of end}) \times (\text{Perpendicular Distance between Ends}).$$

**Right Circular Cylinder.**—

$$\text{Volume} = \frac{\pi}{4} d^2 l,$$

where  $d$  is the diameter, and  $l$  the length.

$$\text{Total surface of right cylinder} = \pi d (l + \frac{1}{2} d).$$

**Right Circular Cone.** —

$$\begin{aligned} \text{Volume} &= \frac{1}{3} (\text{area of base}) \times (\text{height}), \\ &= \frac{1}{3} (\text{volume of circumscribing cylinder}), \end{aligned}$$

where  $r$  is the radius of base and  $h$  the height of the cone.

$$\text{Area of curved surface of a right circular cone} = \pi r \sqrt{h^2 + r^2}.$$

**Right Pyramid.** —

$$\text{Volume} = \frac{1}{3} (\text{area of base}) \times (\text{height}),$$

$$\text{Volume of frustum of pyramid} = \frac{1}{3} (\text{height}) (A + a + \sqrt{aA}),$$

where  $A$  and  $a$  are the areas of the ends respectively.

**Sphere.** —

$$r = \text{radius},$$

$$\text{Area of surface} = 4\pi r^2$$

$$= \frac{2}{3} (\text{total area of circumscribing cylinder}).$$

Area of the surface of a zone of a sphere = area of zone of the same height as this zone projected on to a cylinder.

$$\text{Volume} = \frac{2}{3} \pi r^2 h$$

$$= \frac{2}{3} (\text{volume of circumscribing cylinder}).$$

Volume of a frustum of a sphere =  $\pi r^2 (h \mp A) - \frac{\pi}{3} (A^2 \mp A^2)$ , where  $h$  is the distance of its outer face from center and  $A$  the distance of its inner face from the center, the negative signs in the brackets to be used if both faces are on the same side of the center and the positive signs if on opposite sides of the center.

**Ellipsoid.** —

$$\text{Volume} = \frac{4}{3} \pi abc,$$

where  $a$ ,  $b$  and  $c$  are the three principal semi-axes respectively.

**Paraboloid.** —

Volume of a paraboloid of revolution equals one half that of the circumscribing cylinder.

**MOTOR-CONVERTERS.** — (See also *Converters, Synchronous; Motors, Induction; Standardization Rules.*) A motor-converter is a combination of an induction motor and synchronous converter, with the secondary of the motor and the armature of the converter mounted upon the same shaft and connected together electrically without slip rings. The induction motor receives all the a-c. power, transforms a part of it into mechanical power delivered to the shaft, and also acts as a transformer delivering the rest of the power in electrical form at a lower frequency from its secondary to the armature of the converter. It operates like two induction motors in "concatenation" or "cascade." The object is to obtain the steadiness of a 30-cycle converter on a 60-cycle circuit.

The speed of a motor converter depends upon the supply frequency and varies inversely as the sum of the number of poles in both machines. Thus if a combination of a 6-pole motor and 6-pole converter be operated from a 60-cycle circuit the speed of the armature will be 600 r.p.m. The primary of the induction motor will operate at 60 cycles but the secondary will supply the armature of the converter with 30 cycles. Thus the converter may be built with the good design constants of a 30-cycle machine.

This combination is larger than a converter but smaller than a motor-generator set and its efficiency is lower than that of a converter. It is used somewhat in Europe but not much in the United States.

**BIBLIOGRAPHY.** — Arnold, E., *Wechselstromtechnik, Vol. IV*; Thompson S. P., *Dynamo Electric Machinery, Vol. II*; Steinmetz, C. P., *Electrical Engineering*. Numerous papers in the *Electrical World*, N. Y.

**MOTOR-GENERATORS.** — (See also *Converters, Synchronous; Frequency Changers; Generators; Motor; Standardization Rules.*) A motor-generator set is a combination of a motor and a generator having separate fields and armatures but mounted on the same shaft with common base and bearings. Combinations of various types of motors and generators are used; some of the more important combinations and their applications are described below.

**Frequency Changers.** — See separate article on *Frequency Changers.*

**Direct-current Motor Driving Direct-current Generator.** — These sets are used when it is desired to convert low-voltage direct current into high voltage direct current, or vice versa; they are used in preference to a dynamotor (q.v.) when good regulation is desired in the secondary circuit.

**Direct-current Motor Driving Alternating-current Generator.** — These sets are used for converting direct into alternating current. See also the section on *Inverted Synchronous Converters* in the article on *Converters, Synchronous.*

**Induction Motor Driving Direct-current Generator.** — The induction motor may be wound for potentials as high as 13,000 volts and the transformation from alternating current at this voltage to direct current may be made without the use of transformers. Since the induction motor has a decreasing speed with increasing load the direct-current generator must be compounded to give good regulation; with proper compounding excellent regulation may be obtained. The induction-motor-generator set is sometimes used in preference to a synchronous converter when the service requires specially good regulation. However, the efficiency of such a set (about 85 per cent at rated load) is less than that of a synchronous converter, even if no transformers are required by the motor-generator set. The motor-generator set also occupies from 50 per cent to 80 per cent more floor space, weighs from 30 per cent to 50 per cent more, and costs from 25 per cent to 50 per cent more than a synchronous converter, in spite of the fact that they are designed to operate at the highest practicable speeds.

**Costs and Speeds of Induction-motor-generator Sets.** — Very roughly the prices and suitable speeds are (in 1922) as follows:

Kw. capacity	R.p.m.	Cost per kw.
200	750	\$33
500	500	24
1000	300	19

These prices are about 50 per cent higher than pre-war prices.

**Synchronous Motor Driving Direct-current Generator.** — This combination is preferable in many instances to the preceding, because it operates at constant speed and because the field of the synchronous motor may be adjusted to make use of line compounding or to compensate for low power factor in other apparatus on the circuit (see *Motors, Synchronous*). Provision must be made for the direct-current excitation for the synchronous motor. If the direct-current generator is wound for too high a potential a special exciter must be provided. Since there is no load on the set at starting the synchronous motor may be started in the usual manner.

**SPECIFICATION FOR MOTOR-GENERATORS.** — The following memoranda are intended to assist in writing specifications. See also articles on *Specifications; Motors; and Generators.*

General description and use of machine. Motor: see specifications in articles on *Motors*. Generator: see specifications in articles on *Generators*. Whether or not motor and generator are to be on common bed-plate. Exciter for generator field. Limiting over-all dimensions.

**MOTORS, ALTERNATING-CURRENT COMMUTATOR.** — (See also *Motors, Direct-current; Motors, Polyphase-induction; Motors, Single-phase Induction; Standardisation Rules.*) There are several different types of alternating-current commutator motors designed to operate on single-phase circuits, but they differ chiefly in the electrical connections employed. They may be divided into two general classes, series motors and repulsion motors. While these motors differ in their connections and in slight details in their characteristics, they all have the general characteristics of the d-c. series motor, that is, increasing torque with decreasing speed and a high efficiency over a considerable range of speed. Alternating-current commutator motors with shunt motor characteristics are also used to a limited extent abroad.

**GENERAL CHARACTERISTICS.** — The torque of any a-c. commutator motor is constant in direction, but pulsating in value, and its average value

Fig. 1. Characteristic Curves of a Motor of the Single-phase Locomotives of the N. Y., N. H. & H. R. R. (St. Ry. Jour., Apr. 1906.)

is proportional to the product of the effective value of the flux and the effective value of the armature current. The direction of the torque may be changed

by changing the direction of the current in the field with respect to the armature, or vice versa. The power factor increases with increase of the speed and therefore decreases with increase of load. The efficiency, while not as good as that of a d-c. motor of the same rating is, however, fairly high. The motors have in addition to the losses common to d-c. motors a core-loss in the field, increased core-loss in the armature, increased commutation loss and increased  $R^2I^2$  loss in special windings. In Fig. 1 are given the characteristic curves of the a-c. compensated series motors used on the single-phase locomotives of the New York, New Haven & Hartford Railroad.

**APPLICATIONS.**—The most general application of a-c. commutator motors in large sizes is in railway and hoisting work; see *Railways, Electric*, and *Hoists, Electric*. The same principles of operation are made use of in the devices for starting single-phase induction motors (see *Motors, Single-phase Induction*), the motor being brought up to speed as an a-c. commutator motor and then by a change of connections made to operate as a single-phase induction motor.

**DESIGN.**—The salient features in the design of the various types of a-c. commutator motors are described briefly below.

**Straight A-C. Series Motor.**—Since the torque of an ordinary d-c. series motor does not change in direction when the current through both the field and the armature reverses simultaneously, any d-c. series motor will develop a uni-directional torque when connected across a-c. mains. However, when an ordinary d-c. series motor is thus used the power factor of the load taken by it is very low, there is a large eddy-current loss in the field structure, and violent sparking occurs at the commutator. To make a series motor practicable for a-c. service, the field structure must be laminated in order to avoid eddy currents and the field coils must have only a few turns to avoid too great self-inductance, and the consequent low power factor. The greater tendency to spark in the case of the a-c. series motor is due to the *alternating* field flux which interlinks the coils short-circuited by the brushes, thus inducing in these coils a relatively large e.m.f. not present when the motor is operating on a d-c. circuit. This difficulty can be avoided to a certain extent by designing the motor for a small field flux and with but a few turns in series in each armature coil. In general, therefore, single-phase commutator motors are built for low voltages, such as 200, with one turn per coil, multiple-wound armatures and with the armature ampere turns per pole about four times the field ampere turns per pole. The effect of the armature ampere turns can be neutralized by a "compensating" winding described below. The field flux is practically limited to that value which will give 4 volts per turn in the short-circuited armature coil, as this is about the limit that may be commutated with carbon brushes.

**Resistance Leads.**—As an additional means of preventing sparking, high-resistance leads are frequently used between the commutator segments and the armature coils. These leads are made of a high-resistance metal strip bent back and forth several times, and imbedded in the armature slots along with the armature conductors proper. On account of the dissipation of heat in these leads a lower current density must be used in the armature conductors proper than is used in the case of d-c. motors. The arrangement of the leads is such that the main or useful current passes through two high-resistance leads in multiple as it enters the armature, while the undesirable short-circuited current passes through two high-resistance leads in series. It should be noted, however, that at any instant there is current only in those leads connected to coils which are being short-circuited at this instant.

**Compensating Winding.**—To obviate the high armature reaction in an a-c. series motor and at the same time to improve the power factor, a "compensating" winding is usually employed. This consists of a distributed winding imbedded in slots in the pole faces and connected usually in series (Fig. 2) with the main field winding and armature in such a manner that the current through it sets up a magnetomotive force which practically neutralizes the effect of the armature ampere turns. When the compensating winding is connected in series with the field and armature, as shown in Fig. 2, the motor is said to be "conductively compensated." An "inductively compensated" motor has this winding short-circuited upon itself and the current in it is induced from the armature by transformer action. Inductive compensation is not operative on d-c. circuits, but is as satisfactory as conductive compensation for a-c. operation.

Fig. 2. Compensated Series Motor

**Thomson Repulsion Motor.**—This motor has a stationary structure or field with a completely distributed winding, which may be wound for any voltage. In this is placed a low-voltage armature designed with all the refinements necessary for single-phase commutator work. The brushes bearing on this commutator are short-circuited upon themselves and are so placed that the line connecting the positive and negative brushes makes an angle  $\alpha$  with the neutral axis of the field. The field turns lying within the angle  $(90 - \alpha)$  induce a current in the armature winding by transformer action and the field turns lying within the angle  $\alpha$  constitute the "exciting" turns and set up the necessary flux to produce the driving force. The arrangement is equivalent to the circuits shown in Fig. 3, although actually there is but a single field winding. This motor then acts exactly like the combination of a transformer and a series motor in one structure. It may be reversed by changing the position of the brushes or by shifting the points of connection of the external circuit to the field or stator winding. This motor operates particularly well near synchronous speed as then it has practically a rotating magnetic field and no excessive commutation difficulties, but at starting and at low speeds the commutation is not as good as that of the compensated series type.

Fig. 3. Thomson Repulsion Motor

**Winter-Eichberg-Latour (Fig. 4).**—This motor has the special attribute that, due to the rotation of the armature conductors of the circuit  $B_2$  in the transformer flux set up by the inducing windings, an e.m.f. is generated which is almost exactly  $180^\circ$  in time phase from the e.m.f. of self induction caused by the motor flux. It therefore neutralizes this inductive drop and improves the power factor of the machine. Were it not for the incidental leakage reactance the power factor would be unity at synchronous speed when the ampere turns of the inducing and exciting windings are equal. By a proper adjustment of the series transformer  $T$  this lagging voltage may be made to exceed the inductive drop at speeds near and above synchronism and cause the power factor to be anti-inductive.

Fig. 4. Winter-Eichberg-Latour Compensated Repulsion Motor.

The principle of this action is shown in Figs. 5 and 6, where  $\phi_1$  shows the transformer flux set up by the inducing winding and  $\phi_2$  is the motor flux produced by the series exciting current  $I_2$  in the armature circuit  $B_2$ , in phase with  $I_2$  and  $I_1$ .  $I_1$  is the line or primary current in the inducing winding  $S_1$ .  $I_2$  is the transformer secondary current in the armature circuit  $B_1$ . The resultant of these two m.f.'s produces the transformer flux  $\phi_1$ .  $E_1$  is the voltage consumed by rotation of the armature circuit  $B_1$ , due to cutting  $\phi_2$  and is in phase with  $\phi_2$ , transferred to primary  $S_1$ , by transformer action.  $E_2$  is the e.m.f. consumed by self-induction in

Fig. 5. Position in Space, Compensated Repulsion Motor.

Fig. 6. Time-phase Diagram, Compensated Repulsion Motor.

$B_2$  by the alternation of  $\phi_2$ .  $E_3$  is the e.m.f. consumed by rotation in  $B_2$  due to cutting the transformer flux  $\phi_1$ .

Neglecting drops due to resistance and leakage reactance it can be seen that  $E_2$  and  $E_3$  are inductive drops in the armature, opposite in effects, and may completely neutralize each other, leaving the resultant primary voltage  $E_1$  in phase with the primary current and giving unity power factor. By means of the series transformer  $T$  the current  $I_2$  and thus the flux  $\phi_2$  may be decreased in comparison with  $I_1$  and  $\phi_1$ , which would make  $E_3$  greater than  $E_2$  and the primary current would lead the resultant line voltage.

This principle has been employed in the construction of a number of types of small (1 to 20 h.p.) single-phase motors for industrial use, and these show a great superiority over the straight single-phase induction motor in the matter of starting torque and power-factor.

**Wagner Repulsion-Starting, Induction Running Motor (Fig. 7).**—The stator has two windings, the main or primary  $S_1$  is connected in series with the exciting brushes  $B_3$  on the armature as in the series motor. This gives the starting characteristics of the series a-c. motor. The armature has two sets of brushes. The main pair  $B_1$  in line with the primary flux is short circuited, thus giving compensation as in the compensated series motor. The other pair of brushes  $B_2$  is connected in series with the primary and across a "power factor compensating coil"  $S_2$ , wound on the stator in the same axis as the primary. A switch in this circuit is left open when starting, but is closed by a centrifugal governor just before synchronous speed is reached. Closing this switch short-circuits this pair of brushes through the compensating coil and makes the armature a two-phase rotor, and thus eliminates series-motor action and makes the action that of a true single-phase induction motor. The compensating coil being in circuit causes the anti-inductive effect in this coil to react on the primary as in the compensated repulsion motor, and give a good power-factor or

Fig. 7. Repulsion-starting, Induction-running.

leading current. By adjusting the number of turns or current in this coil  $S_2$  the power factor may be regulated.

To prevent the motor from running away in case the centrifugal switch should fail to act, and to relieve the brushes under load, a regular squirrel-cage winding is placed in the bottom of the armature slots underneath the commutated winding and separated from it by magnetic separators to magnify the magnetic leakage and render the squirrel-cage winding ineffective at starting. This motor is very satisfactory in practice, has a starting torque 1.5 times full load torque for a starting current of three times full load current. The power-factor is anti-inductive at light loads, unity at full load and inductive at overloads. The efficiency at full load is about 80 per cent in the 5 and 10 h.p. sizes. Reversal of rotation is effected by changing the connections to the exciting brushes. Small motors may be thrown directly on the line for starting. Large motors have a series resistance or reactance to limit the starting current to a reasonable amount.

**Repulsion-Induction (R. I.) Motor of the General Electric Co.** — This motor is shown diagrammatically in Fig. 8. It has two windings on the stator, the main or primary  $S_1$  being connected directly and solely across the line as in any induction motor. The armature has two equally spaced sets of brushes displaced a small angle ( $20^\circ$ ) from the axis of the primary flux, thus obtaining the repulsion motor starting effect. The main brushes  $B_1$  are short circuited and the auxiliary brushes  $B_2$  connected permanently in series with the "power factor compensating coil"  $S_2$  on the stator. The method of operation is best understood by considering the motor as being a repulsion motor and a single phase induction motor on the same shaft. At starting the repulsion-motor torque is great and the induction-motor torque is zero. Just below

Fig. 8. Repulsion-Induction (R. I.) Motor.

synchronism the induction-motor torque is great and repulsion-motor torque small. Above synchronism the repulsion-motor torque still exists but the induction-motor torque has become negative (generator). Thus at no load the repulsion motor pulls the induction motor above synchronism until the positive torque equals the negative torque and friction. At full load the speed is nearly synchronous. The compensating coil introduces an anti-inductive effect described above, and by varying the number of turns included, the power-factor may be made unity at any load. The efficiency is about 80 per cent in a 5 h.p. motor. Reversal of rotation is effected by moving the brushes or, if to be done often, by introducing a special coil in the primary whose connection is changed for reversal. An ordinary starting box is used to limit the current to about three times full load current for 1.5 times full load torque.

**Series Repulsion Motor.** — Since the repulsion motor has better operating characteristics at a speed near synchronism than the series motor it is better to run with repulsion motor connections. On the other hand, the series motor has better operating characteristics during starting conditions. These facts have led to the development of the "series repulsion" motor by one of the manufacturing companies. In the control of this motor a compensator with numerous taps is used and the connections so arranged that during starting the armature receives a very large current while the field is excited below the normal value. This gives a considerable torque with little trouble from commutation. As the motor speeds up, the connections are gradually changed until at full speed

the motor operates practically as a repulsion motor with the good commutating characteristics of that motor.

**Polyphase A-C. Commutator Motors.** — The series a-c. motor may be constructed three-phase by providing three exciting and three compensating windings on the stator for each pair of poles and providing three equally spaced sets of brushes per pair of poles on the armature and connecting these in series to the three phase supply as in any "Y" connected machine. This machine has the typical variable speed characteristics of the series motor. The speed may also be varied by changing the position of the brushes.

In order to secure good commutation the armature must be wound for a low voltage and it therefore becomes convenient to connect the stator and rotor by means of a transformer instead of direct conduction. With this arrangement it is possible to use any desired voltage on the line. There has been a considerable development in the application of these motors in the last few years.

The armature and stator may also be connected in parallel with each other (preferable by means of a transformer) thus giving a polyphase shunt motor with constant speed characteristics. This type, however, has not found much commercial application so far.

**DIMENSIONS, WEIGHT AND COSTS.** — Due to the low flux densities used and the special windings required an a-c. commutator motor weighs from 50 per cent to 100 per cent more, occupies from 25 per cent to 50 per cent more space, and costs from 50 per cent to 100 per cent more than a 600-volt d-c. motor of the same rating; see *Motors, Direct-current*.

**MOTORS, DIRECT-CURRENT.** — (See also *Alternating Currents; Electricity and Magnetism, Principles of; Generators, Direct-current; Motors, Industrial Applications of; Standardisation Rules.*) A motor is a dynamo-electric machine for converting electrical power into mechanical power; that is, it performs the converse function of a generator. Direct-current generators and motors are always interchangeable in function, although a machine which is designed specifically for a motor would probably not make a first-class generator and vice versa. Motors of less than 5 horse-power are usually bipolar; larger machines are multipolar.

**CLASSIFICATION.** — There are four types of direct-current motors, differentiated by their characteristics and the connection of the exciting windings or circuits.

**Shunt Motor (Fig. 1).** — This motor has only one exciting winding, which is connected across the armature terminals and is thus in parallel or in shunt with the armature. The field winding consists of a large number of turns of fine wire on each pole, and usually the windings on all the poles are connected in series in one circuit. The current in the field depends upon the line voltage and upon the resistance of the field winding. The resistance of the field winding is purposely made high so that the field current will be between 1 per cent and 5 per cent of the full-load current of the motor. The characteristic of the shunt motor is a fairly constant speed for all reasonable values of load.

Fig. 1. Shunt Motor

Fig. 2. Series Motor

**Series Motor (Fig. 2).** — This motor has only one exciting winding, which is connected in series with the armature so that all the current flows through the field as well as the armature. The field winding consists of a few turns of thick wire on each pole and the windings on all poles are connected in series. The current in the field depends upon the load and is thus large with heavy load and small with light load. The resistance of the field winding is purposely made low so that the loss of voltage and power in that circuit will be small. The characteristics of a series motor are a speed varying with every change in load,

high speed at light load and low speed at heavy load. The efficiency is high throughout a wide range of speed. The speed will be dangerously high at no load; thus a series motor must always be connected rigidly to its load. Since the torque is high at low speeds this motor is particularly adapted to work requiring frequent starting.

**Compound (or Cumulative) Motor.** — This motor has both a series winding and a shunt winding on each pole, wound and connected so that the two windings assist each other in the production of magnetism. It is a combination of a shunt and a series motor designed to give the good starting qualities of the series motor and to avoid the danger of excessive speed at light loads. See also *Motors, Industrial Applications of*.

**Differential Motor.** — This motor has a shunt and a series winding connected so that they oppose each other in the production of magnetism. The motor therefore has poor starting qualities, increases in speed with increase in load but has no tendency to run at a dangerously high speed. The applications of this motor are very limited.

**Inclosed vs. Open Type.** — These terms refer to the mechanical housing of the motor. The open type has all its parts freely exposed to the air and is therefore well ventilated. It is intended to be used indoors and in protected places. The inclosed type is intended to be used in exposed locations where there is a liability of dampness or dirt. Special means must be provided to circulate the air inside the machine, but even then an inclosed motor is larger and more expensive than an open motor of the same capacity.

The relative capacities in output of open, semi-inclosed, and totally inclosed motors are shown by the accompanying data on one of a line of typical commercial motors. In general an inclosed motor weighs about 15 per cent more than an open motor of the same capacity in spite of the fact that it is allowed to operate at 15° C. higher temperature by commercial convention.

Type	Output, h.p.	Temp. rise, °C.	Weight in lb. for 700 r.p.m. and given temp. rise
Open	10	40	970
Semi-inclosed	8	40	....
Totally inclosed	5.75	55	1100

**METHODS OF RATING.** — See *Standardization Rules of the A.I.E.E.* for limiting rise in temperature and for classification of types, Constant Speed, Multi-Speed, Adjustable Speed and Variable Speed.

The Electric Power Club, which includes representatives of most of the manufacturers of electric machinery in the U. S. A., has standardized, for commercial practice, certain temperature ratings which are based on the A.I.E.E. Rules. These regulations, which are for limiting temperatures as measured by thermometer with continuous duty, and the corresponding A.I.E.E. rules are:

	Max. rise on commutator	Max. rise on other parts
Open type	45° C.	40° C.
Protected type	55	50
Enclosed type	60	55
A.I.E.E. Rules	cc	50

**VOLTAGE AND CURRENT.** — Usual values of voltage for direct-current motors are:

110-125 for small motors on lighting circuits.

220-250 for motors in factories, shops, etc.; on power mains or on the outside mains of a three-wire system.

500-600 for general railway work.

1200 for special railway installations.

The current required for any motor is found by the relation

$$\text{Current} = \frac{\text{Output in h.p.} \times 746}{\text{Efficiency} \times \text{Voltage}}$$

Usual values for the efficiencies of motors of various sizes are given below.

**APPLICATIONS OF MOTORS.** — This subject is treated in detail in a separate article on *Motors, Industrial Applications of* (q.v.). The chief applications of continuous-current motors are the following:

*Shunt Motor.* — Driving shafting, machine tools, blowers, reciprocating pumps; motor generators.

*Series Motors.* — Railway and all other transportation work; hoists; cranes.

*Compound Motor.* — Elevators, hoists and machinery that must be started often.

*Differential Motor.* — Very special applications of small units for peculiar speed conditions.

**PRINCIPLES.** — The principles upon which a direct-current motor operates are the same as those upon which a direct-current generator operates (see *Generators, Direct-current*). These principles are briefly as follows:

**Force Acting on Conductor.** — A conductor of length  $l$  carrying a current  $I$  and placed in a magnetic field having a flux density  $B$  is acted upon by a force which is proportional to  $BIl$ , which force is in a direction at right angles to the direction of the magnetic flux and at right angles to the length of the conductor.

This in practical form gives the relation

$$T = \frac{p\phi ZI}{852 \pi \times 10^6}$$

$T$  = torque of an armature in pounds at one-foot radius.

$p$  = number of poles.

$m$  = number of armature paths between brushes.

$\phi$  = flux per pole in armature (lines).

$Z$  = number of active conductors or inductors on armature.

$I$  = current taken by the armature from line.

This torque is exerted whenever a current flows and is independent of the speed. The core-loss and friction absorb some of the torque so that the torque at the pulley is slightly less than the value given by the formula.

**Counter E.M.F. in Conductor.** — A conductor of length  $l$  moving with a velocity  $V$  in a magnetic field of density  $B$  has induced in it an electromotive force  $E$  proportional to  $BIV$ . In practice as soon as the armature starts to move a counter e.m.f. is induced in its conductors which has the value

$$E = \frac{p\phi Zn}{m \times 10^8}$$

where  $n$  = revolutions per second.

Thus as soon as the armature moves, this counter e.m.f. tends to stop the flow of current and the impressed e.m.f. must be increased to maintain the flow of current.

The relation between current and counter e.m.f. is given by the equation

$$E_1 = E + IR,$$

where  $E_1$  = impressed e.m.f.,  
 $E$  = counter or generated e.m.f.,  
 $R$  = resistance of armature circuit.

In practice  $R$  is made as small as possible so that  $E$  and  $E_1$  are as nearly equal as possible.

**Reversing Rotation.**—From a consideration of the equation for the torque it is evident that torque is proportional to the product  $\phi I$ , i.e., to the product of the flux in the armature by the current. If the direction of the current through the armature is reversed, that is, if  $I$  becomes negative, the product becomes negative and the torque is in the opposite direction. If the direction of the flux is changed (the armature current being unchanged) the direction of torque is reversed. But if both  $\phi$  and  $I$  are reversed the torque is not reversed. From this follows the rule for reversing the direction of rotation of any direct-current motor; viz., change the direction of flow of current in either the field or armature winding but not in both.

**Speed Control.**—From the equation for counter e.m.f. it follows that the speed is proportional to  $E/\phi$ . That is, the speed varies directly as the counter e.m.f. and inversely as the flux. Thus to reduce the speed, decrease the counter e.m.f. by decreasing the e.m.f. impressed on the armature or increase the flux by increasing the field current. To increase the speed perform the converse. To decrease the e.m.f. impressed on the armature a resistance may be inserted between the source of potential and the armature terminals. This is the customary manner of controlling the speed during the starting of motors. (See also section below on *Starting of D-C. Motors.*)

**SHUNT MOTOR.**—Since the flux in the armature of a shunt motor is practically independent of load, the characteristics of the motor are: approximately constant speed for all reasonable variations of load, torque directly proportional to the armature current irrespective of speed, efficiency high throughout a wide range of load but for only a small range of speed see Fig. 3.

**Design of Shunt Motor.**—The method of design and calculation of shunt motors is the same as for direct-current generators (see *Generators, Direct-current*) except for the minor details noted below.

The armature reaction of a motor is in the opposite direction to that of a generator running in the same direction, and thus the field is distorted in the opposite direction. Hence, if the brushes are to be moved to assist commutation they must be moved in a direction opposite to the direction of rotation of the armature.

Fig. 3. Speed, Torque and Efficiency Characteristics of a Shunt Motor

The effect of armature reaction is to weaken the field. This causes a tendency to increase the speed and also causes bad commutation.

The stability factor of a motor must be greater than that of a generator because when the motor drops in speed as the load comes on, the field must be weakened to increase the speed. Hence the field is liable to be operated at an excitation less than normal.

**Testing of Shunt Motors.** — (See also *Standardization Rules of the A.I.E.E.*) The tests on shunt motors may be divided into two classes: (a) Commercial, to determine the qualities and serviceability of particular motors; and (b) Special, to determine the general characteristics and actions of a type of motor. Commercial tests are the following:

- Resistance measurements.
- Stray power test, including core-loss and friction.
- Input-output test for heating, efficiency and commutation.
- Insulation test.

**Resistance Measurements** are made with the machine cold and later after the heat run. The resistances of the armature winding and field winding are measured, and the brush-contact resistance may be measured but is usually calculated (see *Generators, Direct-current*). For any value of current the resistance losses ( $RI^2$ ) are calculated from the measured hot resistances.

**"Stray Power" Test.** — The term "stray power" is applied to the lumped sum of the core-loss and the loss due to friction, bearings and windage. The stray power of a d-c. machine can be determined approximately by impressing normal voltage on the field and letting the machine run as a motor without load, varying the voltage impressed on the armature from about 10 per cent above normal to about 10 per cent below normal. The speed, armature voltage and armature current for each adjustment are observed. Then the stray power for any induced voltage is equal to the armature input less the corresponding  $RI^2$ , where  $R$  is the armature resistance and  $I$  the armature current. The value of stray power for any given load on the motor is then equal to the measured value corresponding to the same counter e.m.f.  $E$ , where  $E$  is calculated from the impressed voltage  $E_i$  by the relation  $E = E_i - RI$ ,  $I$  being the armature current for this load and  $R$  the armature resistance as before.

If it is desired to determine the stray power more accurately by taking into account the effect of armature reaction, the field current may be adjusted so that the speed on the above run is the same as the load speed. This gives a flux of the same average value as when the machine is under load.

**Calculation of Efficiency from Losses.** — Let  $P$  = total output in kilowatts;  $R_a$  = resistance of armature, including brushes;  $I_a$  = armature current;  $I_f$  = field current;  $E_i$  = impressed voltage;  $S$  = stray power. Then the per cent efficiency is

$$\epsilon = \frac{100 P}{E_i(I_a + I_f)} = \frac{100 P}{P + E_i I_f + I_a^2 R_a + S}$$

**Input-output Test with Prony Brake.** — The input-output test may be made either by means of a prony or hand brake on a pulley, or by using a d-c. generator as a load. If the brake test is made the output is

$$\text{Watts} = \frac{PLN}{7.04}$$

where  $P$  = net pull in pounds,  $L$  = lever arm or radius in feet,  $N$  = revolutions per minute.

**Input-output Test with Generator as Load.** — With large motors it is desirable to use a generator as a load in making an input-output test. In

this case it is necessary to know the resistance of the generator armature circuit. It is also desirable to have the generator separately excited and to maintain a constant excitation throughout the entire test.

The input of the motor and the output of the generator, together with the speeds of both machines, are observed. A "counter-torque" test must also be made to determine the belt friction loss and the core-loss and friction of the generator. This is performed by making two tests as follows:

(a) The motor input is observed when driving the unloaded generator at normal speed first through the regular leather belt and second through a light cotton belt. The difference in input to the motor in the first and second cases gives the belt-friction loss. As this loss is comparatively small, it may frequently be neglected.

(b) A regular stray power test (see above) is made on the generator when entirely disconnected from the motor. This gives the core-loss and friction of the load machine (generator).

Then for any load during the load run the output of the motor under test is

$$P_1 = P_2 + R_a I^2 + S + F,$$

where  $P_1$  = output in watts of motor, machine 1.

$P_2$  = output in watts of generator, machine 2.

$R_a I^2$  = loss in armature winding of generator.

$S$  = stray power of generator for speed and induced voltage at observed load.

$F$  = belt-friction loss.

The ratio of this motor output to the electrical input as observed gives the efficiency of the motor.

**Heat Run.** — From the input-output test it is also possible to determine the speed regulation, commutation features and heating. The heat run may also be made by "bucking" two machines as described in the article on *Generators, Direct-current*. Small motors will reach a constant temperature in a short time and the heat run need only last 5 or 6 hours for a 100-h.p. motor. A thermometer is usually placed on the machine in a safe and accessible place and read every half hour until it indicates no further rise in temperature.

**Insulation Test.** — The margin of safety on a 110- or 220-volt motor is usually so great that it is not necessary to make an insulation test. If the motor has been exposed to dampness it may be desirable to make the test after the motor has been thoroughly dried out. The method is indicated in the *Standardization Rules of the A.I.E.E.* (q.v.)

**Special Tests.** — As a special test there may be obtained a saturation curve of the machine and possibly the distribution of potential around the commutator. These are of particular interest in an adjustable speed motor. In some of these motors with commutating poles there may exist some very high voltages between bars which are not evident except in the bar-to-bar potential test.

**SERIES MOTOR.** — Since the flux in the series motor is produced by the load current, the flux increases with the current. The torque is proportional to the product  $\phi I$  and therefore increases more rapidly than the current. Thus four times full-load torque can be obtained with from two to three times full-load current.

The characteristics of the series motor are: increase of torque faster than increase of current, variation in speed inversely as the load, and high efficiency throughout a wide range of speed as well as load, see Fig. 4.

**Design of Series Motors.** — In general the method of calculation is the same as for a direct-current generator (*see Generators, Direct-current*). The special considerations are:

A series motor is usually designed to have a large output and low speed at the one-hour rating. At any lesser output the speed will be higher, so the peripheral velocity must be quite moderate at the rated load and speed.

Since the speed is very nearly inversely proportional to the flux the speed curve depends on the shape of the saturation curve, to which very careful attention is paid in designing. By exactly fixing the flux for two extreme values of current the speed for these two values of current is fixed.

The relations between the speed and current of a series motor are shown by the formulas:

$$E_i = E + IR,$$

$$E = \frac{p\phi Zn}{m 10^8},$$

$$n = \frac{m(E_i - IR) \times 10^8}{p\phi Z},$$

where

$E_i$  = impressed voltage,

$E$  = counter e.m.f. induced in armature,

$R$  = total resistance of armature and field,

$I$  = current taken by motor,

$p$  = number of poles,

$m$  = number of parallel paths between positive and negative brush sets,

$Z$  = total number of conductors on armature,

$n$  = speed of armature in revolutions per second,

$\phi$  = total flux per pole in maxwells.

Since the current in the field of a series motor is the same as that in the armature, the ratio of the turns in each is the same as the ratio of ampere-turns or m.m.f.'s. Thus if the magnetomotive force per pole of the field is to be 1.5 times that of the armature the number of turns will be 1.5 times the number of turns in series in the armature.

Since a series motor is usually an inclosed motor with a one-hour rating its rise in temperature and rating are a direct function of the watts lost and the ability of the mass of the motor to store up this heat energy. In a one-hour run the amount of energy radiated is only about 10 per cent of the amount stored in the mass. For a rise in temperature of 75° C. in one hour there should be about 0.4 pound of material for each watt of loss. This assumes reasonable provision in the construction of the motor for the transfer of the heat from the armature to the field and frame.

Fig. 4. Speed, Torque and Efficiency Characteristics of a Series Motor

Much attention has been directed recently to the ventilation of these motors by drawing air from outside the motor by means of fan blades on the armature and by circulation of the air inside the motor through definite paths. This has considerably increased the weight efficiency of these motors.

In railway motors, which are the most general application of the series motor, commutating poles are very generally used, as this construction makes it possible to obtain a much greater momentary output from a motor of a given size (*see below*).

**Testing of Series Motors.** — (*See also Standardization Rules of the A.I.E.E.*) To determine properly the speed and torque characteristics of a series motor an "input-output" test must be made, which involves subjecting the motor to actual load and overload conditions. This may be accomplished by running the motor with a prony brake as a load or with a direct-connected generator as a load (*see section above on Testing of Shunt Motors*).

**Railway Motor Test.** — When two similar motors are available the method used by the manufacturers of railway motors is most desirable. The two motors are direct connected, or geared to each other, and the electrical connections made as in Fig. 5. The test is run through by keeping constant rated voltage on the motor and regulating the load on the motor by changing the load on the generator.

As the two machines are operating under almost exactly the same conditions, their efficiencies are very nearly the same. Thus

$$\text{Efficiency of set} = \frac{E_2 I_2}{EI}$$

$$\text{Efficiency of each motor} = \sqrt{\frac{E_2 I_2}{EI}}$$

The speed and torque curves should be made for both directions of rotation of the armature as an incorrect brush setting will give results differing with the direction of rotation. The direction of rotation is changed by reversing the connections of either the field or the armature of the motor.

Commutation is observed during the speed and torque test.

The heat run is made with the same arrangement as the speed-torque test. In making the heat run the motor must start cold or at room temperature. The covers of the inspection openings of railway motors are customarily left open during the heat run.

**Losses and Efficiency of Series Motors.** — For a more accurate determination of the efficiency and losses the following special tests are made:

1. Resistance of armature, brushes and field. These tests are similar to those for a shunt motor, *see above*.

2. Core-loss test. On account of the variable speed and variable field of a series motor this test consists in repeating the usual core-loss test as described

Fig. 5. Railway Motor Load Test

Fig. 6. Core-loss Curves of Series Motor

above for a generator at several different speeds. The field strength is varied step by step throughout the maximum range for each speed. Fig. 6 shows the curves for these different runs and the dotted line connects the points on the different curves that apply to the normal speed curve of the motor.

**Insulation Tests.** — See *Generators, Direct-current, and Standardisation Rules of the A.I.E.E.*

**STARTING OF DIRECT-CURRENT MOTORS.** — A starting box, Fig. 8, or rheostat is always employed in starting direct-current motors in order to reduce the voltage impressed on the motor when it is not running at a high enough speed to generate the proper counter e.m.f.

Let  $E_i$  = line voltage,

$E$  = counter e.m.f. (approximately proportional to speed),

$I$  = current,

$r$  = resistance of armature circuit,

$R$  = resistance of starting box or rheostat.

Then

$$I = \frac{E_i - E}{r + R}$$

At the first instant the motor armature is stationary and  $E = 0$ ; thus  $I = \frac{E_i}{r + R}$  and the value of  $R$  is determined by the desired value of  $I$ . As the motor accelerates,  $E$  increases. If  $R$  remained constant  $I$  would decrease to such a small value that there would not be sufficient torque to accelerate the load. The current, and therefore the torque, can be brought back to their original values by changing  $R$  to such a value  $R_1$ , that

$$I = \frac{E_i - E}{r + R_1}$$

Fig. 7 shows the sudden rise in current when the resistance is changed and the gradual decrease in current as the speed increases. The number of steps necessary depends upon the ratio of the maximum allowable instantaneous value of the current to the final constant value, upon the value of the armature resistance and upon the inertia of the load.

Fig. 7. Motor Current During Starting

Fig. 8. Starting Box Connections for Shunt Motor

**Starting Box.** — (See also article on *Rheostats*). A starting box usually contains the following features, as indicated in Fig. 8: (a) a means of opening and closing the circuit supplying all the current to the motor including the field current; (b) a set of resistance steps in series with the motor armature and a means of short-circuiting this resistance step by step; (c) a magnet coil connected across the motor terminals to open the circuit if the impressed voltage fails or falls below a specified value (low-voltage release); (d) a magnet coil carrying the main current to actuate a spring and open the circuit if the current exceeds a

specified value (overload release). The usual connections of a starting box to the line and motor are shown in Fig. 8.

**SPEED CONTROL.** — There are three methods of varying and controlling the speed of d-c. motors, namely, potential, rheostatic and field systems.

**Potential Control or Multi-voltage System.** — By means of several generators and several wires various definite voltages are made available, such as 240, 180, 120, etc. By connecting the motor to the 240-volt circuit full speed is obtained; by connecting to the 180-volt circuit  $\frac{3}{4}$  speed is obtained, etc. The shunt field circuit is left connected at all times to a circuit of the proper voltage. A shunt motor with normal field excitation will be stable, that is, it will operate constantly, at the fractional speed. The efficiency will be good at the fractional speeds. A series motor controlled in this manner will be unstable, but for a given torque the speed will be roughly proportional to the voltage.

**Rheostatic Control.** — A rheostat in series with the armature will reduce the voltage impressed on the armature by an amount proportional to the current, and thereby reduce the speed. The speed is unstable with this arrangement, changing with every change of load, and the efficiency is poor.

**Field Control.** — By increasing the resistance in series with the field of a shunt motor the speed is increased due to the weakening of the field. If the motor has commutating poles to assure good commutation the speed may be varied in a ratio of 1 to 2, and even 1 to 3 in small sizes. The shunt motor is stable with this method of control and the efficiency is good. In a series motor the field may be shunted by a resistance to increase the speed but the motor is not stable and this practice is not to be recommended.

**USE OF COMMUTATING POLES (INTERPOLES) IN VARIABLE-SPEED MOTORS.** — In motors intended to be operated over a large variation in speed, obtained by changing the field strength, and in motors which are to be subjected to heavy overloads, it is necessary to use commutating poles in order to obtain good commutation. In a motor without commutating poles the field strength must always be a certain percentage greater than the armature strength to prevent a shifting of the field flux and of the neutral point. Thus,

Fig. 9. Flux Distribution without Commutating Poles

Fig. 10. Flux Distribution with Commutating Poles

W. in Fig. 9, *F* represents the distribution of field flux when existing alone and *A* represents a strong armature flux existing alone, then *R* shows the distribution of the resultant flux when both field and armature are excited.

It will be noticed that the neutral point has been shifted from *XX* at no load in a direction against rotation to *YY* at the load considered. The brushes would have to be shifted from *XX* at no load to a point *ZZ* beyond *YY* at load

in order that they shall commutate a coil in a flux which is producing a voltage helpful to commutation.

**Resultant Flux with Commutating Poles.** — If, however, commutating poles are placed between the main poles and excited with the armature current they will maintain at the geometrical neutral a flux of the direction and value necessary to give good commutation. In Fig. 10, *F* and *A* represent the field and armature flux separately as before and *C* the commutating pole flux that would exist at full load. When at full load these fluxes are combined there exists the resultant flux shown at *R*.

It will be noticed that there remains at the neutral point a small flux of the proper polarity and magnitude to provide an e.m.f. to reverse the current and give good commutation and it is not necessary to move the brushes.

The commutating pole must be of the same polarity as the pole towards which the brush would have to be moved if there were no commutating poles. In fact the principle of commutating poles is nothing more than bringing to the brush a part of the pole instead of moving the brush to the pole. Thus the polarity of the commutating pole is different during motor action from that during generator action. If the windings on the commutating poles are connected in series with the armature the conditions will be correct for either motor or generator action.

**INSTALLATION AND ERECTION.** — In the installation and erection of a direct-current motor there are certain features which must receive careful attention in order that the machine shall operate properly and not deteriorate with undue rapidity. Although this procedure varies with different motors according to their mechanical construction the following brief memorandum of points to be looked after will be found useful:

1. Base bolted down.
2. Bearings clean and filled with oil.
3. Bearings lined up.
4. Magnet frame bolted to base.
5. Field coils secured in place.
6. Field coils tested for open circuit, wrong connection and polarity.
7. Armature in place.
8. Air gap adjusted by shimming.
9. Measure resistance of armature and field.
10. Measure insulation resistance.
11. Brushes properly fitted and spaced and pressure adjusted to about 1.5 to 2 pounds per brush.
12. Commutator smooth and true.
13. Substantial connections of field circuit.
14. Field adjusted for correct direction of rotation.

The motor must be protected from moisture during shipment and if by accident it becomes damp it must be dried out before it is subjected to a voltage.

**OPERATION.** — In the operation of a direct-current motor several factors should be considered.

**Care.** — All motors should be frequently inspected and the following points noted:

1. Bearings filled with proper amount of oil.
2. Brushes securely held in proper position.
3. Brushes fit properly.
4. Commutator smooth: Danger of "high mica" or the insulation between commutator bars projecting above the bars.
5. Air gap true.
6. Commutator not worn in grooves.

**Troubles.**—In the following paragraphs is given a concise list of the troubles that may be experienced in operating continuous-current motors and their causes as given by Crocker and Wheeler in *Management of Electrical Machinery*.

1. *Sparking at the Commutator.*—Causes: Armature carrying overload. Brushes improperly spaced. Brushes not at proper position. Rough commutator. Poor brush contact. Internal short or open circuit. Field too weak. Unequal strength of poles. Vibration.

2. *Heating of Commutator and Brushes.*—Sparking. Bearing trouble. Bad connections. Brush friction too great.

3. *Heating of Armature.*—Overload. Internal short circuit, moisture or ground. Reversed coil. Excessive eddy currents.

4. *Heating of Field.*—Internal short circuit.

5. *Heating of Bearings.*—Bearings dry or dirty. Shaft out of true. Bearings out of line. Thrust due to belt. Unbalanced magnetic pull.

6. *Noise.*—Armature not balanced. Brushes dry or not set at proper angle. Armature strikes.

7. *Speed Too Low.*—Wrong voltage. Overload. Armature strikes. Bearing too tight.

8. *Speed Too High.*—Wrong voltage. Field too weak.

9. *Motor Stops or Fails to Start.*—Overload, open circuit, wrong connection.

#### **SPECIFICATIONS FOR D-C. MOTORS FOR INDUSTRIAL USE.**—

(See next section for *Specifications for Railway Motors*.) The following memoranda are intended to assist in writing specifications. See also article on *Specifications*.

**Principal Characteristics and Conditions of Service.**—Use to which motor is to be put, kind of load and method of drive. Voltage. Rating, horse-power. Speed.

**Style and Description; Details of Construction.**—Whether to be open, semi-enclosed or enclosed. Whether to be series, shunt or compound wound; if shunt wound, whether shunt field rheostat is to be supplied; if compound wound, state whether cumulative or differential. Requirements regarding pulley or length of shaft. Whether rails are required. Whether starting rheostat is to be supplied, and if so, its general characteristics.

**Performance and Tests.**—(See *Standardisation Rules of the A.I.E.E.*) Temperature rises upon which ratings are to be based. Details of overload. Efficiency at 25, 50, 75, 100, and 125 per cent load; whether rheostat losses are to be included in calculating efficiencies. Starting torque with full-load current, pound-feet. High-potential tests of insulation. Requirements regarding effect of moisture upon insulation. Regulation; the supply voltage being constant, and the field rheostat fixed, a variation of load from zero to . . . per cent of full-rated load shall cause a variation of speed not greater than . . . per cent. The shunt field rheostat to give speed variation of . . . per cent in steps not greater than . . . per cent and not less than . . . steps, and to carry the current for any speed continuously without undue heating.

**SPECIFICATIONS FOR SERIES RAILWAY MOTORS.**—The following memoranda are intended to assist in writing specifications. See also article on *Specifications*.

**Principal Characteristics and Conditions of Service.**—General statement of the service, giving type of cars, whether current is direct or alternating,

or both, etc. The motor shall be designed for normal operation at . . . volts and shall operate safely at . . . volts.

**Style and Description; Details of Construction.**—The frame shall be designed so as to allow the easy removal of armature and field coils. It shall be provided with openings at both ends, and both above and below the shaft, which will enable the inside of the motor to be readily inspected and cleaned. Bearings shall be designed so that lubricant cannot enter the frame, and shall be so located that they may be easily emptied and cleaned. The diameter of the driving axle on which the motor is to be mounted shall be . . . inches. Whether motor is to be of interpole type. Whether natural or forced ventilation.

**Brushes and Brush Holder.**—The brush holders shall be readily removable through the hand holes. The springs holding the brushes against commutator shall not be relied on to carry current. The brushes shall be staggered or provided with adjustment parallel to the armature shaft so as to prevent the formation of ridges on the commutator.

**Clearances.**—The minimum distance between motor frame and back of wheel flanges shall be . . . inches, the minimum distance between bottom of motor and top of rail when tires are new shall be . . . inches.

**Gears and Gear Case (if any).**—Single or double reduction; what gear wheels shall be mounted on; material of wheel and pinion; description of teeth, whether cut or cast, and width of face of wheel or pinion; gear case, material, how suspended, oil-tightness.

**Suspension of Motors.**—General description and requirements, location of lugs on motor frames.

**Data to be Furnished by Bidder.**—The armature will be bound with . . . bands. Material and dimensions of the bands. Dimensions of openings in the frame. The brush holders will be adjustable so as to allow . . . inch wear with uniform pressure on the brushes, after the diameter of the commutator has been reduced by . . . inches. The current density in the carbon brushes will not exceed . . . amperes per square inch at normal rated load. The gear ratio will be . . .

**Performance and Tests.**—(See also Specifications in article on Locomotives, Electric.) Either the nominal rating and the continuous ratings at  $\frac{1}{2}$ ,  $\frac{3}{4}$  and full voltage should be specified, or the following data supplied.

Line voltage . . . . .	
Number of motors per car . . . . .	
Weight of loaded car, exclusive of motors and control equipment . . . . .	
Diameter of driving wheels . . . . .	
Schedule speed . . . . .	
Distance between stops . . . . .	
Duration of stops . . . . .	
Acceleration miles per hr. per sec. . . . .	
Retardation, miles per hr. per sec. . . . .	

The engineer should also give a diagram of grades and curves.

**Motor Characteristics.**—The bidder shall submit diagrams showing speed, tractive effort, efficiency,  $R^2I^2$  losses, core losses, and any other information bearing on the performance of the motor. Requirements regarding the effect of moisture upon insulation.

**Tests.** — The motor shall be tested at the Manufacturer's works in the presence of the Engineer's inspector. (In the case of new motor developments it is good practice to make the tests under service conditions; but for standard motors a stand test at the factory is sufficient.) A complete series of tests shall be made upon the first motor manufactured under this specification. These tests shall confirm all the statements made by the bidder in relation to operating characteristics. Should the motor fail to comply with any of these statements, the defects shall be corrected and any changes in construction or design which may be necessary to accomplish this shall be made at the contractor's expense. The first motor shall be submitted to a flashing test to determine the susceptibility of the motor to flash-over on opening the maximum specified line voltage across the motor when running at maximum speed. After the acceptance of the first equipment, any other motors to be supplied under this specification shall be submitted to an approved stand test. The insulation of the armature windings, commutator and field windings, shall be subjected to stated alternating voltages (see *Standardization Rules of the A.I.E.E.*) for a period of one minute.

**PERFORMANCE, WEIGHT AND COSTS (Pre-war prices) \*.** — Usual values of the efficiency and losses, and also values of the weight, speed and cost of shunt and series motors are given in the following tables:

PERFORMANCE OF SHUNT MOTORS

H.P.	Full load efficiency, per cent	Field I <sup>2</sup> R, per cent	Friction, per cent	Core-loss, per cent	Armature I <sup>2</sup> R, per cent
0.5	70	5	10	5	10
1	79	4	8	4	5
2	82	3.5	7	3.5	4
5	85	3	5	3	4
10	87	2.5	4.5	2	4
20	88	2	4	2	4
25	89	2	3	2	4

WEIGHT, SPEED AND COST OF SHUNT MOTORS

H.P.	Speed, r.p.m.	Weight, pounds	Cost *	Speed, r.p.m.	Weight, pounds	Cost *
0.5	2200	60	\$30	.....	.....	...
1	2000	100	50	1675	125	\$60
2	1650	210	75	1175	250	90
5	1100	550	150	920	600	185
10	850	950	240	700	1100	260
20	680	1650	410	550	1900	470
25	650	1950	500	500	2300	600

\* For 1922 prices add 50 per cent.

## PERFORMANCE OF SERIES MOTORS

## Commutating Pole Railway Type

H.P.*	Full-load efficiency, per cent	Field I <sup>2</sup> R, per cent	Friction, per cent †	Core-loss, per cent	Armature I <sup>2</sup> R, per cent

**MOTORS, INDUSTRIAL APPLICATIONS OF.**—(See also *Bearings; Belts and Belting; Blowers and Compressors; Chains and Chain Drive; Conveyors; Couplings, Direct; Cranes; Dredges, Electrically-Operated; Elevators, Electric; Fans; Flywheels for Load Equalization; Gears and Gearing; Hoists, Electric; Machine Tools, Electrical Operation of; Motors, A-C. Commutator, Direct-Current, Polyphase Induction, Single-Phase Induction, Synchronous; Pumps and Pumping Engines; Printing Presses; Ropes and Rope Drive; Shafting; Shovels, Electrical Operation of; Steel Mills, Electric Drive of; Telegraphage; Unloaders, Coal and Ore; Valves.*) The application of the electric motor for driving industrial machinery, either individually or in groups, was at first thought to be of value merely in the saving of power through the elimination of the losses due to friction in line shaftings or other forms of mechanical transmissions. A still higher economy has, however, been found to lie in the remarkable effect that it has in increasing the output of the production.

**ADVANTAGES OF ELECTRIC DRIVE.**—The more important advantages of electric drive are the following:

**Location of Machines.**—The various machines can be placed in almost any desired position and the use of portable tools is readily made possible, as, for example, when a portable drill and slotter are brought to a heavy casting, the slotter being applied to the outside of the piece at the same time the inside is being drilled.

**Head Room.**—A clear head room is obtained by the elimination of belting. This gives better illumination and ventilation and permits overhead cranes to be used freely, which is of greatest importance in any factory as it greatly facilitates the handling of the material, resulting in a considerable saving in time and labor, and thus increasing the output.

The constant source of dripping oil from overhead bearings and shafting is eliminated, and the danger which always accompanies the use of belts is overcome.

**Centralized Power.**—Power can most readily be distributed from a central supply station to the different buildings, and changes or additions to the system can always be made without difficulty.

**Reliability.**—The electric system offers greater reliability than belt drive. A breakdown is usually confined to a single machine, but with belting and a shafting a breakdown will generally cause a shutdown of a considerable portion of the equipment.

**Study of Machine Performance.**—Meters of either the recording or indicating type can be installed easily where desired and the performance of every individual machine ascertained. This is a very important point in all industrial undertakings, as it is then possible to maintain all the machinery in the best operating condition. Any excess power taken is at once readily detected and the defect can be promptly corrected. An accurate record can also be kept of the cost of power for the different operations.

**GROUP VERSUS INDIVIDUAL DRIVE.**—There are two general systems of drive, namely, group and individual, and there is still a diversity of opinion as to the relative advantages of the two. The group drive is to a certain extent an outgrowth of the older system of line shafting. When such a system is to be changed to an electric drive, the most obvious and simple way of making the change is to split the shafting up into such sections as would be most convenient, and drive each of these by means of a comparatively large motor. On the other hand, it may frequently happen that it is necessary to operate only one machine of the entire group for a considerable time, as in overtime work,

and to do this it would then be necessary to keep the motor and the line shafting of the whole group running. Since the efficiency of the motor at this light load would be small, and the friction losses of the entire drive would have to be supplied, it is evident that such a method of operation would result in a waste of power and be most inefficient. Modern installations, therefore, indicate a tendency toward the use of both the group and individual drive.

**Influence of Character of Load.** — It is generally agreed that all large tools or other machinery should be equipped with individual motors, especially if their service is of an intermittent nature. With the group drive there are two distinct loads, the variable of the machines and the friction of the line shafting and belting. The lower the machine load factor, the greater becomes the percentage of friction load and the more inefficient the group transmission.

**Influence of Speed.** — Wide ranges of control and the possible variations of speed are reasons which in many cases are sufficient in themselves for the selection of an individual drive. With group drive the methods of speed control for the individual machines are obviously more limited. It is then generally accomplished by shifting of belts on cone pulleys or by change of gears. Both of these methods, however, take a considerably longer time than the simple manipulation of the controller with the individual electric drive.

With individual motor drive it is possible to obtain very fine speed graduations, this benefit, of course, only being derived with a variable speed motor. Another advantage is the fact that it is possible to speed up a machine with a proportional increase in power. This may be necessary whenever a change is made from carbon to high-speed steel.

**Influence of Relative Cost.** — The increased cost of installation is one of the principal factors that prevent the general installation of individual drives. With this drive the total horse-power rating of the motors installed in the plant will be considerably greater than with group drive, but the maximum power demand of the plant is approximately the same in either case. If power is purchased the price should be based on the actual maximum power demand and not, as sometimes is required, on the total connected horse-power capacity of the motors. This latter method would obviously give a lower basic rate for the group drive, although the higher efficiency of the individual drive would considerably reduce the actual power consumed.

The question of whether or not group or individual drive is to be installed is thus a financial one and each case must be properly analysed. Individual drive necessarily means a larger investment, but in nearly all cases a much greater percentage income will be realized than if line-shaft drive were employed.

**GENERAL CONSIDERATIONS IN THE SELECTION OF MOTORS.** — The conditions of capacity and efficiency are both of importance in any motor installation and should therefore be given careful consideration. The installation of a motor having too large a capacity should in general be avoided, unless an increase in the load is to be expected in the near future, because the efficiency of a motor is usually a maximum at its normal rated output, decreasing above and below this point. With alternating-current motors the effect of the power factor must furthermore be considered. This decreases rapidly below normal load, and on account of its bad effect on the regulation of the system it should be kept as high as possible, which can only be done by operating the motors as nearly fully loaded as possible. Ordinarily, however, it is possible to so group the machinery that the motors may be operated near their rated output at all times. Too small a motor is naturally also very undesirable, as it would then in all probability be subject to overloads, which may result in overheating and a burn-out of the motor, causing a shutdown, not only of the motor itself, but also of the machinery which it drives. The op-

erating conditions of the plant may furthermore be such, as for example in steel mills, that the failure of a single motor may necessitate the shutting down of the entire mill.

The selection of suitable motors requires not only complete information on the power required to drive each group of machines or each machine individually but also a thorough knowledge of the motor design and its inherent characteristics to meet the requirements of the load. Some machines will require motors with very heavy starting torque, although running under light load when up to speed, while for others the requirements may be just the opposite. With a varying speed motor the torque-speed characteristics should agree as nearly as possible with the load which the motor is to drive, and the characteristics of adjustable-speed motors as influenced by different systems of control should also be carefully investigated. See also section below on *Data Required to Determine Type and Size of Motor*.

**Influence of Motor Efficiency.**—A motor of high efficiency is obviously desirable, and it is generally an easy matter to estimate the saving incurred by the installation of a motor of high efficiency as compared to a less efficient one. When a motor is operated for a considerable part of the time on light load, this fact must be given due consideration in the comparison on account of the variation in the motor efficiency for different loads.

**Influence of Torque and Speed.**—In order to obtain the most satisfactory results from motor drive it is essential that the type as well as the size of the motor be properly adapted to the work contemplated. This is especially important in the case of individual drive, where a wrong selection of the proper motor would be more serious than in group drive. The size of the motor may be ample to operate the machine under normal load but it may not be able to develop a sufficient starting torque, or it may draw a too excessive starting current from the line. For example, to start and accelerate the bridge of a crane requires a motor capable of developing a high starting torque, but after the bridge is accelerated comparatively little power is required to keep it in motion.

The condition of maximum torque must also be given due consideration. A motor driving a heavy punch may, in spite of the flywheel, develop insufficient torque to keep up the speed. As a rule, however, where the motor is large enough for starting and normal operation, but not large enough for the maximum overload required for perhaps only a second or two, the addition of a suitable flywheel will sometimes cut down the maximum torque required. In other cases it may be necessary to install a motor larger than necessary for the average work.

The proper speed regulation is also of importance and a motor must be selected which is best meeting these requirements. The size of the motor is also influenced by the cycle of operation, i. e., whether the load is continuous or intermittent. Careful consideration should be given to this point, and, as previously mentioned, motors will undoubtedly soon be rated to conform to the particular service for which they may be required. See also section below on *Classification of Motors According to Speed*.

**Alternating Versus Direct Current.**—The choice of alternating or direct current depends largely on local conditions and on the service requirements. With all other conditions the same, the alternating-current system offers many advantages when the distances over which the power must be transmitted are large. A higher transmission voltage may be selected which will diminish the amount of copper needed in the line conductors. The conditions may be such that high-voltage motors can be used, but in other instances step-down transformers may have to be provided and the expense of these as well as other auxiliary apparatus connected therewith must then be considered. It is gener-

ally conceded that the alternating-current system is more reliable than the direct current. This is mostly due to the absence of commutator trouble and to the rugged design of the induction motor.

There is no reason for installing direct-current motors except where an adjustable speed service is required, and in small plants where such a service is predominating the direct-current system would naturally be the one to install. If a varying-speed feature is only required intermittently, the phase-wound induction motor may be used to advantage, but if the motor must run at reduced speed a considerable portion of the time, the varying-speed, brush-shifting motor should be given careful consideration. As a rule, a considerable part of industrial machinery will require a constant-speed service, for which the alternating-current motor is admirably adapted, and should direct current be required it can be obtained by installing a motor-generator set.

As a rule it may be said that the alternating-current system should be selected if possible. This would furthermore permit of throwing over to a central-station service, in case it should be found that power could be more economically purchased from the central station than be generated on the premises.

**CHARACTERISTICS OF MOTORS AFFECTING THEIR APPLICATIONS.** — (See also the separate articles on Motors.) Motors are divided into two classes — direct-current and alternating-current, according to the system from which they are operated. The direct-current motors are further subdivided into three types, namely, series, shunt and compound motors.

There are also three general types of alternating-current motors, namely, induction, synchronous and commutator motors.

**Series Motor.** — This motor is used when a powerful starting torque and rapid acceleration are required, without an excessive instantaneous demand of energy. The torque is practically independent of the voltage and at low flux densities varies directly as the square of the current, but as the magnetization approaches saturation it becomes more nearly proportional to the first power of the current. The maximum torque exists at low speed, this being the most valuable feature of the series motor. Dangerously high speeds may be attained by the armature with very light loads, and series motors should for this reason be either geared or direct connected to the load.

**Speed Control of Series Motor.** — The speed of a series motor on constant potential varies automatically with the load, increasing as the load decreases. The speed may, however, be adjusted if some means of varying the impressed voltage is provided. As the work required of a series motor is very often intermittent in character, the insertion of resistance in the armature circuit to reduce the speed is permissible from an economic standpoint in such cases. In others, such as railway work, where two or four motors are used, reduced voltage is most readily and economically obtained by connecting the motors in series or in series-parallel.

**Shunt Motor.** — This motor has good starting characteristics and a practically constant speed, varying only slightly with load changes. The speed can, however, be adjusted, either by changing the e.m.f. impressed on the armature, or by changing the field flux.

**Speed Adjustment by Armature-voltage Control,** i.e., by changing the e.m.f. impressed on the armature, does not change the full-load torque which the motor is capable of exerting, since the rated torque depends only upon field flux and rated armature current. These methods are therefore constant-torque methods and are properly adapted to loads in which the torque remains constant regardless of speed. The method most generally used for varying the impressed e.m.f. with a single-voltage system is by means of inserting resistance in series with the armature. The efficiency with this method is, of course,

very low at slow speeds. The speed regulation with varying loads may also be very poor.

There are several systems of controlling the motor speeds by applying different voltages, such as by the use of three-wire generators or two-wire generators with balancer sets or by the Ward-Leonard system. This latter system, which is the most practical, consists of a constant-speed motor driving a generator which supplies current to the motor whose speed is to be adjusted. This arrangement is very satisfactory but on account of the expense of providing three full-sized machines instead of one to perform the work, the cost may be prohibitive except with very large motors, such as for hoists, etc.

**Speed Adjustment by Shunt-field Control**, i.e., by inserting resistance in the shunt-field circuit, is the simplest of all methods of speed variation, but with ordinary shunt motors, the range of speed variation by this means is small. Where a variation of more than from 20 to 30 per cent is desired, a motor of modified design and of a certain increased size is generally required because, the field must be more powerful with respect to the armature than in the case of standard single-speed motors. Varying or adjustable speed motors of the field-weakening type are not constant torque, but constant-output motors, i.e., the torque falls proportionally as the speed increases.

A speed variation up to 3 to 1 meets, as a rule, all requirements and such motors can readily be obtained in commercial sizes. Should a greater speed variation be desired, say 4 to 1 or 5 to 1, it is possible to accomplish this by the commutating-pole shunt motor with field control only. A combined field and armature control would, however, be a better method.

**Compound Motor.** — This motor is provided with both a series and a shunt field. The two fields are usually connected so that they act in the same direction, in which case the motor is called a "cumulative" compound motor. "Differential" compound motors, with the two fields opposing, are sometimes employed for special services. The cumulative, or ordinary, compound motor combines the characteristics of the shunt and series motors, having a speed not extremely variable under load changes, but developing a powerful starting torque and an increasing torque with decreasing load. Motors having a comparatively weak series field are employed extensively in shop practice where the motor may be required to start under heavy load but must maintain an approximately constant speed after starting, or when the load is removed. The heavily compounded motor is used where powerful starting torque and rapid acceleration are necessary, with a speed not varying too widely under load changes, such as for rolling mills, etc.

The speed control employed with compound motors may be any of the various methods explained in connection with the shunt motor. For certain service the control may be entirely rheostatic, the series winding being cut out after the motor has come up to speed.

**Induction Motor.** — The induction motor is essentially a constant-speed machine, although the speed may be varied either by varying the applied stator frequency or by introducing resistance in the rotor circuit. It is built in two distinct types, namely, the squirrel-cage and the phase-wound.

**Squirrel-cage Motor.** — The squirrel-cage type is used for constant-speed service with infrequent starting. It has a relatively small starting torque per ampere and draws a large starting current from the line. By increasing the resistance of the rotor, it may however also be built in the smaller sizes for a high starting torque, rapid acceleration and frequent starting, for such applications as sugar and laundry centrifugals, etc., where simplicity of control is desirable. They are also used for operating punches, shears, etc., where a fly-wheel is provided for storing the energy.

**Induction Motor with Wound Rotor.**— For service requiring high starting torque combined with moderate starting current a motor with the wound type of rotor is best adapted. A motor with the resistance mounted inside the rotor should not be used to operate machinery having large inertia or excessive static friction, since full starting current may be required for a long period before the apparatus attains full speed, and, as the capacity of the internal resistance is small, excessive temperatures may result. This type of motor is, as a rule, not built above 200 horse-power due to mechanical difficulties involved in connection with the internal resistance.

A motor with external resistance should be used for moderate and large sizes. The rotor must then be provided with collector rings and brushes. The contact resistance of these as well as the leads and the controller fingers, which are in the circuit all the time, may impair the efficiency and regulation of the motor especially if the controller and the resistance are located some distance from the motor. The phase-wound induction motor with an external variable rotor resistance is best adapted for a varying-speed service, as the losses necessary to obtain reduced speeds are external to the motor itself.

**Multi-speed Induction Motors.**— It often happens that the service is such that two or three speeds will be satisfactory for the operation of the machinery and that these speeds must be independent of the load. Under such conditions multi-speed motors can frequently be used. In these motors the different synchronous speeds are produced by changing the number of poles in the magnetic circuit. Each of these speeds is fixed, if no resistance is used in the secondary circuit. With multi-speed motors, as with single-speed motors however, resistance may be used in the secondary circuit for varying the speed.

A change of the number of poles may be produced in any of the following ways:

1. By the use of single magnetic and electric circuits, changing the number of poles by regrouping the coils.
2. By the use of single magnetic circuits and independent electric circuits
3. By means of separate magnetic and electric circuits, the so-called Cascade connection.

**Synchronous Motor.**— The speed of a synchronous motor is constant, being fixed by the number of poles and the frequency of the applied voltage. The single-phase type is not self-starting and the polyphase type has in itself a very poor starting torque. They may, however, be made self-starting in the same manner as squirrel-cage induction motors, by the use of an ammortisseur or cage winding, similar in construction to that used for induction motors.

The speed-torque curve of a synchronous motor is similar to that of an induction motor except that the torque values are lower for a given resistance of rotor winding on account of the construction of the machine. The starting winding must be designed with both the load at start and the load at synchronous speed in mind, because too great a slip may cause the motor to shut down when the field is put on. It is, however, seldom that the same motor will be called upon to start a heavy load and at the same time synchronize a heavy load, as the load usually consists principally of either static friction, as in the use of motor-generator sets, line shafting, etc., or it comes up with the speed as in the case of a fan blower or centrifugal pump. The former case would be met by a high-resistance squirrel-cage winding and the latter would require a low resistance.

**Single-phase Series Motor.**— This type of commutator motor has a very powerful starting torque, high power factor and relatively high efficiency. It is most generally used for traction work, the speed being controlled by varying

the applied voltage, which can most readily be done by means of an auto-transformer with a number of taps.

**Repulsion Induction Motor.**—This type of commutator motor has a limited speed and an increase of torque with decrease in speed. The action of the compensating field insures a power factor approximately unity at full load and closely approaching unity over a wide range in load. In addition it serves to restrict the maximum no-load speed and also permits, where varying speed service is involved, an increase over the synchronous speed.

**Starting of Repulsion Motors.**—A repulsion motor, if started by directly closing the line switch, will develop about  $2\frac{1}{2}$  times full-load torque. The starting current corresponding to full-load starting torque is from 2 to  $2\frac{1}{2}$  times full-load running current. As a general rule, starting boxes are not required up to and including 2 horsepower rating. From 2 to 5 horsepower the use of a rheostat is optional, dependent upon the degree and care to be exercised in maintaining voltage regulation. Starting boxes should, however, preferably be used on sizes above 5 horse-power, especially where light and power circuits are combined.

**Reversible Repulsion Motors.**—The repulsion motor may be designed for reversible service. This is accomplished by adding an auxiliary reversing winding spaced 90 degrees from the main field winding and connected in series with it. By reversing the relative polarity of the two windings, the direction of rotation is changed in a simpler manner than by mechanical shifting of the brush holder yoke. Instant reversal may be effected from full speed in one direction to full speed in the other, about 200 per cent of normal running torque being developed at moment of speed reversal in either direction.

**Varying-speed Repulsion Motors.**—In addition to the constant-speed repulsion motor, two other types are also available, one for constant-torque and varying-speed service, the other for adjustable speed independent of torque. In general, varying-speed repulsion motors are not applicable to lathes, boring mills or similar machines where the service requires adjustable speed and constant horse-power at all speeds below and above normal. When a certain amount of varying speed is required at approximately constant torque, such as driving fans, blowers, printing presses, etc., the repulsion motor successfully meets a wide field of application.

**POWER RATING OF MOTORS.**—(See also *Standardization Rules of the A.I.E.E.*) These rules recommend that with the exception of railway motors, all motor ratings shall be expressed in kilowatts (Kw.) available at the shaft. On account of the hitherto prevailing practice of expressing mechanical output in horsepower, it is, however, also recommended that for machinery of this class the rating may, for the present, be expressed both in kilowatts and in horsepower, as follows: Kw. ——— h.p. ———. The horsepower rating of a motor may for practical purposes be taken as  $\frac{3}{4}$  of the kilowatt rating.

It is also highly desirable that the motor ratings should closely conform to the actual service requirements, and for this reason the Standardization Rules also recommend the following two kinds of ratings:

1. **Continuous Rating**, when the motor shall be able to operate continuously at its rated output, without exceeding any of the guaranteed limitations.

2. **Short-Time Rating**, when the motor shall be able to operate at its rated output during a limited period, to be specified in each case, without exceeding the guaranteed limitations. Such service includes runs alternating with stoppages of sufficient duration to ensure substantial cooling.

**SPEED CLASSIFICATION OF MOTORS.**—Motors may, for industrial application, be classified with reference to their speed characteristics. The wording adopted from the standardization rules of the American Inst. of Electrical Engineers is as follows:

**Constant Speed Motors**, whose speed is either constant or does not materially vary; such as synchronous motors, induction motors with small slip, and ordinary direct-current shunt motors.

**Multispeed Motor (Change Speed Motor).**—A multispeed motor (change speed motor) is a motor which can be operated at any one of several distinct speeds (these speeds being practically independent of the load), but which cannot be operated at intermediate speeds.

**Adjustable Speed Motors**, in which the speed can be varied gradually over a considerable range, but when once adjusted remains practically unaffected by the load; such as shunt motors designed for a considerable range of speed variation.

**Varying-Speed Motors**, or motors in which the speed varies with the load, ordinarily decreasing when the load increases; such as series motors, compound wound motors, and series-shunt motors. As a sub-class of varying-speed motors, may be cited adjustable varying-speed motors, or motors in which the speed can be varied over a considerable range at any given load, but when once adjusted, varies with the load; such as compound wound motors arranged for adjustment of speed by varying the strength of the shunt field.

**DATA REQUIRED TO DETERMINE TYPE AND SIZE OF MOTOR.**—In selecting a motor for a certain application complete information must be had with regard to the machines to be driven. This is the first step and in some respects one of the most important parts of the problem, as without complete information on the subject it becomes very difficult, and in certain instances utterly impossible, to intelligently select or design a motor and control equipment which will satisfactorily fulfill the conditions to be met in actual operation. In order to facilitate the work of obtaining such information, an outline of the points to be investigated is given below.

**1. Description of Machine to be Driven. —**

- a. Individual or group drive.
- b. Photographs, drawings and sketches of machines and connections as complete as advisable, especially such drawings as indicate the size of heavy flywheels or rotating masses whose speed must be varied, and also drawings indicating gearings, transmission devices, etc.
- c. Limiting features of product. What are the points in quality and characteristics of product which fix the condition of operation? e.g. limiting speed of tool or mechanism, etc. *Example:* A 26-inch lathe used for finishing requires approximately 3 horse-power to drive. The same lathe for roughing shafting, when equipped with high-speed tool steel and two tools, needs approximately 30 horse-power.
- d. Can electric drive approach nearer the conditions wanted?
- e. If group drive can be considered for several machines, some of which are only to be operated intermittently, give notes with regard to the latter machines.
- f. What arrangements can be made so that intermittently-operated machines need not operate simultaneously, thus giving a smoother load curve and allowing the use of one small motor to drive several intermittent machines?

## 2. Cycle of Operation. —

- a. Starting condition. Torque at start of day, and start of each cycle. Is frequent starting and stopping necessary? *Example:* The adjustment of large boring mills affects the controller, etc. Starting torque may be measured approximately if necessary by adjusting a rough beam to shafting. Find distance from axis at which the weight just starts machine. Knowing the weight in pounds the torque may be calculated.
- b. Curves of loads, speeds, torque, maximum and average conditions through one complete cycle. Where necessary note power required with machines both loaded and unloaded. From this may be determined losses in shafting and transmission.
- c. Time in operation, days per year, per month, per week, hours per day.
- d. Reversing conditions, their frequency, their time, full or partial. Some apparatus, e.g., lathes, printing presses (flat-bed type), etc., only require slight backward movement to release tool or to adjust cylinders.
- e. Starting. Flywheel or line shafting, friction clutches, etc.
- f. Are speeds, torques, accelerations, etc., fixed by conditions of work or of driving machine?
- g. Can any parts of cycle be varied with benefit? This should be investigated carefully.

## 3. Present Method of Drive. —

- a. Prime mover or source of power.
- b. Method of speed variation and speed change or control. Must machine be shut down to change speed?
- c. Adaptability to gearing, etc.
- d. Speed of machine, size of pulley, size of belt, size of gear or chain.

## 4. Mechanical Transmission. —

- a. Rope, belt, chain, gear, direct connection. Direction of pull on belt or gear. Is belt or chain pull on the top or bottom? Is belt tighter advisable?
- b. Clutches. Crab clutch, friction or couplings. Rigid, flexible or insulated.
- c. Method of speed variation.
- d. Brakes, electric. Solenoid or magnetic. Regenerative control, dead load or pumping back.
- e. Brakes, mechanical. Band-post brake, disc brake, automatic safety brake, steam, hydraulic, air- or hand-operated.

## 5. Conditions of Location. —

- a. Near external source of heat, furnace, etc.
- b. Character of dust, conductive, magnetic or wearing, marble or stone, etc.
- c. Possibility of fire or explosion to be caused by sparks from motor. Combustible flyings, e.g., cotton mills.
- d. Explosive gases. Coal gas, benzine fumes, etc.
- e. Presence of injurious gases. Acid fumes or salt air, e.g.,  $SO_2$ , Cl, etc.
- f. Dampness and moisture.
- g. Insurance regulations. Obtain and forward copy of State Insurance Rules, or other state or local regulations, e.g., mining laws, municipal laws. Consider also personal danger or liability due to use of high-voltage apparatus.
- h. Accessibility for inspection and repairs, oiling, etc.
- i. Ventilation.
- j. Allowable space for installation, also space for transportation. Down mine shaft, through doorways, etc.
- k. Foundations and how attached to same.

- l. Sudden temperature variations. This may cause condensation of moisture on windings and insulation.
- m. If controlled from distance where will controller or switch be placed? Give approximate length of leads necessary. Must they pass through or under water, in building, on poles, underground?

**6. Control. —**

- a. Intelligence (probable) of operators.
- b. Is entire range of operation visible to operator or are special automatic features desirable?
- c. Regenerative Control — See item No. 4-d; also *Cycle of Operation*, item No. 2.

**7. Overload and Safety Devices. —**

- a. Can electric automatic devices be made to supersede mechanical overload safety devices, such as slipping clutches, braking shafts or crabs?
- b. Should these devices be time limit or instantaneous? If former, how long?
- c. Are safety devices necessary, other than those to protect overload — e.g., overrun of hoist, stoppage or cessation of load. Must emergency stop be employed, and where placed?
- d. Are undervoltage releases required or advisable?

**8. Probable Cost of Present Method of Operation. —**

*a. Steam Operation.*

1. Coal. Tons per day or month; quality, cost, distance shipped.
2. Fuel and other water. City mains or pumped; source, quality.
3. Is steam required for other purposes beside power? e.g., digesters, heating, etc.
4. Can steam be generated from waste gases or other waste products?
5. Distance of transmission, outdoors and indoors.

*b. Air.* Distance of transmission, air pressure, how obtained?

*c. Water Power.* Has electric installation to compete with water power? If so, report separately on this aspect.

**9. Strength of Present Equipment. —**

- a. Strength of line shafting, foundation, transmission or gearing, machine parts.
- b. Give estimate of limiting horse-power of items in (a), using sketch and dimensions where necessary. The above items should be considered with regard to any change in speed or torque made necessary or desirable, due to the electric drive.

**10. Generating Station or Source of Electric Power. —** Capacity of station or feeder, frequency, voltage, location, voltage or frequency variations.

**BIBLIOGRAPHY.** — It is impossible in the limited space available to give references to all the numerous papers in the technical journals dealing with the industrial applications of motors. The reader should consult the files of the *Transactions of the American Institute of Electrical Engineers*, *American Society of Mechanical Engineers*, *National Electric Light Association*; also the *Electrical World*, *General Electric Review*, *Electric Journal*, *Electrical Review*, *Power*, *Power and Engineer*, *Electrical Engineer*, *Engineering Magazine*, *Cassiers' Magazine*.

**MOTORS, POLYPHASE INDUCTION.**—(See also *Electricity and Magnetism, Principles of; Generators; Motors, A-C. Commutator, Direct-current, Single-phase Induction and Synchronous; Motors, Industrial Applications of; Standardization Rules; Transformers.*) An induction motor may be either single, two, or three phase. Single-phase induction motors are treated in another article (*q.v.*). The induction motor is essentially a polyphase transformer with the secondary free to move; the electric energy transferred to the secondary is transformed by this motion directly into mechanical energy.

**DEFINITIONS AND PRINCIPLE OF OPERATION.**—Certain terms used in connection with the induction motor can best be defined by a brief statement of the principles underlying its operation.

**Primary and Secondary.**—By the primary of an induction motor is meant that part which receives energy by direct connection to the source of electric energy; the other member is called the secondary.

**Stator and Rotor.**—That member of an induction motor which remains stationary, whether it be the primary or secondary, is called the "stator," and the revolving member is called the "rotor." In most machines the primary is the stator. A "squirrel cage" rotor is one in which the conductors are straight bars of copper all connected together at each end of the rotor by copper rings.

**Poles of an Induction Motor.**

—In Fig. 1 is given a diagram of the primary winding of a two-phase induction motor. The small numbered circles represent the conductors forming the winding of one phase, the small black circles the conductors forming the winding of the second phase. The numbers opposite the circles give the order in which the current in phase 1 passes through the conductors, a cross indicating that the current goes down into the page and the open circles that the current is coming up.

Fig. 1. Elementary Induction Motor

The diagram is drawn to represent that instant at which the current in the second phase is zero. At this instant the distribution of flux in the air gap will be roughly as indicated by the lines with arrows on them; that is, the flux will leave the stator iron in the two regions marked *N* and enter it in the two regions marked *S*. Consequently, the current in the winding of phase 1, which consists of 4 bands or groups of conductors, will produce 4 polar regions, or 4 poles, on the stator. As will be shown below, the combined effect of the two phase currents in the two windings is merely to cause a rotation of these polar regions. The "number of poles" is always equal to the number of bands of conductors into which the total winding of each phase is divided. The bands of conductors forming one phase usually overlap the bands of conductors forming the other phase, there being then two or more conductors per slot.

**Rotation of Magnetic Flux.** — In Fig. 1 is shown the distribution of flux in the gap when the current in phase 2 is zero; the curve marked *A* in Fig. 2 represents this same state of affairs, the cylindrical surface of the stator here being bent out into a plane, and the ordinates of the curve giving the value of

Fig. 2. Rotating Field

the flux density in the gap at each point of this surface. The flux distribution is not a smooth curve as shown, but approximates such a curve.

Next consider the case when the current in phase 1 has decreased to, say, 0.7 of its maximum value and the current in phase 2 has increased to 0.7 of its maximum value (this corresponds to  $\frac{1}{6}$  of a cycle). Then the flux distribution due to phase 1 remains in the same position as before but is reduced at each point of the gap to 0.7 of its maximum value, i.e., reduces to the curve marked  $\phi_1$ . Similarly, the flux due to the current in phase 2 is similar in shape to the flux due to the current in phase 1, but its position is to the right of the latter by an amount equal to the width of one of the bands of conductors. The distribution of the flux due to the current in phase 2 is then as shown by the curve  $\phi_2$ , the ordinates of which at the instant under consideration are 0.7 of their maximum values.

The resultant flux in the air gap at this instant is then the sum of the curves  $\phi_1$  and  $\phi_2$ , namely the curve *B*. That is, the effect of the two fluxes due to the two phases is a resultant flux shifted forward, or moved around the gap, a distance equal to  $\frac{1}{6}$  the distance between successive north poles, but this resultant flux curve has the same shape and maximum value as before. This is strictly true only if the windings are distributed with absolute uniformity over the internal periphery of the stator. An extension of this analysis will show that the resultant flux remains constant in value at all times but travels around the air gap with a speed of

$$N = \frac{120f}{p} \text{ rev. per min.,}$$

where *f* is the frequency of the supply and *p* the number of poles.

This same result holds for a three-phase machine.

**Synchronous Speed.** — The speed of rotation of the air-gap flux, namely the speed  $N$  given by the above formula, is called "synchronous" speed. At light loads the speed of the rotor is very nearly equal to this speed.

**Slip.** — The slip of an induction motor is the ratio of the difference between the actual speed ( $N_1$ ) of the rotor and synchronous speed ( $N$ ) to the synchronous speed ( $N$ ), i.e.,

$$s = \frac{N - N_1}{N}.$$

The slip may be expressed as a fraction or as a per cent. The slip at standstill is unity; at no load it is very nearly zero. An induction motor driven at a speed higher than its synchronous speed has a negative slip; such is the case in an induction generator.

**Electromotive Forces in Secondary.** — The electromotive forces in the secondary of a polyphase induction motor are induced by the rotation of the flux produced by the currents in the primary windings, just as the electromotive forces induced in the armature conductors of a generator are induced by the rotation of these conductors in the magnetic field set up by the field winding. In the generator only the conductors move, the field being stationary, but in the induction motor both the field and conductors move. In either case it is the relative motion of the field and conductors which determines the e.m.f. induced.

Let  $v$  be the linear speed at which the field moves, and let  $v_1$  be the linear speed of the rotor conductors, and  $B$  the flux density at any particular conductor  $C$  at any instant. Then the e.m.f. induced in this conductor at this instant is  $B(v - v_1)l = Blsv$ , where  $s$  is the slip and  $l$  is the length of the conductor (see also *Electricity and Magnetism, Principles of*). The rotor electromotive force is therefore proportional to the slip. As the rotor turns, the conductor  $C$  moves slower than the rotating flux, and the state of affairs is just the same as if the flux remained at rest and the conductor moved through the field in the gap at a speed of  $v - v_1 = sv$ . Hence the electromotive force induced in each rotor conductor is alternating, since the flux which it cuts varies from a positive maximum to a negative maximum, and a consideration of the relative speed of the conductor and the flux will show that the frequency of this induced electromotive force is the frequency in the primary multiplied by the slip.

*That is, the secondary electromotive force is proportional to the slip and has a frequency equal to the product of the slip by the frequency in the primary.*

**Secondary Current and Torque.** — The current set up in each rotor conductor by this electromotive force will be practically in phase with this electromotive force, since the rotor conductors have but a small reactance, particularly when the rotor is revolving at a speed near synchronism. Hence the current in any chosen rotor conductor at any instant is proportional to the electromotive force in this conductor at that instant, which in turn is proportional to the flux density at this conductor at this instant. Since the force produced by a magnetic field on a conductor is equal to the product of the flux density by the current by the length of the conductor (see *Electricity and Magnetism, Principles of*), the force acting at any instant on any rotor conductor will then be equal to

$$f = Bli = Bl \left( \frac{Blsv}{r} \right) = \frac{B^2 l^2 sv}{r},$$

where  $r$  is the resistance of the conductor. Since the current and the flux density both change signs at the same time (being in phase) the direction of this force will always be in the same direction and will consequently drive the rotor against whatever opposing force may exist.

Not only is the force on each conductor always in the same direction, but the total force acting on all the conductors is practically constant for a given value of the slip. Consider any two rotor conductors which are a distance apart equal to  $\frac{1}{2}$ th the distance measured along the periphery of the rotor between successive north poles, for example, at  $a$  and  $b$  in Fig. 2. Then, assuming a sine-wave distribution of flux in the air gap, and calling  $B_m$  the maximum flux density, the flux density at  $a$  is  $B_a = B_m \sin x$  and the flux density at  $b$  is  $B_b = B_m \cos x$ , where  $x$  is a function of the distance measured from some fixed point in the air gap. Then the total force on the two conductors at  $a$  and  $b$  is

$$\frac{P_{22} B_m^2}{r} (\sin^2 x + \cos^2 x) = \frac{P_{22} B_m^2}{r}$$

and is therefore constant, since  $B_m$  is a constant. Similarly for any other two conductors this same distance apart. Hence the total force on all the conductors is constant. On any practical machine the flux distribution is not an exact sine wave, and there is a slight pulsation in the total force, and therefore in the torque, but this pulsation is extremely small.

**Magnetizing Current.** — The currents set up in the secondary of an induction motor produce a rotating flux, which travels with the same speed with respect to the primary and in the same direction as the flux set up by the current in the primary, but the direction of this secondary flux at any point in the air gap is opposite to the direction of the primary flux. Hence the resultant flux when there is current in the secondary is equal to the difference of these two fluxes, and this difference remains practically constant irrespective of the secondary currents, just as the resultant flux in a transformer is practically independent of the secondary current. The primary current which would be necessary to produce this resultant flux is called the "magnetizing" current, and is very nearly equal to the current in the primary when the motor is running without load, in which case the current in the secondary is extremely small.

**METHODS OF RATING.** — The Standardization Rules of the A.I.E.E. up to 1914 recommended that the rating of an induction motor should be the load in horse-power which it will deliver continuously at the shaft with a maximum rise in temperature of any part not exceeding  $50^\circ \text{C}$ . by thermometer. In commercial practice three variations of this have been developed to suit different conditions, as noted below. See, however, the new ratings recommended in the proposed rules of 1914, given in the article on *Standardization Rules of the A.I.E.E.*

**A-Rating.** — For cases where there are no excessive overloads and where the load is fairly steady, it is customary to guarantee that the motor will operate continuously at its rated load with a maximum rise in temperature of  $40^\circ \text{C}$ ., and that subsequently it will deliver a load 25 per cent greater than the rated for two hours with a maximum rise in temperature not exceeding  $55^\circ \text{C}$ .

**B-Rating.** — For cases where there are frequent overloads and for intermittent service, that is, a low load factor, it is customary to guarantee that a motor will deliver its rated load continuously with a rise in temperature not to exceed  $35^\circ \text{C}$ ., and that it will deliver an overload of 50 per cent for two hours with a maximum rise in temperature not exceeding  $55^\circ \text{C}$ .

**One-hour Rating.** — Certain motors for special intermittent work, as for hoists, elevators, etc., are rated in accordance with the output they will give for one hour.

**Starting and Break-down Torque.** — In addition to the ability to carry its rated load without excessive heating and with reasonable constants, such as

efficiency, power factor and slip, it is advisable to make sure that the motor is able to start such loads as must be brought up to speed with the motor, as good starting ability in an induction motor involves certain complications and expenses. This subject is treated at length in the section below on *Methods of Starting*. Another important point is that the motor should be able to carry momentary overloads without "breaking down" as it is called, which means gradually decreasing in speed to a standstill when the load is excessive. To be sure of this qualification we must know the maximum output of the motor, which should be at least 50 per cent greater than the rated output.

**VOLTAGE.** — Motors may be wound for any voltage up to 13,000 but the great majority and all the small motors are wound for voltages of 110, 220 or 440 volts between lines.

**FREQUENCY AND SPEED.** — Induction motors may be built for any frequency. The higher frequencies are satisfactory in those cases where the load never exceeds normal conditions. Lower frequencies, such as 25, are more favorable where frequent overloads are met with or large starting torques are required.

The speed of the rotor of an induction motor at normal loads approaches within 5 to 10 per cent of the synchronous speed. The synchronous speed is fixed by the frequency of the system and the number of poles of the winding (see above) so that for a given frequency of the supply circuit there are only certain speeds available. Thus for 25 cycles we have

1500 for 2 poles;  
750 for 4 poles;

500 for 6 poles;  
375 for 8 poles, etc.

**PHASE CONNECTIONS.** — Two-phase or quarter-phase motors are usually wound with independent phase windings. Three-phase motors are connected in Y or  $\Delta$ , depending upon the convenience of the designing engineer.

In a single-phase and two-phase motor the voltage and current per phase are the same as the voltage between lines and current in line; in a Y-connected three-phase motor the current per phase is equal to the line current, and the voltage per phase is equal to the line voltage divided by  $\sqrt{3}$ ; in a  $\Delta$ -connected three-phase motor the current per phase is equal to the line current divided by  $\sqrt{3}$ , and the voltage per phase is equal to the line voltage.

**CURRENTS TAKEN BY MOTORS.** — Let

$P_0$  = horse-power output;

$I$  = current in each line;

$e$  = efficiency as a decimal fraction;

$\cos \phi$  = power factor as a decimal fraction;

$E$  = voltage between lines (between one outside wire and the middle wire for three-wire two-phase line).

Then for

$$\text{Two phase: } I = \frac{373 P_0}{eE \cos \phi};$$

$$\text{Three phase: } I = \frac{431 P_0}{eE \cos \phi}.$$

Usual efficiencies and power factors at full rated load for polyphase motors are as follows:

## POWER FACTORS AND EFFICIENCIES

Horse-power	25 cycles		60 cycles	
	Efficiency	Power factor	Efficiency	Power factor
1	0.79	0.78	0.78	0.78
5	0.83	0.88	0.82	0.83
20	0.88	0.91	0.84	0.91
50	0.90	0.92	0.87	0.92
100	0.905	0.925	0.89	0.92
200	0.91	0.925	0.905	0.92

**DESIGN.** — The methods of calculating two-phase and three-phase motors are practically the same. Most induction motors on single-phase circuits are made with polyphase windings, as the extra winding is necessary in starting.

The factors which must be considered in the design of an induction motor are the same as those considered for a synchronous generator with the addition of the power factor. It is desirable to have a high power factor but a high power factor requires a generous use of material, a small air gap, and a careful arrangement of windings. A high power factor at light load requires a small magnetizing current, and a high power factor at overloads requires a low value of leakage flux.

A small value of magnetizing current is obtained by using a small air gap and a large value of diameter per pole.

A low value of leakage flux is obtained by using a large value of diameter per pole and by subdividing the windings in a large number of slots.

**Preliminary Choice of Main Dimensions.** — In the discussion below the following symbols are employed:

$E$  = volts per phase;

$I$  = full-load current per phase;

$D$  = diameter of armature, in inches;

$L$  = length of armature, in inches;

$p$  = number of poles;

$f$  = frequency in cycles per second;

$g$  = length of gap, in inches;

$B$  = average flux density in gap, in lines per square inch;

$\phi$  = flux per pole, in maxwells;

$S$  = turns in series per phase;

$N$  = revolutions per minute;

$\alpha$  = quotient of no-load current divided by full-load current (ranges from 0.45 for a 1-horse-power motor to 0.25 for a 200-horse-power motor);

$c$  = ampere-conductors per inch of periphery. The values given in the article on *Generators, Alternating-Current*, also apply to the induction motor.

$T$  = ratio of width of tooth at face to slot pitch ( $T$  varies from 0.6 to 0.7 for open slots and from 0.9 to 1.0 for overhung slots);

$q$  = ampere-conductors per slot.

**Diameter and Length of Rotor.** — The first problem in the design of an induction motor is the estimation of the proper diameter of armature. There are three methods of determining the proper value of this very important dimension:

(a.) Reference to machines already built, which shows that  $T$  varies directly with the number of poles and inversely as the frequency for customary values of diameter in inches divided by the number of poles for

25 cycles,  $D/p = 5$  to 6 inches;  
60 cycles,  $D/p = 2.5$  to 3 inches.

(b.) The peripheral speed, being a direct function of the diameter, determines the diameter. As the value of the peripheral speed varies from 3000 to 10,000 feet per minute, depending on the mechanical conditions, the function is not very definite. For lack of more definite figures, 5000 feet per minute may be considered a good average figure for peripheral speed.

(c.) On account of the effect of the magnetizing current on the efficiency, it is desirable to limit the value of this current to a certain percentage of the load current (for values see p. 988). To accomplish this there is a maximum limit to  $D$  and  $L$  which is expressed approximately in the following formula:

$$D^2L = \frac{28.7 \times 10^{12} f g k}{\alpha \sigma^2 N^2} \times (\text{Kv-a. rating}).$$

$k$  = ratio of the actual excitation current to the excitation current for a standard gap;  $k = 1.2$  for 60 cycles and  $k = 1.4$  for 40 cycles.

This gives a relation between  $D$  and  $L$ . Assuming that for a given diameter  $D$  is equal to the pole pitch ( $L = \frac{\pi D}{p}$ ) a value for  $D$  is obtained. This formula also indicates the effect on the general design which would result from changes in any of the quantities.

The formula given for the preliminary calculation of dimensions of an alternating-current generator (see article on Generators, Alternating Current) may also be used if proper values for  $T$  and  $L$  be selected.

**Air Gap** ( $g$ ) varies in length according to the diameter, usual values are given in the accompanying table.

Diameter, inches	Air gap, inch
0 to 12	0.02 to 0.03
12 to 26	0.03 to 0.04
26 to 50	0.04 to 0.06
50 to 100	0.06 to 0.10
100 up	Diameter/1000

**Average Flux Density in Gap ( $B$ ).** — The usual value of the flux density in the air gap for 25 cycle machines is 30,000 lines per sq. inch. For 60 cycle machines is 25,000 lines per sq. inch.

**Conductors per Slot ( $c$ ).** — The "effective" number of conductors is the number of conductors *in series* per slot, i.e., if each phase has two windings in parallel, the two conductors of the two parallel windings are counted as one conductor. Hence the effective conductors per slot is

$$c = \frac{2S \times (\text{Number of phases})}{(\text{Total number of slots})}$$

The permissible number of ampere conductors per slot ( $q$ ) depends on the permissible current density per square inch of copper, usual values are

Size of motor	Voltage	Amperes per sq. in.
Small.....	Low.....	3000
Small.....	High.....	2000
Large.....	Low.....	3000
Large.....	High.....	1600
Large.....	Above 6000.....	1000

Usual values of  $q$  are

Size of motor h.p.	Value of $q$
Up to 5	Up to 250
5 to 50	250 to 350
50 to 100	350 to 450
100 to 200	450 to 600
Greater	Up to 800

**Number and Dimensions of Slots.** — The number of slots is

$$\frac{\pi D \sigma}{q}$$

The conductors should be arranged to give slots having a depth about four times the width, and the width of slot should be about  $\frac{1}{4}$  to  $\frac{3}{8}$  of the pitch of slots at the gap. Machines of small diameter will have slots smaller with respect to the pitch and machines of large diameter will have slots occupying more than  $\frac{3}{8}$  of the pitch.

The slots of one member at least (usually the rotor) should be overhung, *i. e.*, partly closed at the opening. It is better if both members have partly closed slots, as this reduces the magnetizing current and improves the power factor, but it entails a more expensive method of winding.

The dimensions of the slots are determined by the size of conductors and amount of insulation. The allowance to be made is about as follows:

Type of slot	Voltage	Coil sides per slot	Allowance for insulation	
			Vertical	Horizontal
			in.	in.
Straight.....	500	2	0.30	0.04
Straight.....	2200	2	0.45	0.15
Straight.....	6000	3	0.65	0.35
Overhung.....	500	4	0.40	0.15
Overhung.....	2200	4	0.50	0.20

The depth of the slot is found by adding to the total depth of cotton-insulated copper the vertical dimension given in the table.

Turns in Series per Phase ( $S$ ) may be calculated from the formula

$$S = \frac{\pi D \sigma}{2l \times (\text{number of phases})}$$

or from the formula

$$S = \frac{10^8 E}{4.44 \phi / k}$$

where  $\phi$  is the flux per pole and is given by the formula

$$\phi = \frac{0.7\pi BDL}{(\text{number of poles})}$$

and  $k$  is a constant depending on the wave form and winding distribution (see next paragraph). The value of  $S$  as obtained from these two formulas must check in the final design.

Flux per pole ( $\phi$ ). — The flux per pole is given by the formula

$$\phi = \frac{10^8 E}{4.44 / S k}$$

where  $k$ , called the distribution constant, has the values given in the following table, provided the flux distribution in the air gap is sinusoidal.

DISTRIBUTION CONSTANT  $k$

Two phase					Three phase				
Slots per pole	Per cent winding pitch				Slots per pole	Per cent winding pitch			
	100	75	67	50		100	75	67	50
	$k$	$k$	$k$	$k$		$k$	$k$	$k$	$k$
2	1.00	....	....	0.71	3	1.00	....	0.87	....
4	0.93	0.85	....	0.66	6	0.97	....	0.84	0.69
6	0.91	....	0.79	0.64	9	0.96	....	0.83	0.68
8	0.905	0.84	....	0.64	12	0.96	0.89	0.83	0.68

**Choice of Phase Connection.** — The decision whether a motor shall be  $\Delta$  or  $Y$  connected depends on such minor details of design as the convenience of arranging the conductors in the slots. For instance, if for 110 volts and  $\Delta$  connection a desirable flux value and number of conductors would require 7 conductors per slot, a  $Y$  connection having 64 volts per phase and 4 conductors per slot could be substituted and would give a practical winding. 64 volts per phase,  $Y$  connected, gives 110 volts between lines.

**Magnetic Circuit.** — A tentative layout of the magnetic circuit is next made in the same manner as described in the article on *Generators, Alternating-*

**Current.** The values there given for usual values of the flux density also apply to the maximum instantaneous flux density in the magnetic circuit of an induction motor. The magnetic circuit must have such dimensions that the exciting current will not be too large, and the slots must be of sufficient size to accommodate conductors of necessary size (see above).

**Maximum Efficiency and Power Factor.** — Since induction motors frequently operate on an intermittent or variable load, it is desirable that the efficiency and power factor be high at fractional loads. It is therefore quite usual to design the motors so that the maximum efficiency comes at  $\frac{1}{2}$  load and maximum power factor at less than full load. This is accomplished with regard to efficiency by making the core-loss and friction small (the core-loss is made small by using low flux densities) and with regard to power factor by making the magnetizing current small by using a small air gap.

**PREDETERMINATION OF PERFORMANCE OF AN INDUCTION MOTOR FROM ITS DIMENSIONS.** — From the above calculations a preliminary drawing of the motor to scale may be laid out. The next step is to calculate its performance, i.e., predetermine what will be the efficiency, the power factor, and the temperature rise in the various parts. Examples of specific design and tested performance are given below.

**Calculation of Exciting Current.** — The first step is the calculation of the exciting current. This current is practically constant at all loads, and is equal to the no load current, i.e., the current taken by the motor when it is running light. The exciting current has two components, the magnetizing current, which leads the induced voltage by  $90^\circ$  and a component in phase with the induced voltage, which supplies the core-loss and friction. The magnetizing current is much the larger component, and for preliminary calculations may be taken equal to the exciting current.

**Magnetizing Current.** — The magnetizing current is calculated by determining the flux density in each part of the magnetic circuit and the ampere turns required for each part. This is most easily done by means of the following tabulation:

#### MAGNETIC DENSITIES AND M.M.F.'S

(For dimensions refer to Fig. 3.)

Part	Flux per pole	Area	$B_{max}$	A.T. per inch	Length path	Total A.T.
Stator core.....	$\phi/2$	$b_1 \times l$	$1 \times B_{100}$	....	$\frac{\pi D_1}{2 \times \text{poles}}$	....
Stator teeth....	$\phi$	$r_1 \times l \times \frac{\text{slots}}{\text{poles}}$	$1.57 \times B_{100}$	....	$g_1$	....
Air gap.....	$\phi$	See below	$1.57 \times B_{100}$	....	$g$	....
Rotor teeth....	$\phi$	$r_2 \times l \times \frac{\text{slots}}{\text{poles}}$	$1.57 \times B_{100}$	....	$g_2$	....
Rotor core.....	$\phi/2$	$b_2 \times l$	$1 \times B_{100}$	....	$\frac{\pi D_2}{2 \times \text{poles}}$	....
					Total.....	.....

**Stator Core or Yoke.** — The flux divides in the core, one-half going each way. The maximum and average\* densities are practically the same and equal to  $(\phi/2)$  divided by the radial depth  $h$  times the effective length  $l$ . The material is laminated steel of high permeability. The ampere turns per inch length of path are obtained from a magnetization curve of the steel, see *Magnetic Properties of Iron*. The length of path is indeterminate but closely approximates one-half of the pole pitch measured on the circle of diameter  $D_1$ . By multiplying the ampere turns per inch obtained from the magnetization curve by the length of path, the ampere turns required to send the flux through this path are obtained.

**Stator teeth.** — The average density in the teeth is first obtained. The effective area of one tooth is the area one-third the distance from the face to the root of the tooth as shown at  $r_1$ . This gives the average magnetizing force rather than the average density. The total cross section of the path in the teeth is therefore  $r_1 \times l \times$  (the number of teeth per pole). Due

Fig. 3. Dimensions of Magnetic Circuit

to the peaked or sinusoidal space distribution of the flux the maximum density in the teeth is 1.57 times the average density. The ampere turns required depend upon the maximum density. From the proper curve determine the ampere turns per inch necessary to establish this density, and by multiplying this quantity by the distance  $r_1$  in inches, the ampere turns for the stator teeth are found.

**Air Gap.** — The flux is not uniformly distributed in the air gap, especially if the openings of the slots are fairly large. The flux passes through each tooth and spreads out from the iron when it leaves the teeth to cross the gap. The peripheries of the stator and rotor present unequal and dissimilar surfaces passing each other. The lesser of the two is the one that must be considered. The effective area of the air gap is

$$\frac{(t + g) l \times (\text{total number of slots})}{0.9 \beta}$$

and the maximum density =  $\frac{1.57 \times \phi}{\text{gap area}}$

(the  $t + g$  allows for the spreading of the flux in one direction and  $l/0.9$  allows for the spreading in the other direction).

The ampere turns per inch are  $0.313 B_{\text{max}}$ . The length of gap being known, the total ampere turns for the gap are found.

**Rotor Teeth.** — The calculation of the ampere turns for the rotor teeth follows the same method as the calculation for the stator teeth.

**Rotor Core.** — The same as for the stator core.

The effective value of the magnetizing current is then

$$I_m = \frac{(\text{Total ampere turns}) \times \beta}{2 \sqrt{2} S} \quad \text{for three phases}$$

$$\text{and } I_m = \frac{(\text{Total ampere turns}) \times \beta}{\sqrt{2} S} \quad \text{for two phases}$$

\* By average is here meant the average over the cross section of the maximum instantaneous value of the flux density, which, of course, alternates between fixed positive and negative values.

## Motors, Polyphase Induction

**Resistance per Phase of Primary Winding.** — The resistance to direct current, or ohmic resistance, is given by the formula

$$r_1 = \frac{0.0093 S \times (\text{mean length of turn})}{12,000 \text{ cm}}$$

where

$S$  = turns in series per phase,  
 $a$  = cross section of one conductor in sq. in.,  
 $n$  = no. of conductors or circuits in parallel,  
 and 0.0093 is the resistance at 60° C. of a conductor 1000 feet long and 1 square inch cross section. The mean length of turn is approximately (see Fig. 3)

$$2L + 10 \frac{D}{p} \times (\text{pitch as a fraction}).$$

Due to the eddy currents set up in the primary conductors by the total flux and to eddy currents set up in the core by the leakage flux, the "effective" resistance of the primary winding is about 15 per cent greater than the value calculated by the above formula.

**Resistance per Phase of Secondary Winding.** — In a wound rotor the resistance per phase is found in the same manner as the resistance per phase of the stator winding. The secondary resistance reduced to primary is then equal to  $\left(\frac{\text{number prim. turns per phase}}{\text{number sec. turns per phase}}\right)^2 \times (\text{actual effective sec. resistance})$ , when the secondary has the same number of phases as the primary.

The squirrel-cage rotor, in which each slot contains one bar and all bars are short-circuited at each end by a ring presents a more complicated problem. It may be solved as follows:

$$\text{Amp.-cond. per sec. slot} = \frac{\pi D \sigma}{(\text{number of sec. slots})}$$

$\sigma$  = amp.-cond. per inch for full-load current.

$$\text{Current density in sec. bars} = \frac{(\text{amp.-cond. per slot})}{(\text{area of one bar})}$$

$$\text{Watts lost in bars} = 0.775 \times 10^{-8} (\text{vol. of bars}) (\text{amp. per sq. in.})^2.$$

$$\text{Area of bars per pole} = (\text{area of one bar}) (\text{number of bars per pole}).$$

$$\text{Current density in rings} = \frac{(\text{current density in bars}) (\text{area of bars per pole})}{4 (\text{area of ring})}$$

$$\text{Watts lost in rings} = 0.775 \times 10^{-8} (\text{vol. of both rings}) (\text{density in rings})^2.$$

$$\text{Resistance of sec. in terms of primary for a } \left. \begin{array}{l} \text{three-phase motor} \end{array} \right\} = \frac{\text{total loss}}{3 (\text{full load prim. current})^2}$$

**Leakage Reactance.** — When the motor is loaded the currents in the secondary set up a counter m.m.f. which causes part of the flux to pass along the air gap instead of into the secondary core. This flux does not interlink both members and is therefore a leakage or useless flux. It is proportional to the load currents and to the permeance of this path. As the greater portion of the path is in the air and is of high reluctance, therefore that part of the path in the iron may be neglected. The flux in both the primary and secondary must be calculated.

Referring to the diagram Fig. 4, the permeance of these two paths are

$$P_1 = \left[ \frac{g_1}{3w_1} + \frac{2g_1}{w_1 + g_1} + \frac{h_1}{g_1} + \frac{h - g_1}{6g} + 0.37 \frac{l_{g1}}{L} \log_2 \frac{1.5 l_{g1}}{V_{g1}} \right] L_1$$

$$P_2 = \left[ \frac{g_2}{3w_2} + \frac{2g_2}{w_2 + g_2} + \frac{h_2}{g_2} + \frac{h - g_2}{6g} + 0.37 \frac{l_{g2}}{L} \log_2 \frac{1.5 l_{g2}}{V_{g2}} \right] L_2$$

where

$g$  = length of gap in inches,

$l_e$  = length of end connection at one end in inches,

$V_e$  = perimeter of a band of end connection per pole per phase, in inches,

$L$  = total length of iron in inches.

In these formulas the subscript 1 refers to the primary and subscript 2 to the secondary. The first three terms give the slot reactance, the fourth term gives the "zigzag" or "tooth-tip" reactance, and the last term the reactance of the end connections.

The primary reactance in ohms per phase is

$$x_1 = 3.2 P_1 k_1^2 s_1 \times 2\pi f 10^{-9}$$

The secondary reactance in ohms per phase in terms of the primary turns is

$$x_2 = 3.2 P_2 k_2^2 s_2 \times 2\pi f 10^{-9} \left( \frac{c_1 s_1}{c_2 s_2} \right)^2$$

where

$c_1$  and  $c_2$  are the conductors in series per slot (see p. 1058),

$s_1$  and  $s_2$  are the slots per phase,

$f$  = primary frequency,

$k$  = winding distribution constant (see above).

**Losses in Induction Motor.** — The losses in an induction motor are

- Core-loss;
- Friction, bearing and windage;
- Primary copper loss;
- Secondary copper loss.

The first two of these are approximately constant for all loads and the last two vary as the square of the current per phase.

**Core-loss.** — The distribution of the magnetic flux in an induction motor is quite irregular both in the core and in the teeth. The losses are therefore greater and their calculation more involved than in machines having uniform density in each part. In the primary the frequency of the passage of the secondary teeth introduces pulsations which increase the losses. In the secondary the frequency, being proportional to the slip, is so low that the core-loss is negligible.

In order to avoid too lengthy and complex calculations use is made of empirical constants, by which the easily calculated losses are multiplied to derive the practical loss. The total loss consists of hysteresis and eddy loss in the primary core and primary teeth. The loss in watts per cubic inch for one cycle per second at any magnetic density is found by the curves given in the article on *Magnetic Properties of Iron*.

The losses are then calculated as follows:

**Hysteresis Loss:**

In primary core =  $k_h C_1 f V_c$  watts,

In primary teeth =  $k_h C_2 f V_t$  watts.

**Eddy Loss:**

In primary core =  $k_e C_3 f^2 V_c$  watts,

In primary teeth =  $k_e C_4 f^2 V_t$  watts,

where  $V$  = volume in cu. in.,  $C$  = respective loss per cu. in. from curves,  $f$  = frequency,  $k_h$  = empirical constant, 1 to 1.5,  $k_e$  = empirical constant, 3 to 4.

Fig. 4. Slot Dimensions

The higher values of  $k_A$  and  $k_B$  are to be used where open slots are used and where the frequency of the passage of the secondary teeth past one primary tooth is high. The core-loss is the sum of all the above losses.

**Friction and Windage Loss** varies greatly with the style of motor and form of structure, bearings, etc. The loss is made up of bearing friction and wind friction. The latter may be large purposely, as the motor may be designed with fan blades in order to circulate the air for the purpose of keeping the motor cool by ventilation. While each manufacturer has a formula which will calculate the friction loss correctly for machines built according to a particular plan, no general formula can be assumed. The nearest approach to an estimate is obtained from the percentage given in the table below.

**Primary and Secondary Copper Losses.**—The calculation of the effective resistances of the primary and secondary windings is given above. The primary or secondary copper loss is equal to the product of the number of phases, the effective primary or secondary resistance per phase, and the square of the current per phase. The total copper loss is the sum of the primary and secondary copper losses.

**Power Factor.**—The power factor ( $\cos \phi$ ) of an induction motor for a given current input ( $I$ ) may be calculated roughly from the formula

$$\cos \phi = \cos (\alpha + \beta),$$

where 
$$\alpha = \sin^{-1} \left( \frac{I_m}{I} \right) \text{ and } \beta = \sin^{-1} \left( \frac{XI}{E} \right),$$

and  $I_m$  = magnetizing current per phase,

$I$  = total current per phase,

$X = (x_1 + x_2)$  = total reactance per phase, the secondary reactance  $x_2$  being reduced to the primary turns,

$E$  = voltage per phase.

For a more exact formula for power factor and for the usual values of the power factor at rated load, see *below*.

**Efficiency.**—The efficiency (as a fraction) for a given current input is

$$\epsilon = 1 - \frac{F + C + m(r_1 + r_2)I^2}{mEI \cos \phi},$$

where  $F$  = friction loss, in watts;  $C$  = total core-loss, in watts;  $m$  = number of phases;  $r_1$  = effective primary resistance per phase;  $r_2$  = effective secondary resistance per phase reduced to primary;  $E$  = voltage per phase;  $I$  = current per phase;  $\cos \phi$  = power factor.

The corresponding horse-power output is then

$$P_o = \frac{\epsilon mEI \cos \phi}{746} \text{ horse-power.}$$

Usual values of the efficiency are given above in section on *Currents taken by Motors*. Usual values of the component losses for 60-cycle motors are given in the following table.

In 25-cycle motors the exciting current is usually greater than in 60-cycle motors and the  $IX$  drop less. Thus the power factor will be lower at light load and higher at overloads than in 60-cycle motors.

Rating, h.p.	$\frac{I_m}{I}$	$\frac{X_l}{E}$	Friction loss	Core-loss	$\frac{r_1 I}{E}$	$\frac{r_2 I}{E}$
			Input	Input		
1	0.45	0.20	0.06	0.05	0.05	0.05
5	0.35	0.14	0.035	0.04	0.04	0.04
20	0.30	0.13	0.025	0.035	0.035	0.035
50	0.27	0.11	0.015	0.03	0.025	0.03
100	0.26	0.11	0.015	0.03	0.025	0.03
200	0.25	0.11	0.015	0.03	0.025	0.03

The efficiency of 60-cycle motors naturally tends to be higher than of 25-cycle motors. This quality is usually sacrificed by economizing in material and making the 60-cycle motors lighter and cheaper, but of about the same efficiency as the 25-cycle motors.

**Slip and Speed.** — The slip for any given current is approximately

$$s = \frac{r_2 I}{E}$$

where the symbols are defined in the preceding paragraph.

The synchronous speed is

$$N = \frac{120f}{p} \text{ rev. per min.,}$$

where  $f$  is the frequency of the supply and  $p$  the number of poles. The actual speed of the motor is then

$$N_1 = (1 - s) N.$$

**Values of Other Characteristics.** — The energy component of the exciting current is

$$I_e = \frac{(\text{Total core-loss}) + (\text{Total friction loss})}{mE}$$

where  $m$  is the number of phases and  $E$  the volts per phase.

The total exciting current per phase is then

$$I_{e0} = \sqrt{I_e^2 + I_m^2}$$

where  $I_m$  is the magnetizing current per phase.

The impedance per phase at standstill ("short-circuit" impedance) is

$$Z = \sqrt{(r_1 + r_2)^2 + (x_1 + x_2)^2}$$

where  $r_1$  and  $r_2$  are the effective values of the primary and secondary resistances per phase, the latter being reduced to primary turns and  $x_1$  and  $x_2$  the primary and secondary reactances per phase, the latter being reduced to primary turns.

The current per phase at standstill ("short-circuit" current) is —

$$I_s = \frac{E}{Z}$$

The starting torque in pounds at 1-foot radius is

$$T_s = \frac{7.06 m r_2 E^2}{N Z^2}$$

where  $m$ ,  $r_1$ ,  $E$ , and  $Z$  are as defined above, and  $N$  is the synchronous speed in revolutions per minute.

The slip at maximum output is

$$s_m = \frac{r_2}{r_1 + Z}$$

The maximum output in watts is

$$P_m = \frac{0.5 m E^2}{1.3 (r_1 + r_2) + Z} \text{ watts.}$$

This should be from 1.5 to 3 times the rating of the motor. A 25-cycle motor usually has a greater maximum output or overload capacity than a 60-cycle motor.

**Heating.**—Since in most motors the primary member is subject to both a core-loss and a copper loss and is stationary, the heating of this member is very important. As the secondary contains only a copper loss and is usually revolving, its rise in temperature is usually much less than that of the primary.

The problem therefore consists of analyzing the flow of heat and drop in thermal potential in the primary as the energy lost in the windings flows to the iron of the core through the insulation in the slots and to the air around the projecting end connections. The core itself is maintained at a temperature above the air by the core-loss. It is therefore necessary to calculate first the rise in temperature of the iron of the core caused by the core-loss and that portion of the copper loss which is conducted to the core through the slot insulation. It is then necessary to calculate the rise in temperature of the copper above the iron and above the air around the end connections.

Since at times in every motor, when the core-loss is great compared with the copper loss, the iron may be hotter than the copper, it is necessary to distinguish between that portion of the power ( $P_1$ ) which passes between copper and iron (or vice versa), and that portion ( $P_2$ ) which passes from copper direct to the air. The analysis must take account of the fact that sometimes the heat due to core-loss passes to the copper and is dissipated by the end connections.

The method given here is based on the more exact and elaborate treatment given by Arnold in Vol. V of his treatise *Wechselstromtechnik*, but is simplified by assuming that the copper conductors have such a high heat conductivity that they have the same temperature throughout their length. The result is a value for the average temperature of the copper such as would be found by a resistance measurement. For a method of determining the maximum temperature in any spot the reader is referred to Arnold's treatise.

**Temperature Rise of Iron of Core ( $T_i$ ).**—The heat which is dissipated by the core surface consists normally of the core-loss and that part of the primary copper loss occurring in the portion of the winding embedded in the slots. It is

$$H = \text{core-loss} + m I^2 r_1 \left( \frac{2L}{l} \right),$$

where

- $m$  = number of phases,
- $I$  = primary current per phase,
- $r_1$  = effective resistance of primary per phase,
- $L$  = length of armature core between heads,
- $l$  = mean length of a primary turn.

The surface consists of the outer cylindrical surface of the core, the two annular surfaces at the ends, and the surfaces in the air ducts, see Fig. 3. Since the

surface in the air ducts is not as effective as the others, only half the air-duct surface is used.

$$\text{The area is } A_4 = \pi D_1 L + \frac{\pi}{4} (D_1^2 - D^2) (s + d),$$

where  $D_1$  = outside diameter of stator in inches,  
 $D$  = inside diameter of stator in inches,  
 $d$  = number of air ducts.

The rise in temperature of the iron of the core will then be  $T_i = \frac{kH}{A_4}$ , in degrees Cent., where  $k$  ranges from 30 for narrow machines to 50 for long machines.

**Temperature Rise of Copper ( $T_c$ ).** — A part of the heat due to the copper loss flows from the copper to the iron through the slot insulation, due to the small difference in temperature between the copper and the iron,  $T_c - T_i$ , where  $T_c$  is the rise in temperature of the copper above the air. The power in watts so dissipated is

$$P_1 = A (T_c - T_i),$$

where

$$A = \frac{U_s L S_1}{d_s k_1}$$

and  $U_s$  = perimeter of slot insulation,  
 $S_1$  = total number of slots,  
 $d_s$  = thickness of slot insulation,  
 $k_1$  = a constant, 200 to 250 (say, 210).

Sometimes  $T_i$  is greater than  $T_c$  and  $P_1$  becomes negative, which means that some of the energy of the core-loss flows to the windings and is dissipated by the end windings.

Another portion,  $P_2$ , of the copper loss flows through the insulation of the end connections to the air. Here there are paths, insulation and air, in series, across which there is a drop in temperature of  $T_c^\circ\text{C}$ . The flow of energy to the air is affected by the movement of the air, which, in turn, is a function of the peripheral speed  $V$  of the rotor. The value of  $P_2$  is

$$P_2 = B T_c,$$

where

$$B = \frac{U_c l_c Z_1}{d_s k_2 + k_3}$$

and  $U_c$  = perimeter of end connections, in inches,  
 $l_c$  = length of end connections, in inches,  
 $Z_1$  = total number of coils,  
 $d_s$  = thickness of insulation on same, in inches,  
 $k_2$  = a constant, 400 to 500 (say, 430),  
 $k_3$  = resistance to flow of heat from insulation to air and is given by the formula,

$$k_3 = \frac{170}{1 + 0.015 V^2}$$

where  $V$  = peripheral speed of rotor in feet per second.

The total copper loss is  $P = P_1 + P_2$ , whence

$$T_c = \frac{P + A T_i}{A + B}$$

This is approximately the average difference in temperature between copper and air as it would be determined by a measurement of resistance.

**TESTING OF INDUCTION MOTORS.** — (See also *Standardization Rules of A.I.E.E.*) Induction motors may be given either an "input-output" test at load under working conditions, from which the efficiency and power factor may be determined, or the motor may be given a no-load excitation and no-load short-circuit test, from which all the characteristics may be calculated. The latter method requires very little power and is preferable in the case of large motors where it would be expensive to supply power and inconvenient to dissipate the energy.

**Excitation Test.** — In this test the machine is operated without load at constant frequency with the voltage varied through a range from 30 per cent above rated value down to as low a voltage as will cause the machine to rotate. The current in each phase is noted and by means of two wattmeters the power required is noted. This test is sometimes also made with the machine operating single phase for the purpose of checking the core-loss. The curves are plotted with voltage as abscissas and amperes and watts as ordinates. At very low voltages the core-loss is negligible and therefore the watts input may be taken as friction loss. Around normal voltage the real core-loss may be determined by subtracting from the input the small copper and the friction loss.

**Short-circuit Impedance Test.** — In this test the starting resistance, if there is any, is short-circuited and the armature is blocked to prevent rotation. A low voltage is applied to the primary until the ammeter in the primary circuit shows a current of from 1 to 1.5 times the full-load value. Two wattmeters are used to read the power input. As the leakage flux, and hence the reactance, varies with the relative position of the rotor and stator teeth, it is customary to take readings with the rotor in several positions. Sometimes the rotor is allowed to revolve very slowly at, say, two to three revolutions per minute. From this test the impedance ( $Z$ ) of the machine is obtained by dividing the volts per phase by the current per phase; the combined effective resistance ( $R$ ) of primary and secondary is found by dividing the watts input per phase by the square of the current per phase. This latter is the effective value of the resistance, since the watts input includes all losses due to eddy currents. From these values the total reactance (primary and secondary) of the motor is  $X = \sqrt{Z^2 - R^2}$ . With the results of the two preceding tests and the measured resistances of the two members, the characteristics of the motor may be calculated either by the Steinmetz Method or the Circle Diagram. (See below under *Performance, Calculation of.*)

**Stationary Torque Test (Fig. 5).** — This test may be made at the same time the impedance test is made and consists in the measurement of the torque of the motor by means of a brake arm and spring balance. When the current of the machine has been adjusted to a suitable value the brake arm (to which a known weight has been attached to overcome bearing friction) and the spring balance are allowed to move downward through a small arc, during which the spring balance will register a pull ( $P_1$ ) equal to torque ( $T$ ) plus the weight ( $W$ ) minus the friction ( $F$ ), that is,  $P_1 = T + W - F$ . The spring balance and brake arm are then raised against the torque through the same small arc and the spring balance will then register a pull ( $P_2$ ) equal to the torque plus the weight plus the friction, that is,  $P_2 = T + W + F$ . From these two readings the friction can be eliminated

Fig. 5. Stationary Torque Test

and the actual torque of the armature on the shaft is determined. This should be done at two or three equally spaced positions of the rotor, as the torque varies considerably with the position. The corrected torque of the machine is found by solving the two equations for  $T$  and multiplying  $T$  by the lever arm of the brake in feet; this gives the torque in pounds at 1-foot radius.

**Load Test.** — To make this test on a small machine a prony brake is required while for a large machine a direct-current generator may be conveniently employed as a load. The induction motor and generator are direct-connected if possible, otherwise belted together. All the constants of the generator are determined, so that its losses under any condition may be calculated. The motor is then allowed to drive the generator, the rated voltage being impressed upon the motor, and the generator is loaded by means of a rheostat or a water box so that any load may be obtained. The voltage across each phase of the motor, the current in each phase, the total watts input (by two meters), speed, and, if possible, slip (by a slipmeter, *see below*) are all read. Care must be taken that correct voltage and frequency are supplied to the motor. The load on the motor is increased step by step to the maximum output point, which is easily known, since when it is reached a decrease in speed is not accompanied by any increase in output of the motor. The motor is still stable at the maximum output condition, since maximum torque occurs at a lower speed than maximum output.

After the load run the direct-current generator is run as a motor with the same field strength as before, to determine the mechanical losses, first driving the induction motor at the proper speed, and then running alone at the same speed or speeds at which it ran in the load test. Knowing the no-load friction of the induction motor as previously determined in the *Excitation Test*, the increase in friction due to the belt and load is determined and half of it charged against the motor. Let

$EI$  = the output of the direct-current generator in watts,

$I^2R$  = the hot resistance loss in the direct-current armature,

$CT$  = the counter torque or stray power losses in the direct-current generator plus one-half belt loss,

$P_0$  = watts input to induction motor.

Then efficiency of the motor =  $\frac{EI + I^2R + CT}{P_0}$ .

From these tests, curves may be plotted for the speed, efficiency, power factor, current and torque of the induction motor for any horse-power output.

**Use of Stroboscope to Measure Slip.** — One type of slipmeter consists of a disk which is attached to the motor shaft and on which alternate sectors of black and white are shown, preferably as many black sectors as there are poles on the motor. If this rotating disk is illuminated by means of an arc light supplied with the frequency impressed on the primary of the motor, the disk will appear to rotate at a speed proportional to the difference between synchronous speed and actual running speed. The number of these revolutions for one minute, will be the slip in turns per minute, which may be translated into a fraction or percentage of synchronous speed.

**Slipmeter.** — Another type of slipmeter has two disks of insulating material mounted on the same frame, one carrying a wiping finger which makes contact with a button on the other disk. One of the disks is connected to a small synchronous motor which is driven from the same power source as the induction motor under test; the other disk is arranged to be readily attached to the shaft of the induction motor. The circuit of a miniature tungsten lamp is closed when the wiping finger and button are in contact. The number of flashes

of the lamp per minute gives the slip in revolutions of the induction motor behind the synchronous speed.

**Heat Runs.**—On machines of moderate size heat runs are advisable, but on large size machines heat runs are expensive. It is not always necessary to make a heat run in order to know whether the motor is properly designed, as the losses can be accurately calculated from the excitation and short-circuit tests, and the machine may be run without load but with losses equivalent in value to the losses at full load. The usual heat run consists in operating the machine at a certain output for a period from three to six hours, depending on the size, measuring the resistance before and after the run and taking temperatures by thermometer on the following parts after the run: primary winding, the iron surfaces in the air gap, secondary winding, bearings, frame.

A heat run which will indicate whether there is anything radically wrong with a motor consists in operating it for an hour or two with a voltage 15 per cent above normal, but without load.

**Insulation Tests.**—High-potential tests are made on the primary in the manner described under *Testing* in the article on *Generators, Alternating-Current*. The value of the high potential for the primary is chosen in accordance with its rated voltage from the *Standardization Rules of the A.I.E.E.* (q.v.). The potential applied to the secondary, however, has no relation to the rated voltage of the machine; as the working potential in the secondary is low, 1000 to 1500 volts is the usual range of testing potential for the secondary.

**PERFORMANCE, CALCULATION OF.**—The performance of an induction motor at any load may be determined directly from the load tests described above, or the performance at any load may be calculated from the excitation and short-circuit tests by either of the two methods given below. These methods are also applicable to the calculation of performance from the values of the constants calculated from the dimensions of the machine. The first method is given in detail by Steinmetz in his *Elements of Electrical Engineering*, and the Heyland Circle Diagram is given by McAllister in his *Alternating Current Motors*. The former is recommended where accuracy is desired and the latter (graphical) for the student desiring a general understanding of the relations.

**Steinmetz Method.**—This method is based upon the equivalent circuit of a transformer, as given in the article on *Transformers*. Let

$E$  = impressed voltage per phase,

$m$  = number of phases,

$r_1, r_2, x_1, x_2$  = resistance and reactance of primary and secondary respectively, per phase and reduced to terms of primary,

$s$  = slip as a decimal fraction (assumed),

$g$  = primary no-load conductance =  $\frac{\text{core-loss}}{mE^2}$ ,

$b$  = primary no-load susceptance =  $\frac{I_m}{E}$ .

Assume a slip  $s$  and calculate

$$a_1 = \frac{s r_2}{s^2 x_2^2 + r_2^2}$$

$$a_2 = \frac{s^2 x_2}{s^2 x_2^2 + r_2^2}$$

$$g_1 = g + a_1,$$

$$b_1 = b + a_2,$$

$$c_1 = 1 + r_1 g_1 + x_1 b_1,$$

$$c_2 = g_1 x_1 - b_1 r_1.$$

Then

Counter e.m.f. per phase	$e = \frac{E}{\sqrt{a^2 + \alpha^2}}$
Current per phase	$I = e \sqrt{a^2 + b^2}$
Total volt-ampere input to motor	$P' = mEI$
Watts input to motor	$P = me^2 (pa_1 - b_1\alpha)$
Watts output of armature	$P_0' = me^2 a_1 (1 - \gamma)$
Watts output of pulley	$P_0 = P_0' - (\text{friction in watts})$
Efficiency	$\epsilon = \frac{P_0}{P}$
Power factor	$\cos \phi = \frac{P}{P'}$

**Circle Diagram or Graphical Method (Figs. 6 and 7).**—The method of the circle diagram is based on the fact that the electrical reactions in an induction motor (or transformer) may be represented without any great error by the reactions in two parallel inductive circuits as in Fig. 6.  $I_e$  and  $I_m$  represent the two components of the exciting current, which is assumed constant.  $R_m$  and  $X_m$  represent the total resistance and reactance (both assumed constant) of the motor and are in series with a variable resistance  $R_L$  representing the load.

Fig. 6. Equivalent Circuits

The vector relations of the currents are as shown in Fig. 7, where

$OE$  = the impressed voltage per phase,

$OM$  = the current  $I_m$  in  $A$ ,

$MP$  = the variable current in  $B$  (not drawn).

Fig. 7. Circle Diagram

Since the current represented by  $MP$  is equal to  $\frac{E}{\sqrt{(R_m + R_L)^2 + X_m^2}}$ , as  $R_L$  varies the point  $P$  will describe a circle through  $M$ ,  $P$  and  $F$ , where  $MF = \frac{E}{\sqrt{R_m^2 + X_m^2}}$ . The total or resultant current will then be  $OP$ .

**Heyland Circle Diagram (Fig. 7).**—The circle diagram upon which the following discussion is based is a modification of Heyland's transformer, or motor diagram.

$E$  = impressed voltage per phase.

$\theta$  = angle at  $90^\circ$  to  $OE$ .

$I_1$  = exciting current per phase, drawn in phase and magnitude.

$I_2$  = short circuit current per phase, drawn in proper phase and magnitude.

$R$  = energy component of  $OF$ .

$F$  and  $F'$ ; then  $MF$  is the secondary short-circuit current in terms of primary circuit.

$F$  at  $m$ .

$OX$  perpendicular to  $MF$  at middle point, intersecting  $NH$  at  $X$ .

$O$  as center and either  $XM$  or  $XF$  as radius, draw the semicircle  $MCF$ .

This is the locus of the primary current.

$OE \times IF$  = watts input at standstill, draw  $HG$  such that  $OE \times HG$  = primary  $I^2R$  at standstill.

$OG$  = secondary  $I^2R$  at standstill.

$f$ . The vertical distance between  $GM$  and  $NH$  at any point gives a current which if multiplied by  $OE$  gives the power loss in primary.

any point  $P$  on circle; then  $OP$  = current per phase.

$\cos \theta$  = power factor.

$OP$  (drawn) = secondary current reduced to primary turns.

$OE$  = power input to primary, in watts.

$OE$  = no-load loss, in watts.

$OE$  = total motor loss.

$OE$  = total primary loss in watts.

These

$OE$  = primary copper loss, in watts.

are

$OE$  = secondary input, in watts.

all

$OE$  = secondary copper loss, in watts.

per

$OE$  = motor output, in watts.

phase

$OP$  = per cent magnetizing current.

$OP$  = per cent leakage reactance voltage.

$OX$  perpendicular to  $MG$  and  $CG'$  perpendicular to  $NH$ .

$OX \times OE$  = maximum torque in synchronous watts.

$OX$  perpendicular to  $MF$  and  $BJ$  perpendicular to  $NH$ .

$OX \times OE$  = maximum output in watts.

$RP$  = per cent slip (in case of induction motor).

$OE$  = volt amperes input.

$T$  in pounds at 1-foot radius  $T_s = \text{synchronous watts} \times m \times \frac{7.06}{N}$ , where

$m$  = number of phases and  $N$  = synchronous speed in rev. per min.

**Characteristic Curves.**—The observed or calculated values (by either of the methods) of the slip, power factor, efficiency, apparent efficiency, current per phase and torque may be plotted as ordinates with horse-power at the shaft as abscissas. An example of the characteristic curves plotted is shown in Fig. 8. Usual values of the various quantities at rated load are given above. The "power factor" shows the relation between the true power input of the machine and the apparent power, called the "volt-amperes." A poor power factor does not mean any greater registration of the watt-hour meter or cost of energy to the motor, but it does involve poor regulation of voltage in the system and larger capacity of wiring, transformers, etc. The "apparent power" is equal to the product of the power factor and efficiency, or is equal

Fig. 8. Characteristic Curves of an Induction Motor

to the ratio of output in watts divided by input in volt-amperes. Its value determines the actual capacity of the lines and transformers supplying the motor.

**EXAMPLES OF DESIGN AND PERFORMANCE.** — In the accompanying tables are given the essential data for both mechanical and electrical features of six three-phase induction motors. The list of items will be found useful as a guide in collecting data on various machines. Performance data are deduced from tests.

**METHODS OF STARTING.**—In order to start an induction motor of any size without injurious heating either a resistance must be connected in the secondary circuit or the voltage impressed on the primary must be reduced. The two general methods of starting induction motors are known as “Potential Control” and “Rheostatic Control.” The same methods are used for starting synchronous motors (see below).

**Starting by “Potential Control” Method** (Fig. 9).—This method consists of reducing and regulating the voltage impressed on the primary, usually by means of a starting compensator or auto-transformer which provides one or two fractional voltages. In order to make use of this method the secondary must be of higher resistance than with other methods of starting. For this reason and for the reason that there is no need of making any change in the windings, a squirrel-cage rotor winding is customarily used with this method of starting. This winding is made up of one bar per slot, and all bars are connected at both ends to rings. To start the motor the primary is connected to taps on the compensator which give a voltage of from  $\frac{1}{2}$  to  $\frac{2}{3}$  the rated voltage if it is a small motor, and  $\frac{1}{2}$  if it is a large motor. A small motor may be brought up to full speed at this voltage but a large motor may require an intermediate step. The connections are shown in Fig. 9. It is customary to adjust the motor resistance to give the relations in the accompanying table.

Fig. 9. Potential Control

Voltage on Motor, per cent	Current in line, per cent	Starting torque, per cent
33	75	23
50	175	50
66	300	88
100	700	200

**Boucherot Winding.**—This type of winding for the rotors of induction motors is a device designed to give good torque at starting by means of high secondary resistance and inherently to reduce this resistance as the motor accelerates, so that at full speed the secondary resistance will be low, the slip small and the efficiency high.

The device consists of two independent windings on the secondary (usually squirrel cage), one, a high resistance winding of brass or German silver bars is placed near the periphery of the rotor in the usual form of slots. The other winding is of low resistance (large copper bars) and is placed in slots like tunnels below the bottom of the surface slots. A narrow slit or shaft extends from the bottom of the outer slot to the top of the inner slot.

The outer winding acts like any high resistance winding, giving good starting conditions. The inner winding is so highly inductive that at stand-still, when the secondary has full frequency, it has a very high reactance, carries very little current and contributes but little to the action of the motor. At speeds near synchronism the secondary frequency is very low (of the order of one cycle per second), the reactance is low, and the inner low-resistance winding carries most of the current; consequently under running conditions the motor has practically the same characteristics as one having a single low-resistance secondary.

**Starting by "Rheostatic Control" Method (Fig. 10).**—Better apparent torque efficiency, that is to say, more torque for a given current, is obtained by inserting in the secondary circuit a much greater resistance than can be left permanently in circuit. This

is accomplished by having a special starting resistance connected in series with the armature winding and a switch for short-circuiting the resistance either step by step or as a whole, as the motor speeds up. There are two practical methods of doing this:

The first is intended to be used only when the torque required at starting is not very great, in which case the starting resistance may be small and located inside the armature spider. The switch lever is so arranged that the resistance can be short-circuited in steps while the armature is revolving. This obviates the need of collector rings and external connections.

The second method consists in bringing the three terminals of the secondary winding to collector rings. From brushes bearing on these rings conductors lead to external resistances with steps or taps so that the resistance may be

Fig. 10. Rheostatic Control

short-circuited gradually. This scheme is used where a large starting torque (greater than full load torque) is required. It may be used also for speed control as shown in Fig. 12

The proper value of resistance per phase in the secondary is determined by the relation

Torque in pounds at 1 foot =

$$\frac{E^2 r_2}{Z^2} \times \frac{7.06 m}{r.p.m.} = \frac{7.06 m r_2 E^2}{N Z^2}$$

where

$E$  = primary voltage per phase,  
 $r_2$  = total secondary resistance per phase in terms of primary,

$Z = \sqrt{(r_1 + r_2)^2 + X^2}$ , where  $r_1$  is the resistance per phase of primary and  $X$  the total reactance per phase of both primary and secondary,

$m$  = number of phases,

$N$  = synchronous speed in revolutions per minute.

The relation between starting torque and total resistance of the secondary is shown by the curve in Fig. 11.

Total Resistance in Secondary Circuit  
 Fig. 11. Starting Torque, Torque and Current

**SPEED CONTROL OF INDUCTION MOTORS.** — (See also *Hoists, Electric.*) The speed of an induction motor may be controlled in five ways:

- By varying the potential applied to the primary of motor having a suitable permanent resistance in the secondary.
- By varying the resistance in the secondary circuit.
- By changing the connections of the primary winding in a manner to change the number of poles.
- By varying the frequency of the applied voltage.
- By connecting the secondary of one motor to the primary of another, called the "concatenation" method of control.

**Potential Control of Speed.** — This method is an elaboration of the potential-control method of starting. A suitable resistance or auto-transformer reduces the impressed voltage to the fractional value desired (two-thirds is the usual ratio). The auto-transformer wastes less power than a resistance but is more expensive. Because of the reduced voltage the flux and torque-per-ampere are reduced and more current will be required for a given torque. The induction motor should have a very large resistance in the secondary, which is preferably of the squirrel-cage type. This resistance gives the motor a speed characteristic such that its full-load speed is some 10 per cent less than that of a normal motor. As the load is increased the speed may fall to about 30 per cent of the no-load value without the motor breaking down or falling out of step, which in the normal motor usually takes place at about 80 per cent of the full-load speed. This motor is not stable in speed as each slight change in the load will cause a change in the speed more or less inversely proportional to the load. The advantages of this method of control are the simplicity of the connections and devices. The disadvantages are the greatly increased heating in the motor itself with the decreased speed. Thus the motor must be larger than if other speed-control methods are used. The table given below shows the efficiencies obtained.

**Rheostatic Control of Speed.**

— With this method (an elaboration of the method of the same name for starting) the secondary or rotor must have a definite winding (which costs more than the squirrel-cage winding used in the preceding method) with slip rings and brushes to lead out the current. The friction and resistance losses due to these brushes decrease the efficiency of the motor a slight amount. The action of this method is based on the principle that in an induction motor the drop in speed for any given torque is proportional to the resistance of the secondary circuit.

Fig. 12. Torque-speed Curves

Assuming a motor which has at full speed a net resistance of the secondary proper of 1 ohm, the speed-torque curve would be as shown for  $R = 1$  in Fig. 12. This motor would have a slip of 5 per cent for full-load torque and of 25 per cent for maximum torque, a torque at starting of 80 per cent of full-load torque and a very large starting current. If by some means this resistance is doubled the speed-torque curve would be as shown for  $R = 2$ , which shows a slip of 10 per cent for full-load torque and of 50 per cent for maximum torque. For  $R = 5$ ,  $R = 8$ , etc., there would be other speed curves. By starting with a resistance of 8 ohms a torque of about 200 per cent of full-load torque would be obtained at starting with about twice full-load current. By allowing the motor to follow this curve until the torque has dropped to the full-load value, the motor would reach 60 per cent of synchronous speed, or 40 per cent slip. Then by reducing the resistance in steps the torque and speed would follow the heavy zigzag line until the motor reached full speed.

With this method of control the torque per ampere remains practically constant as in a shunt motor regulated by resistance in the armature circuit. The efficiency varies directly with the speed as shown in the table below.

The advantages of this method are the higher efficiency and particularly the smaller losses in the motor itself. The losses are in the rheostat. The disadvantages are the necessity of collector rings, brushes, controllers, etc. The motor is not stable at any fractional speed but the speed will change with every change of load.

**Change of Poles to Control Speed.** — By a proper design of the windings an induction motor may be made to operate with either 4 or 8 poles, 6 or 12 poles, or even 4 or 6 poles or 6 or 8 poles. This is accomplished by a throw-over switch to which taps from the windings are brought. In this arrangement the pitch of the primary winding must be made a compromise between the proper value for the different numbers of poles, and therefore the constants of the motor are not as good as those of a standard motor. It is also necessary to use a squirrel-cage armature, since this is suitable for any number of poles without change of connections. This type of motor operates advantageously only at the two speeds corresponding to the two arrangements of poles and is stable at each of these speeds. If a wider range is desired the potential-control scheme may be combined with it. The speeds and efficiencies with this scheme of control are given in the following table. At half-speed the efficiency is almost double that obtained with the other methods, but the losses in the motor are greater than with the rheostatic control.

## COMPARISON OF METHODS OF SPEED CONTROL

(For constant torque equal to torque at full load)

Nominal speed	Potential			Rheostatic			Change of poles		
	Speed	Volts	Eff.	Speed	Volts	Eff.	Speed	Volts	Eff.
No load.....	1.00	100	..	1.00	100	..	1.00	100	..
Full speed.....	0.89	100	81	0.96	100	86	0.96	100	86
Three-quarter speed.....	0.67	66	59	0.72	100	65	....	...	...
Half speed.....	0.45	57	37	0.43	100	43	0.48	100	74
Quarter speed.....	0.22	56	17	0.24	100	22	....	...	...

**Change of Frequency Method of Control.** — The speed of an induction motor at any load varies directly with the frequency of the supply circuit. If two circuits from two alternators of different frequencies are provided the motors may be connected to one circuit for one speed and to the other circuit for another speed. This method of speed control requires as many separate generators and circuits as the number of speeds desired. It is, therefore, costly and not widely used.

**Concatenation Control or Cascade Control.** — If two motors have definite windings in both the primary and secondary and are rigidly connected to a common shaft, they may be operated at a fractional speed corresponding to a number of poles equal to the sum of the number of poles on the two motors. With the concatenation control the primary (stator) of motor No. 1 is connected to the supply circuit, the secondary (rotor) of No. 1 is connected to the primary (rotor) of No. 2, and the secondary (stator) of No. 2 is connected to a resistance which is eventually short-circuited. When the two motors have the same number of poles, which is the usual commercial condition, motor No. 1 transforms half the power into mechanical power at the shaft at *half speed* and the remainder into electrical power at half frequency. Motor No. 2 receives this electrical power and transforms it into mechanical power at this same speed. If the number of poles is different, the speed in r.p.m. of the combination is

$$N = \frac{120f}{p_1 + p_2}$$

These simple relations are exact only on the assumption of no losses and the secondary of No. 2 short-circuited.

The objections to this method of control are that the first motor has to carry the magnetizing current of both motors, thus having a low power factor. The first motor must receive the power for both motors; therefore, it must be the larger of the two and specially designed or there is an inefficient use of material in the second motor. If the two motors are alike (the usual commercial condition) the torque of the two motors in concatenation is not as great as that of the two motors in parallel.

The efficiency at fractional speed is, however, better than with the rheostatic method of control. Only two "free-running" speeds are available with two motors having the same number of poles. This scheme has been adopted frequently for the speed regulation of induction motors used on electric locomotives in foreign countries. In such applications it is frequently the custom to allow one motor to be idle at the higher speed.

**INSTALLATION AND ERECTION.**—Induction motors are usually built, even in large sizes, as a unit including the bearings, which are usually a part of the end frame of the motor proper. They may be either direct-connected or belted to their load, but the latter method is more general, since each induction motor can only be built for a certain definite speed corresponding to a certain number of poles. The smaller motors need no foundation, and in fact are frequently attached to the wall or to the ceiling, the bearings and end shield being made in such a manner that they may be turned through 90 degrees or 180 degrees so that the oil rings will operate properly under these conditions. In most motors reasonable ventilation, free from dust and dirt, must be available. For certain applications such as cement mills or mines, the motors are built totally inclosed and may then be even submerged in water. In this case, of course, a motor of a given rating is larger and more expensive than one of the open type.

**OPERATION.**—Small motors are designed to start merely by closing the main switch. With larger motors if the starting switch is at the proper position, potential may be applied to the motor and the starting resistance gradually cut out by moving the switch.

Induction motors are very sensitive to variation in the impressed voltage. A decrease in impressed voltage from 100 to 80 would cause the maximum output and maximum starting torque to decrease from 100 to 64 and roughly would cause a proportional increase in the heating for a given load.

Unequal voltages in the different phases also cause a decrease in the maximum output and an increase in the heating for any given output. An unbalancing of 25 per cent in voltage would double the heating effect at full load, i.e., would give the same heating as an overload of 50 per cent.

**Care in Starting.**—Before starting the motor for the first time it is desirable to make sure that the starting device is in operating condition and in the proper position, in order that the motor should not become injuriously heated. Attention should be paid to having the wiring so proportioned as to carry the starting current without an excessive drop in voltage (*see above*).

**Faults.**—Some of the more common faults occurring in induction motors, together with their signs and remedies, are the following.

**Secondary Open-circuited.**—The motor will not start and will not take a current greater than the exciting current. The cause is probably due to the starting resistance not being connected in.

**One Phase of Secondary Open-circuited.**—The motor has a tendency to remain at half synchronous speed although the current is apparently normal. If the armature is blocked it will be found that the current in the three phases will be unbalanced.

**One Phase of Primary Open.**—The motor will not start and the current will be unbalanced.

**One Phase of Primary Reversed.**—The currents in the primary will be very much unbalanced when the motor is running and the starting torque will be very slight.

**Short-circuited Coil in Primary.**—There will be humming when potential is applied to the motor and excessive local heating around the short-circuited coil.

**Vibration.**—Vibration due to mechanical unbalancing is chiefly noticeable at high speeds and particularly in high-speed machines. If the vibration is due to magnetic unbalancing it is probably caused by inequality in the air gap at different portions of the circumference and with different positions of the armature. This may be detected by measuring the air gap with taper wedges

at various points around the circumference, first with the armature in one position and then in several other positions.

**SPECIFICATIONS FOR INDUCTION MOTORS.** — The following memoranda are intended to assist in writing specifications. See also article on *Specifications*.

**Principal Characteristics and Conditions of Service.** — Use to which motor is to be put; kind of load and method of drive. Voltage and number of phases. Rating, horse-power. Frequency and speed.

**Style and Description; Details of Construction.** — Whether to be open, semi-enclosed or enclosed. Requirements regarding pulley or length of shaft. Whether rails are required. Method of starting; compensator, external resistance or internal resistance; whether motor is to be run at speeds other than full speed. Whether the starting devices are to be supplied.

**Performance and Tests.** — (See *Standardisation Rules of the A.I.E.E.*). Temperature rises upon which ratings are to be based. Details of overload capacity. Efficiency at 25, 50, 75, 100, and 125 per cent load. Starting torque with full-load current, pound-feet. High-potential tests of insulation. Requirements regarding effect of moisture upon insulation.

**WEIGHT AND COST (Pre-war prices)\*.** — The weight and cost of an induction motor vary with the type of its armature winding and the character of its mechanical frame and housing, as well as with the speed, frequency and voltage.

The curves in Figs. 13 and 14 give an idea of the weights and costs of a line of 25-cycle and 60-cycle motors respectively, having squirrel-cage rotors (the

Fig. 13. Weight, Cost\* and Suitable Speed of 25-cycle Induction Motor

simplest and least expensive type) and with the simplest form of mechanical frame. They therefore represent minimum values.

**MOTORS, SINGLE-PHASE INDUCTION.** — (See also *Motors, Polyphase Induction; Motors, A-C. Commutator*). A two- or three-phase induction motor may be operated as a single-phase machine after it is brought up to speed. Under these conditions it operates at a lower efficiency, lower power factor and with a lower maximum output than it would have as a polyphase motor. The slip for a given output is less in a single-phase motor than in a polyphase motor.

**Load and Voltage Rating.** — On account of the poorer operating characteristics and particularly on account of the lower maximum output or maximum torque, it is necessary to rate the motor at a lower capacity. When a three-phase motor is operated single-phase with the same voltage between lines, its maximum output will be approximately 40 per cent of the three-phase maximum output.

For best conditions, such as best distribution of losses and ratio of rated to maximum output, it is customary to use a three-phase motor, to reduce the rated output of the motor and to increase the rated terminal voltage in a definite ratio. Thus, if  $P$  be the rated output, in watts, of a given motor when operating on a three-phase circuit having a voltage between lines equal to  $E$ , then it would be advisable to operate the motor single-phase with a voltage between lines equal to  $1.3 E$ , and to assign the motor a rating of from  $0.67 P$  to  $0.75 P$ .

This will result in a distribution of losses in the motor quite similar to that which obtains during three-phase operation. The maximum output as a single-phase motor (at the higher voltage) will be about 67 per cent of the maximum output of the three-phase motor. The efficiency and power factor will be reasonable.

In case the voltage of the single-phase supply circuit must be the same, the winding of the motor is changed to give about 75 per cent as many turns in series per phase as for normal three-phase operation.

**Exciting Current and Power Factor.** — At a given voltage between terminals the volt-amperes input at no load for excitation are practically the same for single-phase and polyphase operation. Thus the no-load current of a single-phase motor is considerably greater than when operating polyphase. The increase in the applied voltage or the decrease in the number of turns makes a still greater increase in the magnetizing current. Thus the power factor of a single-phase motor is very poor at light loads and not very good at rated load.

**CALCULATION OF PERFORMANCES.** — To predetermine the characteristics of a single-phase motor it is calculated as a three-phase motor for the same voltage between lines as the single-phase circuit. The magnetizing current, core-loss, resistance per phase, and reactance per phase are all calculated as usual. The motor primary may be connected either delta or  $Y$ , but for purposes of calculation it is desirable to pro-rate the constants of a  $Y$ -connected motor on the assumption that it is delta connected.

To pro-rate the resistance and reactance per phase of primary and secondary, multiply the values for a  $Y$ -connection by 3 to obtain the values for the equivalent delta constants. The voltage per phase is presumed to increase in the ratio 1 to 1.73, while the voltage between lines remains the same.

The magnetizing current and the core-loss current are found by dividing the 3-phase values by 1.73.

The single-phase magnetizing current is found by dividing the volt-amperes excitation for three-phase conditions by the single-phase voltage. The core-loss in watts remains practically the same single-phase and the energy component of the single-phase exciting current is equal to core-loss watts divided by rated voltage.

The resistance and reactance of the primary of a single-phase motor are taken the same as the equivalent delta values per phase.

The resistance and reactance of the secondary of a single-phase motor are taken as  $\frac{1}{3}$  of the three-phase equivalent delta values.

These values are then substituted in the formulae of the Steinmetz method (*see Motors, Polyphase Induction*) and the characteristics calculated for several assumed values of slip. The only difference in calculation is that the torque in synchronous watts is

$$T = e^2 a_2 (1 - s)$$

and the output of the armature is

$$P = e^2 a_2 (1 - s)^2.$$

It is of course understood that in a single-phase motor the output calculated for one phase is also the total output of the motor.

**METHODS OF STARTING.**—A single-phase motor has no torque at standstill. It must be started by some device such as a phase-splitting device. It may be started in either direction and as soon as it starts to rotate a slight torque develops which increases with the speed. When this torque has reached a great enough value to overcome the friction and inertia the special starting apparatus may be disconnected and the motor will continue to accelerate to its proper speed.

**Starting of Small Motors.**—Small motors may be started without auxiliary electric circuits by giving the armature a spin by hand, after which (if there is no load) they will accelerate. Certain small motors are designed with a loose pulley which is clutched at a predetermined speed of the armature by means of a centrifugal governor. These motors are provided with "shading coils" or a small external phase-splitting device, to give them just enough starting torque to overcome their own friction.

**Starting of Large Motors.**—A phase-splitting device is generally used; either a reactor and resistor or a condenser and resistor may be employed. Commutator devices are also used.

**Use of Reactance Coil and Resistor.**—The connections employed are shown in Fig. 1. This device consists of a resistance and a reactance connected so as to advance the phase of the e.m.f. impressed on one circuit of the motor and retard the phase of the e.m.f. on another circuit, while the line voltage is impressed on the third winding. This may be accomplished either by connecting the resistance and reactance across the line terminals and in multiple with the motor windings as shown in Fig. 1 A, or by connecting the resistance and reactance in series with the respective windings as shown in Fig. 1 B.

In these figures  $L_1$  and  $L_2$  represent line terminals,  $R$  is the resistance coil,  $X$  the reactance coil and  $M_1$ ,  $M_2$  and  $M_3$  the three motor terminals. The former method gives a greater starting torque but takes a greater current in proportion to the torque. The latter method is more efficient. The motor must have sufficient resistance in its secondary circuit to give good starting characteristics as a three-phase motor.

The principle of this device is that the voltages between the outside terminals and the middle point are out of phase with each other and form a somewhat

Fig. 1.

flattened vector triangle similar to that of an unbalanced three-phase system. The ratio of the starting torque obtained with such a device to the normal starting torque with balanced three-phase voltages is the same as the ratio of the altitude of the triangle of vector voltages to the altitude of the equilateral triangle. Thus in Fig. 2 the ratio of altitudes is  $30/95 = 0.316$ ; thus the single-phase starting torque would be 31.6 per cent of the three-phase starting torque.

Fig. 2.

**Use of Condenser and Resistor.** — If a condenser of the proper capacity is substituted for the resistance the starting torque will be increased and the efficiency improved, but this is much more expensive and frequently involves the addition of a transformer across the condenser.

**Use of Commutator.** — Another method of starting single-phase motors involves the use of a commutator which permits the motor to start as a repulsion motor (which has good starting qualities; see *Motors, A-C. Commutator*), and after the motor has reached a considerable speed the brushes are removed from the commutator and a short-circuited squirrel-cage winding comes into play.

**BIBLIOGRAPHY.** — Arnold, E., *Wechselstromtechnik*, Vol. 5, part 1; Bailey, B. F., *The Induction Motor*, N. Y.; Crocker and Arendt, *Electric Motors*; Hobart, H. M., *Electric Motors*; McAllister, A. S., *Alternating Current Motors*; Mailloux, C. O., *The Induction Motor*, N. Y.; Steinmetz, C. P., *Electrical Engineering*; Thompson, S. P., *Dynamo Electric Machinery*, Vol. 2.

**MOTORS, SYNCHRONOUS.**—(See also *Alternating Currents; Generators, Alternating Current; Motors, Industrial Applications of; Motors, Polyphase Induction.*) Any alternator will operate as a motor. If two synchronous alternators are connected in parallel to bus-bars supplying a load, and the driving power be removed from one prime mover, the alternator connected to this prime mover will continue to run at the same speed as before, taking power from the other alternator and driving its own prime mover or other apparatus coupled to it; i.e., this alternator acts as motor. The speed of such a motor depends solely upon the speed of the generator or generators supplying electric energy to it; it is therefore said to run in "synchronism" with the source of supply and is called a synchronous motor. The synchronous speed of a synchronous motor having  $p$  poles, when supplied with a current of a frequency of  $f$  cycles per second, is

$$N = \frac{120f}{p} \quad \text{rev. per min.}$$

If the load on such a motor increases the speed will not decrease, unless the load reaches such an excessive value that the maximum output or "pull-out torque" is reached, when the motor will drop out of step and come to rest, while the current taken will increase to short-circuit value and the torque decrease to a negligible value.

**Differences between an Alternator and Synchronous Motor.**—The difference in construction between an alternator and a synchronous motor is that the latter has placed in the face of the field poles, a squirrel-cage winding, which is intended to give good starting torque and to prevent hunting while running. A synchronous motor usually operates better with a higher value of armature reaction than that of a well-designed generator of the same kilowatt rating. This increase in armature reaction is usually obtained in practice by operating the machine as a motor at lower voltage than that for which it would be operated as a generator. Thus a standard 2300-volt generator will operate very satisfactorily as a motor at 2080 volts, and as these are the natural values of the generated and delivered voltages, this characteristic of the synchronous motor fits in very well with customary distribution practice. Thus a standard generator may have a squirrel-cage winding added to its poles and become a good synchronous motor.

**Field Excitation.**—Synchronous motors always require direct current for field excitation and if a suitable d-c. source is not available an exciter must be provided.

**Number of Phases.**—Synchronous motors may be single, two or three phase. The single-phase motor is not self-starting and has a considerably lower efficiency than the polyphase motor. It is also more liable to hunt (see below) and be unstable, and is therefore far less desirable than a polyphase motor. The two-phase and three-phase motors are very similar in all their characteristics. There is a slight economy in the three-phase over the two-phase motor as there is in the three-phase over the two-phase generator (q.v.).

**Terminal Voltage.**—Since synchronous motors are usually built with a revolving field and a stationary armature, it is possible to insulate the armature winding for voltages as high as 13,000 and thus obviate the need of transformers in many cases.

**Advantages and Disadvantages of Synchronous Motors.**—The advantages of synchronous motors as compared to induction motors are: higher efficiency, higher power factor, power factor may be controlled, constant speed,

high voltage, lower cost. The disadvantages are: need of an exciter, will not start under load, possibility of hunting.

**Relations of Voltage and Current.** — The relations between line voltage and phase voltage are the same as in a-c. generators (q.v.). The current in each line of a three-phase motor is

$$I = \frac{746 P}{\sqrt{3} e E \cos \theta}$$

where

- $P$  = horse-power output,
- $E$  = voltage between lines,
- $e$  = efficiency at load assumed,
- $\cos \theta$  = power factor (may be unity).

Usual values for efficiency are about the same as for a-c. generators (q.v.).

**APPLICATIONS.** — In order to transform from alternating to direct current, or from one kind of alternating current to another differing in frequency, potential or phase relation, motor-generator sets, consisting of a synchronous motor direct connected to one or more generators, are often employed. By this means the potential of the secondary or distribution circuit is independent of the variation in potential of the primary circuit supplying power to the motor. In certain cases it is desired to take power from a 55-cycle circuit and supply power at 60 cycles for lighting purposes. Here a synchronous motor-generator set would be used. Such a set is frequently called a "frequency changer" (see *Frequency Changers*). In some applications of electric drive by induction motors one synchronous motor is installed for the purpose of making it take leading current in order to neutralize the lagging current taken by the induction motors. This effect is produced by over-exciting the fields of the synchronous motor. Such a synchronous motor is called a "rotary phase modifier" or "rotary condenser." It may incidentally be used to drive any machinery that does not require a large starting torque.

**GENERAL PRINCIPLES.** — In any synchronous generator or motor when a current flows in the armature there is a loss of voltage proportional to  $I Z_0$ , where  $I$  is the current and  $Z_0$  is a hypothetical quantity called the synchronous impedance, which includes the effect of the resistance, the leakage reactance and the demagnetizing effect of the armature current. This quantity is obtained by the synchronous impedance test (see below) and is expressed in complex quantities as  $Z_0 = r + jx_0$  and in algebra  $Z_0^2 = r^2 + x_0^2$  where  $r$  is the effective resistance per phase and  $x_0$  is the synchronous reactance per phase.  $I Z_0$  is therefore the drop in voltage per phase in the armature, and this voltage and the current differ in phase by an angle  $\theta$ , where  $\tan \theta = x_0/r$  and  $\cos \theta = r/Z_0$ . If a synchronous motor is running and generating a counter e.m.f.  $e$  and is connected to bus-bars of voltage  $E$ , the current flowing in the armature will be proportional to the vector difference between  $E$  and  $e$  and inversely proportional to  $Z_0$ , all taken per phase.

**Vector Relations for Motor Action.** — In Fig. 1 let  $E$  represent the bus-bar or line voltage (per phase) impressed on the terminals of a synchronous motor. Let  $e$  represent the counter e.m.f. of the motor and in this case assume  $e < E$  and directly opposed to  $E$ . Then the difference between  $E$  and  $e$  will set up a current in the armature of the motor.  $I Z_0$  will be the voltage and the current will lag behind  $I Z_0$  by an angle  $\theta$  where  $\cos \theta = \frac{r}{Z_0}$ . Thus the motor takes a current  $I$  lagging behind the impressed voltage  $E$ .

the relations when  $e > E$ , then  $I Z_0$  will be reversed in phase as it always lag behind  $I Z_0$  by the angle  $\theta$  and will be found drawn behind  $e$  and  $I Z_0$  but  $I$  leads the impressed e.m.f.  $E$  by an angle  $\phi$ . Thus when the field excitation is increased so that  $e$  tends to

Fig. 1.

Fig. 2.

than  $E$ , the machine takes a current leading with respect to the terminal voltage. As in a synchronous generator the field excitation required for a given terminal voltage depends upon the phase relation of the external load, so conversely in a synchronous motor the phase relation of the armature at a given terminal voltage depends upon the load and the load.

When the relations when  $e$  is more than 180 degrees behind  $E$ , that is, when the machine is in the position it had in the preceding examples by an angle  $\alpha$ . The induced e.m.f.  $e$  and  $E$  will be  $I Z_0$  as shown, leading  $E$ . The current  $I$  lags  $I Z_0$  by the same angle  $\theta$ , but is now almost in phase with  $E$  and  $I Z_0$  slightly. Thus power ( $E I \cos \phi$ ) is being sent into the ma-

Fig. 3.

Fig. 4.

chine as a motor, transforming electrical power into mechanical power. When the machine is running as in Figs. 1 and 2 the power is very small. When a mechanical load is applied, the armature will drop back in position. This causes  $e$  to drop back in phase and the machine draws power from the line.

When power is applied to make the armature move forward and the machine is in the opposite direction, the resultant  $I Z_0$  is thrown down and  $e$  is thrown behind  $I Z_0$  by  $\theta$ , is thrown around almost in phase with  $e$ . The machine becomes a generator, transforming the mechanical power into electrical power  $e I \cos \phi$ .

**Synchronous Position.**— In the discussion of the action of a synchronous motor it is convenient to employ the term "synchronous position," by which is meant the position which any definite point on the revolving member occupies at the same period of each cycle of time. It is only necessary for the armature to be in synchronous position by a very slight angle  $\alpha$  to cause current to flow. If  $\alpha$  should become 90 degrees, theoretically the current would become a maximum, and any increase in  $\alpha$  means that  $\theta$  becomes less than 45 degrees, the power decreasing and the machine falling out of synchronous position. When  $\alpha$  becomes 180 degrees a total e.m.f. equal to the sum of the induced e.m.f. and the terminal voltage is cut-circuited by  $Z_0$  and the current is enormous and the power

**Torque.**— If the speed changes for a short instant of time sufficient to move a point on the armature to drop back in synchronous position by an angle of one pole (90 electrical degrees), the motor torque will increase to the maximum available in the motor. Thus, for any torque less than the maximum the armature (or revolving field) need only change its position slightly to drop back some distance less than one-half the pitch of a

poles. If the load demands a torque greater than this maximum the motor will drop back more than 90 degrees and will fall out of step and come to a stop. In most synchronous motors the maximum torque is about 6 times no-load torque.

**DESIGN AND CALCULATIONS.** — (See also *Generators, Alternating Current*.) The design and calculation of synchronous motors is very similar to the design and calculation of alternating-current generators. There are differences in the proportioning of certain details and there are certain details of importance in generators that are not important in motors (armature reaction) and the converse is also true.

**Armature Reaction.** — The armature reaction of a synchronous motor is expressed as  $\frac{1.5 \sqrt{2} SI k_2 k_3}{p}$  for a three-phase machine and  $\frac{\sqrt{2} SI k_2}{p}$  for a two-phase machine, where  $S$  = turns in series per phase,  $I$  = full-load current,  $k_2$  and  $k_3$  have the values given in the article on *Generators, Alternating Current*, and  $p$  = number of poles. The armature reaction of a motor is usually 50 per cent greater than that of a generator of the same size and frequency. The higher value gives greater synchronizing torque and a better starting torque, and reduces the cross-currents between the motor and generator in case of hunting. The armature-reaction ampere turns at full load are equal to the field ampere turns at no load. Too great an armature reaction is objectionable, because it reduces the energy transfer between the motor and generator and therefore reduces the synchronizing power, that is, the tendency of the machines to hold each other in step.

**Excitation.** — The excitation of a motor is calculated in the same manner as the excitation of a generator. The magnetic densities are usually lower. The capacity of the field winding depends upon whether the motor is to be used as an ordinary motor or to regulate the power of a generator system by over-excitation.

**Leakage Reactance.** — The leakage reactance may be higher in a motor than in a generator as regulation is not of so great importance. However, a large leakage reactance will reduce the starting torque of the motor.

**Short-circuit Current and Synchronous Impedance.** — The short-circuit current of the motor depends upon the leakage reactance and the armature reaction. The short-circuit current and the synchronous impedance are predetermined from the no-load saturation curve and the calculated synchronous reactance per phase.

Let  $F$  = excitation in ampere turns per pole for which it is desired to find the short-circuited current,

$I$  = rated current per phase,

$x$  = leakage reactance in ohms per phase,

$E$  = voltage per phase due to  $F$  at no load,

$S$  = turns in series per phase,

$p$  = number of poles.

Then the ampere-turns synchronous impedance for full-load current is

$$\frac{2.12 SI}{p} + \frac{Ix F}{E}$$

and the short-circuit current with excitation  $F$  is

$$I_0 = \frac{E p F}{2.12 S E + x p F}$$

The synchronous impedance at this excitation is  $Z_s = E/I_0$ , and

chronous reactance is  $x_s = \sqrt{Z_s^2 - r^2}$ , where  $r$  is the resistance of the armature per phase.

**Efficiency and Losses.** — The losses are predetermined as in a generator. They are:  $A$  = friction,  $B$  = excitation or field  $RI^2$ ,  $C$  = core-loss,  $D$  = armature  $RI^2$ ; then

$$\text{Efficiency} = \frac{\text{Output}}{\text{Output} + A + B + C + D}$$

**Phase Characteristics or V-Curves.** — The phase characteristic is a curve

showing the variation in armature current for any given load with varying field excitation.

Fig. 5 shows the shape of the curves, which may be determined both by calculation and test.

The phase characteristic for any particular load has the general shape of the letter V, and the group of such curves for various loads are frequently called the "V-curves" of the machine.

There are two methods of calculating the phase characteristics, the electromotive force method and the magneto-motive force method.

There are two methods of calculating the phase characteristics, the electromotive force method and the magneto-motive force method.

Fig. 5. Phase Characteristics of Synchronous Motor

There are two methods of calculating the phase characteristics, the electromotive force method and the magneto-motive force method.

#### Electromotive Force Method. —

Let  $E$  = line voltage per phase,

$e$  = motor counter e.m.f. per phase corresponding to the excitation to be used,

$i$  = component of current in phase with  $e$ ,

$e_i$  = mechanical output of armature,

$i_1$  = reactive component of current, positive for leading, negative for lagging,

$r$  = armature resistance per phase,

$x_s$  = synchronous reactance per phase,

then  $E^2 = (e + ri - x_s i_1)^2 + (x_s i + r i_1)^2 = e_i^2 + e_r^2$ .

$E$ ,  $r$  and  $x_s$  are constant,  $e$  is set by the value of the field current assumed,

then  $i = (\text{watts output})/e$  and  $i_1$  remains the only unknown quantity. Solving

for  $i_1$  the total current  $I = \sqrt{i^2 + i_1^2}$  and the power is  $e_i i - e_r i_1$  (for  $i_1$  lagging).

If  $e$  is greater than  $E$ , then  $i_1$  is leading, and the power factor is  $(e_i i + e_r i_1)/EI$ .

#### Magneto-motive Force Method. —

Let  $E$  = line voltage per phase,

$F$  = field ampere turns per pole for this voltage,

$D$  = any value of field ampere turns per pole,

$I$  = armature current per phase,

$i$  = energy component of current = (power input)  $\div E$ ,

$p$  = number of poles,

$\sigma$  = field leakage coefficient of machine,

$S$  = turns in series per phase,

$i_1$  = wattless component of current for excitation  $D$ .

Then

$$pF = pD - 2.12 Si\sigma \text{ and}$$

$$i_1 = \frac{pD - pF}{2.12 S\sigma}$$

and

$I = \sqrt{i_1^2 + i_2^2}$  is the current in armature for power input  $Ei$  and for the excitation  $D$  assumed. If  $i_1$  is negative ( $P > D$ ) then  $i_1$  is lagging. If  $D > P$  then  $i_1$  is positive and leading.

**Angular Lag Due to Load ( $\alpha$ ).** — For any load on a synchronous generator there is an angular advance of the generated e.m.f. ahead of the terminal e.m.f., and in a synchronous motor there is an angular lag of the generated e.m.f. behind the terminal e.m.f. This phase displacement is accompanied by a shift in the synchronous position of the armature, which may be calculated and actually measured (see *Tests of Synchronous Motors below*).

To calculate this angle  $\alpha$  expressed in electrical degrees (360 degrees per pair of poles), let

- $E$  = line or terminal voltage per phase,  
 $e$  = induced or counter e.m.f. per phase; may be taken from no-load saturation curve for given excitation,  
 $r$  = resistance of armature per phase,  
 $x_s$  = synchronous reactance per phase,  
 $I$  = current per phase,  
 $\phi$  = phase angle between  $E$  and  $I$ .

Then

$$e^2 = (E - Ir \cos \phi - Ix_s \sin \phi)^2 + (Ir \sin \phi - Ix_s \cos \phi)^2,$$

and

$$\alpha = \sin^{-1} \left[ \frac{(Ir \sin \phi - Ix_s \cos \phi)}{e} \right],$$

or roughly

$$\sin \alpha \approx \frac{I \cos \phi}{\text{short-circuit current}}$$

The mechanical displacement of the armature for the load  $EI \cos \phi$  per phase is  $\alpha/p$ .

**Synchronizing Torque.** — The synchronizing power of a machine is a measure of the ability of a machine to keep in step with its supply circuit. It may be expressed in terms of torque per degree of displacement. If  $P$  is the kw. output of a motor and  $\alpha$  is the angular displacement of the armature in electrical degrees for this load, then

$$\text{Motor torque} = \frac{7050 \times (\text{kw.})}{\text{rev. per min.}}$$

$$\sin \alpha = \frac{(Ir \sin \phi - Ix_s \cos \phi)}{e},$$

and

$$\text{Synchronizing torque} = \frac{7050 \times (\text{kw.})}{\alpha \times (\text{rev. per min.})}$$

A high resistance between machines reduces the synchronizing torque as it reduces  $E$ . A reactance between machines is not as bad as resistance. Increasing the excitation increases  $e$  and improves the synchronizing torque.

**Hunting; Natural Period.** — The rotating part of every synchronous machine acts like a pendulum, tending to swing ahead and behind its normal synchronous position. The mass of the armature (and its flywheel) acts like the mass of the pendulum, and the torque of the machine being proportional to the displacement ( $\alpha$ ) corresponds to a spring or gravity acting on a pendulum. Such a combination has an "electro-mechanical period" of its own, and if the frequency of this period is in tune with any other pulsating force in the system, such as engine impulses, "hunting" or "surging" may occur.

Kapp have shown that the natural period of any synchronous motor in seconds or fraction of a second is given by the formula:

$$T = 0.308 N \sqrt{\frac{Wk^2}{fgmEI_0}}$$

$T$  = period of revolving part,  
 $W$  = weight of revolving part including any flywheel in pounds,  
 $k$  = radius of gyration of  $W$  in feet,  
 $f$  = frequency of current, cycles per second,  
 $g$  = acceleration of gravity, in ft. per sec. per sec. = 32.2,  
 $m$  = number of phases,  
 $E$  = terminal voltage per phase,  
 $I_0$  = short-circuit current of machine per phase and at excitation used.  
 $T_0$  = value of the natural period expressed in impulses per minute is

It is shown that the greater the flywheel effect  $Wk^2$  (see *Flywheels*) the longer the periodic time of a swing. The greater the short-circuit current the shorter will be the periodic time. The periodic time may be increased by connecting reactance coils in series with the machine terminals and the bus-bars.

The periodic time of any other pulsating force in the system, as the engine, the danger of hunting is greatest when

$$T/T_0 = 1/4, 1/3, 1/2, 1.$$

Hunting is damped by solid pole pieces, bridges between poles or squirrel-cage winding in the pole face.

Output. — As the current which would flow during maximum synchronous motor is so great that it would burn up the windings it should last more than a fraction of a second, the value of output is only of theoretical interest. In practice the maximum (open voltage) is only reached under two conditions: (1) when, as causes, the line voltage decreases to a fractional value, the current decreasing as the square of the voltage; (2) when, due to resonance, the flow of energy into and out of the machine reaches its maximum momentarily. In one of these swings the power may reach its maximum output or exceed it and the machine shut down. If the power of the machine drops off gradually after the point of maximum has been reached, the motor is unstable in this region and is more likely to shut down when the condition is reached.

Starting. — Synchronous motors may be started either as hysteresis or induction motors. In the former case the motor requires a high voltage and high current, but as the torque is very slight this method is seldom used. When starting as an induction motor a high armature reaction and a low leakage reactance. A squirrel-cage winding in the pole face is provided, and as in an induction motor this squirrel-cage winding has a cross-section approximating a certain value. If the cross-section is too small, the currents will be excessive and the starting torque not the best. If it is too large, the currents will be small and the starting torque not the best. While the cross-section of the squirrel-cage winding may be determined by treating the machine as an induction motor, this

method in a rotating field has a torque produced on it due to the hysteresis currents set up in it. Such an arrangement may be called a "hysteresis" or "circuited field" of a polyphase synchronous motor therefore forms a

method is not accurate because the construction of the field renders the calculation of the leakage reactance inaccurate. It is thus much better determined empirically.

**Rotary Phase Modifiers or Rotary Condensers.** — Synchronous motors are sometimes used to improve the power factor and reduce the line current of an installation of a number of induction motors. If a factory has an installation of 100 kv-a. of induction motors having an average power factor of 71 per cent and taking  $I$  amperes, then by installing a synchronous motor of 100 kv-a. rating, designed to be overexcited, the power available will be doubled and the line current only increased by 41 per cent or to  $1.41 I$ . Such a machine is called a "rotary condenser" and if it is rated at 100 kv-a. it may give 71 kw. of power and 71 kv-a. to balance the reactive effect of the inductive apparatus. Other relations may be obtained in accordance with the principle of vector combinations.

- Let  $P_1$  = true power taken by the induction motors, kw.,  
 $Q_1$  = reactive power taken by the induction motors, kv-a.,  
 $L = \sqrt{P_1^2 + Q_1^2}$  = total kv-a. of induction motors,  
 $P_2$  = true power taken by rotary condenser, kw.,  
 $Q_2$  = reactive power taken by rotary condenser, kv-a.,  
 $K = \sqrt{P_2^2 + Q_2^2}$  = total kv-a. of condenser,

then

$$\text{Line kv-a.} = \sqrt{(P_1 + P_2)^2 + (Q_1 - Q_2)^2}.$$

**TESTS OF SYNCHRONOUS MOTORS.** — Certain tests on synchronous motors are the same as those made on an a-c. generator; the methods of carrying out such tests are described in the article on *Generators, Alternating Current*. The first five of the following tests are of this character:

1. Resistance of armature and field circuits both cold and hot.
2. Saturation curve at no load and under special circumstances at full load.
3. Core-loss.
4. Short-circuit or synchronous impedance.
5. Insulation tests.

6. **Phase Characteristics or V-Curves** at no load, full load and any other specified load. The machine is operated as a motor with the specified load kept constant throughout the run. The voltage and frequency impressed upon the motor are also kept constant. The current in the field is varied from the minimum at which the motor will operate to the maximum (from  $\frac{1}{4}$  normal to  $1\frac{1}{2}$  normal) and the variation in current input to armature noted. Readings are taken of load, volts armature, amperes armature and amperes field. A curve is plotted with amperes armature as ordinates, and amperes or ampere turns per pole in field as abscissae. This gives the characteristic V-curves of the synchronous motor (see Fig. 5). The point of minimum current input for each load is very clearly shown. At this point the power factor is unity. At lesser values of field current the armature current is lagging and the power factor poorer. At greater values of field current the armature current is leading. The point of minimum current occurs at a higher value of field current for the greater loads because the field excitation must be increased with the load to overcome the armature reaction due to the load current.

**Compounding Curve.** — The curve connecting the points of minimum armature current in the group of V-curves is called the compounding curve for unity power factor.

**g Tests.**— A low voltage is impressed on the armature and gradually until the motor starts. The field circuit is open in two or more high potential voltmeter connected across one section to determine induced in the field spools by the rotating magnetic flux. The for several different initial positions of the revolving part and time of the time required for the machine to reach synchronism. which synchronous speed is reached may be determined by the induced voltage in the field becomes zero. Readings are taken are, amperes armature, initial position, maximum volts field, synchronism. See also section on *Starting*, below.

**ure Phase Position.**— The phase position of the armature usually may be measured, although the item is only of theoretical of commercial importance. A synchronous motor is supplied to a special alternating-current generator, and on the end of the machine is placed a contact-making disk, as shown in Fig. 6.

is connected in series with a current, the two disks, and using on the disks. The voltage is a maximum when the two contact with the metal strips. The brush on the motor over a graduated scale or position may be varied and regular movement measured.

Fig. 6. Contact Method of Measuring Armature Phase Position

the generator remains stationary. As the load on the motor is found necessary to move its brush in order to keep the voltage at its maximum value, and the angle  $\beta$  through which the brush moves for the change in load gives the phase position of the motor with respect to the generator armature. It will be found that the angle is directly proportional to the load. The difference in phase of the forces in electrical degrees will be  $\beta$  multiplied by the number of poles of the motor. If hunting exists, the maximum angle of swing is determined by moving the motor brush first one way as far as the effect is noticeable, and then in the other direction. (See *Morecroft, Laboratory*

**CONNECTIONS.**— Synchronous motors are rated in the same manner as generators, and the same heating limits and specifications apply (*Generators, Alternating Current*.) It is customary to specify the current taken by the motor in starting with no load other than its own bearings, or its own friction plus that of the machine to be connected, in case it is part of a motor-generator set. It is also mentioned in the specifications that the motor will not hunt provided the resistance drop between the generator and motor is less than a certain value (10 per cent or 15 per cent).

**STARTING AND OPERATION.**— The precautions to be taken in starting are the same as for a-c. generators (q.v.). Direct current must be supplied for excitation. If a synchronous motor is operated on a polyphase system with unbalanced voltages it will take unequal currents in the different phases and to balance the voltages. These unequal currents, however, may be corrected by adjusting somewhat for a given load.

Provision must be made for a reduced voltage for starting the motor (by means of taps on the transformers or by means of a starting transformer (q.v.)). Large motors require two steps in starting,  $\frac{1}{2}$  and  $\frac{3}{4}$

of normal voltage. Small motors will start with one step at  $\frac{1}{2}$  voltage. The field circuit is opened by the field "break up" switch and a voltage applied to the armature. When the armature current has decreased from its large value at starting to a reasonable value the voltage is increased, step by step. When the motor has reached maximum speed the field is excited and the motor pulls into synchronism. The field current is then adjusted until the condition of minimum armature current is found or until the power-factor indicator records unity power factor. The load may then be applied.

If a synchronous motor is to be started often (several times a day) it is desirable to provide a special starting motor which brings the synchronous motor up to a speed a little above synchronism. Synchronizing must then be effected as in a-c. generators. Such a starting motor would require only about 30 per cent of the full-load current of the motor, and therefore have very little effect on the regulation of the system and not cause disturbance to the lights and other motors on the system. It usually requires less than a minute to bring a motor up to speed.

**DIMENSIONS, WEIGHT AND COSTS.** — These are approximately the same as for synchronous generators of the same kv-a. rating. (See *Generators, Alternating-Currents.*)

**OHMMETERS.** — (See also *Bridges for Electrical Measurements; Galvanometers.*) The name ohmmeter is applied to any portable device designed for the direct measurement of electrical resistance. The simplest form of ohmmeter consists of a slide-wire bridge, battery and galvanometer all mounted in a portable case. Another form of ohmmeter utilizes a special form of galvanometer whose deflection, measured on a properly calibrated scale, gives the value of the unknown resistance directly in ohms.

**BRIDGE TYPE OF OHMMETER** (Fig. 1). — This ohmmeter is based on the Wheatstone-bridge principle, but differs from most Wheatstone bridges in that the rheostat resistance  $R$  is kept constant and bridge arms, formed by the wire  $W$ , are varied by moving a contact  $C$ . Ohmmeters of this type are made in many varied forms. In some a straight slide wire is stretched over a cardboard scale and contact on the wire made with a metallic stylus. In others a slide wire is wound on an insulating cylinder. The scale may be equally divided, or may be divided to read directly the ratio of the resistance measured to the resistance of the fixed rheostat resistance  $R$ .

Fig. 1. Slide Wire Ohmmeter

**EVERSHED MEGGER** (Fig. 2). — This instrument is of the galvanometer type. It is principally useful for the measurement of insulation resistances and other high resistances where extremely high accuracy is not required. The scale is graduated to read directly in megohms, whence the name.

Referring to Fig. 2,  $D$  is a small hand-driven d-c. magnet and  $G$  a special form of moving-coil instrument. One pair of bar magnets supplied the flux for both. The galvanometer contains three coils rigidly attached at a fixed angular distance apart to the shaft which carries the pointer  $P$ . The unknown resistance is connected at  $X$ .

The coils  $BB_1$ , called the pressure coils, are permanently connected through a resistance across the terminals of  $D$ . The current coil  $A$  is made to move through an annular gap in such a manner that the field in which it moves is uniform, whereas the pressure coils  $BB_1$  move from a position midway between the poles, where the field is at a minimum, into a stronger and stronger field, the connections being such that the torque due to the current in the current coil is opposed by the torque due to the current in the pressure coil. With no current in the current coil, that is to say, when the resistance to be measured is infinite, current through the pressure coils will cause them to come to rest with their planes at right angles to the magnetic field. When the current through the current coil is increased by putting in lower resistances the current coil drags the moving system round in a clockwise direction; since the pressure coils come into a stronger and stronger field, the resistance to this motion becomes greater and greater. Hence a definite position is assumed by the system for the particular resistance at  $X$ . An increase in voltage would increase the current in both current and pressure coils in the same proportion; consequently the instrument is independent of the voltage of the generator.

In the cheaper instruments the generator gives a variable voltage depending upon the speed of rotation of the handle. In the higher priced instruments

Fig. 2. Evershed Megger

the generator is designed to give a constant voltage for a constant speed of driving. The voltage at which an insulation test is of great importance (see *Resistance and Conductance*). Con meggers are especially useful for testing insulation resistance associated with large electrostatic capacity, where a varying test voltage would cause and discharging currents to flow with resulting fluctuations in the

**WESTON DIRECT-READING OHMMETER.** — This is a magnet moving-coil instrument having two windings on the moving coil and an adjustable magnetic shunt. Terminals are provided for the unknown resistance and an auxiliary battery. Before use, the instrument is checked by a plug in the checking position. On closing the key, a current from the battery divides through the two windings. The ampere-turns of one winding, in series with a fixed resistance, tend to deflect the pointer up scale, and the ampere-turns of the other winding tend to return it to zero. When the test voltage which is within the designed limits, the magnetic shunt moves to bring the pointer to full-scale position. If the plug be now shifted to the next range position, a resistance equal to that of the low range is removed from the circuit, whose ampere-turns tend to deflect the moving coil down scale, and a resistance equal to that of the low range be now connected across the "X" posts, the previous condition will be restored, and the pointer will be at full scale position. For any value of resistance less than this full-scale ampere-turns will be greater, and will bring the coil back to a lower position on the scale. For zero resistance across the "X" posts, the ampere-turns of the two windings will balance each other, and the coil will stand at the zero position on the scale, corresponding to the unstressed condition of the springs.

Double and triple ranges are available by shifting the plug to the other range positions. This form of ohmmeter is very rapid in operation, and the e. m. f. of the auxiliary battery are taken care of by periodic checking operation.

**VAWTER INDICATING OHMMETER.** — This instrument is of the galvanometer type, containing two coils carried by a shaft and in the field of a permanent magnet. The core is specially shaped to give such scale characteristics as may be desired. Connections to the coils are made by spirals of negligible torque, so that the position of the pointer does not depend on the value of the auxiliary current, nor upon the strength of the permanent magnet. The instrument can therefore be operated on a generator source of voltage. This ohmmeter is made in portable form with from one to four ranges; in switch-board form, applicable for determining the resistance of the windings of electrical machines under load, and as a rail bond tester.

**KELVIN BRIDGE OHM-METER** (Fig. 3). — This is a portable type direct reading ohmmeter used for measuring low resistances.

Current and potential leads are provided which are connected to the unknown resistance.

The two slide wires  $S$  and  $S_1$  are mounted on the same disc and move together. The reading on a scale mounted on this disc gives the ratio of  $x/R$ . The reading multiplied by the value of  $R$  plugged in gives the value of  $x$  between potential points.

**COST, RANGE AND ACCURACY.**— Bridge type ohmmeters range in price from \$60 for ohmmeters having a range of from 0 to 100 ohms and an accuracy of about 2 per cent to \$80 for ohmmeters having a range from 0 to 10,000 ohms and an accuracy of  $1\frac{1}{2}$  per cent. Meggers range in price from \$225 for variable voltage meggers having a range of from 0 to 10 megohms and an accuracy of 5 per cent to \$530 for constant pressure meggers having a range of from 10 to 2000 megohms and an accuracy of about 4 per cent. Kelvin bridge ohmmeters having a range of .0001 ohm to 11 ohms cost about \$100. The above prices are approximate for the year 1921 and should be used only as a rough guide.

**OIL, TRANSFORMER.** — (See also *Transformers; Circuit Breakers; Insulating Materials, Testing of.*) Oil is used in transformers, electrolytic arresters and feeder regulators as an insulating and cooling medium, and in oil-circuit breakers as an insulating and extinguishing medium. For these various uses, it must have certain general characteristics as follows:

- (1) It must have high dielectric strength.
- (2) It must have sufficiently high flash point to prevent its ignition during the opening of circuit breakers, and the failure of transformers, feeder regulators or electrolytic lightning arresters.
- (3) Where oil is used for cooling purposes, it must have low viscosity to allow free circulation and must be free from deposit to prevent the obstruction of oil ducts.
- (4) For use in oil circuit breakers it must have high viscosity to prevent undue splashing.
- (5) For use in electrolytic arresters the oil should not emulsify with the electrolyte.

Mr. D. B. Rushmore gives the following as the characteristics of oil usually furnished with large, high-voltage, water-cooled transformers:

Flash point .....	130° C.
Burning point .....	145° C.
Freezing point .....	-15° C.
Color .....	white
Spec. gravity at 15.5° C. ....	0.830
Viscosity (Saybolt 40° C.)* .....	40

**Dielectric Strength and Specific Inductive Capacity.** — The dielectric strength of clean dry oil should not be less than twenty-two thousand (22,000) volts, when tested between one-inch disks set one-tenth (0.10) inch apart. \*

Oil in service, except in electrolytic lightning arresters, should be filtered when it fails to stand a pressure of sixteen thousand five hundred (16,500) volts when tested between one-inch disks set one-tenth (0.10) inch apart.

According to Tobey, the dielectric strength of transformer oil increases with increase of temperature, the increase from 30° to 90° C. being about 25 per cent.

On the other hand, the insulation resistance of oil decreases very rapidly as the temperature increases. In a typical test Tobey found the insulation resistance of a given sample to fall from 1200 megohms at 50° C. to 250 megohms at 90° C.

The specific inductive capacity of transformer oil is about 2.5 between 25 and 100° C.

**Dryness and Purity.** — Great care should be taken to keep the oil absolutely dry under all conditions. The presence of water in as small amount as one one-hundredth of one per cent is sufficient to impair seriously the dielectric strength of the oil.

Great care should be taken to remove from oil before it is used, foreign material, such as scale from iron drums, which may become dislodged during shipment; also to keep foreign material from entering the oil when the apparatus is in service.

The presence of mineral acid or of alkali in insulating oil is not permissible as they are corrosive or destructive in their action upon the materials of the apparatus. An oil practically neutral is preferable. It should contain no free sulphur, because sulphur in its free form attacks copper. All petroleum oils contain sulphur compounds, but in this form it is not objectionable.

\* The time in seconds required for a certain definite quantity of oil to flow through a definite opening as measured with a Saybolt viscosimeter.

**Deposit or Sludge.** — An oil for transformers and feeder regulators should be as free from deposit as possible. Deposit is objectionable primarily because it clings to the coil windings and fills the coil ducts, thus seriously affecting the cooling action.

The forming of deposit is a function of the temperature and length of time the oil has been used. Different grades of oil differ as to the temperature at which deposit will appear. A satisfactory oil should not show a deposit or any change other than a possible darkening of color when operated continuously under temperature conditions experienced during actual operation.

**Pour Point or Freezing Point.** — The pour point or freezing point is usually of no great importance, except for oil for apparatus where there is a movement of parts. The oil used in transformers, lightning arresters and regulators usually has a pour point of about  $0^{\circ}$  C. For outdoor installation of regulators and oil circuit breakers in extremely cold climates and all oil fuse cutouts and moving coil constant current transformers, the oil used should have a pour point of about  $-30^{\circ}$  C.

**PURIFYING AND DRYING.** — All new oil as it is taken from the drums or tank cars, and all old oil that has been in use for some time, that shows the presence of sediment or dirt, should be filtered. In placing the oil in the transformer case it should be run in through about two thicknesses of finely woven cambric, which has been washed to remove all sizing and thoroughly dried.

The presence of large quantities of moisture in transformer oil is easily detected, since water is heavier than oil and will settle to the bottom, if allowed to stand. If not present in sufficient quantity to settle in this manner, the oil may still contain considerable moisture in a suspended state. If a sample of clean oil shows too low a dielectric strength, there is moisture present and the oil must be dried.

The best method of purifying oil is by means of one of the commercial filter presses produced by the various manufacturing companies. The oil is treated in a filter press by being forced through several layers of blotting paper which remove all moisture and solid matter held in suspension by the oil.

In filtering oil it is preferable to filter from one tank and discharge into another, as in this way the oil is given a more complete treatment than if drawn from the bottom and discharged into the top of the same tank. The latter method is, however, very useful in cases where apparatus cannot be removed from service long enough to empty it completely.

For satisfactory operation of the press, it is important to see that the filter papers are changed with sufficient frequency and are properly assembled. Only new clean filter paper should be used, and it should be thoroughly dried in an oven before being placed in the press. Filter paper will take up moisture from the air rapidly and must therefore be stored under dry oil in case it cannot be used directly from the oven.

If a drying outfit is not available, the oil may be dried in a fairly satisfactory, although slow and inconvenient manner, by passing it through clean, dry, unslaked lime and filtering afterward to remove all particles of foreign matter. Various other methods have been suggested or tried, but they are not to be recommended. For example, passing hot, dry air through the oil is not desirable because of the difficulty of removing all the moisture from the air, and the heating of the oil for a considerable length of time involves the liability of injuring it by such treatment.

**TESTING.** — The most important and frequently made test of transformer oil is the test for dielectric strength. Additional tests are: (a) viscosity, (b) flash point, (c) fire point, (d) pour point, (e) acidity, and (f) sulphur content.

Complete directions for making all these tests are given in *A.S.T.M. Standards*, D 117-21 T.

The following brief description of the test for dielectric strength from Instruction Book 5094-B, published by the Westinghouse Manufacturing Company.

For testing oil for dielectric strength, use some standard form device such as that shown in Fig. 1. The gap terminals are flat and 1/8 in. in diameter, with square edges. The standard gap setting is 0.10 inch.

The following precautions should be observed: Wipe out the testing cup with a clean, dry cloth, being careful to remove any particles of cotton fiber that may adhere to the surface. Adjust and fix the gap in its correct setting and then rinse the cup thoroughly with benzine or gasoline, being particularly careful to see that no particles of dirt remain. Then give a final rinsing with a portion of the oil to be tested before placing the testing sample of oil in the cup.

The temperature of both the oil and the testing cup should be approximately the same and between the limits of 20° C. and 30° C.

Pour the test sample into the testing cup and allow it to stand for a few minutes so that minute air bubbles have had time to escape. This will require 1 to 2 minutes. The oil level should not be less than 1 inch above the electrodes.

Apply the testing voltage, starting at a low value and increasing at the rate of approximately 3000 volts per second without opening the circuit until breakdown takes place. The testing transformer should have a capacity of at least 1 kva.

After each break, jar the testing cup but do not cause the oil to splash. This will tend to loosen the carbonized oil from between the electrodes. Do not introduce any foreign matter into the oil for stirring, as it is likely to cause low breakdown voltages. Be particularly careful of introducing minute particles of foreign matter or moisture.

Repeat the application of voltage until five breakdowns have been obtained. Use the average value as the breakdown value of the test sample of oil.

Sometimes a small, bright spark passes across the gap, but does not cause a circuit breaker or fuse to open the circuit. Such sparks should be disregarded in recording results. They are not likely to occur unless sufficient time is allowed for all air to escape before applying voltage.

The testing cup should preferably be used in connection with a standard high voltage testing outfit, provided with suitable means for regulating the testing voltage. If a testing outfit is not available, a generator and a high voltage transformer may be used, control of the testing voltage being obtained by variation of the generator field. If such an arrangement is used, a high resistance (about 1 ohm for every volt of testing voltage) should be connected in series with the testing cup.

**OSCILLOGRAPHS.** — (See also *Braun Tube; Wave Analysis.*) The oscillograph is essentially a galvanometer of very short period. It is applied in the observation of potentials or currents, as voltmeter or ammeter, mainly when variations are too rapid to be indicated by the more usual instruments; for example in observation of potential waves of generators, potential and current waves in inductive apparatus, short-circuits or switching of transmission lines. As in many cases it is necessary to have two or more curves taken together in their relative phase relation, more than one element is necessary in a practical instrument; it is regularly built as a three-element oscillograph, giving one, two or three curves, as may be required, on the record. One element may be used as a chronograph by connecting it to record a timing wave from an a-c. source of known frequency.

**Types of Oscillographs.** — The most common form of oscillograph is the moving-coil type, the "coil" being two small thin strips or ribbons arranged very close together, thus forming the two sides of a coil of one turn. A moving iron vane can also be used, but this type has not received extended practical application. The electrostatic oscillograph, which is particularly well adapted for direct observation of high potentials, consists of two insulated strips maintained at a constant potential difference, these strips being caused to vibrate by the varying force of attraction and repulsion due to the charges on two fixed plates connected to the varying high-potential source. The vibrator is similar in construction to the vibrator of the ordinary oscillograph, except that the two strips are connected by a light insulating thread. The strips are connected to the terminals of a storage battery, the middle of which is kept at a potential midway between the potential of the two plates, by being connected between two equal condensers in series across the attracting plates. Still another form of oscillograph is the cathode ray, or Braun, tube (see *Bibliography for references*). This last type of oscillograph finds its most valuable application in the laboratory study of high-frequency and high-voltage phenomena which are beyond the range of the ordinary oscillograph. The practical application of this type has been found rather difficult.

#### DESIGN OF MOVING-COIL OSCILLOGRAPH.

— The ordinary or moving-coil oscillograph is described in detail below.

**Construction of Vibrator.** — The vibrator, or moving element (Fig. 1), consists of two strips of flattened wire stretched over bridges, with a very small mirror cemented directly to the strips; the arrangement constitutes a one-turn galvanometer coil of elementary form. The vibrator is placed between the wedge-shaped poles of an electromagnet or of a permanent magnet. It is immersed in a liquid which provides critical damping. The vibrator conductor passes from one terminal post *T* over the bridges *BB*, in narrow grooves, over a pulley *P*, back over the bridges in grooves very close to the former, to the other terminal post *T*<sub>1</sub>. The width of the strip is usually 0.005 inch to 0.007 inch. The mirror *M* is cemented to the strips midway between the bridges, its usual size being 0.060 inch by 0.017 inch. Tension is applied to the strips, for the ordinary vibrator 6 oz. for the two strips, indicated by a small spring balance *SB*. The vibrator is readily rewired in case of break or burn-out.

Fig. 1. Oscillograph Vibrator. *B, B*<sub>1</sub> bridges for supporting strip; *P*, pulley; *SB*, spring balance indicating tension; *TS*, tension screw; *M*, mirror

For efficient operation vibrators are made interchangeable. This is necessary to make expeditious operation possible, and to minimize delay due to accidental destruction of vibrator parts.

**Construction of Field Magnets.** — The galvanometer field is an electromagnet with wedge-shaped poles. The vibrator is so mounted that the strips lie in the narrow air gap between these poles. A direct current through the winding of the electromagnet produces a very strong field in this air gap. The ampere turns of the electromagnet are sufficient to saturate the pole tips and render the strength of the field practically independent of the voltage applied to the electromagnet windings, at least for ordinary voltage variations. One terminal of the vibrator may be connected electrically to the core of its field magnet, each core being insulated from its field winding for a working pressure of 2300 volts.

A permanent magnet can be substituted for the electromagnet as the oscillograph field. This construction is practicable for two elements. The permanent magnet oscillograph is somewhat inferior in sensibility, and greatly inferior in insulation between elements, compared with the electromagnetic type of oscillograph.

**Optical System.** — The light for the oscillograph from a projection arc lamp enters the case at the shutter aperture, and, after being reflected toward the vibrator cell by a total reflecting prism (one for each element), passes through a slit which adjusts the width of the image. It is then reflected by the small vibrator mirror, and passes through a cylindrical lens to the image on screen or film. Very careful adjustment of the optical system is essential to secure records of good photographic intensity.

The arc lamp used as a source of light for the oscillograph is usually a hand-fed lamp with small carbons at right angles, taking 5 to 8 amperes, with *solid positive* carbon in the horizontal position. The light is rendered parallel by a simple projection lens. Any convenient arc lamp, however, may be used with good results. If only an a-c. source is available for the arc, records of fluctuating intensity are obtained, which, however, are usually legible throughout their length. Sunlight source with a heliostat, when circumstances permit, gives photographic records of superior intensity.

The astigmatic optical system of the oscillograph, due to the cylindrical lens, is quite a distinctive one; the geometrical light source for the image in the vertical direction is the adjustable slit, in the horizontal direction it is the vibrator mirror.

**Means for Obtaining Photographic and Visual Records.** — The photographic record is taken on a moving film or plate. The most practical arrangement is a film, having a length of about 12 inches, on a drum driven at suitable speed by a small motor. A contactor opens the shutter for one revolution of the drum, giving exposure once over the film. The exposure can be adjusted to start at the beginning of the film, or if a record is taken in response to a signal, as of switching or short-circuit, the exposure can be started instantaneously at any part of the film. A long film is desirable in some cases, as in transmission line switching, where the whole disturbance lasting perhaps several seconds is to be taken. By the use of a suitable attachment for long films, records can be taken on films 3 to 5 feet in length.

The motion of the spot of light reflected from the vibrator mirror may be projected as a standing wave on a tracing table, for examination or demonstration. An oscillating mirror, actuated by a cam driven by a small synchronous motor, is given a uniform angular velocity during alternate cycles of the current or voltage observed, and draws out the wave longitudinally. Only alternate waves or cycles are utilized, the intervening waves being cut off by a revolving screen on the motor shaft during the return motion of the mirror. The recur-

reverses of the waves are so rapid as to produce an image sensibly continuous to the eye. The synchronous mirror is removed by shift of a simple mechanism to permit photographic record to be taken in the usual manner by revolving film.

**Free Period of Vibrator.**—The free period of the vibrator is about  $1/6,000$  second, but some have been constructed to have a free period as high as  $1/10,000$  second. The higher the free period the less the distortion of the higher harmonics in the current and voltage waves. A free period of  $1/6,000$  second, is ample to secure practically accurate values of all harmonics having a frequency of less than 1200 cycles per second; with a free period of  $1/10,000$  second harmonics having a frequency as high as 3000 cycles per second are recorded with practical accuracy.

The free period of a vibrator depends upon the moment of inertia of the vibrating system and upon the tension on the strips; the less the moment of inertia and the greater the tension, the shorter will be the free period. The free period of a given vibrator may therefore be slightly shortened by increasing the tension on the strips, but this in turn decreases the sensibility, i.e., the deflection for unit current through the strips.

To measure the free period of a vibrator it is placed in the cell between the poles of magnet, in the usual way, but with no damping liquid in the cell. It is connected to a d-c. source through an interrupter which makes or breaks the circuit one or more times during the exposure of a film running at as high a speed as possible. The free vibration in decreasing amplitudes is shown on the film, and the period is readily counted, the film speed being known.

**Sensibility of Oscillograph.**—An oscillograph having a free period of  $1/6,000$  second requires from 0.1 to 0.2 ampere through the vibrator to give a curve of good amplitude; or about 0.006 ampere is required to give a millimeter deflection from the zero line on the film or tracing table. As ordinarily constructed a deflection of 45 mm. on each side of the zero may be obtained, but a deflection of more than 30 mm. is seldom necessary. The resistance of the vibrator is from 1 to 1.5 ohms; hence to obtain a deflection of 30 mm. about 0.2 volt is required across the vibrator terminals. The sensibility of a vibrator may be much increased by using thinner strips and smaller mirrors, but such arrangements are more delicate and should be used only to meet special requirements.

**CONNECTIONS AND ADJUSTMENTS.**—For potential, or voltage, curves the oscillograph is connected similarly to a voltmeter; E in Fig. 2. A suitable amplitude of curve is obtained by an external adjustable resistance.

For current curves the oscillograph is connected similarly to a millivoltmeter across a non-inductive shunt; I in Fig. 2. A shunt potential drop of at least 0.1 volt is required, but for convenient adjustment it should be larger, 0.5 volt being a suitable value where practicable. If the current measured is less than 0.2 ampere, no shunt is used, the whole current being taken by the vibrator.

Fig. 2

For waves of flux distribution in generators or motors, the oscillograph is connected to give the voltage of an exploring coil; sometimes in d-c. machines the voltage between commutator bars can be used.

Potential and current transformers are used where the line voltages and currents are too high for practical or convenient direct observation. The oscillograph potential circuit can be connected to the potential transformer along with voltmeter or other instruments, as it is only a fraction of the rated

potential transformer load. For current curves a shunt is connected in the current transformer secondary circuit.

**Adjustment of Vibrator and Optical System.**—Individual vibrators are provided with movements for vertical and horizontal adjustment of the image. The beam of light is brought vertically to the middle, or axis, of the cylindrical lens; this adjustment is left unchanged, but should be examined occasionally to insure its correctness; this may conveniently be done by viewing the position of the light spot on a thin sheet of paper held against the case where the light comes through to form the image on film or ground-glass screen; the light spot should appear central in the aperture. The horizontal adjustment brings the image to the proper position on the record, and is changed freely according to circumstances. When two curves are to be taken on the record, the images are usually placed for clearness so as not to overlap. If, however, the phase relation is important they are placed with their zero positions near together; it is better not to make them coincident, however, as good superposition is not always secured. After the principal exposure, an auxiliary exposure for zero line is taken with vibrator circuit opened, except in occasional records where the zero line is unnecessary.

**Quantitative Measurements with Oscillograph.**—The values of the curves may be obtained quantitatively when necessary by reference to a d-c. measurement. For potential curves an observation is taken of a d-c. source of known voltage; for current curves similarly an observation is taken of a measured d-c. current. During these d-c. measurements the resistances in the vibrator circuit should be the same as used during the observations. If a number of observations are taken at different resistances, two or three d-c. calibrations can be made with known resistances, and the calibration for the other resistances computed, assuming the deflection proportional to the total resistance of the vibrator circuit. When potential and current transformers are used, the voltages and currents as directly measured are reduced to terms of line voltages and currents by the transformer ratios. In case of short-circuit currents, where it is not practicable to obtain d-c. currents comparable in amount with those of the observation, a measured d-c. voltage, as from dry cells, can be applied to the oscillograph leads detached from the shunts, the corresponding currents being computed from the shunt resistances.

In many cases, the curve is self-calibrating, a portion of the curve being at a constant d-c. value which can be measured by d-c. instruments, as for instance on generator-field voltage and current curves of short-circuits.

**COST OF OSCILLOGRAPH (Pre-war cost).**—An oscillograph complete with a three-element electromagnet galvanometer, optical system, shutter and shutter-operating mechanism, motor and countershaft, photographic and tracing attachments, six film-holders, and the following repair parts: 6 extra suspension strips; 6 vibrator mirrors, 1 box special gold-leaf fuses, 1 bottle mirror cement, 1 bottle damping liquid, costs about \$650.

**PAPER, IMPREGNATED.** — (See also *Insulating Materials, Wires and Cables, Insulated.*) Wires and cables may be insulated by winding paper ribbon helically around the conductor in successive layers until the desired thickness of insulation is obtained. The paper-covered cable, after being thoroughly dried in a hot vacuum dryer is immersed in oil until saturated, and then passed through a lead press, which covers it with a continuous sheathing of lead. The paper serves the triple function of affording a conveyance for the oil, adding to the insulating value of the oil, and being a mechanical separator between the conductor and sheath.

**THE PAPER.** — The most commonly used paper for such cables is that made of Manila hemp or *musa textilis*, a fiber grown in the Philippine Islands for rope making. The original fibers are about 6 millimeters long and have a diameter of 0.024 millimeter but the length is materially decreased in the process of beating described below. The paper made from this fiber is not necessarily the best for cable insulation, but the fact that it has stood the test of twenty years use, makes American manufacturers slow to try others. Hemp papers are often called Manilla, and at the present time mixtures of hemp and *musa* have come into general use, a common proportion being one of hemp and two of *musa*. Jute is sometimes added, but as it is not permanent and adds nothing to the strength, it should be avoided. German manufacturers are using paper containing long fiber wood-pulp in large quantities or even made exclusively of such wood-pulp, and claim that they are better than Manila papers (C. Beaver). American manila paper used for cables is made of old Manila rope.

**MANUFACTURE OF THE PAPER.** — The process of manufacturing Manila paper is as follows: The fibers are cut up, placed in a boiler with lime and caustic soda and boiled under a pressure of from 30 to 50 pounds for between 5 and 10 hours. They are then emptied out, washed free of alkali and put in a beaker where the fibers are partially disintegrated and washed. Sometimes bleaching is performed at this stage, by adding a solution of chloride of lime and again washing. The material is then put into the beater, where it is reduced to the condition necessary for the paper machine. After suitably diluting the material it is passed over sand tables, where gritty matter is deposited and then through strainers, where any coarse particles are retained. It then passes in a continuous flow to the endless wire of the Fourdrinier machine, where the fibers are deposited in the form of a sheet; then to the couch rolls and to the press rolls, where the water is squeezed out. Finally it passes over a series of drying cylinders where it emerges dry and is taken upon reels.

**NECESSARY PROPERTIES OF THE PAPER.** — The paper should have the following qualities.

1. Porosity, in order that it may hold a large amount of oil.
2. Strength and elasticity, in order that it may not break either while being wound or while suffering shrinkage in the desiccator or while being installed. Impregnation with oil should not impair the strength.
3. Freedom from excess of mineral matter, not only to give greater porosity but to avoid electrical weakness.
  1. Freedom from alkalies, in order that the impregnating oils shall not be saponified.
  5. Freedom from metallic salts, such as chlorides and sulphates, in order to avoid short-circuiting the oil by an electrolyte and also to avoid injuring the conductor.

**STRENGTH OF THE PAPER.** — The tensile strength of Manila rope paper is usually about 6000 pounds per square inch, and the elongation at the

breaking-point is about 3 to 4 per cent. The resistance to folding and to tearing are, however, much more important than the resistance to straight pulling, but as no standard methods of test have been agreed upon, it is not practicable to give average values for these quantities. The tearing strength of paper 8 mils thick is between 6 and 18 ounces, depending upon its humidity. The maximum strength is obtained with about 12 per cent of moisture.

**OIL FOR IMPREGNATING.**—Two classes of oils are used for impregnating the paper, rosin oil containing rosin in solution, and a special grade of carefully dried mineral oil or petrolatum, with or without rosin and other substances in solution. The rosin oil has higher dielectric strength at low temperatures, but does not maintain it at high temperatures; furthermore it occasions greater dielectric losses, an important consideration in high voltage cables.

**SPECIFIC RESISTANCE.**—The specific resistance of impregnated paper, depends upon its dryness and upon the nature and quantity of the substances dissolved in the oil. The value of  $K$  in the formula  $M = K \log \frac{D}{d}$  (see article on rubber) varies from 500 to 1500, the usual value being about 800.

**POWER FACTOR.**—The power factor depends greatly upon the temperature, the dryness and the resistivity of the impregnating compound. In the case of paper impregnated with petrolatum compound, the accompanying values are typical.

**TEMPERATURE COEFFICIENT OF RESISTANCE.**—The effect of temperature changes upon the resistance of oiled paper is greater than upon rubber and less than upon varnished cloth. The table below is representative of a typical paper insulation, but the properties of different makes vary considerably.

**DIELECTRIC STRENGTH.**—The dielectric strength of impregnated paper insulation is a very indefinite quantity. It is greatly reduced by crinkling and by the presence of moisture and it decreases rapidly with increasing temperature. The dielectric strength across the cellulose fiber is much greater than along them. It is therefore not surprising to find different experimenters reporting widely different values of this quantity. Thus, E. Jona says that the average commercial impregnated paper subjected to electric stress for an hour with progressively increasing potential, will stand from 8 to 10 kilovolts (effective a-c.) per millimeter and that it is not uncommon to find samples with 20 or 30 per cent greater dielectric strength. E. J. Berg gives 250 to 300 kilovolts per inch, or 10 to 12 kilovolts per millimeter. P. Human says that high-grade

Temperature, deg. C.	Power factor, per cent	
	Minimum	Maximum
40	0.4	2.5
60	0.9	7.5
75	1.5	13.0
80	1.7	15.0
85	2.0	18.0
100	3.4	30.0

Temperature °F.	Per cent of resistance at 60°
60	100
65	62.5
70	42.6
75	30.0
80	23.3
85	18.5
90	15.2

impregnated paper will stand 20 kilovolts per millimeter. The usual testing strength  $H$ , in the formula

$$H = \frac{E}{r \log_e \frac{R}{r}}$$

is about 4 kilovolts per millimeter or 100 kilovolts per inch, but the validity of this formula when applied to paper saturated with ionizable oils is very doubtful. F. Fernie (Beauis, Sept., 1921), says that the failure of single-conductor impregnated paper cables occurs when the stress at the sheath is about 100 kv. per cm. as calculated by the formula

$$H = \frac{E}{R \log_e \frac{R}{r}}$$

In the case of triplex sector cables, failure occurs when the average stress between conductors exceeds about 100 kv. per cm. When impregnated paper is punctured electrically, the paper itself chars, so that even though the oil tends to flow into and repair the gap, the short-circuit is maintained (see *Wires and Cables, Insulated*).

**SPECIFIC INDUCTIVE CAPACITY.** — The specific inductive capacity of dry Manila paper (without oil) is from 1.7 to 1.8 while that of Manila paper impregnated with petrolatum compound is between 2.75 and 3.5 at ordinary temperatures, when measured with alternating current.

**SPECIFICATIONS.** — Specifications for impregnated paper insulation for wires and cables will be found in the article on *Wires and Cables, Insulated*.

**BIBLIOGRAPHY.** — Beadle, C. and Stevens, H. P., *The Composition and Durability of Cable Papers*, Electrician (London), Vol. 63, 1909; Cross, C. F. and Bevan, E. J., *Paper Making*, London, 1916; Dawe, E. A., *Paper and its Uses*, London; Sindall, R. W., *Paper Technology*, London; Sutermeister, E., *Chemistry of Pulp and Paper Making*, New York; Witham, J. S., *Modern Pulp and Paper Making*, New York, 1920.

**PERMUTATIONS AND COMBINATIONS.** — (See also *Factorials*.) Each of the *arrangements* which can be made by taking some or all of a number of things is called a permutation.

Each of the *groups or selections* which can be made by taking some or all of a number of things is called a combination.

The number of permutations of  $n$  things taken  $r$  at a time is

$$n(n-1)(n-2) \dots (n-r+1).$$

The number of combinations of  $n$  things taken  $r$  at a time is

$$\frac{n(n-1)(n-2) \dots (n-r+1)}{r(r-1)(r-2) \dots 3 \cdot 2 \cdot 1}$$

The number of combinations of  $n$  things taken  $r$  at a time is equal to the number of combinations of  $n$  things taken  $(n-r)$  at a time.

**PHASE CONVERTERS AND PHASE BALANCERS.** — (See also *Generators, Alternating-current; Motors, Polyphase Induction; Motors, Synchronous; Transformers.*) — A phase converter is a machine for converting single-phase power into polyphase power, or vice versa. A phase balancer is a machine for balancing the load on one or more polyphase generators when these generators are supplying an unbalanced load to the circuit to which they are connected.

**PHASE CONVERTER.** — The phase converter is a single unit two-phase induction motor, or a two-phase synchronous motor with an extra heavy squirrel cage.

**Polyphase to Single-phase Conversion.** — It is well known that a two-phase induction motor or synchronous motor after once started will continue to run on one phase. The disconnected phase of the motor may be used as a source of single-phase power. The voltage and current of this phase are nearly 90 degrees displaced from the voltage and current of the phase connected to the supply.

In order to change from two-phase to single-phase the connections shown in Fig. 1 are used. Phase *A* of the converter is connected across one phase of the supply and phase *B* in series with the load across the other phase. The voltage of *B* adds to the voltage of the supply, making the total voltage at the load  $2V$ . When the current in the load is  $I$  the volt-amperes in *B* are  $VI$ , and the volt-amperes in phase *A* are approximately  $VI$ . The volt-ampere capacity of the machine must equal the volt-amperes of the load. If the current or the power-factor of the load changes, the currents and power-factors of phases *A* and *B* of the machine change an almost equal amount. The action of this machine is entirely automatic, no complicated regulators being required to control its action.

Fig. 1.

The machine is started as a quarter-phase induction motor, and after it is up to speed one of the phases is reversed and connected to the supply in series with the load. The converter is located near the single-phase load. The phase converter is well adapted to supply electric furnaces or electric welding outfits with single-phase power from polyphase systems.

**Single-phase to Polyphase Conversion.** — The Norfolk and Western Electric Locomotives receive single-phase power through a single trolley. Three-phase induction motors are used to drive these locomotives. The connecting link between the single-phase and polyphase system is a two-phase induction motor operated as a phase converter. The connections to change from single-phase to an approximately balanced three-phase system are shown in Fig. 2.

The machine is driven by power supplied to phase *A*. Phase *B* corresponds to the teaser coil of a transformer T-connection. This phase has an e.m.f. induced in it of the proper magnitude and phase position to make the voltages across the three phases approximately balanced.

The phase converters on the Norfolk and Western are started by single-phase commutator motors. The operating speed of the converter is high, permitting a design of minimum weight for a given output. The converter is

addition to furnishing power to polyphase motors may be used to drive auxiliary apparatus. Polyphase motors receiving their power from phase converters may be used for regenerative braking.

### PHASE BALANCER (Fig. 3).

— The so-called shunt phase balancer consists of a large and a small unit mounted on the same shaft. The large unit has the same capacity as the unbalanced load, and resembles a synchronous motor, with an extra heavy squirrel cage attached to the rotor. The small unit has an ordinary polyphase winding on the stator, and two separate windings displaced 90 electrical degrees on a cylindrical rotor. The rotor for the small machine is wound for the same number of poles as the large unit. The strength and position of these poles is determined by relative amounts of the excitation furnished by two exciters connected to the separate rotor windings.

The stator windings of the two units have the same current rating and are connected in series in opposite phase rotation as shown in Fig. 3.

The phase balancer connected in this way to an unbalanced polyphase system will, if properly adjusted, take balanced current from the system and enable the main generators to deliver balanced currents. This machine will automatically and almost instantly balance any single-phase load, at any power-factor, on any phase, provided the net unbalancing is within the capacity of the machine. It is well adapted to cases where a large single-phase load is taken from polyphase generators for traction purposes. For example, the Philadelphia Electric Co. furnishes single-phase power to the Paoli Division of the Pennsylvania R.R. The outputs of the polyphase generators are balanced by two 5000 kv-a. phase balancers.

The currents taken by a phase balancer can be resolved into "synchronous" and "inverse" components. The synchronous components have the same phase rotation as the bus-bar voltages and are required to keep the machine turning. The inverse components have a phase rotation opposite that of the bus-bar voltages, and are responsible for the balancing action.

It is well known that the addition of an unbalanced polyphase load to a

Fig. 2.

Fig. 3.

balanced polyphase load of inverse phase rotation results in a balanced polyphase load. With respect to the synchronous component of the current the large unit acts like a synchronous motor. By proper excitation the synchronous component can be made small and of negligible value compared to the inverse component. With respect to the inverse component of the current the large unit acts like a motor generator. That is motor and generator action takes place in the same machine. The large unit of the phase balancer with inverse currents flowing through it serves as a medium for transferring power from the under-loaded phases of the system to those which are overloaded. The net power input to the phase balancer due to the inverse currents is zero.

Inverse currents flowing through the armature of an ordinary synchronous motor would encounter considerable impedance. To reduce this impedance the large unit is equipped with a heavy squirrel cage on the rotor. The small unit assists in the circulation of the inverse currents through the balancer. In fact the e.m.f. generated by this unit overcomes the total impedance drop in the balancer due to these currents. This drop is small compared with the supply voltage, and accounts for the lower voltage rating and smaller capacity of the small unit.

**Value and Phase Position of Currents in Balancer.**—The magnitude and phase position of the inverse currents required to balance an unbalanced polyphase system depends on the magnitude of the unbalancing. If  $I_{f1}$  and  $I_{f2}$  represent the feeder currents in two of the feeders in Fig. 3, the value of inverse current required to balance the system, in vector notation, is:

$$I = \frac{-j\rho^2 I_{f1} + j I_{f2}}{\sqrt{3}}$$

$$\rho = \left( -\frac{1}{2} + j \frac{\sqrt{3}}{2} \right)$$

where

The vector diagram showing the relation between the supply voltages, feeder currents and inverse currents is given in Fig. 4.

The value of the inverse current taken by the balancer is also equal to  $\frac{E_1}{Z}$ , where  $E_1$  is the e.m.f. of the small unit and  $Z$  is the impedance of the balancer to the inverse currents.

If the load on the unbalanced system changes, the value and the phase position of the inverse currents are likely to change. It is evident that automatic regulators in the field of the small unit must not only regulate the magnitude of the induced e.m.f., but also its phase position with respect to the bus-bar voltages. The magnitude of the e.m.f. of the small unit is determined by the current in the rotor (field) windings, and the phase position of the e.m.f. is determined by relative values of the currents in these windings. The entire action of the small unit is controlled by two special voltage regulators. The regulators in the Philadelphia Elec-

Fig. 4.

tric installation each control a 1.6 kw. exciter and each small exciter controls a 50 kw. exciter.

The phase balancer is comparatively easy to operate. It may be brought up to speed by induction motor action. When started in this way a special switch must be provided to change the connection between the machines, so they will have the same phase rotation, and a proper starting resistance must be inserted in the rotor of the small unit.

The phase balancer may be installed in the power house or placed anywhere along the line. A phase balancer when installed should be protected from short circuits by suitable relays and circuit breakers. The impedance of a phase balancer to inverse currents is very small and a short circuit on one of its phases might ruin an unprotected machine.

**Rating, Dimensions and Weight of the Phase Balancers of Philadelphia Electric Co.**—Large unit 5000 kv-a. 6-pole, 13,200-volt, 3-phase, 25-cycle, 219 amperes.

Small unit 550 kv-a., 6-pole, 840-volt, 3-phase, 25-cycle, 819 amperes.

One of these balancers will balance 5000 kv-a. continuously, 6000 kv-a. for one hour, and 12,000 kv-a. for 5 minutes.

Weight of complete set 172,660 pounds.

Overall dimensions, 20 feet 9 inches by 12 feet 2 inches by 10 feet 1 inch high.

**COMPARISON OF METHODS FOR OBTAINING SINGLE-PHASE POWER.**—A power company furnishing single-phase power to its customers can do it in the following ways:

1. By a single-phase alternator driven by a steam turbine.
2. By a single-phase alternator driven by an induction motor.
3. By a phase converter connected to a polyphase supply.
4. By taking single-phase directly from the bus-bars of a polyphase system and balancing the generator outputs with a phase balancer.

Method 1 is reliable, but not very economical, because it is an established fact that it is cheaper to generate polyphase power than single-phase power. Method 2 has the disadvantage that the single-phase system is not independent of the polyphase system. Method 3 is good where the load is sufficient to permit the purchase of the converter. This method does not enable power-factor correction. Method 4 is most flexible, because the single-phase load can be taken from any phase. With this method power-factor correction is possible, but has the disadvantage of requiring expensive regulating apparatus.

Rev., 1913, p. 962; *The Norfolk and Western Electrification*, Elec. Ry. Jour., 1915, p. 1058.

**PHOTOMETRIC QUANTITIES.**—(See also *Illumination, Laws of; Photometry; Vision, Laws of.*) The names and sense of the common photometric units are conventional, though a uniform value of the basic unit of the system, viz., the international candle, was established in 1909 by the national standards laboratories of Great Britain, France and the United States. The standard unit in Germany is the Hefner unit, but the relation that 1 Hefner unit equals 0.9 international candle was officially recognized. The terminology and definitions that follow are in agreement with those recognized by the Geneva Congress in 1896 and the proposals made by the Committee on Nomenclature and Standards of the Illuminating Engineering Society in 1912 (*Trans. Ill. Eng. Soc., Vol. 7, p. 723. See also Standardization Rules of the A.I.E.E.*)

**LIGHT FLUX** is a measure of the rate of flow of light from a luminous body. It is not identical with the flow of radiant energy but is an evaluation of radiation in terms of the corresponding light sensation. Light flux is proportional to two factors, power radiated and a stimulus coefficient  $K_\lambda$ . The stimulus coefficient varies with the wave-length of radiation as shown in Fig. 1 in the article on *Vision, Laws of.* (See also *Phil. Mag., Vol. 24, p. 853.*)

**Lumen.**—The lumen, or unit of light flux, denotes the light radiating within one steradian from a source having a uniform luminous intensity of one candle. The steradian, or unit solid angle, is the angular space subtended at the center of a sphere by a portion of its surface equal to its radius squared. An entire sphere includes 12.5664 steradians and a hemisphere 6.2832 steradians. The symbol for luminous flux is  $F$ , that for luminous intensity  $I$ , and that for steradians  $\omega$ . The following relations hold:

Flux in any solid angle,	$F = \int I d\omega;$
Total flux from source,	$F_s = 12.5664 I_m s;$
Flux in lower hemisphere,	$F_{lh} = 6.2832 I_m lh;$
Flux in upper hemisphere,	$F_{uh} = 6.2832 I_m uh;$
Flux in any zone	$F_z = \omega_z I_m z;$

where the  $F$ 's have the designations given in the following paragraph.

**LUMINOUS INTENSITY**, commonly termed candle-power, denotes the solid angular density of light flux emitted in the direction considered, or

$$I = \frac{dF}{d\omega}.$$

Although luminous intensity refers in the strict sense to a single direction, mean intensities within certain limits are widely used. The following designations are employed in this article and also the articles on *Illumination, Laws of, and Photometry.*

Mean horizontal intensity,	$I_h.$
Mean spherical intensity,	$I_s.$
Mean zonal intensity,	$I_m z.$
Mean upper hemispherical intensity,	$I_m uh.$
Mean lower hemispherical intensity,	$I_m lh.$

**International Candle.**—The international candle is the official unit of luminous intensity in France, Great Britain and the United States. The Hefner unit, which is standard in Germany equals 0.9 international candle. For further discussion of photometric standards see *Photometry.*

**Distribution Curves.**—The luminous intensities at various angles about a light source are commonly represented by polar curves of horizontal and vertical

distribution. Caution should be observed in interpreting such curves. The mean horizontal intensity is equal to the mean polar radius of the curve of horizontal distribution. The mean polar radius and the inclosed area of the curve of mean vertical distribution are entirely lacking in significance. For methods of computing mean intensities from vertical distribution curves, see *Illumination, Laws of*.

**Spherical Reduction Factor.** — This factor is the ratio of the mean spherical intensity of an illuminant to its mean horizontal intensity.

**ILLUMINATION** denotes the density of light flux intercepted by a surface or traversing an area in space. The unit of illumination corresponds to unit flux per unit area and is commonly one lumen per square foot, or foot-candle. The metric unit of illumination is the meter-candle, or lumen per square meter, sometimes called the "lux." Based on a suggestion by Blondel, the unit of one lumen per square centimeter is designated by the title "phot." One foot-candle is 10.764 meter-candles and one meter-candle is 0.0929 foot-candle.

For methods of measuring illumination see *Photometry*; for the calculation of illumination, see *Illumination, Laws of*; for values of illumination required for various purposes, see *Vision, Laws of*.

#### INTRINSIC BRILLIANCY OF COMMON ILLUMINANTS

Illuminant	Candles per sq. in.	Candles per sq. cm.
Crater, carbon arc.....	84,000	13,000
Magnetite arc.....	4,000	620
Nernst glower.....	3,010	470
Incandescent electric lamps:		
Tungsten, 1.25 watts per c-p.....	1,060	164
Graphitized carbon, 2.5 watts per c-p.....	750	120
Tantalum, 2 watts per c-p.....	580	90
Carbon, 3.1 watts per c-p.....	485	75
Carbon, 3.5 watts per c-p.....	400	63
Acetylene flame, 1-foot burner.....	53	8.2
Acetylene flame, 0.25-foot burner.....	33	5.1
Welsbach mantle.....	31	4.8
Welsbach mantle, mesh.....	56	8.7
Mercury arc.....	14.9	2.3
Kerosene flame.....	9.0	1.4
Gas flame.....	2.7	0.4
Frosted tungsten lamp, tip.....	1.67	0.26
Frosted tungsten lamp, side.....	6.0	0.93

**BRIGHTNESS OR INTRINSIC BRILLIANCY** is the luminous intensity per unit area of a surface projected on a plane normal to the line of sight. It is measured in candles per square inch or per square centimeter of projected area. Let  $b$  denote surface brightness,  $S$  the area and  $\theta$  the angle between the normal to the surface and the line of sight, then

$$b = \frac{dI}{dS \cos \theta}$$

The specific luminous radiation is closely akin to surface brightness as it denotes the flux emitted per unit area. If the emission agrees with the cosine

law the specific luminous radiation  $E'$  and the surface brightness normal to the surface  $b_0$  bear the relation

$$E' = \pi b_0$$

The brightness of illuminated surfaces is conveniently expressed in lumens emitted per square foot, but this should be clearly distinguished from illumination, or lumens received per square foot.

Mean values of brightness or brilliancy of various illuminants are given in the preceding table (*Ives and Luckeish, Elec. W., Vol. 57*).

The presence in the field of view of illuminants of high brilliancy depresses to a marked degree the sensibility and acuity of vision. The upper limit of brightness consistent with best vision has been variously estimated between 4 and 7.5 candles per square inch. (*See Glare in article on Vision, Laws of.*) For method of measurement of surface brightness see Ives and Luckeish, *ref. cit.*

**REFLECTION OF LIGHT.** — Reflection is regular or diffuse according as the reflector is a polished surface or a matte. Regular reflection is characterized by equal angles of incidence and reflection, the formation of images and the invisibility of the reflecting surface. Diffuse reflection scatters light in all directions, produces no images and renders the reflecting surface luminous. The intensity of light reflected by a perfect matt surface varies in proportion to the cosine of the angle of departure from the normal, and the total flux reflected equals  $\pi$  times the normal intensity. However, some regular reflection always accompanies diffuse reflection and these laws can be applied only approximately. Fair diffusing plates can be prepared from barium sulphate, magnesium oxide or other white materials of extremely fine and even grain. Opal glass with both surfaces carefully depolished is fairly satisfactory for diffuse reflection and transmission of light. Wall coverings of paper, plaster, fabric, paint and kalsomine deviate considerably from the cosine law of diffusion and its corollary and caution must be observed invariably in applying these laws to calculations of illumination. All materials not white, gray or black are selective and vary in their reflecting power with the spectral composition of the light received.

The following approximate values of reflection factors have been collected from various sources and are useful in calculations dealing with reflected light:

Reflector	Factors	Reflectors	Factors
Polished silver.....	0.93	Orange yellow paper.....	0.34
Silvered mirror.....	0.80	Light green paper.....	0.25
White blotting paper.....	0.80	Light pink paper.....	0.25
White bond paper.....	0.75	Light blue paper.....	0.18
White kalsomine.....	0.75	Medium blue paper.....	0.12
Flat white paint.....	0.66	Dull green paper.....	0.08
Chrome-yellow paper.....	0.62	Light red paper.....	0.10
Cream paper.....	0.56	Medium red paper.....	0.08
Flat cream paint.....	0.53	Medium brown paper.....	0.08
Flat ivory paint.....	0.50	Deep red paper.....	0.06
Light buff paper.....	0.45		

The above values refer to light having the spectrum of commercial incandescent illuminants. In general flat paints are slightly below papers of the same tone in reflecting power, whereas glossy paints exceed papers by 0.10 to 0.15 on account of regular reflection.

For further information on brightness values and on the percents of reflected

light from various surfaces see "Principles of Interior Illumination" by Cravath, Harrison and Pierce, and "Modern Lighting Accessories," by W. F. Little, *Illuminating Engineering Practice*, 1916 Lectures, I. E. S.—U. P.

A device for the measurement of diffuse reflection factor applying to matte surfaces which follow Lambert's law fairly closely, is described by Nutting, *Trans. Ill. Eng. Soc.*, Vol. 7, p. 412. The more satisfactory method however, is that in which the integrating sphere is used.

**TRANSMISSION OF LIGHT.**—Transmitting medias possess qualities quite analogous to reflecting surfaces with respect to regular and diffuse transmission and selective absorption depending on color. The absorption of light in the varieties of glassware most used in the lighting art is approximately as follows (see *Trans. Ill. Eng. Soc.*, Vol. 6, p. 98):

Kind of glass	Absorption in per cent	Kind of glass	Absorption in per cent
Clear .....	5-12	Ground.....	20-30
Light sand blast.....	10-20	Medium opalescent.....	25-40
Alabaster.....	10-20	Heavy opalescent.....	30-60
Canary .....	15-20	Flame .....	30-60
Light blue alabaster.....	15-25	Signal green.....	80-90
Heavy blue alabaster.....	15-30	Ruby.....	85-90
Ribbed.....	15-30	Cobalt blue.....	90-95
Opaline.....	15-40		

It should be remembered in interpreting the values in this Table, that the absorption percentages are, in reality, 100 per cent less the transmission, which in itself, does not represent true absorption, but loss by reflection and absorption taken together. For example, the true absorption of clear glass is probably in the neighborhood of 1 per cent or less, depending upon its thickness, but losses take place also by reflections of the incident light away from the surface, which make the apparent absorption percentages higher, as in the above table.

E., *Illumination and Photometry*. Numerous papers in *Trans. Ill. Eng. Soc.*, *Bull. Bur. Stand.*, and *Elec. World*; also *Bibliography* in the article on *Photometry*.

**PHOTOMETRY.** — (See also *Illumination, Laws of; Vision, Laws of; Definitions of quantities and symbols see Photometric Quantities.*) Photometry is the science of light measurement. Its chief aspects are the determination of (a) the intensity of light sources in definite directions, (b) mean vertical light distribution, (c) the mean intensity and light flux emitted within specified limits of distribution, (d) the illumination of surfaces, (e) the reflecting properties of surfaces and (f) the analysis of the color of light. Its methods are essentially visual and consist in equating the brightness of two diffusing surfaces. As an instrument of physical measurement the eye lacks precision as an estimating device, but serves well in the judgment of equality. Photometric devices are of four general types, according to the method of comparison employed, viz. (1) by equality of brightness of two surfaces visible simultaneously, (2) by equality of contrast between two pairs of surfaces differing slightly in brightness, (3) by the disappearance of flicker when two surfaces are viewed in rapid alternation, and (4) by acuity of vision. The latter process does not admit of precision and is used only for rough comparisons.

**Methods of Obtaining Photometric Balance.** — The methods of obtaining photometric balance are: (1) varying the distance of one or both light sources from the surfaces compared, according to the law of inverse squares (see *Illumination, Laws of*); (2) varying the angle of incidence of light according to the cosine law (*ibid*); (3) varying the proportion of light received by means of a sector disk or slit and collimator; and (4) by means of the Nicol prism. In cases (1) and (2), given two diffusing surfaces illuminated to equal brightness  $b$  by respective light sources of intensities  $I_1$  and  $I_2$ ; the reflection or transmission coefficients of the surfaces as  $K_1$  and  $K_2$ ; the angles of incidence as  $\alpha_1$  and  $\alpha_2$ ; and the distances from the light sources  $d_1$  and  $d_2$  respectively; then  $\alpha_1 = \alpha_2$  and  $K_1 = K_2$  and  $I_2$  is the known intensity of a standard lamp,

$$I_1 = \frac{I_2 d_1^2}{d_2^2}.$$

If  $\alpha_1$  and  $\alpha_2$  or  $K_1$  and  $K_2$  differ slightly, a sensibly correct result is obtained by interchanging the light sources for half the observations and using the mean distances in the inverse square relation.

**STANDARD LAMPS.** — A primary standard possesses two essential qualities, definiteness and reproducibility from specifications. None of the existing standards of luminous intensity meet both requirements. Of the flame standards, the Hefner and pentane lamps are approximately reproducible and fairly definite with standard atmospheric conditions and fuel. The incandescent electric lamp is capable of definite calibration, but is not strictly reproducible. The present unit of luminous intensity, the international candle, is derived from the mean intensity of a group of incandescent electric lamps maintained by the U. S. Bureau of Standards, in cooperation with similar custodians in France and Great Britain.

**Hefner Standard.** — The Hefner standard which is the official standard of Germany and which has been extensively used in the United States, is a wick lamp burning amyl acetate of definitely specified chemical and physical properties. Its standard intensity is 0.9 international candle. Expressing the actual intensity as  $I$ , corrections for various atmospheric conditions are made as follows:

For variations from the standard flame height of 40 mm.

$$I = 1 + 0.025 (h - 40) \text{ or } I = 1 - 0.034 (40 - h)$$

heights greater or less than 40 mm. respectively, where  $h$  is the flame height in millimeters. For barometric variations

$$I = 1 + 0.00011 (b - 760),$$

where  $b$  is the barometric pressure in millimeters. \*For atmospheric humidity

$$I = 1.049 - 0.0055 x,$$

where  $x$  signifies the liters of water vapor per cubic meter of air at 760 mm. and  $e$  from  $\text{CO}_2$ .

For atmospheric vitiation by  $\text{CO}_2$

$$I = 1.012 - 0.0072 y,$$

where  $y$  signifies the liters of  $\text{CO}_2$  per cubic meter of dry air.

The objections to the Hefner standard are its low intensity, its reddish color, its flabby flame and its sensitiveness to variation in flame height. The element of uncertainty associated with it is at best not less than 2 per cent.

**Pentane Standard.** — The pentane standard, as represented by the Vernor-Larcourt type, is essentially an argand burner supplied with pentane-air gas and preheated air. The fuel is formed by passing air over pentane in a saturator box subdivided by baffles. The burner is surmounted at a height of 47 mm. by a cylindrical chimney. An annular chamber surrounding the chimney supplies the interior of the flame with preheated air. The flame is shielded from drafts by a conical, blackened hood having a slit at one side through which the flame is exposed. The chimney is fitted with a mica window showing a gauge line to which the flame height is closely adjusted. Under standard atmospheric conditions, viz., a barometric pressure of 760 mm. and a humidity of 8 liters of water vapor per cubic meter of air the flame should have a horizontal intensity of 10 candles. Experience indicates, however, that it is usually less by 2 to 4 per cent and that it is desirable to calibrate the lamp against a more definite standard. Variations from the above standard atmospheric conditions may be corrected by the equation:

$$I = I_n [1 - 0.00567 (e - 8) + 0.0008 (b - 760)],$$

where  $I$  is the actual intensity,  $I_n$  the standard intensity,  $e$  the liters of water vapor per cubic meter of air and  $b$  the barometric height.

The color and intensity of the flame are convenient for practical purposes, especially for the measurement of the illuminating power of gas. An added advantage in the testing of luminous flames of all sorts resides in the fact that their intensities are affected by atmospheric variations in a manner corresponding quite closely to the changes in the pentane lamp, whereby somewhat troublesome corrections are avoided.

**Carcel Lamp.** — The Carcel lamp is the recognized standard of luminous intensity in France. It has a central-draft ring burner fitted with a wick of the light-house type burning colza oil. Its standard intensity is 9.61 international candles.

Standard candles are now discredited for all accurate work, though still used extensively in the routine testing of gas.

**Incandescent Electric-lamp Standard.** — The incandescent electric lamp is superior to all other working standards where corrections for flame luminosity due to atmospheric variations are not required. Carefully selected carbon-filament lamps aged by burning until the hot resistance is constant maintain their candle-power sensibly unchanged for a period of 10 hours or more. With the most precise photometric apparatus such lamps may be standardized

with the mean error of any single determination not exceeding 1.0 per cent.

Lamps are standardized for use in a fixed position or in rotation about a principal axis. No difference exists between the precision of the two methods. Lamps are standardized in terms of a definite voltage or current, and are incidentally calibrated for power consumption. It is desirable to standardize lamps in terms of both voltage and current for the constant can be relied upon as long as both standard conditions exist. Carbon filament lamps were formerly widely used as standards. The Mazda B lamp is even more satisfactory from the standpoint of stability than the carbon, and the Mazda C lamps are now used with very good results. It is best to keep on hand a group of well-seasoned lamps of all colors and to select from these the most appropriate working standard for comparison against the primary carbon standard, so that the latter is used only

Other Standards have had a very limited use. Among these are the acetylene flame; the Methven screen, which is essentially a sharply-defined image of a luminous gas flame, calibrated against a primary standard; the Hefner lamp, which is a kerosene lamp of the student type having a definite portion of its flame exposed by a screen. The utility of these standards is limited to the routine testing of gas.

**Relations of Luminous Standards.** — The relative intensities of the various standards under standard conditions are given in the following table:

	International candle	Hefner	10-c-p. pentane	Carcel	Bougie
International candle.....	1.00	1.11	0.10	0.104	1.00
Hefner.....	0.90	1.00	0.09	0.0936	0.90
10-c-p. pentane.....	10.00	11.11	1.00	1.04	10.00
Carcel.....	9.61	10.66	0.96	1.00	9.61
Bougie decimale.....	1.00	1.11	0.10	0.104	1.00
English candle.....	1.04	1.154	0.104	1.00	1.04
German candle.....	1.055	1.17	0.105	0.109	1.055

**SIGHT BOXES.** — A photometric sight box consists of two parallel plates of glass or other transparent material, with various faces and accessories to facilitate the comparison of brightness. The following are of greatest utility.

**Bunsen Sight Box.** — The bunsen screen is a disk of white material, with a well-defined region of which is made translucent by impregnation with a substance or other material. The disk is set transversely in a sight box, as shown on the plan in Fig. 1. Light from the sources enters the apertures *A-A*, and falls normally on the disk surface. Two mirrors *M<sub>1</sub>* and *M<sub>2</sub>* enable both sides of the disk to be viewed at the same time. The opaque portion of the disk reflects diffusely, while the translucent portion partially reflects and partially transmits the light received. Balance exists when the two sides of the disk appear alike. If the two sides appear alike in color and the absorption of both regions of the disk is equal, the primary disappears and both sides appear uniformly bright. With unequal absorption, balance exists when equal contrast exist between the translucent regions on both sides of the disk. The contrast principle is of distinct advantage with slight color differences. The sensitivity depends largely on the definition of the boundary of the impregnated

**Leeson Disk.** — This is a useful modification of the Bunsen type built up pasting opaque paper disks with accurately matched star-shaped apertures the two sides of disk of translucent paper. By a careful selection of the materials the disk may be made to embody either the equality-of-brightness or equality-of-contrast principle. The paper used should agree closely with cosine law of diffusion. The later types of Leeson disks are not pasted, but two outer thin sheets are pressed tightly against the centre opaque sheet of glass. This makes a very sensitive and satisfactory type of disk.

Fig. 1.

Fig. 2.

Fig. 3.

**Lummer-Brodhun Sight Box.** — The plan of this box is shown in Fig. 2. An opaque diffusely-reflecting screen  $S$  receives light from the sources to be compared and reflects it along the paths indicated by aid of the mirrors  $M-M$  and the prisms  $P_1-P_2$ . The prisms present to the eye a composite field in which the brightness of the two sides of  $S$  can be conveniently compared. Fig. 2 also shows the arrangement for equality-of-brightness working. The prisms are in optical contact over an elliptical portion of their hypotenusal faces, and the remainder of one is cut away. The central portion of the field is illuminated by direct transmission through the contact area, the outer portion by total reflection from the face of the uncut prism.

For equality-of-contrast working the arrangement of the prisms is as shown in Fig. 3. The hypotenusal face of  $P_2$  is recessed over the area shaded in (B). The face of  $P_1$  is plane. Two thin glass absorbing strips  $a_1$  and  $a_2$  are set before the faces of  $P_1$  and  $P_2$  as shown in the plan (A). By tracing the several paths indicated it is seen that the field has the appearance of (B) and that the regions shaded are darkened by the absorption of light in  $a_1$  and  $a_2$ . In a state of balance  $b$  and  $d$  appear equally bright and  $c$  and  $e$  equally dark in contrast. The degree of contrast created by  $a_1$  and  $a_2$  is ordinarily about 8 per cent, this being in accordance with Fresnel's formula. A method of securing less than 8 per cent would be to place a sheet of glass over the entire side of the cube and to increase the thickness of the glass (either by cementing two pieces together, or by grinding) over the contrast field. A degree of contrast as low as 2 per cent has been secured by this method, which has been found satisfactory. Accuracy of adjustment and cleanliness of all parts are essential in photometers of the Lummer-Brodhun type.

**Comparison of Bunsen, Leeson, and Lummer-Brodhun Boxes.** — Bunsen, Leeson and Lummer-Brodhun sight boxes should be so mounted as to admit the complete reversal of the optical system about its axis of symmetry in order that optical asymmetry may be corrected as explained above. The Bunsen and Leeson types are binocular and therefore less fatiguing in a long

series of observations than the monocular Lummer-Brodhun more, they are the more readily balanced with slightly flicker. Lummer-Brodhun contrast type excels in sensitiveness and gives steady lights of equal and slightly dissimilar color.

It may be stated, however, that the complete reversal system in practical photometry, with the exception of measurements where the substitution method cannot be readily followed. In practical operators of photometric equipment, there is relative between steady and flickering light for the different types of ph

**Flicker Photometer.**—The flicker photometer affords the means of comparing light sources of distinctly unlike color. alternately illuminated by two such sources displays a flicker which may be due to color dissimilarity or to difference in brightness. At a moderate rate of alternation the color sensations blend and the absence of flicker is a true indication of equal brightness, as concluded by Ives, who recommends the following conditions as suited for precision: (a) a field illumination of 25 meter-candles; (b) a photometer field about 2 in. in diameter; and (c) a background field about 25 in. in diameter. The photometric field and about equal to it in brightness. The flicker, though not essential to precision, is an aid to comfort.

Reference should also be made to the work done with the flicker photometer, which has a very ingenious eyepiece, made by attaching to the contrast type of Lummer-Brodhun photometer contrast glasses removed. The approximate specifications are as follows:

The flicker field shall subtend an angle of approximately 2° from the eyepiece. The field shall have an effective brightness for all loss of lens absorption and reflection of  $2\frac{1}{2}$  millilamberts, and the flicker field is to be surrounded by an illuminated field of approximately the same brightness, the pupil aperture to be 5 millilamberts in diameter.

**Bechstein Flicker Photometer** (Fig. 4).—This photometer employs a train of lens and prism oscillating before a fixed diffusing wedge. The field of view consists of a circle and ring, alternately illuminated by the respective sides of the wedge as the lens system revolves. The highest sensitiveness exists at the lowest speed at which the flicker can be made to disappear.

**Wild Flicker Photometer** (Fig. 5).—The Wild flicker photometer is the simplest of this class. It consists of a disk *D* of white diffusing paper, one half of which is made of a material of high absorption. This disk is revolved about an axis slightly above the path of light and a mirror *M* reflects one side of the disk to the sight tube *T*. A high degree of precision is claimed by Wild for this device.

**Color-equalizing Filters.**—The simplest method of comparison for lights of dissimilar color is to employ a Lummer-Brodhun photometer in connection with a set of glass filters of graded tints, selecting one which renders the light of the standard lamp equal in color to that of the lamp under measurement. The absorption of each screen for the light of the standard lamp must be determined by means of the flicker photometer, but the inconvenience of this instrument is limited to the process of calibration.

**Sector Disk.**—The sector disk affords a most convenient method

the intensity of the light received from an illuminant on the photometric screen. It consists of one or more disks with sector apertures revolving on a common axis. By advancing one disk with respect to the other the net aperture may be altered at will. By Talbot's law the intensity of transmitted to incident light equals the ratio of the total angular opening to 360 degrees. The sector disk has the advantage over other absorbing media in that it is adjustable, is not affected by time, and is independent of color.

**Photometric Bar.**—The devices above described are best suited for use in connection with a photometric bar or bench, which should be level and straight, and preferably greater than 100 inches in length. A plan of the layout is shown in Fig. 6. For convenience the sight box and at least one of the lamps should be mounted on movable carriages. The bench should be provided with a series of screens *D* of dead black material having graded apertures along the photometric axis and with solid screens at the ends. These screens should completely occlude from the sight box all extraneous light, and should protect the eye of the operator from the direct light of the lamps. If these conditions are met the photometric room need not be blackened. The sight box should have a dark background, however, and all light in the room should be well diffused. The bar should be provided with a scale of equal divisions and a scale reading directly the ratio of the inverse squares of the distances from the ends of the bar. For use with a standard lamp of definite value in a fixed position a direct reading scale of candle-power is readily obtained from the ratio scale.

Fig. 6.

**Connections for Testing Incandescent Electric Lamps.**—In testing incandescent electric lamps the effects of voltage fluctuation must be reduced to a minimum. A storage battery or special generator of very close regulation should be employed if possible. In practically all cases double circuit photometers are used, and the simpler the wiring the better.

**Manipulation of Photometric Bar.**—Direct comparison between the test lamp and the standard may be made with the two in fixed positions by moving the sight box to a point of balance. In this case half the observations should be made with the sight box reversed. For the substitution method a fixed socket is provided at one end of the scale. The second socket and the sight box are on movable carriages coupled at a fixed distance. A well-seasoned lamp is placed in the movable socket and adjusted to a suitable voltage, which is subsequently held constant. The standard lamp is placed in the fixed socket and a balance secured by setting the movable carriages. The standard lamp is then removed and test lamps substituted in turn, a balance point being observed for each. The intensity of each test lamp equals that of the standard multiplied by the direct ratio of the squares of their distances from the screen at the times of balance. Reversals are unnecessary in the substitution method. The comparison lamp should be checked against the standard at intervals.

For further information on the *substitution method* see Wickenden, W. E., *Illumination and Photometry*, N. Y., pages 56 and 57.

**MEASUREMENT OF PHOTOMETRIC DISTRIBUTION.**—Mean horizontal intensity is measured with the lamp rotating about its vertical axis. Special mountings, driven by motor or hand wheel, are provided for this purpose. Rotators are made universal by provision for the turning of the lamp by definite angular steps about its luminous center in a vertical plane including the photometric axis. The speed of horizontal rotation should be only sufficient to equalize differences in intensity.

**Mirror Rotators.**—In testing the light distribution of arcs, heavy reflector

units, gas lamps, etc., which must remain in an upright position, mirrors rotated are generally employed to direct the light from any desired vertical angle toward the photometer. A three-mirror device is shown schematically in Fig. 7. A two-mirror arrangement could also be used. In either case the lamp remains stationary, or is revolved about its vertical axis only, while the mirror system is turned by steps about the photometric axis. Numerous other devices for this purpose are described in standard works on photometry.

Fig. 7.

**INTEGRATING PHOTOMETERS.** — An integrating photometer enables the measurement of mean spherical or mean hemispherical intensity, or of total flux of light from an illuminant, to be made by a single observation.

**Sphere Photometry.** — Since the sphere is practically the standard method of photometry, the following notes are important in their relation to the practical testing by this method. One type of sphere known as the Ulbricht Integrating Sphere is shown in Fig. 8, in which it will be seen that the apparatus consists of a hollow sphere whose inner surface is coated with a white material giving approximately true diffusion. In the following notes on sphere photometry, the type developed by the Electrical Testing Laboratories will be referred to.

Fig. 8.

**Sphere Theory.** — The theory of the sphere photometer is that the illumination on any part of its interior surface when a lighted lamp is introduced into it at any location is made up of two parts: (a) the direct light from the lamp; and (b) the light diffusely reflected from all parts of the sphere wall which is proportional to the total flux. It is only necessary therefore to measure (b) and this may be done by putting translucent milk glass in a window contiguous with the inner wall of the sphere. (a) is screened off from the window by an opaque screen. Another method to measure (b) is by viewing directly as the test surface a portion of the inner surface of the sphere.

**Equipment.** — **The Photometer.** — When translucent windows are used, the photometer head may be arranged so that the sphere window forms one side of the photometer field and the comparison lamp window the other side.

In the selection of a comparison lamp it is desirable that its construction should be as nearly perfect as possible with the filament lying in a single plane, preferably without an anchor support or with supports such that variable cooling may be obviated.

In connection with the screen practice has shown that the best position for the screen inside the sphere is two-thirds the distance from the lamp to the window. This screen should be the smallest that will adequately screen the largest lamp.

The lumen scale is computed with relation to its location from the comparison lamp window. This position is fixed and must not be changed.

The slide aperture used in conjunction with the 40-inch sphere as developed by the Electrical Testing Laboratories is proportioned to the scale and is made adjustable.

**Photometer Calibration.** — **Slide Apertures.** — When the photometer is calibrated the apertures are adjusted so that a continuous range is given for the measurement of lamps from 10 to 1000 watts. The size of the lamp bulb and base are likely to introduce discrepancies, however, which prevent the use of this range in its entirety with one setting.

As far as color is concerned, for the photometry of Mazda B lamps the comparison lamp should be operated at such a temperature or efficiency as to produce a color match with the average size of lamp. In most cases the sphere coating is slightly selective, absorbing more light toward the blue end of the spectrum, therefore the comparison lamp may be operated at a somewhat lower temperature than the test lamp and still give a good color match and prolong the life of the comparison lamp.

When the color match has been secured, the intensity may be adjusted by varying the glass either in the comparison lamp window, sphere window or both. All the glasses should be non-selective in so far as practicable. The brightness of the field for best sensibility should be equal to or slightly brighter than the immediate surroundings. In a dark room the average should not be less than 5 millilamberts or the equivalent of three foot-candles on a white blotter.

As to filters for the photometry of Mazda C lamps, or other lamps where a color difference is involved, glass light filters may be used to correct the color of the test lamp to that of the comparison lamp or vice versa. Theoretically the color of the comparison lamp should remain unchanged and the filter should be placed between it and the window. Under these conditions the transmission of the filter will remain fixed, regardless of the color of the test lamp. However, as a practical matter, it is more convenient to change the color of the light from the test lamp, because Mazda C lamps are usually high in candle-power to begin with, and the filter reduces the intensity of the test surface and also changes the color. Therefore it is preferable to allow the color of the comparison lamp to remain unchanged as the transmission factor of the filter will remain constant regardless of the color of the test lamp. The filter should be placed between the prism and the window and not between the lamp and the window for the reason that light travels more rapidly through air than through glass. Should it be placed between the lamp and window it would be equivalent to increasing the distance between the lamp window thus introducing error. Also the distance between the filter and window should be sufficient to reduce the inter-reflection to a negligible quantity, two inches is usually sufficient. However, this applies only when the transmission of the filter has been determined independent of the photometer, namely, not calibrated in place in the photometer.

Regarding alignment, all optical parts, track and comparison lamp carriage should be kept in alignment. A non-uniform field is an indication of poor alignment or soiled test plate. The prism is screened with a small diaphragm not slightly larger than the field so that a small shift in the prism may cause a dark shadow on the field.

In selecting a coating for the sphere, a number of points must be borne in mind. The surface must have good diffusing qualities; it must be reasonably non-selective in its absorption; it must have a relatively high reflection factor and it must be permanent in color. These qualifications necessitate a pure white pigment with a colorless binder. A number of experiments have been conducted using zinc oxide, lead oxide, magnesium carbonate and the like, with binders of cellulose, sodium silicate, white shellac, and the like. The Bureau of Standards has developed a formula for a coating which has been found very satisfactory though difficult to make and apply. For all practical purposes a good grade of calcimine carefully applied with a wide camel's hair brush makes a reasonably good coating easily applied and always available. A little Prussian blue mixed with the calcimine will somewhat lower its reflection factor but will make it less selective.

**Possible Reasons for Erroneous Results.** — Bulb absorption. — The substitution method should be adhered to even more rigidly in the sphere

than on the bar photometer. A discolored or tinted bulb may absorb some of the reflected light which it intercepts thus lowering the photometer setting. This is not an error though it may render an erroneous result. To photometer a lamp of this character, if the substitution method cannot be applied, a checking lamp may be introduced into the sphere and measured, first alone and second with the discolored or tinted lamp cold. The difference in reading represents the per cent of the reflected light absorbed by the latter. In making these measurements, the direct light should be screened off from the discolored or tinted lamp. A simple method is to place the two base to base with the test lamp in the regular socket.

A change in the size or shape of a bulb or base of the test lamp may give a wrong reading. The proper standard lamp or the use of the method described for measuring tinted lamps may be used with good results.

As to the coating, it should be kept in mind that the inside surface of the sphere under the best of conditions will collect dust and this accumulation tends to settle in the lower half of the sphere with denser accumulation in the bottom of the sphere. This may change the character of the light distribution between standard lamps and the lamps tested and give fallacious results. The solution of the difficulty is properly to maintain the surface by frequent cleanings or recoatings.

Undue voltage drop in the lamp socket contact may give rise to incorrect results. A double center contact should be employed and the shell of the socket kept clean.

Screening. — Photometer. — Stray light reaching the test plate either from an extraneous source or reflected from the photometer lamp may give an incorrect answer. To test for stray light, the test plate should be removed and the eye or a mirror substituted in order to see if light from any source other than the comparison lamp may reach the window. A perfectly protected test plate should not be visible from any position from which light may come other than the comparison lamp.

In screening the sphere it must be remembered that it is only the reflected and not the direct light that is to be measured, therefore, it is well to be certain that the screen in the sphere is performing its function. A hole should be provided in the sphere so that the shadow cast by this screen may be seen when the test lamp is in place.

An improperly located scale will give fallacious results but it is easily discovered and remedied. A gauge with a forked end to span the comparison lamp and reach the comparison lamp window should be a part of the equipment of every sphere.

Extension of Range. — If lamps are to be tested that are beyond the limits of the scale, the range may be extended in two ways. If the range is to be changed temporarily and but slightly, the comparison lamp voltage may be raised or lowered until the lamps can be read on the scale. Standard lamps are then read and the factor which is obtained, applied. The range may be considerably extended by changing the glass in the comparison lamp window. If the brightness of this window is to be decreased, one thickness of denser opal glass (or several thicknesses) may be employed. On the other hand, if it is to be increased, several thicknesses of ground glass may be substituted. In any case, the distance from the scale to the window should be measured from the first diffusing surface.

Verification. — A slight dust accumulation on the sphere window may cause the light emitted through the slide apertures to vary. If the substitution method is not adhered to, it is necessary to verify these apertures from time to

time. This can be done by using the largest opening as standard and reading on the other scales in turn. If they are not in agreement, the substitution method should be used throughout. Simple and accurate methods of determining the position of the scale, with a moving comparison lamp, is available with this type of photometer.

**Standard Lamps.** — A very important part of the sphere equipment is a complete range of standard lamps. There should be a sufficient number of lamps to permit the use of the substitution method and the extent to which the substitution method must be followed will depend largely upon the grade of electrical instruments used.

The qualifications for a standard lamp demand that it must pass a most rigid inspection for appearance in every particular. The construction may differ considerably from the same type of commercial lamp, for instance, lamps where copper supports are employed must be so made that each clamp is tight in order to obviate a variable cooling effect. Where spring supports are used, they must be such that too much tension is not placed upon the filament, at the same time they must be tight enough to prevent locked filaments. It is hardly necessary to mention the vacuum for type B lamps and the proper treatment of the type C lamps as any slight defect will impair the constancy of the standard.

Standardization values may be relied upon only for a limited period of time, therefore, lamps should be verified every three months if they are in current use. If they are used only occasionally they may be returned less frequently. To prolong the life as much as possible without materially changing the color, lamps are standardized at slightly lower than rated efficiency. If lamps are subjected to a higher voltage than labelled it is readily seen that the life will be shortened and the standardization values changed. It is good practice, therefore, always to put resistance in the circuit when changing lamps.

**PORTABLE PHOTOMETERS.** — **Weber Photometer.** — Portable photometers exist in great variety and have for their purpose the measurement of illumination and of the intensity of light sources in place. The great majority are modifications of the Weber photometer, shown schematically in Fig. 9. This comprises two cylindrical tubes of blackened interior, one fixed and the other attached to it at right angles by means of a sleeve to allow rotation. A Lummer-Brodhun prism device is placed at the junction of their axes, and permits the brightness of two translucent glass plates  $P_1$  and  $P_2$  to be compared at the eyepiece  $E$ .  $P_1$  is illuminated by an external source  $I_1$  at a distance  $d_1$ .  $P_2$  is movable along the tube by a knurled head and is illuminated by a small standard lamp  $L$  mounted in a convenient housing. Assuming both plates to be illuminated by light incident normally at a state of balance, then

$$I_1 = \frac{I_2 T_2}{T_1} \times \frac{d_1^2}{d_2^2}$$

where  $T_1$  and  $T_2$  are the respective brightness coefficients of the two plates. A calibration for intensity measurements is readily obtained by the use of a standard lamp as  $I_1$  and by observing the scale readings  $d_2$  giving a balance with various values of  $d_1$ , keeping  $I_2$  constant.

Two methods are available for the measurement of illumination. In the first the terminal tube  $T$  is removed and a flush test plate of depolished milk glass fitted in its place. This test plate is placed in the position where the illumination is to be tested and the instrument balanced as usual.

Fig. 9.

For the second method of illumination measurement the terminal tube is removed, but the plate  $P_1$  is omitted. A large, white diffusely reflecting card is placed in the position where the illumination is to be tested and the tube pointed in its direction so that the entire cone of light entering  $T$  arises from the test tube. So long as this condition is met the inclination and distance of  $T$  is not important.

The first method is preferable where it is possible to make the attached test plate coincide with the position of the test. In the second method it is difficult to avoid interference with light which should reach the test plate.

**Sharp-Millar Photometer.** (Fig. 10).—This photometer is a modified Weber instrument which is extensively used in America. It comprises a

elongated wooden box divided into two compartments, one of which contains a fixed Lummer-Brodhun photometric cube and the other a lamp carriage movable along the box by turning a knurled head  $H$ . Observations are made at  $E$  at one side of the box. The two compartments are separated by a ground-glass window whose brightness is balanced against illumination from an outside source admitted through an elbow tube  $T$ . Stray light in the lamp compartment is screened from this window by a series of diaphragms with central apertures. The elbow tube  $T$  is fitted on a collar and may be turned to an desired inclination. At the elbow is a circular, reversible plate one side of which is a mirror for measurements of illumination and the other a white diffusing surface for measurements of candle-power. In the former case the end of the tube is fitted with a flush plate of depolished milk glass. The range of the photometer is controlled by a pair of glass absorbing screens mounted in the compartment with the Lummer-Brodhun cube. These plates are respectively of high- and low-absorbing power. They may be turned so that either one may be used to reduce the illumination of either part of the field. But one may be employed at a time. In this way a range from 0.004 foot-candle to 2000 foot-candles may be secured. In the most recent design the need of a voltmeter or ammeter to keep the standard lamp constant is obviated by a small Wheatstone bridge arrangement with a telephone receiver, whereby the lamp may be kept at constant hot resistance. The Sharp-Millar photometer may be used with a detached test plate similar to that described for the Weber photometer.

Fig. 10.

Another type of portable photometer which has come into fairly wide use is that known as the Macbeth Illuminometer. This instrument has certain features which differ from the Sharp-Millar type, although in principle the two instruments are fairly similar.

**COLORIMETRY.**—The Ives colorimeter is an instrument for tri-chromatic color analysis. (See *Vision, Laws of*.) It consists essentially of an oblong box, at one end of which are placed four slits, one clear, and the three others equipped respectively with red, green and blue screens. By means of levers the openings of the three colored slits can be altered to read by scales from 0 to 100. By rotating a wheel of lenses the three colors are mixed. The observer views a divided field, one part consisting of the mixture of the three primary colors and the other of the color to be matched as viewed through the clear slit. To make a measurement, the three colored slits are opened until white is matched, and the scales are set to read 100 for each color. Then any color matched by moving the levers can be read off in terms of the per cent of red, green and blue necessary to match white. The precision of the instrument is from 2 to 5 per cent under favorable conditions.

**ING POWER OF SURFACES.**— See section on *Reflection of*  
*article on Photometric Quantities.*

**CTIONS IN PHOTOMETRIC OBSERVATIONS.**— The eyes  
 er should be constantly shaded from bright light to maintain their  
 in a state of dark adaptation. For best photometric sensibility a  
 ation of about 2 foot-candles is desirable. At low intensities the  
 t (see *Vision, Laws of*) may prove disturbing. Should a daylight  
 e used, a field or screen brightness far in excess of 1.7 millilamberts  
 y be advisable but necessary.

on of photometric settings may often be improved by a process  
 down between points equally out of balance. Many good photo-  
 ject their first observation in a set as untrustworthy. Not more  
 ures in the result are significant.

ter bar need not be more than 18 to 20 inches in length. The  
 a large unit to the screen should not be less than about ten  
 r-all maximum dimension of the unit under test.

of electric lamps, or current, in the case of series lamps, should be  
 the most accurate device obtainable. In life tests of incandescent  
 egulation of voltage is of the utmost importance and a sensitive,  
 ulator is most desirable. In tests of illuminants in place, the  
 nt or power, or the gas consumption and pressure should be ascer-  
 rded if possible. In tests of gas illuminants the volume con-  
 d be reduced to the corresponding volume at a temperature of  
 barometric pressure of 30 inches.

**VALUE OF.**— The letter  $\pi$  is used to represent the ratio of the  
 of a circle to its diameter; it is an incommensurable quantity. Its  
 59265. . . . The value 3.1416 is sufficiently accurate for all  
 uses, and for rough calculations the value 22/7 is convenient. The  
 ors frequently occur:

1.14159	$\frac{\pi}{4} = 0.785398$	$\frac{1}{2\pi} = 0.159155$
2.28319		
3.42478	$\frac{\pi}{6} = 0.523599$	$\frac{1}{4\pi} = 0.079578$
4.56637		
5.7080	$\frac{4\pi}{3} = 4.18879$	$\pi^2 = 9.86960$
6.8496		$\pi^3 = 31.00628$
7.9912	$\frac{1}{\pi} = 0.318310$	$\sqrt[3]{\pi} = 1.77245$
9.1328		$\sqrt[3]{\pi} = 1.46459$

**PIPES AND PIPING.**—(See also *Boilers; Electrolysis of Grounded Structures; Hydraulics, Principles of; Power Stations; Valves.*) In the following table is given a list of the metals ordinarily used for steam, gas and water pipes, together with their average weight per cubic inch, their tensile strength and the expansion per 100 feet for various temperature differences. The expansions are based on data given in Gebhardt's *Steam Power Plant Engineering*.

TENSILE STRENGTH, WEIGHT AND EXPANSION OF PIPE MATERIALS

Material	Lb. per cu. in.	Tensile strength, lb. per sq. in.	Expansion (in. per 100 ft.) Temp. rise above 60° F.				
			100°	200°	300°	400°	500°
Brass, wrought	0.30	50,000	1.15	2.41	3.80	5.38	7.11
Copper, wrought	0.32	30,000	1.08	2.26	3.56	5.05	6.66
Iron, cast.....	0.26	18,000	0.72	1.50	2.38	3.36	4.44
Iron, wrought...	0.28	50,000	0.79	1.65	2.61	3.70	4.89
Lead.....	0.41	1600 to 2400	.....	.....	.....	.....	.....
Steel, mild.....	0.28	65,000	0.79	1.65	2.61	3.70	4.89

The material for steam pipe, whether high or low pressure, is now almost uniformly open-hearth steel. This may be made by the acid or basic process but Bessemer pipe or wrought-iron pipe should not be used if the best results are to be obtained. The use of Bessemer-steel pipe brings in difficulty in flanging and bending is usually uncertain at the welds. It has in its composition rather more phosphorus and sulphur than is considered good when severe strains are to be placed on the material. Wrought-iron pipe, when it can be obtained, may be very good for certain uses but it is almost impossible to flange a piece of wrought-iron pipe satisfactorily, and its use is now confined mainly to unimportant work at localities close to the place where the pipe is made. Steel pipe when used for oil or salt water is often galvanized and its thickness should be proportioned to meet the pressures in use.

Where warm water is to be distributed, cast-iron pipe has been and is the standard. Cast-iron pipe, when properly made, has proved to be the best for large and small water mains for either low or high pressures. Where the water pipe is small or where many bends are required, or where the heat and wear are excessive, bronze pipe has been substituted for cast-iron with very good results. The smaller sizes of pipe used in oiling systems are almost invariably made of brass. The use of copper pipe for steam work has been almost entirely superseded, the introduction of superheated steam with the resulting action of the high temperature on the copper rendering it unfit for such employment. There are many stations in which nothing but open-hearth steel and cast-iron piping are used and it may be noted that this practice is increasing and these materials will be the standard for the future.

**DIMENSIONS AND WEIGHT OF COMMERCIAL PIPE.**—The size of iron and steel pipes is usually specified in terms of the "nominal" inside

The actual inside diameter is usually greater than the "nominal," the difference being the greatest for small sizes. The thickness of pipe per lineal foot of a given size of pipe varies over a considerable range on account of the different processes of manufacture. Manufacturers specify that "full weight" pipe may have a variation of from 5 per cent above to 5 per cent below the nominal weight, but "merchant pipe," which is the ordinary pipe used by fitters and makers, is almost invariably from 5 to 10 per cent below the nominal weight.

When specifications for pipe, engineers should be careful to state what is desired, whether "merchant," full weight, or extra strong, and to specify the class according to the table below.

## DIMENSIONS AND WEIGHT OF CAST-IRON PIPE

Class A		Class B		Class C		Class D	
Thick-ness, in.	Lb. per ft.	Thick-ness, in.	Lb. per ft.	Thick-ness, in.	Lb. per ft.	Thick-ness, in.	Lb. per ft.

1.72	1633.4	2.22	2104.2	....	.....	....	.....

Working pressures recommended for the four classes are:

## SAFE WORKING PRESSURES, CAST-IRON PIPE

Working Pressure	A	B	C	D
per square inch.....	43	86	130	173
per foot.....	100	200	300	400

**Cast-iron Pipe.** — The dimensions and weights given above are from the catalogue of the U. S. Cast-iron Pipe and Foundry Co. (1908), and are figured on the basis of a pipe length of 12 feet, and include part of weights of standard sockets.

**Welded Pipe.** — The first table following is based on Briggs' sizes up to 10 inches, and upon the National Tube Co.'s Standard sizes (1910). Weights per foot, up to and including 15 inches inside diameter, are based upon a length of 20 feet including the coupling; weights for larger sizes are for plain end pipe.

The second table gives the dimensions of "Extra Strong" and "Extra Extra Strong" welded tubes (*National Tube Co., 1902*).

DIMENSIONS AND WEIGHT OF WELDED PIPE

Size, nominal internal diam., in.	Diameter in inches		Thickness of metal, in.	Number of threads per in.
	Actual external	Approx. internal		
1/8	0.405	0.269	0.068	27
1/4	0.540	0.364	0.088	18

**Wooden Stave Pipes** are usually built up in place. Staves of redwood, fir, yellow pine, and spruce are used. The staves range from 1¼ to 2½ inches in thickness and from 6 to 8 inches in width; these are held in place by steel bands ranging from ¾ to ¾ inch in diameter. The interior surfaces of the staves wear smoother by the action of the flowing water and do not become fouled. Stave pipes have been installed in sizes ranging from 18 to 144 inches in diameter, and for heads up to 300 feet.

**FORMULAS FOR WEIGHT, CIRCUMFERENCE, SURFACE, CONTAINED VOLUME AND SAFE PRESSURE.** — Let

- $A$  = external surface per lineal foot in square feet,  
 $C$  = external circumference in inches,  
 $D$  = internal diameter in inches,  
 $D_0$  = external diameter in inches,  
 $f$  = factor of safety,  
 $H$  = safe head in feet of water,  
 $P$  = safe pressure in pounds per square inch,  
 $S$  = tensile strength in pounds per square inch,  
 $T$  = thickness of wall in inches,  
 $V$  = volume of contents (water, steam or gas) per lineal foot in cubic feet,  
 $w$  = specific weight of metal in pounds per cubic inch,  
 $W$  = weight of metal per lineal foot in pounds.

Then

$$A = 0.262 D_0, \quad C = 3.14 D_0, \quad D_0 = D + 2T,$$

$$H = \frac{4.62 ST}{Df}, \quad P = \frac{2ST}{Df},$$

$$T = \frac{D_0 - D}{2} = \frac{DfP}{2S} = \frac{DfH}{4.62S},$$

$$V = 0.00545 D^2, \quad W = 9.42 w (D_0^2 - D^2) = 37.7 wT (D + T).$$

The values of the specific weight  $w$  and tensile strength  $S$  are given in the table at the beginning of this article. The tensile strength of riveted pipe is about 70 per cent of the tensile strength of the metal.

**JOINTS.** — Pipe joints have been a great source of trouble in the past and the various kinds and "standards" have been as many almost as there were individual engineers. For low-pressure pipe work the screwed joint with the standard pipe thread and cast-iron flanges has been and is the standard for the best work. For pressures above 100 lb., however, another type of joint should

is adopted if the best work is desired. For this purpose there has been no joint found better than the so-called Van Stone joint. This is made by flanging the end of the pipe against the outside of a steel or cast-iron flange. There are many varieties of welded flanges in which the flange is welded directly to the pipe, but these do not seem to have been as popular or as good in construction as the so-called Van Stone, although many people use them. All welded flanges have the disadvantage that they cannot be turned on the pipe, making great care necessary to avoid mistakes in drilling them.

The best joints are made by grinding the seats to a perfect surface and then bolting them together without a gasket. This, however, takes a high-grade mechanic and has been satisfactory only when made in the proper manner. Instead of grinding the faces, it is now considered at least as good to finish them and insert a gasket which in the best work has been made of very soft steel approximately 1/100 inch thick. Duralite and other indurated fibers make good gaskets. Copper gaskets appear to deteriorate very rapidly in this position and are not used on high-pressure work as much as formerly. The tongue-and-groove joint cannot be recommended for steam work as it is almost impossible to bring two joints to the same degree of tightness. For the lower steam pressures copper gaskets work very nicely and are now standard. These are usually stamped with corrugations which flatten out when the bolts are tightened up, assuring a surface practically the whole width of the face. For exhaust work rubber with wire insertion such as the "Rainbow" is mostly used. For water, whether hot or cold, the "Common Sense" or other babbitt composition gaskets are quite satisfactory. The gasket made up of a soft lead ring with a copper wire ring outside of it has also been largely used with very good results and "Rainbow" gaskets are satisfactory when the pressures are not too high.

**PIPE FITTINGS.** — For low-pressure work, either steam, exhaust or water, the Master Steam Fitters' Association has adopted a standard of pipe fittings which is used practically throughout the United States. It is only for pressures higher than 300 pounds that special fittings are required. Up to 200 pounds steam pressure with no superheat, cast iron or gun iron forms the ideal material for pipe fittings and is practically the only material in use. With the advent of superheated steam, however, the cast-iron fittings soon proved themselves to be useless with the high heats and semi-steel and steel fittings were tried with the best of results. To-day no plant using superheated steam installs cast-iron fittings for high-temperature work. All fittings should be provided with proper means of draining and drainage pockets or outlets should be placed at the lowest points for the attachment of the drainage system.

For dimensions and weights of various pipe fittings see *Kent's Mechanical Engineers' Pocket Book*. See also article in this book on *Valves*.

**PIPE COVERINGS.** — To prevent loss of heat by radiation, steam and feed-water pipes are usually protected with a cover, 1 inch or more in thickness, of loose non-conducting material. About 3 B.t.u. per square foot per hour per degree difference in temperature is radiated from a bare pipe under ordinary conditions. By the use of any good commercial covering from 75 to 85 per cent of this loss may be prevented. Pipe covering is usually applied in sections, moulded to fit the pipe, and held in place by bands. The covering for fittings and valves is usually applied in plastic form.

**Cost of Pipe Covering (Pre-war figures).** — Eighty-five per cent magnesia 1 inch thick costs in the neighborhood of 30 cents per square foot in place. In general such covering costs about one-half list price including labor. One writer states that one man will cover 100 feet of straight pipe

or 40 fittings per day up to 4-inch pipe size. Above 4 inch the cost per 100 feet of pipe length will be greater owing to the increased labor of handling.

**FLOW OF WATER THROUGH PIPES.** — The pressure required to force a stream of water through a pipe is usually expressed in terms of the height of a column of water which would produce a static pressure equal to this pressure. A pressure of

1 pound per square inch = 2.31 feet of water column,

1 foot of water column = 0.433 pound per square inch.

**Friction and Velocity Head.** — The head required to overcome the resistance of a pipe is called the "friction head," and for a given pipe and velocity of flow is proportional to the length of the pipe. The head required to overcome the resistance at the entrance to a pipe is called the "entry head; in the case of long pipes the entry head is negligible in comparison with the friction head. In addition to these two heads, a certain pressure, and therefore a corresponding head, is required to produce any change in the velocity of flow. As, for example, when water enters a pipe from a reservoir. This velocity

head is equal to  $\frac{V_1^2 - V_2^2}{64.4}$ , when the velocity changes from  $V_1$  to  $V_2$  feet per second. A decrease in velocity gives rise to a *negative* velocity head. In long pipes the velocity head is negligible.

**Hydraulic Grade Line.** — Imagine a horizontal line drawn over a pipe line from a reservoir, and let this horizontal line be at the same elevation as the surface of the reservoir. From each point of this horizontal line drop perpendiculars equal in length to the loss of head between this point and the reservoir. The locus of the foot of these perpendiculars is called the "hydraulic grade line." In a pipe leading from a reservoir no part of the length of the pipe should be above the hydraulic grade line. If the pipe has vertical curves, valves should be provided at the high points to permit the escape of the air which tends to collect at the top of such curves, otherwise the pipe may become "air-bound," i.e., water will not flow although the supply is higher than the outlet.

**Formulas Connecting Velocity, Discharge, and Head.** — Various formulas have been proposed to express the relation between velocity, discharge and head. Let

$d$  = diameter of pipe in inches,

$D$  = diameter in feet,

$H$  = loss of head in pipe in feet of water,

$L$  = length of pipe in feet,

$p$  = loss of pressure in pipe in pounds per square inch,

$Q$  = discharge in cubic feet per second,

$V$  = velocity of flow in feet per second.

Unwin gives the following formula:

$$V = 4.012 \sqrt{\frac{DH}{fL}}$$

where  $f$  is the coefficient of friction. This coefficient depends upon the smoothness and cleanness of the pipe and also upon whether the pipe is straight or crooked, and upon the velocity. (See *Kent's Mechanical Engineers' Pocket Book*.) Rankine gives the following formula for  $f$  for smooth, clean, straight pipe:

$$f = 0.005 \left( 1 + \frac{1}{12D} \right).$$

This formula is approximate only, since it does not take into account the velocity of flow. It is sufficiently accurate, however, for velocities up to 6 feet per second. Combining these two formulas the following are obtained:

$$V = 16.4 d \sqrt{\frac{H}{L(d+1)}} = 25 d \sqrt{\frac{p}{L(d+1)}},$$

$$V = 57 D \sqrt{\frac{H}{L(D+0.083)}} = 87 D \sqrt{\frac{p}{L(D+0.083)}},$$

$$Q = 0.00545 d^3 V = 0.089 d^3 \sqrt{\frac{H}{L(d+1)}} = 0.136 d^3 \sqrt{\frac{p}{L(d+1)}},$$

$$Q = 0.785 D^3 V = 44.7 D^3 \sqrt{\frac{H}{L(D+0.083)}} = 68 D^3 \sqrt{\frac{p}{L(D+0.083)}}.$$

When the pipe is not completely filled with water, the same formulas hold provided  $d$  and  $D$  are taken as 4 times the hydraulic radius. The "hydraulic radius" is defined as the ratio of the area of the cross section of the water to that portion of the perimeter of the pipe in contact with the water.

These formulas apply approximately to any kind of clean, straight pipe, provided the interior surface is smooth. The formulas involving the head  $H$  also apply approximately to any kind of liquid or gas, provided  $H$  is taken as the height of a column of the given liquid or gas which will produce a static pressure equal to the fall in pressure in the pipe. The coefficients in the formulas

involving the drop of pressure  $p$  should then be multiplied by  $\sqrt{\frac{62.4}{w}}$ , where  $w$  = weight in pounds of 1 cubic foot of the given liquid or gas, and 62.4 = weight in pounds of 1 cubic foot of water.

These formulas are for new, clean, straight pipes. For cast-iron pipes that have been in service a number of years the loss of head will be larger on account of corrosion and incrustation, and the value of  $H$  in the formulas should be multiplied under average conditions by the factors opposite; but they must be used with much discretion, for some waters corrode pipes much more rapidly than others.

The same figures may be used for wrought-iron pipes which are not subject to a frequent change of water.

From the above formulas for velocity the loss in head due to pipe resistance is

$$H = \frac{LV^2(d+1)}{270d^2} = \frac{LV^2(D+0.083)}{3250D^2}.$$

William Cox (*Amer. Mach.*, 1893) gives the following formula for pipes over 6 inches in diameter:

$$H = \frac{L(V^2 + 1.25V - 0.5)}{300d}.$$

The Pelton Water Wheel Co. advocates the following formula for riveted pipe for pipes over 6 inches in diameter:

10 years	1.3
20 "	1.6
30 "	2.0
50 "	2.6
75 "	3.4

$$H = \frac{L(V^2 + 1.25V - 0.5)}{250d}$$

**Effect of Curves and Valves.**—The resistance of curves and valves may be allowed for approximately by taking for  $L$  in the above formulas the actual length of the pipe plus a length equal to

$$\frac{kd^2}{d+1} \text{ feet, or } \frac{KD^2}{D+0.083} \text{ feet,}$$

for each curve or valve, where  $k$  and  $K$  have the following values:

	45° angle	90° angle	Gate valve	Globe valve	Angle valve
$k =$	0.8	4.2	0.8	8.1	12.4
$K =$	9	49	9	96	148

These coefficients are based on data given by Gebhardt (*Steam Power Plant Engineering*). Variations of 100 per cent or more from the values given may be expected, depending on the radius of the bends and design of the valves.

According to Briggs the effect of each right-angle bend is equivalent to increasing the length 40 diameters, and the effect of each globe valve is equivalent to increasing the length 60 diameters.

**Water-Hammer.**—From the formula given by Prof. I. P. Church the pressure developed by the instantaneous closing of a valve in a water pipe is

$$P_t = \frac{63.5 V}{\sqrt{1 + \frac{300,000 d}{MT}}} \text{ pounds per square inch,}$$

where  $M$  = modulus of elasticity of the pipe material and the other symbols are as above.

**FLOW OF AIR AND GAS THROUGH PIPES.**—(See also preceding section.) Let

- $d$  = internal diameter of pipe in inches,
- $L$  = length of pipe in feet,
- $p$  = fall of pressure in the pipe in pounds per square inch,
- $Q$  = discharge in cubic feet per second,
- $V$  = linear velocity in feet per second,
- $w$  = weight of 1 cubic foot of air or gas in pounds.

Then from Unwin's formula, using the same coefficients as for the flow of water, when the fall of pressure is small,

$$V = 198 d \sqrt{\frac{p}{wL(d+1)}} \quad (1)$$

$$Q = 1.08 d^3 \sqrt{\frac{p}{wL(d+1)}} \quad (2)$$

For air:  $w = \frac{2.70 P}{460 + t}$ ; for any other gas:  $w = \frac{2.70 GP}{460 + t}$

where  $P$  = absolute pressure in pounds per square inch and  $t$  = temperature in degrees F and  $G$  = the specific gravity of the gas referred to air as unity. For ordinary illuminating gas  $G = 0.65$ .

Various authorities give different values of the numerical coefficients in the formulas for  $V$  and  $Q$  (see *Kent's Mechanical Engineers' Pocket Book*). The values given above, which are the same as for the flow of water ( $w = 62.4$ ), are sufficiently accurate for rough calculations. The formula for  $Q$  may also be written

$$Q = Cd^2 \sqrt{\frac{dp}{wL}}, \quad (3)$$

where  $C = 1.08 \sqrt{\frac{d}{d+1}}$ , corresponding to the coefficient 1.08 in equation (2).

$C$  is frequently taken as unity for all sizes of pipes.

When the *fall of pressure is large*, the above formulas for  $Q$  give approximately the quantity per second at the *average* pressure in the pipe, provided the weight per cubic foot is taken corresponding to this *average* pressure. Or, putting  $P$  = the pressure in pounds per square inch at the *outlet* of the pipe, and  $p$  = weight per cubic foot at this pressure  $P$ ,  $p$  being the fall in pressure, then the discharge in cubic feet per second at the pressure  $P$  is approximately (from equation 2)

$$Q = 1.08 d^2 \sqrt{\frac{p(P+0.5p)}{PwL(d+1)}}$$

For  $d$  large compared with unity,  $\frac{d}{d+1}$  may be taken sensibly equal to unity, and this expression may be written

$$Q = 1.08 d^2 \sqrt{\frac{p(P+0.5p)d}{PwL}}$$

For  $P = 14.7$  pounds per square inch, and  $t = 60^\circ$  F., then for air

$$Q_a = 1.02 d^2 \sqrt{\frac{p(P+0.5p)d}{L}}, \text{ cubic feet per second,}$$

and for illuminating gas of 0.65 specific gravity,

$$Q_g = 1.26 d^2 \sqrt{\frac{p(P+0.5p)d}{L}} \text{ cubic feet per second.}$$

Instead of the coefficients 1.02 and 1.26 the following values correspond to the coefficients in the formulas used by the authorities named:

	Instead of 1.02	Instead of 1.26
Wm. Cox ( <i>Am. Mach.</i> , 1902).....	0.95	1.18
J. E. Johnson ( <i>Am. Mach.</i> , 1899).....	0.96	1.19
E. A. Rix ( <i>Pac. Coast Gas Assoc.</i> , 1905).....	1.05	1.30

**Effect of Bends, Valves, etc.** — The Norwalk Iron Works Co. give the following table; radius of elbow and length of pipe are both expressed in terms of the pipe diameter:

Radius of elbow.....	5	3	2	1½	1¼	1	¾	½
Equivalent lengths of straight pipe.....	7.85	8.24	9.03	10.36	12.73	17.51	35.09	121.2

W. L. Saunders (*Compressed Air*, 1902) gives the following figures for the length of pipe in feet equivalent to each of the items listed:

Diam. of pipe, in..	1	1½	2	2½	3	3½	4	5	6	7	8	10
Globe valves.....	2	4	7	10	13	16	20	28	36	44	53	70
Elbows and tees..	2	3	5	7	9	11	13	19	24	30	35	45

**FLOW OF STEAM.** — The formulas given in the preceding section apply only approximately to the flow of steam. Putting  $v$  = volume of 1 pound of steam in cubic feet (see *tables under Steam*), the above formula for flow in cubic feet per second becomes

$$Q = 1.08 d^3 \sqrt{\frac{vp}{L(d+1)}}$$

and the corresponding flow in pounds per second is

$$W = 1.08 d^3 \sqrt{\frac{p}{vL(d+1)}}$$

G. H. Babcock, in *Steam*, gives the flow in pounds per minute as\*

$$W = 87 \sqrt{\frac{wpd^3}{L\left(1 + \frac{3.6}{d}\right)}}$$

The corresponding flow in cubic feet per second may be written

$$Q = 1.45 d^3 \sqrt{\frac{p}{wL(d+3.6)}}$$

For a given drop in pressure this formula gives a less flow for pipes under 2 inches in diameter and a greater flow for pipes over 2 inches in diameter than is given by the corresponding formula for air or gas.

**Size of Steam Mains.** — Formerly steam mains of 18 to 24 in. in diameter were considered necessary in small stations and the radiation owing to the poor quality of pipe covering then used was enormous. At the present time very few mains are put in of larger size than 14 in. I. D. and in some cases a 10 or 12-in. main is considered sufficient. The drop in pressure between boiler and prime mover is considerably larger than formerly but the actual heat loss due to friction and radiation is very much less than it was. This reduction in pipe sizes also brought in great economies in the upkeep cost of the steam lines as with the high pressures carried at the present day it would be almost impossible to keep a 20 in. or 24-in. main tight under the conditions of actual service.

\*  $w$  is pounds per cubic foot at entrance pressure.

For years a standard practice for the speed of steam in steam lines was 4000 ft. per minute as the minimum, 6000 as the average and 8000 as the maximum. This was considered the standard in the days when 125 pounds steam pressure was carried without superheat. At the present time with 200 pounds pressure and superheat which may extend as high as 200° F. above the saturation temperature, the minimum steam speeds are much higher and very few engineers are using as the minimum speed less than 8000 ft. per minute, the maximum in some cases running as high as 18,000 ft. with no bad results.

Many formulas have been used for determining pipe sizes for steam engines, but most of them are now obsolete. In "Power" for January 19, 1915, F. W. Salmon presents results secured by plotting the necessary data from a large number of successful plants.

Let  $A$  = area of pipe bore in square inches,  
 $d$  = diameter of pipe bore in inches,  
 $W$  = average pounds of steam per hour,  
 $C$  = a constant for a given pressure in the pipe,  
 $K$  = a constant =  $\frac{\pi \times C}{4}$ ,

$$W = A \times C = d^2 \times K,$$

$$d^2 = \frac{W}{K}$$

The values of  $C$  and  $K$  are given in the following table.

Vacuum, in. of Hg	$C$	$K$	Gage pressure lb. per sq. in.	$C$	$K$
28	50	39.2	80	267	210.0
26	84	66.0	100	275	216.0
24	105	82.5	125	284	223.0
22	122	95.7	150	291	229.0
20	134	102.0	175	298	234.0
18	144	113.0	200	304	239.0
16	151	118.6			
13	162	127.0			
6	176	138.0			
0	187	147.0			

**EXPANSION OF PIPE.** — The coefficient of expansion for ordinary steam pipe is about 0.000006 of its length for each degree F. A rough and ready rule is to allow  $\frac{1}{2}$  in. for every 100 ft. for every 100° F. difference of temperature. All pipe lines should be laid out to take care of this expansion, and to this end large radius bends should be employed wherever possible. It is usual to cut the pipe so it will be the right length when it is hot, making up the joints and pulling them together, so that an initial stress is put in the cold pipe. When the pipe becomes hot, this stress disappears and the pipe will then be in equilibrium. Suitable hangers should be provided every 10 or 12 ft. to support the pipe in its proper place. These may consist of a band around the pipe with a

rod hanger from some of the floor beams overhead, or the pipe may be supported from below on a roller. Anchors should also be provided at certain intervals so that the direction of expansion may be controlled. On very long lines expansion joints become necessary, or the corrugated-steel expansion joint may be used.

Bibliography.....	1158

**Methods of Specifying Pole Dimensions.** — A pole for supporting an overhead line is usually specified by its *total* or "nominal" length and by the diameter of its top; e.g., a 40-ft 7-in. top pole. When set, the distance a pole stands above the surface of the ground is less than the nominal length by the amount it sets in the ground. Poles are standard in lengths which are multiples of 5 feet. The ordinary range of length is from 30 to 60 feet.

The top of a pole is sometimes specified by inches circumference instead of by diameter. Poles are standard in diameters which are even multiples of one inch. The ordinary range of top diameter is from 7 to 8 inches except on the Pacific Coast, where from 8 to 10 inches is common.

**Taper of Poles.** — The taper of various kinds of poles, specified as the difference, measured in inches, between two circumferences 10 feet apart, is given as follows in *Forest Service Bull. No. 84*: Chestnut (Maryland), 3.8 to 4.0; Northern white cedar (Michigan), 5.2; Western yellow pine (California), 4.0; Lodgepole pine (Montana), 3.0; Loblolly pine (Texas), 2.4; Western red cedar (Washington), 3.5. Trees grown upon a high elevation have a greater taper in the trunk than trees grown lower down.

**WOODS USED FOR POLES AND CROSS ARMS.** — (Based on publication of the Forest Service, see *Bibliography.*) Of the timbers used for poles, chestnut and northern, southern and Idaho cedar easily rank first. Longleaf and shortleaf pine, red cedar, cypress, redwood, locust, catalpa and several of the oaks are used, but in much smaller numbers, and their employment is generally confined to the region of their growth. Still other timbers are used, but in numbers insignificant in comparison with those mentioned above.

For cross arms, longleaf, shortleaf and loblolly pines of the South and Norway pine of the North are most largely used, while the demand for cedar, cypress, spruce and red fir is but little less. Again, as in the case of pole timbers, a third group may be formed of those timbers used in small numbers and very locally.

In 1915, of the 4,077,964 poles purchased in the United States, 61.8 per cent were cedar, 16 per cent were chestnut, the remainder being oak, pine, cypress, etc.

**Desirable Timber for Poles.** — The several qualities which timber must possess to adapt it to use for poles are stated to be: Durability in contact with the soil, minimum weight, straightness coupled with relatively small size and little taper. The wood must be soft, so that the spikes of a climber may enter readily and at the same time it must have strength to support considerable

weight. These qualities are admirably combined in cedar and in juniper, which commercially is a cedar; no other woods possess so many.

**Uncertainties in Names of Timber Trees.**—The terms cedar, pine, etc., used in describing poles and cross arms and even the apparently more exact terms, such as white cedar, yellow pine, etc., each cover several kinds of trees and have different meanings in different localities.

There are at least eight pines (of the thirty-five native ones) in the market, some of which so closely resemble each other in their minute structure that they can hardly be told apart; and yet they differ in quality and should be used separately, although they are often mixed or confounded in the trade.

Referring to the use of yellow pine as the material for cross arms the Committee on Overhead Line Construction of the N. E. L. A., says: "Yellow pine is understood to cover what is commonly known as longleaf pine. It is understood that the term is descriptive of quality rather than of botanical species." *Forestry Bulletin* No. 10 states: "'Yellow pine,' is applied in the trade to all the Southern lumber pines; in the Northeast it is also applied to the pitch pine; in the West it refers mostly to bull pine. 'Yellow longleaf pine,' 'Georgia pine,' chiefly used in advertisement, refers to longleaf pine."

**Timbers Ordinarily Used for Poles and Cross Arms.**—The principal timber trees from which poles and cross arms are obtained are briefly described below in accordance with the names used in the publications of the Forest Service:

**Chestnut.**—Chestnut ranks next to the cedars in the quantity of poles used. The reported number purchased in 1909 was 608,000. The sapwood is very narrow, usually from about  $\frac{1}{4}$  to  $\frac{3}{8}$  of an inch wide. Chestnut is widely distributed throughout the entire Appalachian mountain region. A small territory embracing parts of Pennsylvania, Maryland, Virginia and West Virginia furnishes nearly all the chestnut poles. Chestnut is not so straight as cedar and is liable to be knotty. It has greater strength, but this advantage is more than counterbalanced by its greater weight, which prohibits long shipments.

**Northern White Cedar or Arborvitæ.**—This species is very commonly used for poles throughout the central and eastern portion of the United States. The principal source of supply is in the states bordering the Great Lakes. It makes a very desirable pole on account of its durability but is high-priced. The sapwood varies from  $\frac{1}{2}$  to 1 inch in thickness. A very large portion of northern white cedar poles have unsound butts. Northern white cedar, common in the northern woods of New England, New York and the Lake States, occurs as far south as North Carolina and Tennessee, but only in the mountains where the elevation is sufficiently great to permit northern species to thrive.

On account of its strength, lightness, durability and form it is the most desirable pole timber. Arborvitæ is extremely slow in growth. The sapwood zone is narrow at the butt and gradually widens as the top is approached. The average time it takes to produce a 30-foot arborvitæ pole is about 190 years.

**Southern White Cedar.**—The number of southern white cedar poles purchased in 1909 was 44,000. The woods known under the general name of "cedar" comprise a number of distinct species which differ in their durability, the white cedar of the southern swamps being somewhat less durable than the cedar of the Lake States. The sapwood, which is usually from  $\frac{1}{2}$  to 1 inch wide, decays very quickly. Southern white cedar, though sometimes found as far north as southern Maine, is of commercial importance chiefly south of Delaware and New Jersey.

**Red Cedar.**—A small to medium-sized tree scattered through the forests, or, in the West, sparsely covering extensive areas (cedar brakes). The

red cedar is the most widely distributed conifer of the United States, occurring from the Atlantic to the Pacific and from Florida to Minnesota, but attains a suitable size for lumber only in the Southern and more especially in the Gulf States.

**Juniper.** — The term Juniper is commonly used by telephone men for southern white cedar; the term also is applied to red cedar. Juniper poles come from Virginia, the Carolinas and other South Atlantic States.

**Western Red Cedar.** — The light and durable western red cedar is much used for poles on the Pacific coast and throughout the Northwest. Also it competes to a certain extent with northern white cedar in the East, its form and size making it especially desirable for the larger classes of poles. The principal points of production are northern Idaho and western Washington. The relative durability of western red cedar and northern white cedar under similar conditions is not known, and the testimony by pole users on this point is somewhat contradictory.

**Cypress.** — The cypress is a large deciduous tree, occupying much of the swamp and overflow land along the coast and rivers of the Southern States. Cypress is usually considered a durable wood, and the heartwood is, in fact, one of the most durable of our native species. The sapwood, however, decays quickly and this seriously weakens the pole. The width of the sapwood on pole-size trees is from  $\frac{1}{4}$  of an inch to  $1\frac{1}{4}$  inches. Cypress frequently is too large for use as a pole and has greater value for lumber. Even when its general diameter is small enough the butt will often be so big that it adds too much weight.

**Longleaf Pine.** — Large tree; forms extensive forests and furnishes the hardest and strongest pine lumber in the market. Coast region from North Carolina to Texas. The longleaf pine is strikingly heavy, hard and resinous, and usually very regular and narrow ringed, showing little sapwood, and differing in this respect from the shortleaf pine and loblolly pine, which usually have wider rings and more sapwood, the latter excelling in that respect.

**Shortleaf Pine.** — Resembles loblolly pine; often approaches in its wood the Norway pine. The common lumber pine of Missouri and Arkansas, North Carolina to Texas and Missouri.

**Loblolly Pine.** — Large-sized tree; forms extensive forests; wider-ringed, coarser, lighter, softer, with more sapwood than the longleaf pine, but the two often confounded. This is the common lumber pine from Virginia to South Carolina and is found extensively in Arkansas and Texas, Southern States, Virginia to Texas.

This pine is not durable when used as a pole unless treated with preservatives, but because of its cheapness and ease of impregnation is very desirable if preservative treatment is contemplated. Its distribution, ease of reproduction and rapidity of growth insure a steady and cheap supply. When this timber is used it is necessary to treat the entire pole instead of only the butt, especially in the warmer and more humid localities of the South.

**Norway Pine.** — Large-sized tree; never forming forests, usually scattered or in small groves, together with white pine; largely sapwood and hence not durable. Minnesota to Michigan; also in New England to Pennsylvania. The Norway pine, which may be confounded with the shortleaf pine can be distinguished by being much lighter and softer. It may also, but more rarely, be confounded with heavier white pine, but for the sharper definition of the annual ring, weight and hardness.

**Western Yellow Pine.** — Western yellow pine is used for poles to a limited extent in certain parts of the Southwest, where the high cost of more

durable pole timbers makes it necessary to find a cheaper substitute. The life of this timber, untreated, is very short. In the upper part of the San Joaquin Valley of California, where a study of this species was made, untreated pine poles last only two or three years; but since the wood when not exposed to the sun is fairly durable, it is believed that a butt treatment with a good wood preservative will result in a pole that will give good service. A butt-treated pine pole costs considerably less than an untreated cedar pole in this locality.

**Lodgepole Pine.** — Lodgepole pine is cut to a limited extent for poles. It grows at high altitudes in the Rocky Mountains. It decays quickly in contact with the soil, but is durable when not so exposed. The tree grows tall and straight, with very little taper and makes a well-shaped pole. In certain parts of the West, where there are large bodies of fire-killed lodgepole that remain standing for many years, sound and thoroughly seasoned, conditions for effective treatment are excellent. If given a butt treatment, this dead timber makes a durable pole, and in many localities the cost of the pine pole plus the cost of the treatment is less than that of the Idaho cedar untreated. The sapwood of pole-sized timber may be an inch or an inch and a quarter thick.

**DEFECTS IN WOOD USED FOR POLES AND CROSS ARMS.** — (See also *Timber*.) The following are the defects in timber which are frequently referred to in specifications for poles and cross arms.

**Pith.** — The pith of a tree is the central core about which the annual rings are formed. It goes through the tree from top to bottom and branches into the limbs. The pith is quite thick, usually  $\frac{1}{8}$  to  $\frac{1}{2}$  inch in Norway pine and in the southern species, though much less so in white pine and is very thin,  $\frac{1}{16}$  to  $\frac{1}{32}$  inch in cypress, cedar and larch. The pith of the tree is the weakest part on account of the many knots which it invariably and necessarily contains.

**Sapwood.** — The sapwood of a tree is a zone of wood next to the bark 1 to 3 or more inches wide and containing 30 to 50 or more annular rings (in coniferous trees). It is of lighter color than the inner, darker part of the wood which is the heartwood. Sapwood changes to heartwood as the tree grows.

The width of the sapwood is small for longleaf and white pine and great for loblolly and Norway pines. In old trees of longleaf pine the sapwood forms about 40 per cent of the merchantable log, while in the loblolly and in all young (coniferous) trees the bulk of the wood is sapwood.

Sapwood, being the normal condition of the outer rings of a tree, is not a "defect" in poles, where the whole cross section of the tree (except bark) is used. Being weaker and more liable to decay it is considered a "defect" in pins and cross arms, which are better if made from the heartwood only.

**Cup-Shakes.** — These are cracks extending circumferentially at one or more places, caused by the separation of the annual rings.

**Doatiness.** — This is a speckled stain found in beech, American oak and other timber, due to incipient decay. It is produced by imperfect seasoning or by exposure for a long period to a stagnant atmosphere.

**Heart-Shakes.** — These are splits or clefts occurring in the center of the tree. They are common in nearly every variety of timber and are very serious when they twist in the length, as they interfere with the conversion of the tree into boards or scantlings. They sometimes divide the log in two for a few feet from the end.

**Star-Shakes.** — When several heart-shakes occur in one tree they are called star-shakes from the appearance produced by their radiation from the center.

**Wind-Cracks.** — Shakes or splits on the sides of a balk (a log which has been squared off) of timber, caused by shrinkage of the exterior surface, are called wind-cracks.

**Dry Rot.** — Dry rot is a special form of decay in timber caused by the growth of a fungus which spreads over the surface like a close network of threads, white, yellow or brown, and causes the inside to perish and crumble. Causes which render timber favorable to the growth of this fungus are; large proportion of sapwood; felled at wrong season when full of sap; if cut down in the spring or fall of the year instead of in midwinter or midsummer, when the sap is at rest; stacked for seasoning without sufficient air spaces being left; fixed before thoroughly seasoned; painted or varnished while containing moisture. (Six preceding definitions from *Carpentry and Joinery* by Paul N. Hasluch.)

**Sound Knot.** — A sound knot is one which is solid across its face and which is as hard as the wood surrounding it; it may be either red or black, and is so fixed by growth or position that it will retain its place in the piece.

**Loose Knot.** — A loose knot is one not firmly held in place by growth or position.

**Pith Knot.** — A pith knot is a sound knot with a pith hole not more than one-fourth of an inch in diameter at the center.

**Encased Knot.** — An encased knot is one which is surrounded wholly or in part by bark or pitch. Where the encasement is less than one-eighth of an inch in width on both sides, not exceeding one-half the circumference of the knot, it shall be considered a sound knot.

**Rotten Knot.** — A rotten knot is one not as hard as the wood it is in.

**Pin Knot.** — A pin knot is a sound knot not over one-half inch in diameter.

**Spike Knot.** — A spike knot is one sawn in a lengthwise direction. The mean or average width shall be considered in measuring these knots.

**Pitch Pocket.** — A pitch pocket is an opening between the grain of the wood containing more or less pitch or bark.

**Pitch Streak.** — A pitch streak is a well-defined accumulation of pitch at one point in the piece. When not sufficient to develop a well-defined streak, or where the fiber between grains — that is, the coarse-grained fiber, usually termed "spring wood" — is not saturated with pitch, it shall not be considered a defect.

**Wane.** — Wane is bark, or lack of wood from any cause, on edges of timber.

**Shakes.** — Shakes are splits in timber which usually cause a separation of the wood between annual rings.

**Checks.** — Checks are splits in timber, which usually cause a separation of the wood across annual rings. (Last twelve definitions are those used in the timber-test work of the Forest Service in describing defects. *Forest Service Circular 38, Revised.*)

**Wind Shake.** — A crack or incoherence in timber produced by violent winds while the timber was growing.

**Wind.** — A turn or bend. A piece of timber is out of wind when it is perfectly straight or flat.

**Warped.** — Twisted out of shape by seasoning.

**Cat-Faces.** — Old wounds, partially overgrown, leaving a long, narrow, dead surface exposed.

**VOLUME AND WEIGHT OF POLES.** — A quick way to find the approximate volume of a pole is to multiply the area of the circle at the center of gravity

by the length of the pole. The formula for the volume, considering a pole as a frustum of a cone is

$$v = \frac{\pi}{1728} (d_1^2 + d_1d_2 + d_2^2)h,$$

where  $v$  = volume in cubic feet;  $d_1$  = diameter at butt in inches;  $d_2$  = diameter at top in inches;  $h$  = length of pole in feet.

The following table gives the volume of some standard poles:

Kind of pole	Nominal size		Volume, cubic feet
	Diameter, inches	Length, feet	
Chestnut.....	7	30	20.0
Southern white cedar.....	7	30	20.8
Northern white cedar.....	7	30	19.6
Western red cedar.....	8	40	27.3
Western yellow pine.....	8	40	26.0

The weight of a pole may be found by multiplying its volume in cubic feet by its weight per cubic foot. The following table gives the weight per cubic foot

#### WEIGHT PER CUBIC FOOT OF POLES

Kind of pole	When cut		When seasoned	
	Weight,* pounds per cubic foot	Moisture, per cent of dry weight	Weight,* pounds per cubic foot	Moisture, per cent of dry weight
Southern white cedar.....	38.9	88	25.0	21
Chestnut (N. C.).....	56.5	101	43.2	54
Chestnut (N. J.).....	51.8	85	42.2	50
Chestnut (Pa.).....	54.0	92	40.7	45
Chestnut (Md.).....	56.4	86	44.9	48
Northern white cedar.....	34.2	90	22.9	27
Western red cedar.....	42.4	133	23.5	29
Western yellow pine.....	66.6	154	30.3	16

\* Including contained moisture.

**SEASONING.**—Poles should be seasoned because it increases their resistance to decay, increases their strength and decreases their weight. The strength of partially seasoned timber, other things being equal, increases as the amount of moisture it contains decreases. Thoroughly seasoned timber of small size is sometimes three or even four times as strong as the same timber, when green.

Seasoning of poles reduces their weight, commonly from 16 to 30 per cent, and even more for some species, with a corresponding decrease in the cost of transportation. Thorough seasoning is essential if the poles are to be treated with preservatives. The percentage of moisture in a pole when cut varies with the season when cut as shown in the table at top of p. 1149.

In general, poles cut during the spring and summer lose weight most rapidly. Poles cut during autumn and winter lose weight less rapidly, but more regularly.

seasoning may be detrimental to the timber by causing excessive shrinkage of poles during seasoning is very slight and does not exceed 1 per cent on the circumference.

#### MOISTURE CONTENT WHEN CUT, PER CENT OF DRY WEIGHT

Kind of pole	Spring	Summer	Autumn	Winter
white cedar (N. C.)	68	77	87	88
(N. C.).....	97	91	95	101
(N. J.).....	81	83	81	85
(Pa.).....	89	92	88	88
(Md.).....	83	84	85	86
white cedar (Mich.)	77	82	79	90
red cedar (Cal.).....	...	133	...	...
yellow pine (Cal.).....	149	147	145	154

The number of months required for poles cut at different periods of the year to reach approximately air-dry weight is as follows:

#### TIME REQUIRED FOR SEASONING

Kind of pole	Spring	Summer	Autumn	Winter	Moisture content* seasoned
	Months	Months	Months	Months	Per cent
(Md.).....					
white cedar	5	4	8	7	55
white cedar	3	3	8	5	26
red cedar (Cal.).....	12	9	7	6	37
yellow pine (Cal.).....	5	3	9	6	43

\*Average amount of moisture remaining in the poles after seasoning as above in terms of the weight of the dry wood.

**ROOFING.**— If the top of a pole is left flat rain water will not run off and will penetrate the pole by following the grain, causing early decay at the top. Poles are accordingly "roofed" by cutting the top to give a conical surface which is sometimes conical but usually is merely two inclined planes meeting in a horizontal ridge. The angle of the planes with the horizontal is usually 45 degrees. Where a bracket is to be bolted to top of pole a flat strip 1 inch in width is sometimes left, instead of a sharp ridge, in order to provide material in the pole top where the strain from the upper bracket is applied. Roofs should be painted to close the grain which is porous, in order to prevent the entrance of water.

**CONSERVATIVE TREATMENT.**— The forest service estimate that it takes 30 years to grow a 30-foot cedar pole whose average life, when set in the ground in its natural state, does not exceed 15 years. They also find that the majority of the poles in use have to be replaced annually. Taking into account the enormous number of poles in use, they conclude that the enormous demand must soon

deplete the supply and have made extensive experiments on preservative treatment as a means of conserving the pole supply.

Preservative treatments are used to increase the resistance of poles to decay. The advantages of such treatment are:

1. It increases the life of the pole.
2. It makes possible the use of smaller poles as less allowance need be made for decay.
3. It makes possible the use of species of timber not naturally durable.

The butt of the pole near the ground line is most subject to decay and treatment of the butt alone is usually deemed sufficient. In some of the Southern states the whole pole is subject to decay, in which case the whole pole is treated.

**Cause of the Decay of Timber.** — Decay of wood is due to low forms of plant life called fungi. The germs of decay are not inherent in the wood. The wood-destroying fungi start from the outside, either from adjacent rotten wood or by spores, which correspond to seeds, being carried by the wind and deposited on the surface. While the fungi from these spores begin at the "outside" of the wood, this surface must be understood to include all holes or cracks which the spores may enter.

Fungi require for their growth and development air, heat, moisture and food. Warmth, preferably between 60° and 100° F., favors decay. Cold retards it and temperatures above 150° F. prevent it. Under water or deep under the surface of the ground where the air is excluded, decay does not take place. Ordinary wood which is seasoned until it is air-dry does not contain sufficient moisture to support the growth of fungi.

**Preservatives.** — The best method of checking the growth of fungi is to deprive them of food. This can be done by injecting poisonous substances into the timber. These substances are called preservatives. Of the many antiseptics which have been proposed for the preservation of timber only four have been largely used with success in the United States. These are creosote, zinc chlorid, corrosive sublimate and copper sulphate. Copper sulphate has fallen into almost total disuse. At present creosote and zinc chloride, pure or in mixture, are the only preservatives which are in general use.

**Corrosive Sublimate (Bichlorid of mercury).** — This is used in the so-called "kyanizing" process. This process consists in steeping the timber in a dilute solution of corrosive sublimate long enough to insure thorough penetration.

**Zinc Chloride.** — Zinc chloride is an excellent antiseptic; it is obtained by dissolving metallic zinc in hydrochloric acid. This is further diluted by water before it is used for wood preservation. Zinc chloride is much cheaper than creosote, and since it is shipped in the form of a solid the freight charges are considerably less. Zinc chloride is soluble in water, being in fact, injected into the timber in water solution and so when timber treated with it is exposed to moisture the leaching out of the salt is only a question of time. Hence zinc chloride is most commonly used in comparatively dry situations.

**Creosote.** — Creosote is a by-product of coal tar, which is produced at most plants for the manufacture of illuminating gas and at by-product coke-oven plants. Wood tar, when distilled in a similar manner, gives "wood creosote," which like that derived from coal tar, possesses strong antiseptic properties. There is also on the market a so-called creosote, a by-product of water-gas tar or tar manufactured from kerosene oils, which, for wood preservation, is probably inferior to the true creosote. In general, however, by "creosote" is meant the dead oil of coal tar.

Creosote is not a single chemical compound but a mixture of a number of compounds. Not only does the relative proportion of the several constituents vary, but some may be absent or other compounds, not normally constituents of creosote, may be present. Creosote proper is the fraction of oil passing over between  $240^{\circ}\text{C}$ . and  $270^{\circ}\text{C}$ . during the first distillation of the crude coal tar. In practice, however, many of the creosote oils of commerce contain considerable amounts of materials having boiling points higher than  $270^{\circ}\text{C}$ . and lower than  $240^{\circ}\text{C}$ . Some commercial creosotes are rather thin oils, some are almost entirely solid with naphthalene and some are heavy oils with a large proportion of high-boiling constituents.

An analysis of creosote in well-preserved timbers (*Forest Service Circular 98*), led to the conclusions that light oils, boiling below  $205^{\circ}\text{C}$ ., will not remain in timber, but that heavy oils, containing a high percentage of anthracene oil, will remain almost indefinitely and protect the wood from decay and boring animals.

The cost of creosote in carload lots (including transportation) is (1921) about 40 cents per gallon for points east of the Mississippi River and in the vicinity of the Gulf ports west of the Mississippi. West of the Rocky Mountains the cost is about 50 cents per gallon. A gallon of creosote is estimated to be  $8\frac{1}{2}$  to 9 pounds.

**Patented Preservation.** — There are many other patented substances known by various names, but most of them have for their base creosote or zinc chloride.

**Carbolineum.** — Carbolineum, like creosote, is derived from the distillation of coal tar. The compounds included in carbolineum are derived from the coal tar at a higher temperature of distillation and are therefore somewhat different.

**Crude Petroleum.** — Crude petroleum has been experimented with but there is little definite knowledge of its value as a wood preservative.

**Methods of Treatment.** — The methods of applying the preservatives to the pole are the brush treatment, open tank treatment and pressure tank treatment.

The brush treatment is applied to a part of the butt at the ground line, the open-tank treatment to the whole butt and the pressure-tank treatment to the whole pole.

The brush treatment is least expensive and gives the least protection and the pressure tank is most expensive and gives the most protection.

For a full description of these methods of treatment and estimates of cost see *U. S. Forest Service Circulars, Nos. 84, 147, etc.*

An estimate in 1921 for a two-coat brush treatment of the butts with creosote is approximately 50 cents per pole. Another way in which this may be figured is on the basis of the amount of creosote and the amount of labor required to treat one pole, as follows: It takes 2 to 3 pounds of creosote ( $\frac{1}{2}$  to  $\frac{3}{4}$  pound per square foot of surface treated) for one pole, and an efficient man about  $\frac{1}{2}$  hour to apply it. The cost of open-tank treatment of the butt with creosote varies from \$2 for a 25-foot 7-inch pole to \$13 on a 60-foot 8-inch pole. This cost mounts rapidly for large poles because the butt is not only of greater diameter but a greater depth has to be treated.

**LIFE OF POLES.** — Statistics compiled by the National Electric Light Association give the following figures for the average life of *untreated* poles; the figures for *butt-treated* poles are according to estimates by the U. S. Forest Service.

Untreated	Years	Butt-treated	Years
Cedar.....	13.5	Chestnut.....	20
Chestnut.....	12.0	Western cedar.....	20
Cypress.....	9.0	Northern white cedar.....	20
Pine.....	6.5	Pipe, in dry climates.....	20
Juniper.....	6.5		

Records of the German Postal and Telegraph Department covering 52 years show an average life of 20.6 years for crosscutted pine poles.

**SPECIFICATIONS FOR POLES.**—In the report of the Committee on Overhead Line Construction of the National Electric Light Association (abbreviated N.E.L.A.) are given very complete specifications for chestnut, eastern white cedar and yellow pine poles. Space does not permit of the incorporation of these specifications here; copies may be had from the National Electric Light Association, 33 W. 39th St., New York.

**FORCES ACTING ON A POLE.**—A pole is subject to the following forces:

- (1) Vertical forces due to weight of pole, wires, sleet, etc., and to downward pull of guys.
- (2) Lateral horizontal forces due to wind across line on pole, wire, sleet, etc.
- (3) Longitudinal horizontal forces due to unbalanced pull of wires.
- (4) Torsional forces due to unbalanced pull of wires.

A pole is strong as regards the vertical forces but weak for horizontal forces and the cross arms are weak for the torsional forces. The theory of good line work is, therefore, first to reduce the horizontal and torsional forces as much as possible by balancing the stresses and second to convert remaining unbalanced horizontal stresses into vertical stresses on the pole by the use of guys.

In practice the lateral horizontal force of the wind is one which cannot ordinarily be provided for by guys. Calculations for strength of poles, when made, are ordinarily limited to the effect of side wind.

**Breaking of Pole by Cross Wind.**—The principal forces tending to break a pole are wind pressures on pole and conductors when the wind blows transversely. These tend to break it by cross bending.

- Let  $M_1$  = moment of the wind on the pole,  
 $M_2$  = moment of the wind on the wires,  
 $M$  = moment of resistance of the pole.

Then the condition that the pole shall not break is that

$$M_1 + M_2 < M.$$

The calculation of  $M_1$ ,  $M_2$  and  $M$  is given below.

**Moment of Wind on Pole ( $M_1$ ).**—Moment at ground level due to wind pressure on pole is

$$M_1 = \frac{P_1 H_1^3 (D_1 + 2 D_2)}{72}$$

- $M_1$  = moment at the ground in pound-feet,  
 $P_1$  = wind pressure in pounds per sq. ft. of projected area of pole,  
 $H_1$  = height of pole in feet,  
 $D_1$  = diameter of pole at ground in inches,  
 $D_2$  = diameter of pole at top in inches.

imum bending moment due to horizontal forces at the top of the arily assumed to be at the ground level; it is really a little below and opposite the center of pressure of the resistance furnished by

ment of Wind on Wires ( $M_2$ ). — Moment at ground level due to e on the wires is

$$M_2 = \frac{P_2 H_2 n d (S_1 + S_2)}{24}$$

ment at the ground in lb.-ft.,

l pressure in pounds per sq. ft. of projected area of wires,

ht of wires above ground in feet,

ber of wires,

meter of wires (including ice) in inches,

= lengths of adjacent spans in feet.

es are of different diameters or at different levels the formula is to each size and each level separately and moments summed.

of Rupture.

**Moment of Resistance ( $M$ ).**—The moment of resistance or strength of a circular pole for cross bending is

$$M = \frac{f\pi D^3}{384} \quad \text{or} \quad \frac{fD^3}{122}$$

$M$  = moment of resistance of the section considered in lb.-ft.,

$f$  = fiber stress in pounds per sq. in.,

$D$  = diameter of pole in inches.

The maximum allowable moment  $M$  is found by using the maximum allowable value for the fiber stress  $f$ .

**Fiber Stress ( $f$ ) and Actual Tests of Strength.**—The table on page 1153 gives the value of the fiber stress for various kinds of timber and the actual breaking load from tests of a number of poles.

**Weakest Point of a Pole.**—A pole is approximately a truncated cone in shape. For a bending force applied at one end such a cone is weakest at the point where the diameter is  $\frac{2}{3}$  the diameter at the point (near the small end) where the force is applied. A pole with 8-inch diameter at the cross arm is, therefore, weakest where it is 12 inches in diameter and may be expected to break at this point provided this point is above the place where maximum bending occurs. If it is less than 12 inches in diameter at the point of maximum bending then the break may be expected here. This rule must be considered approximate as it neglects the fact that the pole is not homogeneous, i.e., outer annual rings are sapwood and inner are heartwood, and also neglects effect of knots, etc.

**ATTACHMENT OF CROSS ARMS TO POLES.**—Wooden cross arms are attached to wooden poles:

- (1) By gaining the pole, see below.
- (2) By one or two lag screws or bolts.
- (3) By one or two cross-arm braces.

The forces at the point of attachment which these fastenings must resist are:

- (1) A force vertically downward, equal to weight of cross arm, pins, insulators and wire (including sleet).
- (2) A horizontal force parallel to axis of arm, equal to pressure of wind blowing across line on wires.
- (3) A horizontal force at right angles to axis of arm: (a) toward pole or (b) away from pole and equal to difference in pull of wires on two sides of arm.
- (4) A couple in a vertical plane parallel to arm, equal to difference in moments of weight on the two ends of arm.
- (5) A couple in a horizontal plane parallel to arm, equal to difference in moments of wire pull on the two ends of arm.
- (6) A couple in a vertical plane at right angles to arm, equal to difference in moments of wire pull (caused by pin leverage) in the two directions.

**Framing and Hardware.**—Typical framing and hardware for the three principal combinations of arms (single arms, double arms and buck arms on corner poles) are shown in Figs. 1, 2 and 3, respectively. These are standard framings of the Stone & Webster Engineering Corp. The arms shown are all 6 pin, but the framing would be the same, except for length of arm for 4-, 8- or 10-pin arms.

**Gaining.**—A gain is a notch cut in the side of a pole to receive a cross arm. The width (vertical dimension) of the gain should be just large enough for the cross arm. The depth of gain varies from  $\frac{1}{2}$  to 1 inch. With gains shallower than  $\frac{1}{2}$  inch the cross arm has insufficient support below and the flat bearing

surface at the back is inadequate unless the pole is of larger diameter than usual. Deep gains greatly weaken the top of the pole especially when double arms are used. Gains should be painted before arms are attached to prevent moisture entering the wood through the cut surface.

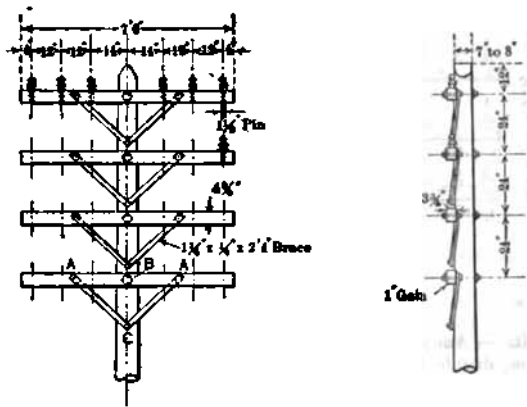

Fig. 1. Pole Top Framing, Single Arm

Fig. 2. Pole Top Framing, Double Arms

**Specification for Framing.** — Gaining shall be as follows:

Top of pole to center of top gain, 12 inches.

Center to center of gains, 24 inches.

Gains for buck arms shall be located centrally between gains for main arms.

Gains shall be cut not over 1 inch deep.

Arms shall be fastened to pole by one through bolt. Back of pole shall be flattened to give true bearing surface for washer under head of bolt. Each arm shall be braced by two braces fastened to back side of arm. Ends of double arms shall be separated by spacing blocks and shall be bolted together.

**Specification for Hardware.** — All hardware shall be galvanized iron.

Fig. 3. Pole Top Framing, Corner Poles

**Bolts.** — Arms shall be fastened to pole with one  $\frac{5}{8}$ -in. machine bolt. Double arms shall be fastened together by one  $\frac{5}{8}$ -in. machine bolt. Above bolts shall have 6-in. thread to allow for variation in thickness. For fastening double arms to poles stud bolts having a nut at each end shall be used. Braces shall be fastened to arms by  $\frac{3}{8}$ -in. machine bolts.

**Washers.** — Square-cut iron washers shall be used at both ends of bolts fastening arms to poles and at both ends of bolts fastening double arms to each other. Round-cut washers shall be used with machine bolts for fastening braces to arms.

**Nuts.** — Square nuts shall be used.

**Braces.** — Two braces shall be used on each arm. Braces shall be 28 in. by  $1\frac{1}{4}$  in. by  $\frac{1}{4}$  in. except on corner poles, where 24 in. by  $1\frac{1}{4}$  in. by  $\frac{1}{4}$  in. braces shall be used.

**Lag Screws.** — Braces shall be fastened to pole by  $\frac{1}{2}$ -in. lag screws.

**DEPTH OF SETTING IN GROUND.** — The following table gives the depth of setting recommended by the National Electric Light Association.

Total length of pole, feet	Depth of setting, feet		Total length of pole, feet	Depth of setting, feet	
	Straight line	Curves and corners		Straight line	Curves and corners
30	5.0	6.0	60	7.0	8.0
35	5.5	6.0	65	7.5	8.0
40	6.0	6.5	70	7.5	8.0
45	6.5	7.0	75	8.0	8.0
50	6.5	7.0	80	8.0	8.0
55	7.0	7.5			

**GUYING OF POLES.** — A guy is ordinarily composed of guy wire, strain insulators, turnbuckles (sometimes) and guy stub or guy anchor.

**Guy Wire.** — Iron wires are used for guy wires but should always be galvanized (see Galvanizing). Solid wire was formerly common but st

is now generally used. Various sizes have been used but the  
ably the best. The N.E.L.A. specification for the two sizes  
em is:

	Strands	Size of indi- vidual wires, B. W. G.	Ultimate break- ing strength
			Pounds
	7	14	2300
	7	12	5000

ators.— Strain insulators are placed in guys to prevent the  
guy wire, which is accessible to the public, becoming charged  
or contact with a conductor. Two strain insulators should be  
d about 5 feet from the pole and the other 8 feet above the

strain insulator are used. In one the insulation (usually im-  
is in tension, while in the other (usually porcelain) it is in com-  
ormer has the disadvantage that failure of the insulation causes  
e of the guy. The latter has the disadvantage that the insulator

Fig. 4.

Fig. 5.

may fail and the guy become charged without the failure being recognized. The N.E.L.A. specification favors the latter type and requires a strength of twice the strength of the guy wire and a wet flash over of four times the line voltage.

**Guy Stubs and Guy Anchors.**—A common guy stub is shown in Fig. 4. This is made from parts of defective poles and is fastened together by an arm bolt. Fig. 5 shows another common form of guy stub and anchor.

There are also various forms of patented anchors which screw into the pole or are placed or driven into small holes and then expanded. These are used to economize labor of installation of standard anchors.

**REPAIRING DECAYED POLES.**—Where poles have become decayed above the ground line by decay the strength may be restored by cutting off the decayed part and resetting pole, thus reducing its height by six to eight feet. If a reduction of height is not permissible, the pole may be stubbed by cutting off the decayed part and setting a short pole or stub extending a few feet above ground to the top of the pole or the undecayed part above ground is bolted or otherwise fastened to the stub. This method does not look well and is unsuitable for city distribution lines. It has been used for transmission lines. A more recent method is to encase the decayed pole by a sleeve of concrete (usually reinforced) extending above and below the decayed portion. (See *Electrical World*, April 1, 1903, p. 1013 for Orr patented process.)

**COST OF POLES.**—The cost of wooden poles varies between \$3.75 and \$43.00 depending upon the part of the country in which they are produced. The following figures are rough approximations and are exclusive of freight.

#### APPROXIMATE COST OF POLES

Length, feet	Chestnut	Cedar, Iowa	Northern white cedar
25	\$ 3.75*	\$ 5.50*	.....
30	4.00*	10.00*	.....
35	6.25*	13.50*	.....
40	9.00†	17.00*	\$8.00†
45	10.50†	22.00*	11.75†
50	16.75†	26.00*	14.50†
55	18.50†	40.00†	.....
60	14.50†	43.00†	.....

**POTENTIOMETERS.** — (See also *Cells, Standard; Galvanometers; Resistors, Standard.*) A potentiometer is primarily an arrangement of resistances for the accurate comparison of two potential differences by balancing one against the other. In connection with suitable resistance standards (see *Resistors, Standard*) it may also be used for the accurate measurement of electric currents. The accessories for making ordinary d-c. measurements are a standard cell (see *Cells, Standard*) and a galvanometer (q.v.), and suitable keys or switches. For making a-c. measurements certain additional apparatus is required; see below under *Alternating Current Potentiometer*.

**USES OF THE POTENTIOMETER.** — For the calibration of current, voltage and power-measuring instruments, both d-c. and a-c., the potentiometer is the most accurate and satisfactory instrument available. A technical laboratory relies almost entirely upon the standard Weston (or Clark) cell and a set of standard resistances as its ultimate or primary standards, leaving the testing of the accuracy of these latter to a central standardizing bureau, such as the Bureau of Standards at Washington. It is, of course, convenient to have suitable precision ammeters, voltmeters and wattmeters as secondary laboratory standards but, as such secondary standards tend to "lose their calibration," they should be frequently checked against the standard cell and standard resistances by means of a potentiometer.

**PRINCIPLE OF THE POTENTIOMETER** (Figs. 1 to 3). — The potentiometer in its simplest form consists of a uniform wire stretched over a scale divided into a number of even parts, say 1500. A battery *B* (Fig. 1) having an e.m.f. of about 2 volts and a rheostat *R* are connected in series with this wire and two contact points *A* and *S* are provided, one contact *S* being movable. *G* is a galvanometer. At *P* there may be connected either a standard cell or any other source of potential difference.

At *P* is first connected a standard cell, say a Weston cell, having an e.m.f. of 1.01830 volts and the contact *A* is placed at

and the contact *S* at 1.0183 on the scale. By varying the rheostat *R* it is possible to so adjust the current in the slide wire that the fall of potential between *A* and *S* due to the current from the battery *B* is exactly 1.0183 volts. This can be determined by closing the switch *K*; if *R* is properly adjusted there will be no deflection of the galvanometer. Care must be taken that the positive terminals of both *B* and the standard battery are connected to the same end of the wire.

To measure any other p.d. the standard cell is taken out of circuit and the terminals between which the p.d. is to be measured are connected to *a* and *b* respectively. The contact *S* is then moved until the galvanometer shows a balance. The corresponding position of the contact *S*, as read on the wire, then gives the value of this p.d. in volts.

**Increase of Range by Use of Volt Box or Multiplier.** — To measure voltages above 1.5 one must resort to the "volt box" or "multiplier," which is simply a standard high resistance, *R*<sub>1</sub> (Fig. 2) being provided with taps, so arranged that a definite fraction of the total drop can be measured on the poten-

Fig. 1. Simple Potentiometer

tometer. The unknown p.d. is connected at *E*. Fig. 2, the terminals *a* and *b* being the same as the like-lettered terminals in Fig. 1. The potentiometer reading would then be multiplied by 10 or 100 depending on the position of the switch *D*. The resistance  $R_1$  must be sufficiently large so that the current taken by  $R_1$  does not appreciably affect the value of the p.d. in the circuit being tested.

**Increase of Accuracy by Use of Additional Series Resistance.** — The accuracy of measurement may be increased by inserting in series with the slide wire a known multiple of the resistance of, say, 1000 divisions of the slide wire. This is equivalent to increasing the length of the slide wire, and therefore, each division on the scale represents a correspondingly smaller fraction of a volt.

**Current Measurement.** — If it is desired to measure current, the drop across a known low resistance  $r$  is measured as shown in Fig. 3. The resistance  $r$  is usually so adjusted that its resistance between the potential terminals *PP'* is an even fraction of an ohm, in which case the potentiometer reads the current directly, with the exception of the proper pointing of the decimal. For instance, using a 0.01 ohm standard the potentiometer reading is to be multiplied by 100.

**Caution.** — In using any form of potentiometer a balance with the standard cell in circuit should always be obtained just before and after a balance with the unknown p.d. in circuit. In other words, the potentiometer current should always be checked both before and after a measurement.

**TYPICAL DIRECT-CURRENT POTENTIOMETERS.** — Potentiometers are made in such varied forms that it would take considerably more space than is available to describe them all. The most generally used direct-current types are the high-resistance "null" type, the low-resistance "null" type and the Brooks deflection type.

The Brooks potentiometer is particularly well adapted to the requirements of a large electrical engineering laboratory, where many instruments must be checked and kept in adjustment, and where it is imperative that the work be done with great speed, combined with a degree of precision ample for engineering work.

**Low-resistance Null Type (Fig. 4).** — A diagram of the connections of a Leeds and Northrup low-resistance null-type potentiometer is shown in Fig. 4.

Fifteen 5-ohm coils are connected to the studs of a dial switch, the contact

*M* arranged to make contact with any stud. The slide wire *DB* consists of 11 turns of manganin wire wound on a marble cylinder 6 inches in diameter. The contact *M'* is mounted on the inside of a light aluminum hood, which serves to protect the slide wire from dust. It moves over the entire length of the slide

Fig. 2. Volt box

Fig. 3.

Fig. 4. Leeds &amp; Northrup Potentiometer

wire and carries a scale from which the number of turns and the fraction of a turn can be easily read.

This potentiometer is designed for use with commercial "standard" Weston cells, which differ slightly in e.m.f. Each one, however, is accompanied by a certificate giving its e.m.f.

The switch  $T$  should be set at the stud corresponding to this stated e.m.f. In other words, the switch  $T$  is used for adjusting the potentiometer to the particular cell which is used. The rheostat  $R$  is then adjusted until no current flows through the galvanometer with the double-throw switch  $U$  thrown across the contacts marked Std. Cell.

In closing the galvanometer circuit close the keys  $R_1$ ,  $R_2$ , and  $R_3$  in the order stated.  $R_1$  puts the galvanometer in series with a high resistance,  $R_2$  puts the galvanometer in series with a medium resistance and  $R_3$  puts the galvanometer in circuit without series resistance. If the potentiometer is considerably off balance this may thus be detected without causing a violent deflection of the galvanometer, and a closer balance obtained before the other keys are closed.

**Range of Low-resistance Null Type.**—With the rheostat  $R$  adjusted to give a perfect balance the current through the potentiometer is  $\frac{1}{2}$  ampere, and the drop across each coil and across 1000 divisions of the slide wire is consequently 0.1 volt and across 1 division of the slide wire 0.0001 volt.

**Range-lowering Device.**—The shunt  $S$  serves as a range-shifting device, by which the range may be reduced to 0.1 the normal, one division of the slide wire in this case being equal to 0.00001 volt. This shunt has such a resistance that when the plug opposite  $K$  is shifted to the lower hole the drop over  $AD$  will be  $\frac{1}{10}$  its previous value.

**High-resistance Null Type (Fig. 5).**—A diagram of the connections of a Wolff high-resistance null-type potentiometer is shown in Fig. 5. In this instru-

Fig. 5. Wolff's Potentiometer

ment the slide wire is dispensed with altogether. The double-dial switches are so arranged that the total resistance between the terminals  $B$  is constant and equal to 15,000 ohms irrespective of the position of the switches. The means whereby this is accomplished is evident upon tracing out the circuits in the diagram. By using this high resistance and keeping it constant, the effect of the contact resistances in the various switches is rendered negligible. The adjustments are made in the same manner as for the simple slide-wire potentiometer, except that instead of moving a sliding contact along a wire, one manipulates the various dial switches. The potentiometer circuit proper and all necessary keys and switches, are provided in this instrument. The accessories necessary for making measurements up to 1.5 volts are a regulating rheostat of about 5000 ohms total resistance, a standard cell, a suitable galvanometer and two cells of storage batteries or other source of e.m.f. of about 4 volts.

**Range of High-resistance Null Type.**— This potentiometer has a range up to 15 volts in steps of 0.0001 volt and up to 1.5 volts in steps of 0.0001 volt.

**Brooks Potentiometer (Fig. 6).**— In this instrument no attempt is made to obtain an exact balance; the dial switches are set so near to the null point that

Fig. 6. Connections of Brooks Potentiometer

the galvanometer deflection is small. The galvanometer is so graduated that it gives the amount that must be added to the reading of the dial in order to give the unknown p.d. The potentiometer proper, regulating rheostat, galvanometer and necessary keys and switches are mounted in one box, making the instrument semiportable. The only accessories required to make measurements within the range of the instruments are a standard cell and storage battery.

For complete description of these instruments see *Bulletin of the Bureau of Standards, Vol. 8, No. 2.*

**White Potentiometer (Fig. 7).**— This is a four-dial low-resistance potenti-

Fig. 7. White Potentiometer.

ometer used for measuring small potential differences to high precision. It is well adapted for making high precision temperature measurements using thermocouples. The potentiometer is so constructed that parasitic thermoelectric forces are entirely eliminated. The resistance in the galvanometer circuit is kept constant by means of compensating coils which enable the instrument to be used as a deflection potentiometer.

A description of this potentiometer is given by Walter P. White in *Zeitschrift für Instrumentenkunde* 27, 210, 1907.

**Queen-Gray Potentiometer** (Fig. 8).—This potentiometer is of the "split circuit" type and is a compromise between high- and low-resistance instruments,

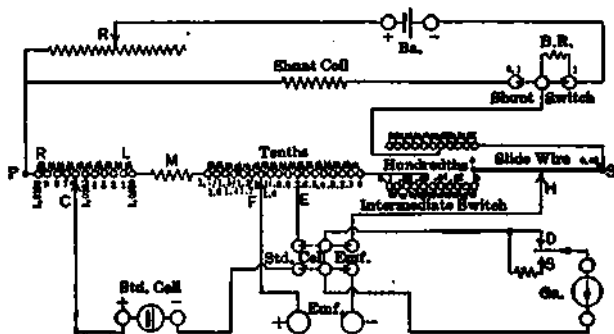

Fig. 8. Queen-Gray Potentiometer.

thereby possessing the advantages of each form without their disadvantages. The current to operate is 0.002 ampere, thus permitting the use of a dry battery. The drop over each resistance in the first group of coils is 0.1 volt, over the second is 0.01 volt and over the slide wire which consists of but one turn is also 0.01 volt. The slide wire is divided into 200 parts or 0.0005 volt. Each scale division can easily be estimated to its 0.2 part, thus making the final reading 0.00001 volt, which can be reduced 0.1 by a shunt coil, thereby making the lowest reading 0.000001 volt. The maximum direct range is 1.8 volts, which can be extended by means of multipliers. It is direct reading with any cadmium cell and has a contained rheostat for accurately controlling the 0.002 ampere regardless of the type of battery used.

**ALTERNATING-CURRENT POTENTIOMETER.**—The principles involved in the use of the potentiometer for alternating-current measurements are the following: Referring to Fig. 1, a balance is obtained with a battery at *B*, a standard cell at *P* and the contact *S* at the point on the scale corresponding to the e.m.f. of the standard cell, and the current flowing in the potentiometer circuit noted by means of an electro-dynamometer or a.c.-d.c. ammeter connected between *B* and *A*. The battery *B* is then replaced by a source of alternating current and the rheostat *R* adjusted until an alternating current of the same effective value, as read on the electro-dynamometer or ammeter, flows through the potentiometer. The standard cell at *P* is replaced by the unknown alternating p.d. to be measured and the galvanometer by an alternating-current galvanometer (see *Galvanometers*). To obtain a balance, however, it is now not only necessary that the contact *S* be moved along until the drop between *A* and *S* has the same effective value as the unknown p.d., but also that this drop and the unknown p.d. have the same frequency and are in the same phase. Con-

sequently the p.d. at *B* must be supplied from the same source as the p.d. to be measured, and means must be provided for shifting the phase of one with respect to the other.

The coils of an a-c. potentiometer are wound non-inductively, and consequently the p.d. due to the potentiometer current is in phase with this current. Hence the phase adjustment consists in bringing the potentiometer current into phase with the unknown p.d.

**Phase-shifting Device.**— One means of shifting the phase of the potentiometer current with respect to the unknown p.d. is to use two small alternators mounted on the same shaft, with the field frame of one adjustable with respect to the other. This, however, can be more conveniently accomplished by using a device similar in construction to a polyphase-induction motor, the primary of which is supplied either from a two- or three-phase circuit, or from a two-phase circuit derived from a single-phase circuit by connecting a resistance and condenser in series, and tapping off the p.d. across the resistance for one phase and the p.d. across the condenser for the other phase. By setting the secondary of this phase shifter at a fixed angle with respect to the primary, a p.d. can be obtained from the secondary at any desired phase with respect to the source of supply. A phase-shifting device based on this principle, and so designed that the change of phase resulting from shifting the position of the secondary does not alter the effective value of the secondary e.m.f., has been recently devised by C. V. Drysdale (*Phil. Mag.*, 1909, Vol. 17, p. 402). With this instrument the phase of the potentiometer current and p.d. to be measured may be adjusted to  $0.1^\circ$ .

**Drysdale-Tinsley Alternating-current Potentiometer (Fig. 9).**— A diagram of connections is shown in the figure. A vibration galvanometer is used

Fig. 9. Drysdale-Tinsley Alternating-current Potentiometer

as an a-c. detector and is tuned to the impressed frequency. The potentiometer is first balanced with an ordinary battery and standard cell and the reading of the electro-dynamometer noted. By means of the change-over switch, alternating is substituted for direct current and the reading brought to the same point and held there. The phase of the potentiometer current is then roughly adjusted and the unknown p.d. is balanced as nearly as possible by shifting the potentiometer slides. The balance is then improved by shifting the phase of the potentiometer current and by resetting the slides; thus, by a process of double adjustment, the vibration galvanometer is brought to rest.

As the vibration galvanometer is a tuned instrument, the frequency of the a-c. supply must be kept constant. Also, the wave shape of the potentiometer current

and that of the unknown p.d. must be the same, as the vibration galvanometer shows a balance for the fundamental frequency only.

**Current and Power-Factor Measurements.** — By the use of suitable non-inductive shunts alternating currents may also be measured with this potentiometer. Also, by noting the reading of the phase-shifting device corresponding to a balance first of the given p.d. and then for the given current, the phase angle between the p.d. and current can be obtained by taking the difference of the two readings.

**Range of Drysdale-Tinsley Potentiometer.** — This potentiometer has a range of from 0 to 1.5 volts in steps of 0.001 volt. With suitable non-inductive volt boxes its range may be extended to 750 volts. It may also be used, in conjunction with suitable shunts, for measuring alternating currents of any value.

**PRECISION OF POTENTIOMETER MEASUREMENTS.** — The precision obtainable with a potentiometer depends upon the accuracy to which the e.m.f. of the standard cell is known, the accuracy to which the various resistance coils in the potentiometer circuit and shunts are adjusted, and the relative magnitude of the various contact resistances, and the proportion of the total resistance in the potentiometer circuit. For a-c. measurements the accuracy is also dependent upon the inductance and capacity of the coils. The Bureau of Standards calibrate the Weston cell to  $\frac{1}{50}$  per cent. The various coils of a potentiometer are adjusted to different degrees of accuracy, little attention being paid to the absolute accuracy of coils as long as they bear definite relations to each other. Instruments are calibrated as potentiometers to give the following accuracies.

PRECISION OF POTENTIOMETER MEASUREMENTS

Kind of potentiometer	Degree of precision, per cent	
	Voltage measurements	Current measurements
Low-resistance null type.....	$\frac{1}{50}$	$\frac{1}{50}$
High-resistance null type.....	$\frac{1}{50}$	$\frac{1}{50}$
Brooks.....	$\frac{1}{25}$	$\frac{1}{10}$

**COST OF POTENTIOMETERS.** — The following are approximate costs of the potentiometers proper, exclusive of the standard cell, galvanometer, volt box and shunts for current measurements.

Low-resistance null type (pre-war price).....	\$240
High-resistance null type, rheostat not included (pre-war price) .	250
Brooks deflection type, including galvanometers (pre-war price) . .	350
White, including rheostats (1920 price).....	500

**BIBLIOGRAPHY.** — A complete bibliography on potentiometers is given in *Circular No. 21, Bur. Stand.*, 1910; H. B. Brooks, *Bull. Bur. Stand.*, Vol. 8, 1911, p. 395. See also Laws, F. A., *Electrical Measuring Instruments*; Pedersen, P. O., *A. C. Potentiometer for Telephone Frequencies*, *Electrician*, 83, p. 523, 1919; Kennelly and Velandar, *A. C. Potentiometer giving Rectangular Components*, *J. Frank. Inst.*, 188, p. 1, 1919; Ryan, H. J., *High Voltage Potentiometer*, *Proc. A.I.E.E.*, 35, p. 1187, 1916.

**POWER-FACTOR INDICATORS AND REACTIVE VOLT-AMPERE INDICATORS.**—(See also *Alternating Currents; Generators, Alternating-Current; Wattmeters.*) A power-factor indicator is an instrument designed to give a direct reading, at any instant, of the power factor in a circuit or system of circuits as well as to indicate whether the current is leading or lagging; see *Alternating Currents*. The power factor of a single-phase circuit may be calculated from the readings of an ammeter, voltmeter and wattmeter. The power factor of a balanced three-phase circuit can also be calculated directly from the readings of the two wattmeters used to measure the power (see *Wattmeters*). A direct-reading power-factor indicator, however, is usually to be preferred for station purposes, since it gives the power factor directly and also indicates directly whether the current is leading or lagging.

Under certain conditions it is more convenient to obtain a direct measure of the reactive (wattless) power supplied to a circuit; ordinary wattmeters may be thus used as explained below.

Closely allied to power factor meters are the "reactive factor meters" which, however, should not be confused with "reactive volt-ampere meters." Reactive volt-ampere meters are also often called "reactive component indicators," or "reactive component watt-hour meters." In order to clearly indicate the various instruments involved in phase angle measurements of a-c. power circuits the following table is appended:

Instrument	Measurement	Symbol
Wattmeter . . . . .	True power . . . . .	$V. A. \cos \phi$
Volt-ammeter . . . . .	Apparent power . . . . .	$V A$
K V. A. meter . . . . .		
Reactive volt-ammeter	Reactive component of apparent power or of volt amperes . . . . .	$V. A. \sin \phi$
Power factor meter . . . . .	Angle of lag between $C$ and $V$ , indicating according to cosine . . . . .	$\cos \phi$
Reactive factor meter.	Angle of lag between $C$ and $V$ , indicating according to sine . . . . .	$\sin \phi$

**SINGLE-PHASE POWER-FACTOR METERS.**—Instruments for measuring the power factor of single-phase circuits are provided with one current coil circuit and one potential coil, the latter, however, being generally a double-circuit coil, the two portions being located with axes at right-angles to each other. The one is supplied with current from the potential binding posts through a non-inductive resistance and the other through a highly inductive resistance or "choke coil" so as to receive currents in the divided circuits corresponding in electrical phase angle to the mechanical angle between the coils.

**POLYPHASE POWER-FACTOR METERS.**—These can be classified as follows:

**For Balanced Polyphase Circuits.**—Such instruments are provided with a single-current coil connected to one phase of a polyphase circuit, and two or more voltage coils star-connected to each polyphase line. They are calibrated to indicate the cosine of the angle of lag between the line supplying the current coil and the voltage from this line to the artificial neutral point formed by the voltage coils within the instrument. It is assumed that the angle of lag is equal

in all phases within an accuracy sufficient for the purpose for which the instrument is used.

From the above it will be understood that "balanced polyphase" instruments differ from single-phase instruments only as regards the voltage coil connections and the calibration.

**For Unbalanced Polyphase Circuits.**—The development of such instruments in the United States can be said to date from the adoption of a standard definition by the A.I.E.E. for power factor of unbalanced polyphase circuits (see A.I.E.E. Standards.)

Let the active (power) and reactive (stored) components of the volt-amperes of each phase be represented in Fig. 1 by the small triangles  $a$ ,  $b$ ,  $c$ , in which the watts are plotted horizontally and the reactive components vertically. Then the total power in the polyphase circuit is  $OX$ , the total volt-amperes  $OA$ , and the power factor is the cosine of the angle  $AOX$ .

Power-factor meters for correctly measuring unbalanced polyphase circuits are inherently quite complicated, comprising three voltage circuits and three current circuits or their equivalents. However, by measuring the power factor of each phase separately with instruments having single-phase current coils, the unbalanced-circuit polyphase power factor can be determined.

An instrument intermediate between the balanced and the unbalanced circuit types consists of three star-connected current coils one connected to each line and one voltage coil connected to one phase. Although more accurate on moderate unbalances than the single current-coil instrument, and simpler than the instruments for unbalanced circuits, it is more difficult to connect and calibrate than the single-current coil type. An unbalance of 20 per cent produces an angular error of indication of  $7^\circ$  maximum in such instruments.

**MOVING-COIL TYPE.**—Power-factor indicators of this type operate on the same principle as wattmeters of the electro-dynamometer type, except that the coils are so arranged and so connected to the circuit that a differential action is produced which depends only on the power factor of the load.

In order that the differential action may be correct under all balanced-load conditions, mechanical control forces such as springs must be avoided or made negligibly weak.

**Three-phase, Moving-coil Type.**—Fig. 2 is a diagram of a three-phase power-factor indicator having three voltage coils and one current coil.  $C$  and  $C'$  are current-coil sections in series with one leg of circuit and  $P_1$  and  $P_2$  are potential coils connected as shown through the non-inductive resistances  $r_1$  and  $r_2$ . Connections into and out of the moving coils are made by light spirals having very small torque, or through the bearings, so that the final position of the moving system depends solely upon the relative forces between the fixed and moving coils.

If the instrument is connected properly, the current coil acts with the two potential coils like the two elements of polyphase wattmeter (see *Wattmeters*). The torques of the two moving elements are developed in opposite directions. The torque of each element depends on the position of its potential coil. The potential coils are fixed with relation to one another at such an angle that the torque of one element always increases when that of the other decreases, due to the movement. Hence the needle will come to rest where the two torques

Fig. 1

are equal, and will give a scale reading dependent upon the ratio of the watts supplied to the two elements, i.e., in the case of a balanced load dependent on the ratio  $\cos(30 - \theta) + \cos(30 + \theta)$ , where  $\theta$  is the power-factor angle. Hence, for unity power factor, ( $\theta = 0$ ), the moving element will take up a position which is symmetrical with respect to the two potential coils, i.e., the pointer will take up a vertical position. For 50 per cent power factor, lagging, ( $\theta = 60^\circ$ ), the moving element will swing to the right until the axis of the potential coil  $P_1$  coincides with the axis of the current coil. Similarly, for 50 per cent power factor, leading, ( $\theta = -60^\circ$ ), the moving element will swing to the left until the axis of  $P_2$  coincides with the axis of the current coil. The character and range of the scale can be modified by varying the angle between the two potential coils.

Fig. 2. G. E. Moving-coil Type

Should the direction of flow of power reverse, the pointer would tend to take up the dotted position in Fig. 1. Some instruments are provided with scales to take advantage of this effect.

**MOVING-VANE TYPE.** -- In place of the movable coils this type of power-factor meter contains a movable soft iron vane, which, in the case of polyphase instruments, is magnetized through a stationary coil carrying a current in phase with the current of one phase of the circuit. There is one stationary voltage coil for each phase, the arrangement being such as to produce a rotating field. The iron vane then takes up a position in which the direction of the flux produced in it by the current coil when at a maximum, is coincident with the direction of resultant flux due to the voltage coils. In the three-phase instrument three voltage coils, placed  $120^\circ$  apart, are used; in the two-phase meter two voltage coils at  $90^\circ$  are used. In the single-phase type the iron vane is magnetized by a stationary coil placed in series with the line, while the rotating field is produced by two potential coils  $90^\circ$  apart, one of which is connected to the line through an inductance, the other being connected to the same line through a non-inductive resistance. For the purpose of damping the deflections, an aluminum disk moving in the field of two permanent magnets is attached to the movable system.

**REACTIVE WATTESS VOLT-AMPERE INDICATORS.** -- Operating conditions on polyphase circuits are sometimes such that the reactive component of the volt-amperes in the circuit does not vary through wide limits of load between light load and full load, whereas the power factor may vary greatly. Under such circumstances it is frequently more convenient to have a direct measure of the reactive volt-amperes rather than the power factor.

Ordinary wattmeters may be used for indicating the reactive component of the volt-amperes, by changing the voltage connections so as in effect to rotate them through  $90$  electrical degrees, thereby causing the instrument to read  $VA \sin \theta$  instead of the usual  $VA \cos \theta$  or "active" component usually known as watts or kw. If this rotation is affected without varying the ratio of transformation the calibration of the wattmeter is the same as for ordinary watt measurements. If such connection alters the ratio of transformation, the calibration constant is altered accordingly.

When applied to circuits which may either have lagging or leading current the

zero may be placed in the center of the scale, like zero-center wattmeters which are applied to circuits which are liable to reverse in direction of power flow. Fig. 3 (a) shows connections when the phases are rotated without change in calibration being necessary, but requiring voltage transformers having taps. This is the preferable method. Fig. 3 (b) shows connections when the phases are rotated requiring special calibration, but not requiring special transformer taps. Fig. 3 (c and d) shows connections combined with a double-throw switch

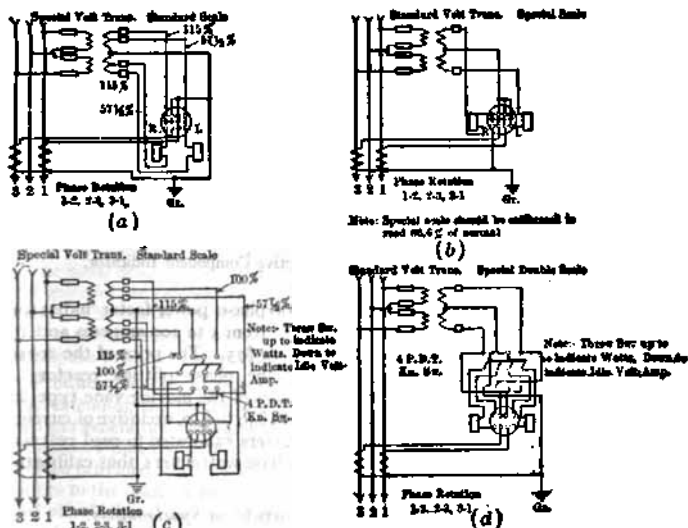

Fig. 3. Diagram of Connections for Reactive Component Indicator.

to read either reactive or active component ( $KW$ ). Fig. 4 shows corresponding connections for 3-phase, 4-wire circuits.

**RANGES OF THE VARIOUS TYPES.** — The largest capacity of instrument of the moving-coil type for direct connection to the circuit is 100 amperes and 300 volts for the single-phase and 200 amperes and 600 volts for the two-phase and three-phase types. The range of power factor on standard instruments is from 0.60 leading to 0.60 lagging, although instruments with ranges as low as 0.00 leading to 0.00 lagging have been made.

Instruments of the moving-vane type have a current capacity of 5 amperes. They are made for direct connection to circuits of 110, 220 and 440 volts. For all other capacities and voltages the 5-ampere, 110-volt instrument with suitable current and potential transformers is used. The instruments are made for frequencies of either 25 or 60 cycles per second. The range of power factor on the moving-vane type of meter is unlimited.

Power-factor indicators of either type may be connected to instrument transformers which are used in connection with other meters.

Five amperes and 115 volts are standard for wattmeters used as reactive volt-ampere indicators, with transformers for higher ranges. (However, single-

phase instruments for direct connection are furnished up to 100 amperes and 600 volts, and polyphase instruments for direct connection, up to 60 amperes and 600 volts.

Fig. 4. Diagram of Connections for Reactive Component Indicator.

**COSTS.**—The approximate prices of polyphase power-factor indicators of the moving-coil type, for current capacities of from 5 to 100 amperes and for voltages from 100 to 600 volts, range from \$45 to \$75. The price of the corresponding single-phase instruments, including the phase-splitting reactor, is approximately \$10 more. Power-factor indicators of the moving-vane type for voltages from 110 to 440 cost approximately from \$30 to \$40, exclusive of current or potential transformers. Single-phase wattmeters calibrated to read reactive volt-amperes cost about \$45 each and polyphase wattmeters thus calibrated cost about \$65. (Prices as of 1921.)

**BIBLIOGRAPHY.**— See *Bibliography* in article on *Synchronizers*.

**POWER STATIONS, GAS-ELECTRIC.** — (See also *Gas; Gas Engines; Gas Producers; Generators; Power Stations, Steam-Electric; Power Stations, Hydroelectric.*)

**Number and Capacity of Units.** — As gas engines have little overload capacity a total rating of engines should be installed sufficient to carry the extreme peak load and afford ample emergency reserve. In many cases the kilowatt rating of generators is made but 60 to 65 per cent of the horse-power rating of the engines, in order to provide overload generating capacity. This is not always wise, as the most efficient load of a gas engine is quite near its maximum capacity. The units in very large plants are usually of the horizontal, twin, tandem type and range from 4000 to 6000 h.p. in rating, the latter size being the largest available. Producers are quite flexible in capacity, but heavy forcing is apt to produce clinker and impair the quality of the gas. The total producer capacity usually corresponds with the total engine capacity, unless the load fluctuates greatly and considerable tank capacity for gas storage is available. In most cases not less than three engine and producer units should be provided.

**Buildings.** — The practice in this field follows quite closely that described in the article on *Power Plants, Steam-Electric* (q.v.). In a few cases producers are set in the open air. Producers and engines are sometimes in separate buildings. In the usual design the engine and producer rooms are parallel and electrical control galleries are provided on the side of the engine room opposite the producer room. The engine room should be spanned by an electrically operated crane with capacity sufficient to handle the heaviest engine part. In some important plants the producer room is also provided with a crane.

**Producer Room Lay-out.** — The gas producers are usually set in a single row extending the length of the producer room. Each unit comprises one or two gas generators, an evaporator, a scrubbing tower, a gas pump and tar filters grouped so that the path of the gas is toward the engine room. A coal bunker is often provided above the producers, preferably along the outside wall. Downspouts to the charging bells of the several producers should be somewhat inclined and should have cut-off valves. When desired, automatic weighing hoppers may be attached between the bunker and each down-spout to record the coal consumption of each producer. In some producer rooms a shallow pit is provided along the front of the gas generators so that ashes may be raked into this pit. In other cases ashes are raked out onto the main floor to be carted away. A skeleton gallery of steel connecting the producers at their charging levels is often a convenience.

**Engine Room Lay-out.** — Horizontal engines are usually set in a single row with piston rods across the engine room. The power end of each unit is on the side of the gas supply and the electrical end on the side nearer the control gallery. In a-c. plants a group of independently driven exciters is placed near the middle of the room. The spaces between units and the clearances at their ends are determined by the room needed for erection, dismantling, making repairs and access during operation.

**Piping.** — The piping scheme is usually a simple parallel plan. A main gas header is provided and runs the length of the wall between the engine and producer rooms. Branches from this header run to each producer unit, to each engine and to the storage tank. Piping may be of relatively light weight and needs no special provision for expansion, but all joints should be secure, as producer gas is of a poisonous nature. The storage tank may properly be at one end of the building. Each producer is usually set beneath a vent pipe or short steel chimney run a few feet above the roof to discharge the smoke and raw gases produced when starting up.

**Space Required.** — The following table shows the floor space provided per kw. of plant capacity in modern stations.

Plant capacity, kilowatts	Number of engine units	Number of producer units	Square feet per kilowatt	
			Engine room	Producer room
360	3	3	6.0	2.3
700	3	3	4.5	2.9
1,620	3	3	5.5	1.96
3,000	3	3	3.7	0.93
34,000 (a)	17	0	3.0	....

(a) Blast-furnace gas plant.

**Fuel, Labor and Water.** — *Fuel.* — Assuming the coal to have 12,000 B.t.u. per lb., about  $1\frac{1}{4}$  lb. coal are required per kw-hr. generated at full load;  $1\frac{1}{2}$  lb. per kw-hr. at  $\frac{3}{4}$  load; and  $1\frac{3}{4}$  lb. per kw-hr. at  $\frac{1}{2}$  load. For coal of any other heating value the weight required is approximately inversely proportional to the B.t.u. per lb.

*Labor.* — 1 fireman required for each producer in operation and 1 oiler for each engine in operation. Supervision, switchboard attendance, coal handling, etc., as for a steam-electric station. The total cost of labor for operation is usually about 50 per cent of the fuel cost.

*Water.* — About 9 gallons of water per kw-hr. are required when the supply water is at 50° F., and about 13 gallons per kw-hr. when at 70° F.

**COST OF GAS POWER PLANTS.** (Pre-war figures.) — The cost per kilowatt of gas power plants varies with the capacity of the plant, the number of units installed and the source of gas supply. The construction cost of engine plants using natural gas ranges from \$65.00 to \$100.00 per kw., depending on the size of plant. The construction cost of blast-furnace gas plants, including the necessary gas-cleaning equipment, ranges from \$85.00 to \$120.00 per kw. and of producer plants from \$90.00 to \$125.00 per kw. according to capacity. The cost per kw. diminishes very slowly above a plant capacity of 12,000 kw.

The reported cost of five blast furnace gas-electric installations is as shown in the following table :

Power plant No. ....	1	2	3	4	5
No. of units .....	17	2	3	4	5
Cap. kw., max. con. rating....	40,000	4,500	9,000	9,000	11,400
Cap. b.h.p. max. con. rating....	56,400	6,400	12,800	12,800	16,300
Cost of installation per kw. max. con. rating:	\$	\$	\$	\$	\$
(a) Buildings .....	9.87	.....	10.17	10.90	10.52
(b) Eng. equipment .....	71.78	75.50	72.75	77.78	80.32
(c) Gas cleaning plant .....	5.85	16.80	14.40	13.00	12.76
Grand total, power plant, complete, per kw.....	87.50	92.30	97.32	101.66	103.60

**Operating Costs of Producer-gas Plants.** — The following division of the items making up the cost of operation of producer-gas plants is taken from a typical plant in commercial operation:

	Minimum	Normal	Maximum
Output, kw-hrs. per day.....	5000	8000	10,000
Cost, cents per kw-hr.....	0.25	0.22	0.20
Price, cents per kw-hr.....	0.28	0.17	0.14
Supplies and repairs, cents per kw-hr..	0.17	0.13	0.11
Operating cost, cents per kw-hr.....	0.70	0.52	0.45
Fixed charges, cents per kw-hr.....	0.45	0.28	0.22
Total cost, per kw-hr.....	1.15	0.80	0.67

**Cost of Blast Furnace Gas-Electric Power.** — The cost of producing electric power by means of blast-furnace gas engines in one of the large steel plants is reported to be as follows:

	1910	1911	1912
Capacity in kw.. .. .	40,000	40,000	50,000
Kw-hr. produced.....	116,535,000	157,742,510	286,575,000
Efficiency factor, per cent .....	33.3	45.0	64.5
Cost of installation, per kw.....	\$88.00	\$88.00	\$88.00
Operating cost, cents per kw-hr.:			
Labor.....	0.0678	0.0421	0.0302
Repairs and maintenance.....	0.0366	0.0305	0.0273
Lubricants.....	0.0116	0.0100	0.0085
Water.....	0.0074	0.0057	0.0036
Miscellaneous.....	0.0064	0.0153	0.0128
Cost of purified gas, cents per kw-hr	0.1951	0.1727	0.1608
Fixed charges, 15 per cent, do....	0.4520	0.3360	0.2310
Grand total at switchboard....	0.7769	0.6123	0.4742

**POWER STATIONS, HYDROELECTRIC.**—(See also *Power Stations, Gas-Electric; Power Stations, Steam-Electric; Dams; Generators; Hydraulics, Principles of; Hydrology; Pipes and Piping; Switchgear Equipment for Power Stations; Transformers; Water Wheels; etc.*) This article deals primarily with those features in which a hydroelectric plant differs from a steam electric plant; these features arise chiefly from the nature of the prime movers and from the use of the very high voltages (up to 150,000) at which power from hydroelectric stations is transmitted. The individual constituent items, such as generators, water wheels, transformers, switchgear, etc., are treated in the separate articles, dealing with these subjects. The following is a brief table of contents of this article:

Location of Power House.....	p. 1174

**LOCATION OF POWER HOUSE.**—The location of the power station of a hydroelectric plant is determined primarily by the head utilized and by the location of the dam (see *Dams*). In the case of low head developments the sub-structure of the power station is usually a portion of the dam itself or a "wing" offset from it. In choosing the location of both the dam and the position of the power station relative thereto, particular attention should be paid to the liability of ice and debris clogging the intakes. For high head developments, using penstocks, the power station is so located as to give the maximum head consistent with economy of construction and availability of a suitable natural channel for carrying off the discharge. Available sites for storage reservoirs should also be considered.

The location of the development generally has to be such that high-tension transmission is necessary, so that provision must also be made for housing the transforming and high-tension switching apparatus. If it is desired to place them indoors, or if it is decided to place the high tension equipment out of doors, an ample area of preferably flat ground should be selected to accommodate, without congestion, this apparatus along with the necessary structures for supporting the buses, etc.

**DESIGN OF BUILDING.**—(See also *Water Wheels and Their Setting*.) The design of power houses differs greatly, depending on the conditions which are to be met. It is affected to a very great extent by natural conditions, such as the location with respect to the stream, the condition of the soil, etc. Low and high head developments require different types of turbines and these may furthermore be of horizontal or vertical construction, necessitating entirely different lay-outs.

A hydroelectric power-house building is generally divided into two longitudinal bays, a front or main bay, containing the turbines and generators, and a rear bay containing the transformers, switching apparatus, etc.; see Figs. 1 and 1a.

Fig. 1. Cross Section of Power House

Fig. 1a. Cross Section of Power House; Roof Trusses with Raised Chord

The two bays are separated either by a wall or by a row of supporting columns. The rear bay is divided into two or more floors and these, in turn, into various rooms or compartments to accommodate the step-up transformers, switches, bus-bars, lightning arresters, etc.

**Outdoor Step-up Substations.** — During recent years, as a result of the cost of buildings necessary to house high-tension transformation and switching apparatus, outdoor substations have come into general use. This is particularly true in those cases where the operating potential exceeds 100,000 volts. Experience confirms the wisdom of this type of construction, for when compared with the indoor type, it is found that although it is a little more difficult to make repairs in the case of the outdoor station, this is largely offset by lower cost of the installation and reduction of the fire hazard. The difference in cost of apparatus designed for the two classes of service is insignificant. The net difference in cost is that between the cost of the large buildings necessary for housing the high-tension equipment and the cost of the light concrete bases and steel structures required in the case of the outdoor installation. The operation of these stations does not seem to be in any way impaired by the low temperatures and snow of our Northern winters nor the heat of our Southern summers.

**Bearing Power of Soils.** — The most important part of the building is the foundation, and careful soundings must be made to ascertain the underlying strata. If bedrock is found within moderate depth, the foundation should be carried down to the same. The safe bearing loads usually allowed for soils in this country are given in the following table:

SAFE BEARING POWER OF SOILS  
(From Baker "Treatise on Masonry Construction")

Material	Load in tons per sq. ft.	
	Minimum	Maximum
Rock, hardest kind.....	200	..
Rock, equal to Ashlar masonry.....	25	30
Brick, equal to Ashlar masonry.....	15	20
Brick of poor quality.....	4	7
Clay in thick beds always dry.....	4	6
Clay in thick beds moderately dry.....	3	4
Clay, soft.....	1	2
Gravel and coarse sand.....	8	20
Sand, fine and compact.....	4	6
Sand, clean and dry.....	3	4
Alluvial soils and uncertain sand.....	0.5	1

For foundations it is considered good practice to use somewhat lower values. About one-half is a good working basis for such work, thus allowing a maximum load of about 1000 lb. per sq. ft. for ordinary alluvial soils. Clean sharp sand is considered to be a good bearing soil, and it may only be necessary to cover it with a concrete mat, which requires a minimum amount of concrete. For soft or alluvial soils piling is almost always required. These may be of wood, although in the last few years much use has been made of concrete piles, both plain and reinforced. Such piles are less apt to decay and their bearing power is higher, due to their greater friction. They may also be made of larger diameters than can be obtained with wood piles and a less number is therefore required to support a given load.

**Design of Foundations.**—The weight on a foundation includes the machines, fittings, the weight of the foundation itself, and, in the case of the turbines, the weight due to the water thrust unless this is balanced. Separate foundations should be provided for the different units so as to isolate any failure as far as possible. Concrete is always used for the foundations.

Machinery foundations should be solid, but buildings may be supported on columns or arches so as to economize the concrete (*see Concrete*). Where there is danger of high water in the tail race, the outside foundation walls should necessarily be made water-tight so as to prevent water from entering the basement. For such cases a sump is generally provided into which the seepage may collect and from which it can be pumped out.

**Basements.**—A basement should be provided below the generator room when vertical turbines are to be used. That part of the floor on which the turbine discharge casings rest should be reinforced by heavy I-beams, and provision should be made for supporting the penstocks and draft tubes. There must be provided an intermediate basement floor which is generally made of concrete and should be carried on I-beams supported by the concrete piers which also support the generators and the main floor. With horizontal turbines no basement is needed. Ventilating and cable ducts for the generators and tunnels for piping, etc., are, however, often installed below the main floor.

**Floors.**—No combustible material of any kind should, if possible, be used in the construction of a power house. As the sub-structure of the building is generally built of concrete, it is but natural that the floors should also be of concrete. A dark color is preferable so as to render drops of oil inconspicuous. A tile or mosaic floor is smooth, easy to keep clean and has a very handsome appearance if made to conform with the general interior finish of the station.

**Walls.**—The walls may be either of reinforced concrete construction or of brick with a steel skeleton frame work. Where future extensions are contemplated a false wall is provided on one end of the building. The interior should be kept as light as possible and it is therefore advisable to apply a smooth surface of cement plaster and whitewash or paint the same. For more important stations the walls may be faced with pressed brick and up from the floor to about ten feet with enameled brick so that they may be readily washed and cleaned. Where the extra expense is warranted, the walls may be entirely lined with enameled brick and a wainscoting of contrasting color, preferably olive-green.

**Roof.**—The roof of the building should always be supported on the steel trusses, carried on the side walls or on steel columns. The slope should not be excessive, two inches per foot being sufficient with gravel covering. This construction requires less material, and is advantageous when the transmission wires are to enter the station through roof entrance bushings, or where the lightning arrester horns are to be installed on the roof.

The roof covering may simply consist of boards covered with roofing paper, tar and gravel. Reinforced concrete is sometimes used in place of boards so as to make an absolutely fireproof construction. Roofs covered with red tile are often used and present a very pleasing appearance. Corrugated iron roofs are objectionable due to the liability of moisture condensing on the inner surface and dripping into the station. They may also cause the station to be extremely hot in the summer unless an insulating lining is provided below the roof trusses to keep out the heat. With tile or metal roofs it is necessary to provide steeper inclines than with gravel roofs so that the water may run off rapidly. Monitors are sometimes provided so as to give additional ventilating facilities.

Roof trusses with a raised chord, shown in Fig. 1a, are in many instances of great advantage in that they provide an increased headroom without unneces-

sarily raising the walls of the building. This is of special importance in the high-tension part of the station, where ample headroom must be provided for the busses.

**Windows.** — Good lighting is imperative, and large windows are therefore essential. They should be symmetrically located with regard to the generating units and their design should be such as to harmonize with the building, arched windows being very generally used. Skylights of glass tile placed in the roof will also add considerably to the lighting. The window sashes should preferably be metallic and the glass reinforced with wire netting so as to prevent shattering when broken. Ribbed or non-transparent glass is also desirable, because it keeps out the intense rays of the sun. In order to provide for ventilation, provision should be made so that the windows can be opened, but precaution should be taken so that rain, snow or dust will not blow in on the machinery or apparatus. This is especially important on the switchboard side where the wiring is exposed and it is therefore better practice not to provide any means for opening the windows on that side. For tropical climates the windows which are liable to be opened should be equipped with mosquito screens.

**Doors.** — The location of the doors is naturally governed by local conditions. One of the openings should be of sufficient size to admit a railroad car, for which tracks should be provided. Very often these doors are of the rolling type, this design being most economical as regards space.

**Traveling Crane.** — Provision should always be made for supporting the track for a traveling crane, which should span the generator room and run the full length of the station. The track is generally supported on pilasters in the outside wall and on the steel columns separating the generator and switch rooms. There should be ample headroom allowed so that the various machine parts can be readily removed when repairs are to be made. This is especially important with vertical units where the water-wheel rotor is mounted on the same shaft as the generator field, and in which case it should be possible to lift out the whole revolving element by simply removing the top bracket and bearing of the generator.

**Miscellaneous Rooms.** — Repair rooms, store rooms, offices, toilets, etc., should be provided. Ample stairway provision is essential so as to permit a ready access to important points, such as between the generator room and the switchboard gallery.

**LOCATION OF APPARATUS.** — The arrangement of the apparatus should be very carefully considered from the standpoint of simplicity and reliability of operation. The purpose of the station being to give reliable service consideration must also be given to the causes of disturbances and means for minimizing their effects. In anticipating these abnormal or so-called emergency conditions, the failure of every piece of apparatus must be considered as a possibility, and a definite plan worked out for limiting the magnitude and area of such disturbances.

**Location of Generators.** — The turbo-generator units are located on the main floor and are almost always arranged in a line along the long axis of the station. They should be spaced far enough apart so that ample space for passage is provided between them. Horizontal sets may be installed either at right angles or parallel to the long axis, the latter method being necessary for high heads where impulse wheels are used. The arrangement of the rest of the equipment, such as the transformers, may also be a determining factor in regard to which direction the sets should be installed. If one transformer bank, consisting of single-phase units, is to be installed for each generator, the space occupied by them may be of such a length that it would be more economical to install the

turbo-generator sets parallel to the long axis, thus reducing the width of the building.

**Location of Turbines.** — (See *Water Wheels*.) With horizontal sets the turbines may be located together with the generators in the generator room or in separate wheel chambers built in the dam. The latter practice is only used for very low head developments, where one of the power-house walls forms part of the dam structure. With vertical units the turbines are always located in a basement, the thrust bearing being supported on an intermediate floor below the main floor, unless suspension bearings are used, these being mounted on top of the upper generator-bearing bracket.

**Location of Exciters.** — The exciters are as a rule installed on the same floor as the main generators and in the center of the station. The advantage of such an arrangement is that the exciters will be located close to the operating switchboard and the amount of copper required for the exciter leads is thus a minimum. The system may readily be sectionalized, one exciter serving the generators located in one-half of the station, and the other the generators on the opposite side. This does not, of course, refer to direct-connected exciters.

**Location of Transformers.** — Due to their weight, the step-up transformers should preferably be located on the main floor. They are generally installed in isolated compartments in the rear bay, separated from the generating room by fireproof steel curtains. These compartments should be sufficiently large to allow a good ventilation. A car track is provided on the generator-room floor in front of the transformer compartments whose floors are raised so that the transformers can be run out on the car and moved to some convenient place in the station where repairs can readily be made. For large units it may be necessary to provide a hole in the floor above the repair room so as to enable the transformer core to be lifted out of the tank, or a pit may be provided into which the transformer may be lowered so that sufficient headroom is obtained for lifting out the core. Sometimes the repair room is so situated that the main crane cannot be utilized for dismantling the units. In such a case a chainfall supported from a heavy I-beam in the floor above may be provided.

**Transformers Installed Out-of-Doors.** — Considerable activity has recently taken place in installing transformers and associated high-tension apparatus outdoors. With the exception of the bushings the transformers for such installations differ comparatively little from the indoor type; the only feature out of the ordinary being the necessity of keeping the moisture from entering the transformer cases under the covers and leads. To prevent this the joints have been made with waterproof gaskets and breathing chambers have been provided.

Special precautions must naturally be taken to protect transformers of the outdoor type both from the extreme heat and from the cold in the winter. The former can readily be obtained by providing sunshades, and in certain instances very good results have been obtained by simply painting the cases white. It is more difficult, however, to provide for the cold winter temperatures, especially with water-cooled transformers. With the transformers in service there seems to be no danger of freezing and if such should be the case some sort of heating grids could readily be provided in the bottom of the tanks. The main difficulty lies in the formation of moisture which takes place when the temperature of the transformer is allowed to fall below that of the surrounding air; this applies also to indoor transformers. Precautions must therefore be taken that this does not happen, and may be accomplished by either reducing the water rate at times of cold weather, or by using the cooling water over and over again. Non-freezing oil may be used in such transformers, but its cost is so high that it is almost prohibitive from a commercial standpoint.

**Location of Switchboards and Switchgear.** — (See also *Switchboards and Switchgear Equipment for Power Stations*.) The different pieces of apparatus comprising the switching equipment are distributed on the various floors in the switch-section of the station, each story being partitioned to suit the various purposes. The operating room with the control switchboard is generally located on the second floor and in such a position that the operator may have an unobstructed view of the station, and be able to readily communicate with the turbine operators: A balcony, somewhat overhanging the generator room in front of the switchboard, is often provided or the operating room is built with a curved front wall extending out over the generator room.

**Location of Oil Switches.** — The low-tension oil switches are generally of the enclosed type and, together with the low-tension bus-bars (see *Bus-Bars and Bus-bar Structures*), are located generally in compartments on the main floor back of the transformer compartments. The switches themselves should preferably be set opposite the generator and transformer bank which they control, so as to call for as short a connection as possible and in order that these connections may be of equal length. The high-tension oil switches and bus-bars, and also as a rule the lightning arrester tanks, are installed on the floor above, or outdoors as the case may be.

**Disconnecting Switches.** — It is customary to install disconnecting switches on both sides of an oil switch so that they may be entirely disconnected from the circuit when repairs are to be made on them, when the oil tanks are to be refilled, etc. Disconnecting switches may also be used in a number of cases for changing connections, when this is not to be made under load. Such switches should be provided with locking devices, as experience has shown that the magnetic fields caused by short-circuits may cause disconnecting switches to open, which in turn may cause serious disturbances by the arcs set up.

**Spacing of Bus-Bars.** — (See also *Bus-Bars and Bus-bar Structures*.) The following spacings are suggested in laying out bus-bar structures:

Voltage	Dimensions in inches			
	Outdoors		Indoors	
	To ground	Between live parts	To ground	Between live parts
2,000 - 3,500	3 ½	4	3	3 ½
3,501 - 7,500	5 ½	6	4 ½	5 ½
7,501 - 15,000	9	10	7	9
15,001 - 25,000	14	15 ½	10 ½	14
25,001 - 37,000	19 ½	22	14 ½	19 ½
37,001 - 50,000	25 ½	29	19	25 ½
50,001 - 73,000	36	41	27	36
73,001 - 95,000	47	53	34 ½	47
95,001 - 115,000	56	64	41	56
115,001 - 135,000	66	75	48	66
135,001 - 155,000	75	86	55	75

**Location of Lightning Arresters.** — (See also *Lightning Protectors; Switchgear Equipment for Power Stations.*) The aluminum arrester is now generally used in all high-voltage stations. Both the arrester tanks and the associated horn gaps may be located within the building, or the horn gaps may be placed outside and the tanks inside, or both may be placed outside, provided there is no danger of the electrolyte freezing. Standard equipments of 27,000 volts and below are usually designed as complete units to be installed inside the station, whereas for those above 27,000 volts the horn gaps should preferably be installed outside the station and the tanks inside. Exception to this rule can be made where there is sufficient space in the station over the gaps.

The arrester tanks should naturally be located close to the line entrances. The horn gaps, when installed out-of-doors, may be placed on the roof of the building if roof-entrance bushings are used, or on a separate structure at the side of the building if wall-entrance bushings are used. The location of the arresters should also be such that the path for the discharge from the line conductors to the arresters and ground will be as straight as possible.

**Clearance over Horn Gaps.** — Wherever horn gaps are mounted inside the building sufficient clearance should be allowed over them. There is no appreciable arc at the gaps, but in abnormal cases where the film has been allowed to get out of order, the arc may be of considerable size. Where there are no fuses or inflammable apparatus, the following are the minimum clearances from the tops of horns to be allowed:

Volts	Clearance, feet
Up to 16,100.....	3
16,101 to 37,900.....	4
37,901 to 70,000.....	6

These clearances should be materially increased when there are wires, cables, fuses or any inflammable material over the horn gaps.

Above 70,000 volts, the horn gaps should never be placed indoors.

**Effect of Climatic Conditions on Arresters Installed Out-of-Doors.** When aluminum arresters are installed out-of-doors, there is always present the possibility of freezing the electrolyte in cold weather and that of abnormal ion dissolution during extremely hot days. The electrolyte is not permanently injured by freezing, but when frozen, the internal resistance of the arrester is considerably increased and hence its discharge rate is materially lowered. This is not of any practical consequence, for during the winter months there is usually a total absence of lightning. The rapid dissolution of the films on the cores of the arrester during warm summer days may be counteracted by more frequent charging. In some locations it may be found advisable to charge two or more times a day. When operating under conditions of high temperature, failure to regularly charge the arrester increases the liability of damage from a heavy electrical discharge through it.

There has recently been introduced a new form of arrester designed to overcome the necessity of periodic charging as in the case of the aluminum arrester. This new arrester is known as the oxide-film type. It requires no charging, has about the same discharge capacity, may be built for either indoor or outdoor operation, and due to the small arc formed across the gaps during discharge, may be covered in the case of out-door arresters thereby obtaining prac-

tically the same arc-over potential for these outdoor arresters during dry or wet weather.

**WATER WHEELS AND GOVERNORS.** — The available types of water wheels and governors and the conditions under which they should be used are treated in detail in the articles on *Water Wheels and Their Settings*, and *Water Wheels, Speed Regulation of*.

**GENERATORS AND THEIR CONNECTIONS.** — (See also *Generators, Alternating-Current*.) Water-wheel-driven alternators are always of the revolving field type. Machines of this type are generally direct-connected to the water wheel. The horizontal construction has been used mostly, but recently the vertical construction has been used to a great extent, especially in low-head developments. The choice is usually determined by hydraulic conditions; see *Water Wheels and Their Settings*.

**Use of Power-limiting Reactances.** — See article on *Reactance Coils*.

**Operation of Generators in Parallel, Synchronizing, etc.** — (See *Generators, Alternating-Current; Synchronizers*.)

**EXCITATION AND EXCITER SYSTEMS.** — It is a good practice to have the combined normal capacity of all the exciters correspond to the excitation required for all the generators, when these are operating at their maximum overload, and at the actual operating power factor. A spare unit to be kept in reserve in case of the break-down of any exciter should generally be provided. This is especially desirable where an uninterrupted service must be secured at any cost and where the exciter units are few in number, as in such a case the shutdown of one exciter would seriously cripple the system.

**Amount of Excitation.** — The curves in Fig. 2 give approximately the average excitation required for water-wheel-driven alternators of high and slow speeds. It is seen that, as compared to the rating of the generator, the exciter capacity ranges from 0.75 per cent for large high-speed machines to 3 per cent for small slow-speed machines.

**"Time Element" of Exciters.** — The "time element" of the exciters should be such that the insertion into its field circuit of an external resistance equal to about three times the resistance of its field circuit, will cause the voltage to drop from 125 to 25 volts in from 4 to 6 seconds. This is particularly important when automatic voltage regulators are used (see below), for the exciter voltage must respond quickly to the short-circuiting of the field rheostat by the regulator.

**Exciter Voltage.** — For large installations a 250-volt system of excitation will generally be found more economical than a 125-volt system. This higher voltage will permit the use of smaller exciter and field switches, leads of reduced size may be used between the exciters and the generator field, and the cross-section of the exciter bus-bars will be

Fig. 2. Excitation Required for Water wheel-driven Alternators

reduced. A considerable saving can also generally be accomplished in the exciter itself.

**Methods of Driving Exciters.**— Although the exciters can be either belt-driven or direct-connected to the machines driving them, the latter practice is almost exclusively used except in the very smallest plants. The direct connection may be either to the main generators, to separate water wheels, or to motors. Sometimes (although rarely) an exciter is connected to both a motor and a turbine, the latter running idle when the motor is carrying the load, and the motor running idle when the turbine is doing the work.

**Exciters Direct-connected to Main Units.**— The practice of installing an exciter direct connected to each generator is very common and desirable. As a rule each exciter is only of sufficient capacity to excite its corresponding generator and is operated as a unit with it. In those stations where it is felt advisable to install spare exciter capacity, this spare capacity usually takes the form of a motor-generator set.

The generator of the set is connected to a bus and the switching so arranged that it can be used to excite the field of any one generator in the case of failure of the corresponding direct connected exciter. Fig. 3 shows another arrangement of connection commonly used in which all exciters are paralleled on a common exciter bus and the fields of all machines in operation excited from this bus.

This method of employing direct-connected exciters is mostly applicable in the case of medium- and high-speed generators. In the case of low-speed generators the high cost of the slow-speed exciters usually makes the arrangement prohibitive.

**Three-exciter System.**— A system which is commonly used and which offers a sufficient degree of reliability, is that in which the excitation is obtained from a common source, consisting of as few exciters as possible, Fig. 4. Three units are then generally provided, of which two are all that are needed for supplying the required excitation, the third unit being held in reserve. Sometimes the two exciters normally in service are driven by water wheels, the reserve unit being motor-driven. From the point of view of economy, however, it is evident that two motor-driven units with a water-wheel driven set as the spare will cost less. In the latter case, however, the exciter trouble with the exciter driven by the prime mover would prevent starting up the system, unless a storage battery were provided.

**Individual Motor-driven Exciters.**— Fig. 5 represents the practice when an individual motor-driven exciter is used for each main unit. Each ex-

Fig. 3. Exciters Direct Connected to Main Units

Fig. 4. Three-exciter System

citer is connected directly to the field of its respective generator. The exciters are not arranged for parallel operation, but are each provided with its own automatic regulator, so that it is possible to compensate for "wattless" or reactive cross-currents between the generators. In the system shown, the induction motors are fed either from two low-voltage alternating-current generators driven by separate water wheels, or alternatively from the main alternating-current bus-bars through step-down transformers. The auxiliary low-voltage generators are the normal source; the exciter system is thus entirely free from voltage fluctuations or disturbances on the alternating-current system. In another installation of this kind the auxiliary generators are provided for combination drive, one end being connected to a water wheel and the other to an induction motor, which in turn can be connected to the main alternating-current buses through step-down transformers, unless the voltage will permit of a safe operation of the motors without the transformers. In such an arrangement the exciter sets are not provided with independent group connections to the main bus, as shown in the illustration, as it is considered that a breakdown would most commonly be caused by a clogging up of the turbines, in which case the alternating-current units could be driven by the motors. It would seem, however, that the scheme shown in the diagram is more flexible and reliable.

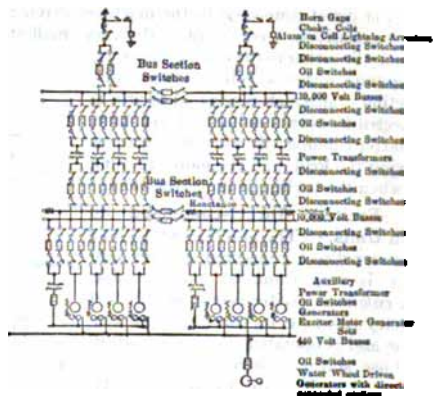

Fig. 5. Individual Motor-driven Exciters

**Electric Connections of Exciters.** — In those cases where exciters are not chosen to operate as a unit with the generator, it is general practice to provide one or two sets of common bus-bars to which all the exciters are connected in parallel and from which the fields of the different generators are excited, a rheostat being inserted in each generator field circuit. Where exciters are chosen of just sufficient capacity to excite the field of one generator, they are usually operated independently of each other, each with its armature connected to its corresponding generator field. If no spare exciter set is provided in the station, no exciter bus is necessary. Where a spare exciter is installed a single bus is used to permit of transferring it to any one generator field, in which case the corresponding direct connected exciter is taken out of the field circuit. In these latter two cases, no generator field rheostats are necessary.

Hand-operated field rheostats mounted on the back of the switchboard, or operated by chain drive from a hand wheel on the switchboard, are generally used. For large plants the alternator field and the exciter field rheostats are nearly always electrically operated. This method of operation should be used in plants where the main control board is on another floor or distant from the machines.

No automatic overload circuit breakers or fuses should be installed in the exciter circuits. The field current may rise to several times its normal value when the alternator is subject to a short circuit, and an automatic circuit breaker would then naturally open the exciter circuit, which must not be allowed. A

such troubles are rather infrequent, it is considered better practice to risk injury to the exciter rather than to install overload devices which may operate at the wrong time. With exciters operating in parallel on a common bus it may be desirable to have reverse current circuit breakers in the connections between the exciters and the bus.

The alternator field switches should be provided with discharge resistances, and these field switches as well as the exciter switches should be electrically operated in all large plants. The field switches should never open on overload, but may be made to open automatically when the main alternating current circuit breaker opens by the action of reverse power or differential relays in the main alternator leads.

**Shunt versus Compound-wound Exciters.** — Compound-wound exciters are generally considered preferable for parallel operation with automatic voltage regulators. Non-regulating exciters should be more or less highly saturated to insure a stable parallel operation. However, if such exciters are used with automatic regulators, they will be rather slow to correspond to the changes in field excitation. If a shunt-wound exciter is designed for a low saturation, so as to make it a good regulating exciter, there is a tendency to unstable operation when operating in parallel with other machines and without a regulator. For regulating exciters, which are not to be operated in parallel, the shunt-wound type is entirely satisfactory, provided it has been designed with this point in view, that is, for low saturation.

**Storage Battery on Exciter Bus.** — The use of storage batteries in connection with exciters is sometimes employed. The storage battery is generally floating on the exciter busses, the pressure of which is kept constant. A separate exciting bus is provided and between this bus and one of the exciter busses a booster is installed which can be operated to either raise or lower the voltage, its field being controlled by an automatic voltage regulator. In case of failure of the exciters the excitation would be furnished by the storage battery, and the booster in connection with the regulator would take care of the voltage regulation.

**AUTOMATIC VOLTAGE REGULATION.** — Without some form of automatic voltage regulator it is impossible to take care of the heavy swings in the voltage caused by fluctuating power and railway loads. Even in the case of a purely lighting load it is exceedingly difficult to properly take care of the voltage by hand regulation, especially at peak loads. The present tendency of designing generators for a high internal reactance, in order to reduce destructive short-circuit currents, results furthermore in a rather poor inherent regulation of the generators.

Many different forms of automatic regulators have been devised. Some of them have been designed to operate directly on the alternating-current generator field rheostat by varying the resistance. Such a system has, however, proved to be entirely too sluggish in operation. The most successful type of automatic regulator is the T. A. Regulator in which the regulation is effected entirely in the field circuit of the exciter, by rapidly opening and closing a shunt circuit across the exciter field rheostat. See the article on *Regulators*.

**TRANSFORMERS AND THEIR CONNECTIONS.** — (See also article on *Transformers*.) The number and size of the transformers depends entirely on the nature of the development and on the conditions to be met. With a moderate voltage development it has in the past been the general practice to install one transformer bank for each generator and having a capacity equal to that of the generator, even if this size was not the most economical.

In some instances transformer capacities are selected so that a bank of transformers corresponds in capacity with the rated carrying capacity of a trans-

mission line. In such cases a bank of transformers is usually operated as a unit with one of the lines. During the early stages of high-tension transmission development this method was almost invariably employed as it permitted the employment of low-tension switching to clear trouble on the high-tension system. In such cases as this the transformers might be considered as a part of the transmission line. With the advancement of the art of building high-potential apparatus and as a result of the experience gained in operating high-tension systems, this manner of operation is gradually giving way to the use of high-tension switching, in which case it is no longer necessary to select transformer banks of the same capacity as that of the transmission lines. The tendency is rather to select them on the basis of the generator capacity.

In order to facilitate moving the transformers in or out of their compartments, wheels should be provided in the base or trucks may be installed on which the transformer will rest. The design should also preferably be such that the complete core and coils, with the cover and leads can be lifted from the tank as a unit. Eyebolts are provided for this purpose and also for lifting the entire transformer filled with oil.

**Single-versus Three-phase Transformers.** — No specific rule can be given regarding the selection of single-phase or three-phase transformers since both designs are equally reliable; local conditions will generally determine which type is preferable. See the article on *Transformers*.

**Use of Auto-Transformers.** — (See also *Auto-Transformers*.) Auto-transformers are sometimes used in connection with Y-connected generators for obtaining a moderate rise in the voltage. Where such is the case a path must be provided for the flow of the triple-frequency exciting current, which is required for the normal magnetizing of the transformer. With a grounded generator neutral (see *Generators, Alternating-Current, and Grounding of Electric Circuits*), this can be obtained by also grounding the neutral point of the auto-transformers, although it is also highly desirable to connect the two neutrals together as any ground offers more or less of a resistance. If a sure path for the triple-frequency exciting current is not provided, a third harmonic will appear in the no-load e.m.f. from line to neutral and cause an excessive strain in the windings, which under such conditions should in all cases be insulated for a higher voltage than the normal.

**Cooling of Transformers.** — Transformers for hydroelectric generating stations should obviously be of the water-cooled type. Ordinarily the water rate to keep a transformer of this type cool is approximately one-half gallon per minute per kw. loss, the temperature of the incoming water being 15° C.

Cooling coils are generally made of extra heavy lap-welded wrought iron pipe with electrically-welded joints. These coils will withstand a hydraulic test of 1000 pounds per square inch. In some cases the quality of water available for cooling purposes may make it necessary to use either brass or copper pipe, in order to avoid corrosion which would prohibit the use of iron pipe.

**Drying of Transformers.** — It was formerly customary in shipping transformers to pack the cores separately from the tanks. Where the railroad clearances will permit, transformers are now shipped assembled with the oil in the tanks, the cores being securely braced in the tank. In this manner the transformers should arrive at the destination with the insulation and oil practically dry and free from moisture. Where transformers are shipped without the oil in the tanks it is almost invariably necessary to dry them out first. This may be accomplished in several ways, as explained in the article on *Transformers* (q.v.).

**Transformer Oil.** — The oil, whether shipped in the transformer case or

separately, should always be tested before it is used in service (*see the article on Oil, Transformer*), and should be dried if it punctures at too low a voltage. Oil for transformers of 40,000 volts and over should be dried before using, if it punctures below 35,000 volts. For transformers having voltages less than 40,000 volts, the oil must be dried if it punctures below 25,000 volts. Where oil is dried it may easily be brought to a puncture of 40,000 volts. If a sample contains sediment, it will puncture at a lower voltage than it would without the sediment.

**Transformer Connections.** — With the three-phase system the transformers are usually connected in delta or Y, and when the Y-connection is used the neutral may be grounded or not. It is a much-disputed question which connection is to be preferred. In general it may, however, be said that in transmission systems where continuity of service is the most important factor, delta-connected transformers (both primary and secondary) are preferable on account of the increased reliability which such a system affords. See articles on *Transformers and Grounding of Electric Circuits*.

For high-voltage systems it is, however, now being generally conceded that the Y-connected system with the neutral grounded is preferable, if not almost essential. The fact that any ground will then constitute a short-circuit followed by a shut-down, is outweighed by the limitations of the rise in voltage caused by such grounds. Modern transmission line apparatus must furthermore be designed to withstand the mechanical strains imposed by short-circuits. With a ground on a delta-connected system it is evident that the neutral is shifted from the center of the delta to one corner, and the charging current, which is a function of the voltage from wire to neutral, is therefore increased in proportion, or about 73 per cent. This increased charging current will in turn cause a corresponding increase in the voltage rise which may take place when the lines are cut in circuit at no load. Actual experience has shown that this voltage may reach prohibitive values which, of course, would not be the case with the Y-connected, grounded system.

#### SWITCHING EQUIPMENT AND ELECTRICAL CONNECTIONS.

— Continuity of service is the most essential part in the protection and operation of a large high-tension power system. A maximum degree of reliability can naturally be obtained by providing reserve and duplicate apparatus, the maximum reliability thus being governed by the permissible investment in the apparatus, by the price paid for the power and by the competitive situation.

In small and medium-size power plants the switching equipment may be of the hand-operated type, mounted directly on the back of the switchboard panels or on a separate framework and operated by hand by means of levers located on the front of the panels. For large modern power houses the switches should, however, always be of the remote-control type. The control board is then located so that the operator may obtain the best view of the station, while the switches and bus-bar structure are installed with regard to convenience of wiring and safety.

The switch and bus-bar structure for large stations may be either of the enclosed or open type, but is mostly a combination of the two.

The entire subject of switchgear equipment is discussed in detail in the separate article on *Switchgear Equipment for Power Stations*, which see.

**Sectionalized Low-tension Bus.** — (*See also Bus-Bars and Bus-bar Structures.*) The generators should preferably be paralleled on a low-tension bus, and where the total capacity is large the bus should be sectionalized, it being the general practice to limit the normal capacity of each section to from 30,000 to 50,000 kv-a. The sections may be connected by means of automatic switches provided with instantaneous overload relays which in case of trouble in one section will immediately disconnect the same from the other sections and thus

limit the power which the oil switches will have to rupture to the capacity of one section. In some of the recent systems reactance coils have been inserted between the bus sections, and the sectionalizing switches have been made non-automatic. The reactances are selected of such a value as to limit the short-circuit current to an amount that can be safely ruptured by the installed circuit breakers.

In sectionalizing the bus it is desirable to make such provision that sufficient generator capacity to supply the charging current of one transmission line can be entirely separated from the rest and used for testing out the lines. A ring bus will generally insure sufficient flexibility to accomplish this, although for large systems a double bus may be desirable if the extra expense is warranted.

**Generator Switches.**—The generator switches are usually made non-automatic, as it is of the utmost importance to keep the generators in service, and the possibility of trouble between the generators and buses is rather remote. If, however, automatic protection is desired for the generator switches, the relays (*see Relays*) should be of the definite-time limit type, set very high so as to trip the switches as a last resort, after the automatic switches more remote from the generators have failed to isolate the trouble.

Sometimes the generator switches are provided with reverse energy relays which will cut out from service a damaged generator on the reversal of the power. In the case of large important generator installations the most highly recommended practice, perhaps, is to equip each with differential relay protection. This type of protection is so designed that in case of an internal electrical failure within the generator armature, the generator will be instantly cut out of service. The protection is also usually so arranged that, when the generator main switch opens, the field circuit is simultaneously opened, thereby reducing burning within the machine to a minimum.

**Transmission-line Connections.**—(*See also Transmission Lines.*) Double transmission lines are nearly always provided to important load centers, and it is then also desirable to so proportion the line conductors that in case of trouble, one line alone or together with a section of the other can take care of the greater part of the load without causing too poor a regulation.

Up until recent years it was customary to recommend that high-tension lines be normally operated electrically apart from one another, each connected at each end to a bank of transformers, the paralleling and switching being done on the low-tension side of the transformers in both generating and substations. This method of operation was early adopted to reduce to a minimum the electrical stresses resulting from high-tension switching. With the growth of high-tension transmission systems with their multiplicity of interconnected transmission lines and as a result of the cost of equipment to adopt a large high-tension net-work for operation in this manner, the method has to a large extent been superseded by the simpler one based upon high-tension switching. Due to the rapid advancement in the art of designing high-tension apparatus and the practical experience gained in its operation, it is now possible to construct high-tension systems with perfect assurance that high-tension switching will give entirely satisfactory results.

All switches should be provided with carefully selected relays, so arranged as to select and cut out of service in the minimum time any circuit in which a fault has occurred so that uninterrupted service may be maintained over the remaining circuits.

**LIGHTNING ARRESTERS, EQUIPMENT AND CONNECTIONS.**—Aluminum and oxide film lightning arresters are now generally used for lightning protection of high-voltage transmission systems, *see article on Light-*

*ning Protectors*, for description of the various available types of arresters. The arrester, however, is not a universal protector against all kinds of interruptions. For example, while it meets the usual, and most of the unusual, needs in protection against disruptive potentials from lightning, an arrester located in the station cannot, and is not expected to, protect an insulator out on the line from a lightning flash. Neither is it designed to protect against surges of comparatively low voltage.

**Arresters for Grounded and Ungrounded Circuits.**—It is important to avoid the mistake of choosing an arrester for a thoroughly grounded neutral when the neutral is only partly grounded; that is to say, grounded through an appreciable resistance. In an arrester for a grounded neutral circuit, each stack of cones normally receives the neutral potential when the arrester discharges; but if a phase becomes accidentally grounded the line voltage is thrown across each of the other stacks of cones until the circuit breaker opens the circuit. Line voltage is 173 per cent of the neutral or normal operating voltage of the cells and therefore about 150 per cent of the permanent critical voltage of each cell. This means that when a grounded phase occurs this 50 per cent excess dynamic potential is short-circuited through the cells until the circuit breaker opens. The amount of energy to be dissipated in the arrester depends upon the kilowatt capacity of the generator, the internal resistance of the cells and the time required to operate the circuit breakers. It is evident that the greater the amount of resistance in the neutral, the longer will be the time required for the circuit breakers to operate. Therefore, in cases when the earthing resistance in the neutral is great enough to prevent the automatic circuit breakers from opening practically instantaneously, an arrester for a non-grounded neutral system should be installed. It is difficult to determine these factors of ground resistance and time elements in the operation of switches and therefore no mistake can be made by adopting the 4-tank arrester even on grounded Y circuits.

**Wiring Connections for Lightning Arresters.**—The wiring connections of lightning arresters are an important consideration. The discharge circuit should contain minimum impedance and hence must furnish the shortest and most direct path from line to ground. The most severe disturbances which an arrester is called upon to handle are of high-frequencies and it is, therefore, imperative to eliminate all unnecessary inductance. The features favorable for low inductance are short length of conductor, large radius bends and large surface of conductor. For wiring high-voltage arresters the use of copper tubing is therefore recommended. Such copper tubing has the advantage over either copper-strip or solid conductors in that it is easily supported, requires fewer insulators and is, therefore, cheaper to install. From arrester to ground it is sometimes more convenient to use copper strip than tubing. Copper strip, say 1.5 in. by 0.03 in., can be fastened to the station wall leading directly down to ground.

**Ground Connections for Lightning Arresters.**—In all lightning-arrester installations it is of the utmost importance to make proper ground connections since many lightning-arrester troubles can be traced to bad grounds; see article on *Ground Connections*. As noted in the article referred to, a very satisfactory method of making a ground is to drive a number of one-inch iron pipes six or eight feet into the earth about the station, connecting all these pipes together by means of a copper wire, or preferably, by a thin copper strip. A quantity of salt should be placed around each pipe under the surface of the earth and the ground thoroughly moistened with water. It is advisable to connect these earth pipes to the iron framework of the station, and also to any water mains, metal flumes or trolley rails that are available. For the usual size station the following recommendation is made: place three earth pipes equally spaced near each outside wall, making twelve altogether, and place three extra

pipes spaced about six feet apart at a point nearest the arrester. When plates are placed in streams of running water, they should be buried in the mud along the bank in preference to laying them in the stream. Streams with rocky bottoms are to be avoided.

From time to time the resistance of these ground connections should be measured to determine their condition; see article on *Ground Connections*. The resistance of a single pipe ground in good condition has an average value of about 15 ohms. A simple and satisfactory method of keeping account of the condition of the earth connections is to divide the earth pipes into two groups and connect each group to the 110-volt lighting circuit with an ammeter in series. If there is a flow of about 30 amperes the conditions are satisfactory, provided the earth pipes are properly distributed around the station.

**Charging of Aluminum Cell Arresters.** — This is accomplished as follows:

*First.* — Operate the charging mechanism so as to bring the charging contact securely against the horn gap and charge for five seconds. The contacts should be so adjusted as to eliminate arcing when gaps are closed. The closing and opening of the charging contact should be performed quickly so as to avoid unnecessary arcing. Note should be made of the size and color of the arc which forms when the contact is broken at the close of the charging period.

*Second.* — With the horn gaps in normal position reverse the transfer device, thereby interchanging the connections to the ground stack of cones and one of the line stacks.

*Third.* — The first operation should again be repeated, thus charging the fourth stack of cones, which was originally the ground stack.

When an arrester is first installed and also when one has been off the circuit for several days the initial charging current is sometimes above normal. It is recommended that the cells be charged six or eight times the first day and three times a day during the remainder of the first week. This charging should be performed as just described. After the first week the regular daily charging will usually be found sufficient. It is important that the charging should be done at a time of the day when the line voltage is at a maximum value. The charging period should always be five seconds.

In cases where aluminum lightning arresters are installed in places where the temperature is excessive, it is sometimes advisable to charge the arresters twice a day. This condition will be indicated by an increase in the charging arc and charging current from day to day.

**Charging-current Indicator.** — The charging-current indicator is a device for measuring the current taken by an alternating-current aluminum arrester during charging; it also indicates the condition of the arrester cells. An arrester in good condition has a charging current of approximately 0.25 ampere on 25-cycle circuits, 0.30 ampere on 40-cycle, and 0.40 ampere on 60-cycle circuits. Should these values be doubled, the arrester must be charged more frequently and the current carefully measured until it comes down to normal. It is only when this additional charging fails to reduce the charging current that an inspection of the cells is necessary.

The essential parts of the charging-current indicator are an ammeter mounted on a specially-constructed switch stick and a set of jacks. These jacks are so connected in the arrester circuit that when the ammeter switch stick is inserted in them and the horn gaps short-circuited, the charging current flows through the meter.

**Choke Coils.** — Choke coils should always be installed in the power circuit between the lightning arrester and the apparatus to be protected. All choke coils should be very rigidly supported as they are subject to severe mechanical strains when short-circuits occur on the system. See article on *Lightning Protectors*.

**Use of Arcing Ground Suppressor.** — This apparatus is described in the article on *Ground Detectors and Arcing Ground Suppressors*. One arcing ground suppressor is sufficient for controlling the entire system. When several power stations feed into one transmission system special attention should be given to the best location of the suppressor.

**STATION WIRING.** — The design and construction of the cabling and wiring system of the station is of equal importance to the rest of the equipment. Experience has shown that in a great number of instances the shut-down of power plants was caused by defective installation of the station wiring. Every cable and wire should have a definite place provided for it in advance, just as much as any other piece of machinery, and wires carrying currents of different voltages should, as far as possible, be kept apart from each other.

**Braided vs. Lead-covered Cables.** — For generator and low-tension transformer leads, braided or lead-covered cables are used, and may be run in ducts or exposed upon racks in cable-ways or tunnels. Lead-covered cables are necessarily more expensive than braided cables, and their use seems to be justified only in places where protection against water and moisture is required. As the lead sheath is necessarily grounded along its entire length, such cables are more apt to be punctured. As a protection against fire the lead covering is obviously useless and due to its softness it is not very efficient in withstanding mechanical injuries.

**Installation of Cables.** — (See also article on *Wires and Cables, Insulated*.) In many plants the cables are installed in ducts in the floor, and in such instances the cables should preferably be lead-covered to protect the cables from abrasion when drawn into the ducts. There are, however, several other objections to installing the cables in ducts. With high-voltage single-conductor lead-covered cables, static discharges may take place through the insulation to the lead, which rapidly injures the insulation and a breakdown soon follows. If the cable is not lead-covered a static discharge may take place to the tile duct, this also having a tendency to break down the insulation in time. In multiple-conductor cables this action does not occur, the static activity probably being neutralized. With cables carrying large low-voltage currents the lack of ventilation in the ducts may furthermore cause overheating of the cables.

In a large number of stations the open method of cabling is used. Tunnels or cable subways are then provided in which braided cables are supported in free air upon insulators mounted on racks, these insulators themselves having sufficient insulation to withstand the operating voltage of the cable. Where single-conductor, high-voltage cables are used, they should be separated far enough to prevent static discharges between the cables, and also in order to obtain the best possible ventilation and to minimize trouble in case of short-circuits. The cables should also be rendered fireproof by wrapping them with asbestos tape.

**Size of Cables.** — Due to the skin effect it is generally considered good practice to limit the size of single-conductor cables to 1,250,000 cir. mils for 25-cycle service and 700,000 cir. mils for 60 cycles. Where the value of current is such that it can be carried safely by one three-conductor cable, this is preferable in every respect to three single-conductor cables. If more than one cable has to be used to carry the current the difficulty of making connections will generally offset the advantages of three-conductor cables, and under such conditions it is usually found to be more advantageous to use single-conductor cables.

**High-tension Wiring.** — Bare wire or tubing supported on post insulators or hung from suspension insulators is generally used for all high-tension wiring. High-tension station wiring is described in detail in the article on *Switch-gear Equipment for Power Stations*.

**OPERATION AND OPERATING RECORDS.** — The selection and

maintenance of an efficient and reliable operating force is essential. Most modern systems of any size have a method of operation which corresponds to that of a train dispatcher on steam railroads, and where many different plants are attached to the same network, this becomes practically necessary. The directions for operating the different stations and apparatus come from a central source, where the dispatcher has before him a diagram of the whole system and information regarding the capacities of the generators in use and the magnitudes of the loads at the different places of distribution.

**Organization of Operating Force.** — The organization of the operating force of a hydroelectric generating station is necessarily less complicated than in a steam station. It is determined largely by the location and the arrangement, and there are so many different conditions in such systems that it is impossible to recommend any exact form of organization, as really no two can be quite alike. If the station is not too large, it is desired to have the hydraulic superintendent report to the station superintendent, but if the development is of such a magnitude as to require the entire time of a superintendent for each of the departments under consideration, a position is warranted for a man to whom both electric and hydraulic superintendents will report, thus still bringing the responsibility of operation of the two departments under one head.

As a general rule, for the same capacity installed, a plant having horizontal units can get along with a smaller force than one using vertical units. It is a general practice to maintain one man at all times on each of the different levels or floors of the power house, such as the switchboard gallery, the main floor and the basement, where with vertical units the turbines proper as well as the oil pumps and other auxiliaries are located. The man in the basement could in all probability be dispensed with in plants using horizontal units. In addition to these men a chief operator should be provided for each shift, whose duties should carry him to all parts of the building. For a very large station the above force may be entirely inadequate, and for small plants the force may be reduced.

**Switching Operations.** — The switching operations are determined by the general method of operation. It is desirable to eliminate all high-tension switching under load, due to the fact that such switching may set up surges which may be dangerous to the transformers and other apparatus.

When a line is to be cut into service, the high-tension switches in both the main and substations should be closed first, then the low-tension transformer switch in the generating station should be closed, energizing the transformers and the line, after which the low-tension transformer switch in the substation is closed and the load picked up. In case it becomes necessary to open a high-tension switch in a loaded line, the circuit should if possible first be paralleled with another before opening the switch. If, on the other hand, transformers are to be paralleled on both high- and low-tension sides, the low-tension switch should be closed first, assuming that the low-tension bus is energized. Similarly, in cutting out the transformer the low-tension switch should be opened last.

**Operating Records.** — One of the essential things in connection with the operation of hydroelectric generating stations is the keeping of accurate records. Record sheets should contain only the most important readings, as with complicated forms the attendant generally realizes that a large number of the readings are of no importance and for this reason he becomes very lax in his attention to the readings in general and as a consequence the important ones may suffer.

The following description applies to an actual record sheet which has been found to give satisfactory results. The sheet is of the size of ordinary letter paper and is ruled for hourly records of "Water," "Main Units," "Cycles," "Power Factor," "Exciters," "Transformers" and "Floodgates." These items are listed vertically and the sheet is divided into 24 vertical columns, one for

each hour. At the top are given the "Forebay" readings and "Tail Race" readings, the difference between which gives the "Effective Head." Immediately below are listed the indicated kilowatts and per cent gate opening of each generator in service, following which are given the "Total Indicated Kilowatts" and "Total % Gate." The total kilowatt-hours during each hour, as read from the watt-hour meters, is plotted as a block-curve extending across the face of the sheet.

This serves as a better record for the actual station output than the indicated kilowatts. It has been found necessary, however, to follow the indicated kilowatts to serve as a check on the efficiency and condition of the units in general, from time to time, as well as to determine what capacity would be required for short interval peaks. The station voltage is also plotted as a block curve across the face of the sheet.

The exciters form an individual group, and for each exciter the voltage, current and per cent gate opening are recorded.

Transformer records are limited to the temperatures. These are taken hourly, at which time the oil elevation is noted but not recorded. If the transformer is not in service the column in which the temperature is listed is left blank; if in service the temperature is taken and recorded.

Under the item, "Floodgates" the total opening of the floodgates in feet is recorded, rather than each one separately. This record is maintained daily, the flow of the river at each of the stations being followed very closely.

At the bottom of the sheet appear the daily readings of the various generator and feeder watt-hour meters taken at midnight of each 24 hours. The following items are also recorded at the bottom of the sheet: "Total Generated," or the total output of the station for 24 hours; the "Maximum Hour Time," or the maximum kw-hr. of any particular hour during the day; the "Maximum Kw. Time," or the maximum indicated kilowatts at any particular instant; the "Average Load," obtained by dividing the total kilowatt hours generated by 24; the "Load Factor," obtained by dividing the "Average Load" by the "Max. Kw. Time"; the "Average Flow of the River in Cubic Feet per Second," calculated each day and converted into "Available Capacity of River," which is shown in kw-hr.; the "Available Capacity of Power House," shown in kw-hr., and determined by calculating the capacity of the machines under the average head for 24 hours; the "Kw-hr. Lost," or the difference between what was actually generated by the machines and what could have been secured from the river during the same number of hours.

Any important notes of operation are entered on the back of each day's log sheet. These notes, together with certain records for log sheets, are also entered each day in a log book kept on the operator's desk at all times, for reference purposes. Weather conditions and temperatures are recorded four times daily, at midnight, 6 A.M., noon and 6 P.M. A rain gauge is provided on the roof of the station, from which records of precipitation covering each 24 hours are obtained.

**CAPITAL COSTS AND APPROXIMATE DIMENSIONS.** — (See also section below on *Capital and Annual Costs of Some Typical Plants.*) The cost of a large water-power development is generally very great. The estimates of the amount of power available are always subject to error and many times are greatly exaggerated. On account of unforeseen obstacles in dam construction, it is always possible that the actual cost will exceed the engineering estimates, and such elements of uncertainty must always be taken into consideration. Moreover, as the large water powers of the country are generally more or less remote from power markets, there is necessitated the construction of expensive high-tension transformer equipments and transmission lines to transmit the power to the point of consumption. This additional cost is often greater than that of the

dam and power-house construction. The provision of large storage reservoirs is often necessary in order to meet the irregularities in the flow of streams, while, on the other hand, the most economical utilization of water power often requires the erection of auxiliary steam plants.

The main items entering into the cost of construction of a hydroelectric power plant are: (1) Dam, (2) Water Conductors, (3) Reservoirs, (4) Power house, (5) Land and Water Rights, (6) Transmission Lines. In addition to the cost of the above physical equipment certain overhead and organization expenses must also be included. These may be classified as follows: (7) Engineering and Contingencies, (8) Administration, (9) Organization, (10) Taxes and Insurance, (11) Interest during Construction, (12) Working Capital.

**Range of Total Capital Cost per Horse-Power.** — Extensive investigations by the Bureau of Corporations show that the cost of a hydroelectric power development, including the construction of dams, the erection of transmission lines and other equipment, ranged from \$50 to \$375 per horse-power delivered at the substations. These figures represent extremes, as the usual cost will fall between \$100, and \$200 per horse-power, depending upon physical conditions and the length of the transmission lines.

**Approximate Dimensions and Construction Costs.** — It is obvious that there are certain minimum costs that can readily be approximated when the rough dimensions of dams, pipe lines, etc., are available, so that rough minimum figures can readily be made. Such rough figures cannot be expected to take into account expensive contingencies that must be anticipated.

**Dams.** — Given the length and height of dam, the dam structure itself will have a cost of material that can be estimated roughly, and the ordinary cost of placing such material — including tools and forms — can be added, but the extraordinary labor costs due to the construction of expensive foundations and coffer dams and the cost of placing dam material under difficult conditions can, of course, only be estimated by experienced engineers thoroughly familiar with the local conditions.

Expressing the height of dam in yards as  $h$ , the approximate sections of dams and approximate costs of dams not used as weirs or spillways are:

SECTIONS AND COST\* OF DAMS NOT USED AS SPILLWAYS

Type of dam	Batter or slope		Approx. section in sq. yards	Approx. cost per cubic yard	Approx. cost per lineal yard
	Common upstream batter horizontal to vert.	Common down stream batter			
1. Earth.....	2 to 1	3 to 1	2.5 $h^2$	\$0.90	\$1.25 $h^2$
2. Crib.....	1½ to 1¾	1½ to 1	1.5 $h^2$	1.50	2.25 $h^2$
3. Rock fill.....	2 to 1	2 to 1	2.0 $h^2$	2.00	4.00 $h^2$
4. Masonry, straight....	Vertical	¾ to 1	¾ $h^2$	12.00	4.80 $h^2$
5. Masonry, arched....	0.15 to 1	0.30 to 0	¼ $h^2$	15.00	3.90 $h^2$

It should be borne in mind that maintenance and depreciation on Types 1, 2 and 3 are far heavier than on Types 4 and 5.

\* Pre-war conditions

These figures are intended to cover all costs under ordinary conditions, for the cost per cubic yard is taken sufficiently high; but they cannot be used for extraordinary conditions, producing costs possibly four or five times greater.

Low crib or masonry dams used practically throughout their length as weirs or spillways may easily cost many times these figures.

No figures are given for intakes, owing to the great variety of conditions to be met.

**Flumes.** — The use of flumes of wood becomes less and less as hydroelectric work becomes more permanent in character. For estimate purposes it is then suggested that the cost of wood-stave or riveted-steel pipe be used instead of using the presumably lower cost of the flume. It is obvious that repairs and depreciation on flumes are heavy, and hence they would seem to have little use in permanent construction.

**Low-pressure Pipes.** — (See also *Pipes and Piping*.) In hydroelectric work cast-iron pipes are seldom used. Wooden-stave and riveted-steel pipes have been widely used for low pressures. The approximate costs of these, as compiled by A. L. Adams for Chicago, are given in the following tables.

**COST \* PER FOOT OF WOODEN-STAVE PIPE**  
Including laying but omitting hauling

Diameter in inches	25-foot head	50-foot head	100-foot head	200-foot head
12	\$0.42	\$0.49	\$0.63	\$0.85
18	0.69	0.80	1.00	1.46
24	0.79	0.91	1.14	1.61
30	0.96	1.13	1.44	2.06
36	1.19	1.40	1.82	2.65
42	1.40	1.68	2.23	3.33
48	1.55	1.85	2.46	3.67
54	2.23	2.62	3.43	5.02
60	2.85	3.35	4.37	6.40
66	3.21	3.81	5.00	7.38
72	3.65	4.38	5.83	8.73

**COST \* PER FOOT OF RIVETED-STEEL PIPE**  
Including laying but omitting hauling

Diam. in in.	No. 14	No. 12	No. 10	No. 8	No. 6	1/4 in.	5/16 in.	3/8 in.
12	\$0.32	\$0.38	\$0.44	....	....	....	....	....
18	....	0.57	0.65	\$0.78	\$0.98	....	....	....
24	....	....	0.85	1.04	1.28	\$1.55	\$1.99	....
30	....	....	....	1.27	1.59	1.93	2.46	\$3.04
36	....	....	....	1.55	1.93	2.30	2.92	3.58
42	....	....	....	1.61	2.18	2.66	3.37	4.12
48	....	....	....	....	2.48	3.03	3.83	4.66
54	....	....	....	....	2.80	3.41	4.29	5.21
60	....	....	....	....	....	3.79	4.75	5.74
66	....	....	....	....	....	4.35	5.21	6.29
72	....	....	....	....	....	4.52	5.66	6.83

\* Pre-war conditions.

**High-pressure Piping.** — In high heads the high-pressure piping may be either riveted-steel pipe or lap-welded pipe with bolted flanged joints. It is suggested that a percentage amount be allowed for this, as the cost must vary widely for different conditions.

**Tunnels.** — Tunnels for hydroelectric work are usually lined. Naturally the cost per cubic yard varies, but for ordinary conditions an average unit cost of \$15 per cubic yard will cover all expense including timbering and lining. Allowing a velocity of 10 ft. per second (except in the smallest tunnels), approximate dimensions and costs are as follows:

COST \* AND DIMENSIONS OF TUNNELS

Carrying capacity in cubic feet per second	Velocity in feet per second	Net sectional area, square feet	Dimensions in feet, width by height	Approximate slope, feet per 1000 feet	Approximate cost per linear foot
100	3.6	28	4 by 7	0.46	\$16.00
500	10.0	50	7 by 7 $\frac{1}{4}$	2.0	28.00
1,000	10.0	100	10 by 10	1.5	56.00
1,500	10.0	150	12 by 12 $\frac{1}{4}$	1.1	85.00
2,000	10.0	200	14 by 14 $\frac{1}{4}$	0.9	115.00
5,000	10.0	500	20 by 25	0.6	280.00
10,000	10.0	1000	30 by 33	0.3	500.00

**Canals.** — In ordinary earth a velocity too small to produce erosion and yet sufficiently great to prevent undue deposit of silt and other matter, and sufficiently great to prevent growth of weeds, should be used. For preliminary calculations a velocity of 2 ft. per second will give approximate results. For this velocity the following approximate figures will serve:

DATA ON AND COST \* OF CANALS IN ORDINARY EARTH

Cubic feet per second	Velocity in feet per second, V	Area of wet section, sq. ft.	Water depth, feet	Approximate slope in feet per mile	Approximate cost per running foot	
					Low	High
50	2	25	2.5	4	\$0.375	\$0.75
100	2	50	3.5	2	0.75	1.50
200	2	100	5	1 $\frac{1}{2}$	1.50	3.00
300	2	150	6	1	2.25	4.50
400	2	200	7	$\frac{3}{4}$	3.00	6.00
500	2	250	7	$\frac{3}{4}$	3.75	7.50
1000	2	500	10	$\frac{1}{2}$	7.50	15.00
1500	2	750	12	$\frac{1}{2}$	11.25	22.50
2000	2	1000	12	$\frac{1}{2}$	15.00	30.00
3000	2	1500	15	$\frac{1}{2}$	22.50	45.00

In rock the velocity in a canal may be much higher, and if the canal be lined 8 ft. per second may be used. For preliminary calculations this velocity will give approximate results. The following approximate figures are on this basis:

\* Pre-war conditions.

## DATA ON AND COST\* OF CANALS IN ROCKS

Cubic feet per second	Velocity in feet per second, V	Area of wet section, sq. ft.	Water depth, feet	Approximate slope in feet per mile	Approximate cost per running foot	
					Low	High
50	8	6.25	2.5	40	\$0.32	\$1.28
100	8	12.5	3.5	25	0.63	2.50
200	8	25.0	5.0	16	1.25	5.00
300	8	37.5	6.0	12	1.87	7.50
400	8	50.0	7.0	10	2.50	10.00
500	8	62.5	7.0	9	3.25	13.00
1000	8	125.0	10.0	6	6.00	24.00
1500	8	175.0	12.0	4½	8.75	35.00
2000	8	250.0	12.0	3½	12.50	50.00
3000	8	375.0	15.0	3	18.75	75.00

Values are given for lined canals only, since a higher velocity will be allowable without producing too great a lost head and the cost will probably be more favorable.

It must be considered that these figures are wholly approximate since even for a desired useful section the amount of excavation per lineal foot of canal must vary with the character of the route — whether this be flat, rolling or side-hill.

In this connection the following approximate costs based on the annual reports of the United States Reclamation Service are of interest.

## APPROXIMATE COST\* OF EXCAVATION PER CUBIC YARD

Class	Cost per cubic yard		
	Low	High	Fair value
1. Plowable with 4 horses.....	\$0.098	\$1.00	\$0.18
1a. Plowable with 6 horses.....	0.1225	2.00	0.30
2. Indurated material.....	0.29	2.00	0.60
3. Loose Rock.....	0.35	3.00	0.75
4. Solid Rock.....	0.60	5.00	2.00
4a. Excavation below plane of saturation..	0.20	3.00	1.60
4b. Solid rock under water.....	.....	.....	4.50

**Tail Race.** — Frequently the cost of the tail race is negligible, but for some developments the cost is an appreciable percentage of the total. No data are given for estimating tail race since those given for canals, pipes and tunnels can be used.

**Receivers.** — No data are given for approximation of the costs of reservoirs, vent-pipes and surge tanks on account of the varied character of these. Generally speaking the percentage of the total hydro-electric cost to be allowed for these is small and a lump sum or a percentage can be allowed for the same.

**Hydroelectric Power Houses.** — The following figures upon the approximate space and cost of hydroelectric power houses are wholly approximate, and will give only a rough idea of what may be expected under ordinary conditions, without any allowances for high freight, long haulage, unusually expensive labor charges, etc.; and a wide departure from these figures is to be expected. See also the articles on *Water Wheels, Generators, Transformers, Switchgear, etc.*

\* Pre-war conditions.

## DIMENSIONS AND COST OF POWER HOUSES (Pre-war Conditions)

Item	Low head*			Medium head*			High head*		
	Small†	Medium†	Large†	Small†	Medium†	Large†	Small†	Medium†	Large†
Cu. ft. per kw. for hydraulic apparatus.....	30	30	30	7	6	5	6	5	4
Cu. ft. per kw. for generators, exciters and switchboards (no transformers).....	20	18	15	18	13	10	16	12	10
Cu. ft. per kw. for generators, exciters, transformers and switchboards.....	30	25	20	28	20	15	26	19	15
Total cu. ft. per kw. for hydroelectric power house (without transformers).....	50	38	25	25	19	15	22	17	14
Total cu. ft. per kw. for hydroelectric power house (with transformers).....	60	45	30	35	26	20	32	24	19
Approx. cost of power-house building not including foundations (without transformers) per kw.:									
Low.....	\$5.00	\$3.80	\$2.50	\$2.50	\$1.90	\$1.50	\$2.20	\$1.70	\$1.40
High.....	15.00	11.40	7.50	7.50	5.70	4.50	6.60	5.10	4.20
Approx. cost of power-house building, not including foundations (with transformers) per kw.:									
Low.....	\$6.00	\$4.50	\$3.00	\$3.50	\$2.60	\$2.00	\$3.20	\$2.40	\$1.90
High.....	18.00	13.50	9.00	10.50	7.80	6.00	9.60	7.20	5.70
Approx. cost per kw. for hydraulic machinery.....	15.00	12.00	7.00	12.00	10.00	7.00	10.00	8.00	5.00
Approx. cost per kw. for exciters, generators, switchboards and cables (without transformers).....	24.00	15.00	10.00	20.00	12.00	9.50	15.00	9.50	7.50
Approx. cost per kw. for exciters, generators, switchboards, transformers and cables.....	32.00	22.00	16.00	27.00	17.00	14.00	23.00	14.00	12.00
Approx. cost per kw. for complete power-house and foundations (without transformers).....	54.00	38.40	24.50	39.50	27.70	21.00	31.60	22.60	16.70
Approx. cost per kw. for complete power-house and foundations (with transformers).....	65.00	47.50	32.00	49.50	34.80	27.00	41.60	29.30	22.70

\* Low head = 50 to 200 ft.

Medium head = 200 to 600 ft.

High head = 600 and above.

† Small capacity = 200 to 1000 kw.

Medium capacity = 1000 to 5000 kw.

Large capacity = 5000 kw. and above

It is assumed that the large capacity stations with transformers will be for a line stage of from 60,000 to 110,000, the medium from 40,000 to 60,000 and the small 20,000 to 40,000.

**Overhead and Organization Expenses.** — In addition to the expenditures for the actual construction of the physical plant allowance must be made for the following items to cover overhead and organization expenses.

**Engineering and Contingencies.** — This item should cover all the cost of engineering, drafting and supervision of construction and of all the items properly chargeable to construction engineering; 5 per cent of the construction cost is a conservative estimate for this item. An equal amount (5%) is also generally allowed to cover contingencies, errors, etc.

**Administration.** — All items which go to make up the cost of administration for construction, general office expense, etc., come under this head. An additional charge of 5 per cent of the construction cost should also be ample to cover these expenses.

**Organization.** — This item covers the cost of organization and promotion, such as legal expenses, allowance for brokerage connected with the disposal of the securities, discount on the same, etc., 5 to 10 per cent of the construction cost is usually allowed for this item.

**Taxes and Insurance.** — Taxes must be provided for until the operation is begun, and usually for some time thereafter, until the income is available for such expenses. Similarly with insurance, including fire, casualty, etc. One per cent of the construction cost is generally allowed to cover these items.

**Interest During Construction.** — Allowance must also be made for the accrued interest on the idle capital during the construction period.

**Working Capital.** — A certain amount of money should be provided for working capital, the amount depending on the nature of the business transactions. About 1 per cent of the construction may be allowed to cover this item.

**OPERATING COST AND FIXED CHARGES (Pre-war figures).** — (See also section below on *Capital and Annual Costs of Some Typical Plants.*) The cost of hydroelectric power can be considered as made up of two parts: the operating expenses and the fixed charges. The former consist of: (1) Labor; (2) Administration; (3) Oil, Waste, etc.; (4) Maintenance and Repairs; and the fixed charges of; (5) Interest; (6) Depreciation; (7) Taxes and Insurance.

It is difficult to give any general figures as to the cost of generating hydroelectric power, on account of the widely varying cost of such developments. The load factor also has a very great bearing on the cost, much more so than with steam plants because the items making up the power cost are affected very little by a change in the load.

The annual operating cost per kilowatt of generator capacity in general (excluding transmission costs) ranges between the following values:

Labor	\$1.00 to \$2.00
Administration	0.25 to 0.50
Oil, Waste, etc.	0.25 to 0.50
Maintenance & Repairs	1.00 to 2.00
Total operation	\$2.50 to \$5.00

Or, considering the annual cost items as percentage of the capital cost, the following figures are representative for a large station for which the capital cost is \$125 per kilowatt, transmission costs excluded:

	Per cent
Labor	1.00
Administration	0.25
Oil, Waste, etc.	0.25
Maintenance & Repairs	1.00
Taxes & Insurance	1.00
Depreciation	3.50
Total	7.00

The cost of power per kilowatt-year is thus 7 per cent of \$125 or \$8.75. Power at the bus bars of such a station could then be sold for \$16, say, per kilowatt-year, leaving \$7.25, or approximately 6 per cent for interest on the investment.

**Primary and Secondary Power.** — Hydroelectric power is generally sold as primary and secondary power. The former must be supplied continuously and is usually marketed by the horse-power-year or kilowatt-year. The secondary power is only available during certain months of the year, and the price obtained for it is necessarily considerably less than for the primary power. To maintain the primary power at the most economical value a steam auxiliary station is usually required; this is frequently obtained by operating the hydroelectric plant in conjunction with an existing steam plant.

**CAPITAL AND ANNUAL COSTS OF SOME TYPICAL PLANTS** (Pre-war figures). — Below are given data on some typical plants, ranging in size from 750 to 16,000 horse-power.

**Minidoka Project.** — The following data illustrate the development and power cost of the Minidoka project of the U. S. Reclamation Service:

#### COST \* OF GENERATING STATION

Capacity of station, 7000 kw.  
Transmission voltage, 22,000  
Hydraulic head, 46 feet

Item	Total cost	Cost per kw.
Building.....	\$80,000	\$11.70
Hydraulic machinery.....	73,000	10.40
Electric machinery.....	83,000	11.80
Freight and hauling.....	26,200	3.75
Erection.....	55,500	7.90
Tailrace.....	60,000	8.50
Roads and telephone lines.....	7,300	1.20
Camp and permanent quarters.....	23,200	3.30
Engineering and incidentals.....	11,100	1.55
Administration charges, etc.....	15,000	2.10
Total.....	\$438,300	\$62.30

#### ANNUAL COST \* OF OPERATION

Item	Expense per year
Operation:	
Labor.....	\$5,700
Supplies.....	350
Repairs:	
Labor.....	900
Supplies and material.....	200
Superintendence, clerical, camp, etc.....	2,700
General expense and administration.....	450
Operating expense.....	\$10,000

\* Pre-war conditions.

A depreciation of 5 per cent (\$21,800) has also been charged to this development. No taxes or interest is charged, the undertaking being done by the Government. Assuming 7 per cent for interest and taxes the total operating expenses would amount to \$62,000. A total of about 15 million kw-hr. were delivered during the year, thus corresponding to a cost of \$0.0041 per kw-hr.

**Costs\* Reported by Ontario Commission.** — The following table gives the estimated cost of development and yearly operating expenses of various plants from reports of the Ontario Hydro-Electric Power Commission.†

Location of development	Available head in feet	Developed power in horse-power	Estimated capital cost	Cost per horse-power	Annual operating expenses, including administration	Annual maintenance and repairs	Depreciation	Interest at 4 per cent	Total annual charges

(a) Expensive dam.

(b) Inexpensive construction of canal and headworks.

(c) Includes storage development.

\* Pre-war conditions.

† Capital costs cover hydraulic development (such as dams, headworks, pipe lines), power house, hydraulic and electrical equipment, with one spare unit, and step-up transformer station with electrical equipment. It does not include cost of vested rights and land damages or transmission lines.

**BIBLIOGRAPHY.**— In the preceding table are given references to some of the more important hydroelectric stations. A great amount of valuable data on the control and transmission of energy from hydroelectric stations is also given in the report of the Engineering Data Committee of the A.I.E.E., entitled *Engineering Data Relating to High-Tension Transmission Systems* presented at the annual convention of the A.I.E.E., June 25, 1914.

In addition to the above the following articles on the subjects listed contain valuable data: **Exciters and Excitation:** *Elec. World*, 1907, Vol. 49, p. 880; 1912, Vol. 59, p. 1247; *Trans. A.I.E.E.*, 1912, Vol. 31, p. 1841; *G. E. Rev.*, 1912, Vol. 15, p. 626; 1914, Vol. 17, p. 567; *Power Plant Eng.*, 1920, p. 888. **Voltage Regulation:** *G. E. Rev.*, 1912, Vol. 15, p. 468, p. 530; 1912, Vol. 15, p. 44, p. 626; *Trans. A.I.E.E.*, 1912, Vol. 31, p. 1841; *Elec. Jour.*, 1912, Vol. 8, p. 943; 1912, Vol. 9, p. 609; *Elec. World*, 1912, Vol. 60, p. 996. **Station Wiring:** *Elec. Jour.*, 1904, Vol. 1, p. 123; 1906, Vol. 3, p. 412; 1907, Vol. 4, p. 43; *G. E. Rev.*, 1913, Vol. 16, p. 361. **Operation:** *G. E. Rev.*, 1913, Vol. 16, p. 355. **Ventilation of Station:** *G. E. Rev.*, 1914, Vol. 17, p. 572. See also *Bibliography* in articles on the component apparatus.

**POWER STATIONS, STEAM-ELECTRIC.** — (See also *Power Stations, Gas-electric; Power Stations, Hydroelectric; Boilers; Condensers; Generators; Steam Engines; Steam Turbines; etc.*) The following is a brief table of contents of this article:

Location.....	p. 1205
Foundations.....	1205
Superstructure.....	1206
Boiler-room Layout.....	1206
Generating Room Layout.....	1211
Piping Systems.....	1213
Generator and Control Equipment.....	1215
Costs, Capital and Operating.....	1217

**LOCATION.** — The selection of a site for a power plant depends on the following factors:

(1) The cost and availability of land, adequate in area and suitable in form for present and future needs.

(2) Provision for the economical handling of fuel and ashes. The site should afford navigable water frontage if possible and railroad connection in every case unless the delivery of coal by water is assured at all seasons. In comparing sites the cost of dredging channels and of track construction, including right of way, should be carefully considered.

(3) The nature of the water supply. Ample water supply from natural sources suited to all the needs of the plant is highly desirable. The life, efficiency and cost of maintenance of boilers and condensers depend greatly on the quality of the water supply. Water analyses should be made in connection with preliminary surveys.

(4) The bearing power of the sub-soil for foundations, the probability of costly difficulties in construction, the elevation of ground water, the normal, maximum and minimum stages of adjacent bodies of water.

(5) The general character of the surroundings and the existence of restrictive ordinances relating to smoke, noise, vibration and the movement of coal cars.

(6) Proximity to the load center of gravity, if power is to be distributed at low voltages.

**FOUNDATIONS.** — (See also *Concrete; Concrete, Reinforced.*) The design of foundations depends on the bearing power of the soil, the concentration of loads and the necessity of suppressing vibration. For table of the bearing power of various soils see the article on *Power Stations, Hydroelectric.*

The taking of borings is usually essential to the proper design of foundations, especially where the site is on alluvial soil near a water frontage. Concentrated loads may reach a maximum of 15 tons per square foot. Foundation footings should rest on rock whenever practicable. Soils of inadequate bearing power are reinforced by driving piles of wood or concrete at points of concentrated load or under the entire foundation, as the soil may require. Rafts of reinforced concrete resting on a soil stratum or on piling are often used to distribute loads, to prevent the flowage of alluvial soil and to reduce the transmission of vibration. The foundation structures proper are usually of reinforced concrete. The following table of safe loads on foundations is given in Snell's *Power House Design.*

Foundations for machinery are usually made separate from those of the walls to reduce the transmission of vibration. Boiler-room equipment is usually carried on the steel framing of the superstructure, but main generating units have separate foundation piers of concrete. Foundations for reciprocating engines have extended bases, and in extreme cases cushions of felt, sand or rubber composition are provided to suppress vibration. Anchor bolts for machinery are

TABLE I. — SAFE LOADS ON FOUNDATIONS

Loads in tons per square foot

Good concrete.....	4
Steel rails in concrete.....	8
Concrete piles.....	13
Ordinary bricks in cement mortar.....	5
Hard bricks in cement mortar.....	6
Blue bricks in cement mortar.....	12

accurately located in concrete work by means of templates. Bolts may be cast in the foundations, or holes may be provided, together with side holes to permit the adjustment of the bolts. When the concrete has set, the machine is lifted into place, aligned and leveled and the interstices run in with cement grout.

The datum line of a power plant should be fixed by consideration of water levels. Tidal limits and flood water stages fix the levels of condenser intake and outlet tunnels, of engine room floors and of furnace grates.

**SUPERSTRUCTURE.** — A power house should be fireproof in every respect, clean, well-lighted, well-ventilated and well-drained. The skeleton structure is usually of steel with wall panels of brick or of reinforced concrete. All structural members should be computed with a factor of safety of not less than 3 (*see Structures, Simple*). The most heavily-loaded members are the pillars carrying overhead bunkers and those supporting an engine-room crane. The roof should be of fire-proof material, truss-supported and with sufficient pitch to insure good drainage. The roof may properly have glazed monitors to assist in lighting and ventilation. Windows in the generating room and switch houses should be designed to exclude rain when partly open.

Interior walls are usually finished in brick set with close joints and neatly pointed. Glazed brick or tile are appropriately used for walls in generating rooms. The upper portion of such walls should be of light color. The basement floors are usually of smooth cement. Generating room floors should be of tile, brick or other material not tending to form dust. The boiler room floors are usually hard-burned brick or special concrete. The battery rooms should have floors of brick or acid-resisting asphalt. Stairways are preferably of iron and should be provided with non-slip treads.

Recent practice has evolved a standard type of building division, providing a boiler room and a generating room side by side and separated by a solid wall. All electrical-control apparatus is placed at the side of the generating room opposite the boiler room on galleries outside the crane span or in a separate section of building. This general ground plan has a number of important advantages. The framing may be proportioned to the loads in the different sections, the boiler plant and generating plant may be extended with equal facility, all wiring is isolated from steam piping, dirt and smoke are excluded from the generating room and accidents may be isolated in the section in which they arise.

**BOILER-ROOM LAYOUT.** — (*See also Boilers; Chimneys; Draft, Mechanical; Fuel; Smoke Prevention; Steam; Stokers, Mechanical; Feed-water Heaters and Purifiers.*)

**Capacity and Number of Boilers.** — The rating of boilers is purely nominal and their evaporative capacity is limited largely by the rate at which fuel can be economically burned in their furnaces. A well-designed unit is capable of giving from 75 to 100 pounds of equivalent evaporation per hour per rated horsepower. Considerably higher rates have been maintained in some of the large

central stations. This high capacity demand may result in some sacrifice of efficiency. The boiler plant should have sufficient steaming capacity to operate all steam machinery at its maximum output during the period of peak load, plus reserve capacity to insure against boiler shut-downs. The most economical boiler capacity depends largely on the form of the load curve. It is economical to force boilers to very high outputs during short and severe peaks, due to the reduction of investment and of fuel required for banking fires. With a very even load curve lacking extended banking periods it is most economical to install capacity sufficient to carry the average load at the highest efficiency. In modern public service stations it is customary to draw on boilers up to 200 or 250 per cent of their nominal ratings during peak loads. In a large number of modern stations ranging in capacity from 400 to 10,000 kw. the average boiler installation was found to be 0.4 boiler horse-power per kilowatt of generating capacity. In very large stations of recent design this ratio is from 0.25 to 0.3 boiler horse-power per kilowatt.

The simplest arrangement possible is to group with each generating unit one or two boilers, but this scheme lacks operating flexibility. In large steam plants the boilers are all operated in parallel on a common steam header, though provision is often made to isolate groups of boilers in emergencies. With this arrangement the boiler plant may properly be subdivided into the number of units affording the greatest economy and convenience. Large boilers are usually more efficient than small. The unit costs of boilers, stokers, piping, flues, air ducts and building are apt to be less for large boilers than for small. The crippling of a large boiler withdraws from service a larger portion of the total capacity and correspondingly larger reserve equipment may be needed. There is no evidence to show that small boilers afford greater safety than large. In general a boiler plant should comprise not less than 4 units if continuous operation is anticipated.

**Grouping of Boilers.** — Two common boiler room plans exist. In one the boilers are ranged in a single or double row facing a firing aisle which runs the length of the plant. In the other there are several lateral firing aisles, each serving a double row of boilers. The former plan is appropriate when the aggregate length of firing aisle does not exceed the length of the generating room. The latter plan lends itself well to the unit or group scheme of connection to generators. When the greatest economy of ground space is necessary, the boiler plant is double-decked, but this plan complicates the handling of fuel and ashes, reduces the natural light and ventilation and requires a building of very heavy framing. A basement space is provided below the boiler room. This space contains the ash hoppers, air ducts for forced draft and ash disposal equipment. Boiler feed pumps, blowers, hotwells, feed water heaters and flues are often placed in this space. The head room of the basement should be not less than 10 feet.

**Boiler Spacing and Clearances.** — With few exceptions boilers are set in batteries of two, with a space of 5 feet or more between batteries. A space not less than 5 feet wide should be left behind the settings for repair work, access to blow-off valves and minor piping. If the main piping or flues occupy this space it should be at least 8 feet wide. Each firing aisle should afford ample space to withdraw boiler tubes, drums and furnace structures for replacement or repairs. The width is usually between 18 and 25 feet and varies with the type of boiler and furnace. Clear head room above the boilers should be ample to install and repair the main piping and valves and to remove and replace boiler drums. An allowance of from 10 to 12 feet is usually ample. The following table gives minimum allowances of floor space for water-tube boilers of the most widely-used types, set in batteries of two:

TABLE II. — MINIMUM BOILER ROOM SPACE ALLOWANCES FOR WATER-TUBE BOILERS

400-hp. units in batteries of two.....	1.35 sq. ft. per hp.
300-hp. units in batteries of two.....	1.20 sq. ft. per hp.
500-hp. units in batteries of two.....	1.05 sq. ft. per hp.

In power plants of modern design the actual boiler room area per boiler horse power ranges from 0.9 to 2.00 square feet, the average being very nearly 1.4 square feet.

**Location of Flues.** — Boiler flues may be placed on the floor at the rear of the settings, in the basement space beneath the rear of the boilers, or may be carried overhead. Flues may be of brickwork or of steel plates reinforced with angle-iron stiffeners. In the most compact designs steel flues are used over the rear of the settings. Brick flues should be lined with firebrick. Steel flues are built up from  $\frac{1}{8}$ -inch plates when indoors and of  $\frac{1}{4}$ -inch plates outdoors. Flues should be as short, air-tight and straight as possible and should preferably have an upward gradient toward the chimney. It is good practice to allow from 4.5 to 5.5 square feet of flue section for each 1000 pounds of coal burned per hour in the boilers served. Branch flues should be equipped with swivel dampers to permit boilers to be shut down independently.

**Location of Economizers.** — Economizers are most frequently set on a steel gallery above the rear of the boiler setting. Less frequently they are set on the boiler room floor behind the boiler settings or on a floor above the boiler room. Each economizer unit is provided with a by-pass flue below or behind the economizer setting. A soot chamber is provided beneath the tubes and should be from 2 to 2.5 feet in depth. Access must be allowed along the front of the economizer to permit the opening of the cleaning holes in the bottom branch pipes. Clear space of 10 feet or more is required above the setting to permit the withdrawal and replacement of the tubes. Economizers are usually set in brickwork and subdivided into sections, each associated with a battery of boilers. A large central economizer can often be installed at lower cost, but affords less flexibility in operation.

**Chimneys and Mechanical Draft Appliances.** — (See also *Chimneys; Brick and Brick Masonry; Draft, Mechanical.*) Brick chimneys are usually carried down to foundations independent of the building and outside of its walls. In exceptional cases where greatest space economy is necessary, brick chimneys are carried by steel columns integral with the framing of the boiler house. Steel stacks are usually supported on cast-iron base plates carried by the structural frame work of the boiler house. Fans for forced draft are commonly set at centrally located points on the boiler room floor and distribute air to the various furnaces through ducts of sheet steel beneath the main floor. Induced draft fans are usually installed in duplicate and are located at the bases of the chimneys. Short steel chimneys are generally employed with induced draft systems.

**Coal and Ash Handling Equipment.** — (See also *Conveyors; Cranes; Fuel; Hoists, Electric; and Unloaders.*)

**Coal Storage, External.** — Continuity of fuel supply is a vital necessity to power stations. Insurance against interruptions of delivery is commonly made by use of internal bunkers and external coal storage yards. The amount of fuel to be kept in reserve is a local problem and depends on the certainty of delivery, the fluctuation of the market, the rate of deterioration of coal in storage and the danger of spontaneous combustion. Coal exposed to the weather loses heat value at a rate which depends on its content of volatile fuel and which may

exceed 1 per cent per month. Coal stored in deep piles is liable to spontaneous ignition, especially if it contains much sulphur. Both difficulties may be obviated by storing coal in basins under water. Bituminous coal should not be piled deeper than 35 feet unless submerged. As a precautionary measure iron pipes may be sunk into coal piles at intervals and the temperature read periodically by a suspended thermometer. A coal yard is commonly spanned by a gantry crane carrying an automatic grab bucket for distributing and reclaiming.

For the latest information regarding storage of fuel, see *Bituminous Coal Storage*, Univ. of Illinois Bulletin 116, 1920.

**Coal Storage, Internal.** — Internal storage is provided in overhead bunkers supported by the boiler house framing above the firing aisles. Bunkers are of two general types, suspended steel tanks hung from the framing, and hopper-shaped structures of reinforced concrete incorporated into the building proper. Suspended bunkers are usually concrete-lined and have a limited storage capacity, the practicable limit being about 10 tons per linear foot. Built-in bunkers are best adapted to large storage capacities up to 40 tons per linear foot. Bunkers should be divided by transverse bulkheads to increase their strength and assist in isolating trouble from spontaneous combustion. Hopper bottoms should have a slope of 45° or more to make them self-clearing. Cut-off gates should be provided at point of attachment to down-spouts. Automatic weighing and recording hoppers may be installed between bunkers and down-spouts to good advantage as their records assist in keeping check on boiler performances. Down-spouts should be not less than 12 inches in diameter and should be slightly inclined to lessen the tendency of the coal to pack. The firing aisle is sometimes equipped with an electrically-operated traveling hopper which may draw coal from any desired bunker section and distribute it to the several stokers.

The bunker capacity desirable in a boiler plant depends on the extent of the external storage and the facilities for fuel handling. Bunker capacity sufficient for from 4 days' to 7 days' supply is generally adequate. Very large bunkers are costly and are apt to lead to trouble from spontaneous ignition. In computing bunker capacity it is customary to allow 40 cubic feet per ton of coal.

**Coal Handling.** — The handling of coal which is delivered by rail and is to be delivered directly to overhead bunkers is most readily accomplished by the following plan. The loaded car is run over a track hopper into which it dumps from beneath. The hopper delivers to a crusher which reduces the coal to a uniform size suitable for the use of the stokers. The coal is delivered by the crusher to an elevator which may consist of some type of skip hoist, inclined belt or endless chain of buckets. If a skip hoist or belt is used the coal is dumped into a receiving hopper after its ascent and is finally distributed to the bunker by a horizontal belt, flight or bucket conveyor. A chain of pivoted buckets may be used as both elevator and distributor.

When the boiler room is arranged on the unit plan, i. e., boilers in rows facing transverse firing aisles, each aisle should have its bunker system, track hopper, crusher, elevator and conveyor. Such a conveyor may properly be of the pivoted-bucket type and may serve to elevate and distribute coal or to collect ashes from the ash hoppers beneath the boilers and deliver them to an ash bunker built out over the railroad track.

Reliability is a most important factor in all coal-handling systems and is promoted by making the system mechanically simple and rugged, by installing duplicate sets of equipment and by the sectionalizing of bunkers and conveyor outfits into independent units.

Coal delivered by water is usually handled by a clam-shell or grab-bucket unloader which dumps it into a receiving hopper. After being crushed the coal is conveyed to the storage yard or bunkers by equipment similar to that just described.

**Ash Handling.** — If ashes are handled by a conveyor when wet or hot the corrosive action on the buckets may make maintenance costly. When the ashes are not handled by a conveyor system it is customary to provide a track running beneath the ash hoppers on which small cars may be run to haul ashes to the dump.

**Feed-water Systems.** — (See also *Pipes and Piping; Feed-water Heaters and Purifiers; Pumps and Pumping Engines; and Valves.*) Condensing plants usually draw feed water from the hot-wells of the condenser system. When surface condensers are used a small amount of make-up water must be added from outside sources. The water discharged from jet condensers may be used for boiler feeding if of suitable quality. Non-condensing plants operating in connection with steam heating systems usually draw feed water from the return system, with added make-up water as required. Open heaters of all types are placed on the suction side of feed pumps. Closed heaters are placed on the delivery side. Meters are usually placed in the delivery pipe and should be in duplicate if continuous indication is important. Otherwise they should be bypassed, as are all heaters and economizers, to provide for cleaning and repairs during operation.

Water is supplied to boilers through a feed main which is run along the front or rear of the boilers, often in the basement space below. Double and ring mains are occasionally used though the gain in reliability is doubtful. An auxiliary injector main running direct to boilers from the source of cold water is sometimes installed as a reserve. Iron pipe is generally employed with cold water and brass pipe for water above 200° F., or water which has a pitting tendency. Screwed joints are generally used with pipe diameters less than 2 inches. Larger pipes are fitted with screwed flanges.

Feed pumps should be installed in duplicate on each feed main or cross-overs provided between pumps. There is wide divergence in the location of feed pumps. In most plants of the unit type each feed pump is associated with the auxiliaries of a generating unit and is cared for by the turbine operator or oiler. In other cases feed pumps are grouped in a central position on the main floor of the boiler room and are cared for by a water tender. In other cases the feed pumps are placed in a separate basement pump room.

A relief valve should be placed in the pump delivery to prevent strains from excess pressure. The size of feed pipe is usually such as to allow a maximum velocity of from 300 feet to 400 feet per minute. At least two valves, a regulating valve and a check valve, should be placed in each boiler branch.

**Condenser Water System.** — (See also *Condensers, Steam; Cooling Systems for Power Stations.*) Cooling water for condensers is obtained from an adjacent body of water whenever possible and in other cases from a cooling pond or the basin beneath a cooling tower. In the former case large concrete intake and discharge tunnels are usually provided. These run beneath the generating room in alignment with the intake and discharge pipes of the condensers. The cross-section of these tunnels should be ample to keep the flow of water down to 5 or 6 feet per second. Intakes should have generous openings fitted with trash racks and should if possible be placed at a considerable distance upstream from the discharge outlet. In some cases it is necessary to build a baffle wall in the stream between the two tunnels. A shut-off gate is usually provided in each tunnel to facilitate cleaning and repairs. The tunnels should be of sufficient depth to insure an adequate supply of water at the lowest stage of tide or stream flow. The circulating system of surface condensers is fully enclosed and the work done by the circulating pump is merely that necessary to overcome the fluid friction in the system.

**GENERATING ROOM LAY-OUT.** — (See also *Condensers, Steam; Cranes; Feed-water Heaters and Purifiers; Generators, Alternating Current; Generators, Direct Current; Lubricants and Lubrication; Pipes and Piping; Pumps and Pumping Engines; Steam Engines; Steam Turbines; and Valves.*)

**Capacity and Number of Units.** — A generating plant should have sufficient capacity to serve its peak load with any one generating unit shut down. The reserve capacity needed above normal requirements may be provided most economically by selecting types of equipment capable of giving large overloads in emergencies, by maintaining in service condition obsolete machinery which is physically sound but uneconomical, by installing a large reserve storage battery, or by tying in parallel several power plants so that a moderate reserve may be shared in common. More reserve capacity is needed when a plant contains few large units than with many of small size. A smaller number of units than four is disadvantageous, due to the relatively large reduction of capacity by the disabling of one. A larger number than eight units has no inherent advantages. Large units are generally more economical than small units if kept well loaded. If the plant has a normal daily period of very light load it may be economical to employ one small unit well suited to this load.

**Types of Equipment.** — Steam-turbine generators are used almost exclusively for alternating-current generation in units exceeding 500 kw. The turbine has little or no advantage over the engine in smaller sizes and in non-condensing plants the engine is often superior. On account of its high speed the turbine is poorly adapted to the direct driving of d-c. generators. Large d-c. generators are becoming obsolete in steam plants, for it is usually more economical to generate alternating current in turbine units and convert it to direct current either locally or in distant substations. A self-contained unit comprising boiler, engine and condenser, known as the *locomobile*, has been largely used in very small European plants and to some extent in this country.

**Arrangement of Generating Rooms.** — The modern standard power house has a long and narrow generating room placed between a boiler house and a switch house or series of electrical control galleries. The generating room is spanned by an electrically-operated crane. The generating units are usually ranged along this room in a single or double row. Each unit comprises a prime mover, electric generator, condenser and the associated pumps and their motive power. In most instances a basement space or series of open pits is provided below the main floor in which the condensers, pumps and most of the piping are located.

**Arrangement of Turbines.** — In many plants using vertical-shaft turbines the basement has been omitted and the auxiliaries grouped about the base of the turbine on the main floor. In such cases the condenser is either incorporated into the base of the turbine or is placed on the floor immediately beside it. This grouping of equipment on a single floor has several operating advantages. All apparatus has good light. A single operator can give efficient attention to a large group of equipment, and machinery so placed usually receives closer attention than it would in a pit or basement. All pieces can be readily handled by the crane without interference with other apparatus. The ample head room is advantageous in making repairs. The basement plan is especially economical of floor space, but makes the auxiliaries relatively less accessible. Placing condensing equipment in open pits beside the engine or turbine piers makes it accessible for inspection and for handling by the crane.

In determining the arrangement of a generating room it is essential to provide each element with ample space for all needed attention during operation or repairs. Sufficient clear floor space about a unit is usually provided to permit it to be dismantled without removing the parts to a distance. Clear trucking

space is also desirable. The separate pieces of machinery should be so arranged that the crane can be conveniently used in assembling or dismantling any piece without interference with others. Clear overhead space below the crane hook should be sufficient to permit any heavy part to be lifted clear of its setting and carried away. The crane girder and trolley must clear all roof trusses and lighting fixtures. Clearance must be allowed at the generator ends of horizontal turbine units to withdraw the revolving field structures.

**Arrangement of Condensers.** — In setting surface condensers clear working space must be allowed at both ends to remove the heads and at one end clear space must be allowed to permit the withdrawal and replacement of tubes. Jet condensers should be set in such a manner that the head can be conveniently opened for repairs. Condensers in general should be set below the level of the associated prime mover and as close as possible to its exhaust port. The condenser connection should provide natural drainage for condensed steam. It should have as few joints as practicable to avoid occasion for air leaks. It is usually desirable to provide a copper expansion section in this connection as joints in a rigid pipe are difficult to keep air-tight with varying temperatures. The arrangement of a central condenser serving a group of prime movers is uncommon in electric power plants. Barometric jet condensers are often placed outside of the wall of the building on account of the long tail pipe required.

**Floor Space in Generating Rooms.** — The floor space provided per kilowatt varies greatly with the size, type and arrangement of equipment. The following data from modern steam-turbine stations are illustrative of the range of best practice.

TABLE III. — SPACE COVERED BY STEAM-TURBINE POWER STATIONS

Station No.	Capacity, kilowatts	Boiler room, square feet per kilowatt	Turbine room square feet per kilowatt	Total, square feet per kilowatt
1	3,000	0.71	0.70	1.41
2	8,200	0.74	0.69	1.43
3	11,000	1.11	0.70	1.81
4	13,500	1.13	0.50	1.63
5	16,000	0.90	0.37	1.27
6	24,000	0.92	0.40	1.32
7	30,000	0.44	0.40	0.84
8	32,000	0.60	0.30	0.90
9	100,000	0.48	0.17	0.65

**Oiling Systems.** — (See also *Lubricants and Lubrication*.) Steam power plants afford three classes of lubrication problems, viz., wearing surfaces exposed to high temperature steam, as in cylinders, valve chests and stuffing boxes; atmospheric surfaces of open guides and journals; and enclosed surfaces, chiefly journals. Steam surfaces are lubricated with cylinder oils of mineral origin supplied in atomized form by forcing the oil in small quantities into the steam supply pipe. Oil may be supplied by a local force-feed pump or hydrostatic lubricator or may be supplied from a central tank and pump supplying a group of cylinders. Bearings, guides and other exposed surfaces are lubricated by oil or grease supplied by hand or from adjustable feed cups. Enclosed surfaces are usually lubricated by splashing or by flooding with oil from a central source of supply. The flooding system is most efficient. Oil from a central tank is

forced by pump or gravity to the various working parts whence it returns through a drip system to collecting pans and filters. After purification a small amount of make-up oil is added and the reclaimed supply restored to the oiling system.

**PIPING SYSTEMS.** — (See also *Pipes and Piping; and Valves.*) The various piping systems in a power plant are subdivisible into the following groups: (a) High-pressure steam piping between boilers, main units and auxiliary engines; (b) exhaust piping to condensers; (c) exhaust piping to feed-water heaters; (d) atmospheric-exhaust piping; (e) feed-water piping; (f) cooling-water piping; (g) pipe-drainage system and (h) oil piping. To facilitate the identification of pipes of various classes it is desirable to paint each a distinctive color.

**High-pressure Steam Piping.** — The chief considerations in laying out high-pressure piping are (a) to produce a reliable system without complexity; (b) to make all joints permanently steam tight; (c) to take up all expansion strains; (d) to maintain proper steam pressure at all points of delivery; (e) to reduce to an economic minimum the loss of heat by radiation and (f) to drain from the entire system all water of condensation. In many older systems of piping elaborate ring and multiple headers, with numerous by-passes, cross-overs and duplicate-connection branches were employed in the endeavor to promote reliability by making possible the isolation of any fault. Reliability is sought in modern systems by very simple connections with skillful design and the best possible construction.

**Unit and Parallel Systems of High-pressure Piping.** — The *unit system* and the *parallel system* of connection with their various modifications are now most extensively used. The unit system of piping connects a separate group of boilers to each prime mover and its auxiliaries. The parallel system provides a large steam header running the length of the plant into which all boiler branches deliver and from which all prime movers are supplied. Unit systems are usually provided with cross-overs between unit steam and water headers to permit the parallel operation of different sections in emergencies. Parallel systems are often provided with sectionalizing valves to permit the isolation of any section in case of accident. Diagrammatic sketches of unit and parallel grouping are shown in Figs. 1 and 2.

**Size of Piping.** — Pipe sizes for high-pressure work are generally determined by the maximum allowable steam velocity. It has been found satisfactory and economical to allow a maximum velocity of 6000 feet per minute with saturated steam and from 9000 to 12,000 feet per minute with superheated steam. The flow to piston engines is intermittent and the pipe size should be proportioned according to the velocity during admission unless a receiver is installed. The steam header of a parallel system serves as a reservoir to equalize pressures and prevent vibrations in the piping. Its cross section is properly proportioned according to the maximum cross flow of steam with any boiler section inoperative.

**Joints.** — Joints in high-pressure piping are usually of the screwed type for diameters under 3 inches and of the flanged type for larger sizes. Flanged joints may be made between ground faces or by aid of gaskets, the former type being preferable for high-pressure steam. An excellent joint is made by drawing up with loose collar flanges the turned-over ends of pipe sections with faces ground true, often called a Van Stone joint. Such joints are more expensive than rigid flanged joints but the possible swing of the pipe about its axis is a great advantage in the final aligning and connecting up of a system with many branches.

**Provisions for Expansion.** — Provision for the expansion of pipe without straining joints and fittings is imperative. Between two points which must be rigidly fastened expansion is taken up in expansion loops and bends. The

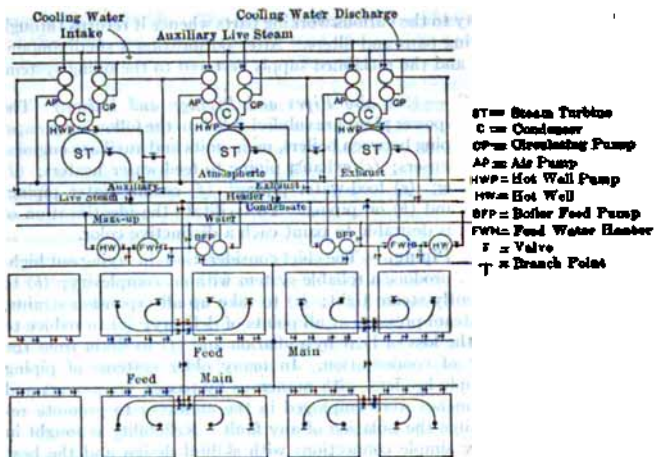

Fig. 1. Parallel Method of Connection

Fig. 2. Unit Method of Connection

radius of such bends should in all cases be not less than five times the pipe's diameter and at each end of the curve there should be a length of straight pipe not less than twice the diameter. Welded flanges are recommended for the attachment of bends. When bends cannot be used recourse must be had to swivel joints or slip joints, which should be avoided if possible. When screwed joints are employed expansion is commonly provided for by the use of sections having single, double or triple swing about a screwed connection. Pipes of considerable length must be anchored at more than one point to prevent vibration. Between each anchor expansion bends are required and the pipe must be support-

ed by hangers, roller brackets or pedestals allowing longitudinal motion. Anchorage is usually made at points of attachment to branches, and fittings with anchor bases are employed for the purpose.

**Lagging.** — Live-steam pipes, boiler-feed pipes, steam drums, receivers and separators should be covered with heat-insulating material to reduce the radiation losses to a minimum. The loss from bare pipe is approximately 3 B.t.u. per square foot per hour for each degree difference of temperature. Good commercial coverings, such as magnesia, felt, asbestos, mineral wool, etc., will prevent from 75 to 90 per cent of this loss if properly applied.

**Drainage.** — Saturated steam in passing through pipes undergoes a small amount of condensation due to friction and heat radiation. The presence of water in steam piping is a source of danger, for a water slug, if picked up by the moving column of steam, may be driven with tremendous force against any opposing surface, such as a valve, sharp bend or cylinder, with destructive results. Pipes should be slightly inclined so that water drains away from the prime movers and every point where water may collect must be provided with a drip connection. These drip connections are run through traps to the hot-well so that the hot water may be returned to the boilers. In other systems the drip water is returned directly to the boiler. Separators are often installed at the inlets to reciprocating engines and exhaust steam turbines taking wet or saturated steam, to drain the moisture from the entering steam. Drip connections should always be made to these separators. Bleeder connections to live steam lines are provided in order that the water condensed in warming up the pipe when steam is turned on may be drawn off.

**Valves.** — Valves for steam pipes are of two general types, gate valves and globe valves. Either type may be outside screw or inside screw, according as the screw of the spindle is outside or inside of the casting. Outside screw types are preferred for high-pressure work as the position of the spindle is then an index showing whether this valve is open or closed.

Check valves are required in boiler connections to prevent steam flowing into the boiler when cold or when its pressure is below that of the header to which it is connected. Emergency valves are often provided to cut off the steam under abnormal conditions, such as the bursting of a pipe or the racing of an engine. These often take the form of a weighted valve which closes itself when a trip is released. Electric motors and hydraulic pistons are sometimes connected to ordinary valves to provide for remote control during emergencies.

Blow-off valves of boilers are subjected to very severe service and are made exceptionally rugged. Such valves must close without leaks, open readily and furnish a free path for the ejection of scale and sediment. The wearing parts of such valves should be readily renewable. Best practice requires the use of two blow-off valves or a valve and a cock. The steam, water and sediment are usually blown through a tank partially filled with water before being exhausted to the air.

A few rules relative to the installation of high-pressure valves and piping may be noted. All valves of a diameter above 6 inches should be by-passed to facilitate opening under pressure. Valve stems are often placed horizontally to lessen the tendency to form water pockets. Angle valves should be selected whenever convenient because of the greater room in them. Branches from mains to boilers should have at least two valves, an ordinary stop valve next to the main and an automatic check valve near the boiler. Valves are best placed at the highest points in the pipe to simplify the drip system. When the flow of steam is intermittent heavy valves should not be placed far to one side of a line joining the points where the pipe is supported as they may cause vibration.

Branches from a main to a prime mover should have a stop valve at the highest point near the main. A receiver-separator from three to four times the volume of the high-pressure cylinder should be placed as close to the throttle of a piston engine as possible to equalize steam flow and drain moisture from the steam. When superheated steam is used cast-steel fittings and valves are preferred to cast iron. Branch pipes are almost invariably connected to the top of the main to prevent water from passing into the branches. When superheated steam is supplied to the main units and saturated steam to the auxiliaries a separate steam main for the latter is employed.

**Exhaust Steam Piping.**—The size of the exhaust pipe of a prime mover is determined by the permissible back pressure. High vacuum requires ports and exhaust piping of large diameter and the length of pipe to the condenser as short as possible. An atmospheric-relief valve which is normally closed by air pressure against a spring or weighted lever but which opens automatically when the vacuum falls should be installed in the condenser pipe. Atmospheric-exhaust pipe is usually spiral riveted as no precaution against leaks is required. This usually terminates in an enlarged exhaust head which contains baffles to drain from the steam condensed water and oil before it discharges to the air. A common exhaust main for a number of units is often employed. When exhaust steam is used for heating purposes the system is supplied through a back-pressure valve which automatically opens the atmospheric exhaust if the back pressure exceeds that required to operate the heating system and closes when normal back pressure is restored.

**GENERATOR AND CONTROL EQUIPMENT.**—(See also *Batteries, Storage, Applications of; Bus-Bars and Bus-bar Structures; Circuit Breakers; Generators, Alternating Current; Generators, Direct Current; Reactance Coils; Regulators; Relays; Switches; Switchboards; Switchgear Equipment for Power Stations; Transformers; Transformers, Instrument; Wires and Cables.*)

**Direct-current Generators.**—Three-wire lighting service may be provided (a) by the connection of generators in sets of two in series, (b) by the use of three-wire generators with external or internal compensator coils or (c) by the use of voltage balancer sets associated with standard two-wire generators. Railway generators are operated at or near 600 or 1200 volts and are grounded at one pole, usually the negative. Series fields and equalizer connections may be on either the positive or the negative side. Equalizer switches are often carried by pedestals near the generator terminals to save wiring to the switchboard. Satisfactory voltage regulation for railway systems is usually provided by the use of compound generators. The close voltage regulation required by lighting systems is best provided by the use of a regulator of the Tirrill type. (See *Regulators.*)

**Alternating-current Generators.**—Synchronous 3-phase generators are used most extensively. Induction generators are often advantageous in connection with exhaust-steam turbines. Synchronous turbo-alternators are now designed with high internal reactance to prevent excessive transient currents immediately after the creation of a short-circuit. If the internal reactance is inadequate they may be connected to the bus-bars through reactance coils. (See *Reactance Coils.*) In some cases the generators are operated at half the bus-bar voltage and are connected through raising auto-transformers wound with large reactance.

**Grounding the Neutral.**—Three-phase alternators are usually Y-connected and provision is frequently made for the grounding of one generator at the neutral point to prevent dangerous potential rise should a wire become accidentally grounded. More than one grounded neutral in a group of genera-

ers in parallel is undesirable, due to the possibility of a third-harmonic circulating current passing through the neutral connection.

**Air Ducts for Forced Ventilation.** — Modern turbo-alternators are designed for forced ventilation. A system of ducts should be provided, either overhead or beneath the floor of the generating room from which each generator may draw a supply of clean outside air. This air is forced through the ventilating spaces of the stator and rotor by the fan action of the rotor. Discharge ducts are also provided in case it is undesirable to discharge the heated air to the generating room. It is desirable to equip such ducts with dampers so that the air may be discharged indoors or outdoors as desired. In many cases where the air supply is dusty it is desirable to install air-conditioning equipment in the intake of the system. See *General Electric Review*, Vol. 16, p. 627 for a full discussion of turbo-generator ventilation.

**Excitation.** — Fig. 3 shows the exciter capacity required by modern alternators. In small plants each alternator is often provided with its individual exciter driven by the main shaft. Large stations are provided with central

Fig. 3. Exciter Capacity Required by A-C. Generators

systems of excitation comprising not less than two, and generally more, direct-current generators, driven by independent motive power. At least one exciter in every plant should be steam-driven. Three-phase induction motors are quite generally used for the electric driving of exciters. The exciter system is frequently reinforced by a floating storage battery to insure the supply of exciting current in every emergency. (See *Batteries, Storage, Applications of.*) All alternator fields are supplied through adjustable rheostats from a set of excitation bus-bars, except that in a few very large plants the excitation system is sectionalized for the sake of reliability. Exciters are commonly rated at 125 or 250 volts, and are usually compound-wound, with magnetic circuits normally in a state of low saturation. The best position for exciters in large stations is generally near the center of the generating floor.

**Voltage Control.** — In both alternating- and direct-current stations very sensitive regulation of the bus-bar voltage may be obtained by the use of appropriate types of Tirrill regulators. (See *Regulators.*) When the load variations of different feeders are quite unlike it is often desirable to provide each feeder or group of parallel feeders with independent feeder regulators, which may be hand-operated or may be automatically controlled by voltage relays.

**Transformers.** — The arrangement of the transformers depends to some extent upon the type used. When it is not convenient or possible to allow above

each transformer clear head-room for crane handling, the transformer cells may be arranged to open at one side along a track and have raised floors at the level of a flat car, so that the assembled units may be slid into or out of place.

**Air-blast Transformers.** — These are largely used for step-up service in power stations in connection with feeders operating at 20,000 volts or less. Railway transmission lines and feeders operated at more than 20,000 volts are usually supplied through oil-insulated, water-cooled transformers. Air-blast transformers are usually placed above a common pressure pit whose air-supply is drawn from out-doors by electrically operated fans. Each transformer may be equipped with adjustable dampers to regulate the air supply.

**Oil-insulated Transformers.** — In some cases oil-insulated transformers are isolated in fire-proof cells built of concrete or masonry. The fire-risk is usually not sufficient to warrant isolation for each unit, but it is often desirable to enclose each 3-phase bank. Large oil-insulated transformers should be connected to an oil-drainage system to facilitate the withdrawal and replacement of oil.

**Switching Equipment and Wiring.** — For descriptions and standard arrangements see the following articles: *Bus-Bars and Bus-bar Structures; Circuit Breakers; Regulators; Relays; Switches; Switchboards; Switchgear for Power Stations; Synchrosopes; Transformers, Instrument;* and the articles on the various kinds of meters.

**Wiring.** — In direct-current stations the power conductors are usually rubber-insulated copper cables run from generators to switch-board and thence to outside circuits in ducts of tile or fiber. In some cases the duct system is dispensed with and the conductors are carried on open wallracks spaced by insulating knobs. In small alternating-current stations the wiring to and from the switchboard is usually in a duct system, but the switchboard and bus-bar wiring is open and is supported by porcelain insulators on walls and on a light frame work of pipes or angle-irons.

In plants of 12,000 kilowatts and up, operating at voltages of 20,000 or less, it is customary to isolate all conductors of unlike polarity as fully as possible in fireproof cells and barriers. The essential features of such a system of isolation are as follows: — (1) Each horizontal run of conductor is drawn into its individual duct of tile or fibre set in a concrete floor; (2) each bus-bar is mounted in a separate horizontal cell of concrete or masonry; (3) each instrument transformer and disconnecting switch is in a separate cell; (4) each pole of a bottom-connected oil switch or each complete top-connected switch is in its separate cell; and (5) vertical fire-proof barriers are placed between all vertical runs of conductor. Isolation of this nature is seldom practiced in systems above 30,000 volts, but open overhead wiring with generous spacing is employed.

In an enclosed system the power connections are appropriately formed by single-conductor copper cables, insulated with rubber or with cambric tape, and covered with a fire-resisting sheath. Lead sheathing is seldom employed unless the wiring is exposed to dampness. The cross section of such conductors is determined by the safe limits of temperature rise.

**COST OF STEAM POWER STATIONS (Pre-war figures).** — Power station costs are subject to wide variations with the type and elaborateness of equipment, construction difficulties and rated capacity.

**Capital Costs.** — Illustrative data showing the range of unit costs of the chief divisions of plant equipment are given by O. S. Lyford, Jr., and R. W. Stoval of the Westinghouse, Church, Kerr Co., in the *Electric Journal*, 1917, Vol. 9, p. 323, as follows:

TABLE IV.—COSTS OF STEAM-ELECTRIC POWER STATIONS

Capacity, 2,000 to 20,000 kw., based on maximum continuous capacity of generators at 50° C. rise

Item	Dollars per kw.	
	High	Low
Preparing Site: Dismantling and removing structures, making construction roads, tracks, etc.....	0.25	0.00
Yard Work: Intake and discharge flumes for condensing water, railway siding, grading, fencing, sidewalks.....	2.50	1.00
Foundations, including foundations for building, stacks and machinery, together with excavation, piling, water-proofing, etc.....	6.00	1.00
Boiler Room Equipment, including boilers, stokers, flues, stacks, feed pumps, feed-water heater, economizers, mechanical draft, and all piping and pipe covering except for condenser water.....	24.00	12.00
Turbine Room Equipment, including steam turbines and generators, condensers with condenser auxiliaries and water piping, oiling system, etc.....	22.00	12.00
Electrical Switching Equipment, including exciters, masonry switch structure with all switchboards, switches, instruments, etc., and all wiring except for building lighting.....	5.00	2.00
Service Equipment, such as cranes, lighting, heating, plumbing, fire protection, compressed air, furniture, permanent tools, coal and ash-handling machinery, etc.....	5.00	2.50
Building, including frame, walls, floors, roofs, windows and doors, coal bunkers, but exclusive of foundations, heating, plumbing and lighting.....	12.00	4.00
Starting Up.—Labor, fuel and supplies for getting plant ready to carry useful load.....	1.00	0.50
General Charges, such as engineering, purchasing, supervision, clerical work, construction plant and supplies, watchmen, cleaning up.....	6.00	3.00
Total Cost, except land and interest during construction....	\$3.75	38.00

The same authorities give the costs of foundations at from \$1.25 to \$4.00 per square foot of building area, depending on the nature of the sub-soil. Table III shows that the ground area of buildings ranges from 0.8 to 2.0 square feet per kw. Building costs range from 8 to 12 cents per cubic foot of space, over-all. Power plant buildings range from 50 to 100 cubic feet per kw.

W. E. Wickenden has correlated miscellaneous data on power plant costs in the form of curves, see Fig. 4. The curves are shown in an additive sense, e.g., for a 2,000 kilowatt plant, boiler room equipment and piping cost \$17.50 per kw., generating plant \$37.00—\$17.50=\$19.50 per kw., etc., the total cost except land and interest during construction being \$66.00 per kw.

**Operating Cost and Fixed Charges.**—The cost of producing electrical energy comprises two groups of items, viz., fixed charges on the investment in the power plant to cover interest, depreciation, taxes and insurance, and the

TABLE V. — COSTS OF BOILER ROOM EQUIPMENT.

Item	Dollars per boiler horse-power	
	High	Low
Boilers, except settings.....	\$11.00	\$8.00
Superheaters.....	3.00	0.00
Stokers.....	5.50	3.00
Masonry settings of boilers.....	3.50	2.00
Flues.....	1.50	0.75
Stacks.....	4.00	2.00
Economizers.....	4.00	0.00
Mechanical draft.....	3.00	0.00
Feed pumps.....	1.50	0.50
Feed heaters.....	1.00	0.40
All piping and pipe covering.....	10.00	6.00
Coal chutes and ash hoppers.....	1.25	0.00
Miscellaneous items.....	1.00	0.50
Totals.....	\$50.25	\$23.15

cost of operating the plant. Fixed charges on the investment range from 10 to 14 per cent of the investment per annum and are practically independent of the load factor of the station. The amount assignable to each kilowatt-hour is therefore inversely proportional to the load factor and equals, in cents,

$$F = \frac{100 RI}{8760 K}$$

where  $I$  is the investment per kw. of capacity, in dollars,  $R$  is the rate of fixed charges expressed as a decimal fraction and  $K$  the annual station load factor expressed as a decimal fraction.

Operating costs include supervision, labor, fuel, other materials consumed and current repairs. The cost of supervision per kw-hr. varies almost inversely

Fig. 4. Approximate Division of Construction Cost of Steam-electric Power Plants. (In additive sense, see text.)

with the load factor. Labor cost per kw-hr. in boiler plants vary in almost direct proportion to the weight of coal burned per kw-hr. Labor cost per kw-hr. in generating rooms varies greatly with the size of the station and the number of units operated, since the number of men required depends more on the number of units of apparatus to be cared for than on the ratings of these units. Large plants are therefore at a large advantage in the item of labor cost. The cost of fuel per kw-hr. varies directly with the price of heat units in the coal burned and inversely with the over-all efficiency of the station. In modern steam turbine

stations the cost of supplies other than fuel averages about 20 per cent of the total labor cost. The cost of current repairs in such stations is from \$0.75 to \$1.50 per annum per kw. of generating capacity. A high load factor is distinctly favorable to good physical efficiency, due to the reduction of stand-by and light-load losses, and to economy in the use of labor. H. G. Stott has pointed out that the production cost per kw-hr. varies inversely with the 4th root of the annual load factor. (See *Proc. A.I.E.E.*, Vol. 32, p. 1127.)

Wickenden has also correlated the records of the operating costs of a considerable number of railway and public service stations having load factors between 25 and 33 per cent, and from these data has prepared the curves in Fig. 5. (For the B.t.u. equivalent of a ton of coal see article on *Fuel*.) These curves are shown in an additive sense, in the same manner as the curves in Fig. 4.

Fig. 5. Approximate Division of Operating Expenses of Steam-electric Power Plants. (In additive sense, see text.)

**PRINTING PRESSES, ELECTRICAL OPERATION OF.**— (See also *Motors, Industrial Applications of.*) Owing to the great variety of work performed, printing machinery as a rule requires a certain degree of speed variation in order that with a given equipment and operating force, the maximum of high-grade production may be turned out. All necessary speed variations are most readily, economically and satisfactorily obtained with electric drive and control. Each press can then at all times be under instant control, so that the entire time of the operator may be devoted to the work in hand.

Individual drive is particularly applicable to printing establishments, as in this class of service the ratio is small between the power required to drive the machines running idle and when performing actual productive work. With group drive the ratio between average and connected load is high, due to the large and constant character of the friction losses. The economy in power consumption is, therefore, in favor of separately-driven units, which may be shut down when not operating productively.

Printing presses may be divided into three principal classes, viz., job, flat-bed and web presses.

**JOB PRESSES.**— The job press is the smallest type and requires from  $\frac{1}{4}$  to 1 horse-power, depending upon the size. The motor is generally mounted on or near the press and the drive may involve either a short belt with idler or occasionally some form of friction device. With these presses a speed variation of 60 per cent is often required, which, as a rule, is accomplished by armature control, shunt-wound motors being used with direct-current installations and single-phase repulsion motors with alternating-current.

**FLAT-BED PRESSES** are considerably larger than job presses and consist of a reciprocating bed containing the type form and a main cylinder on which the impressions are made. The presses require from 2 to 10 horse-power to drive them according to work and size. In the majority of plants a 50 to 60 per cent speed variation is desired, and as these presses require a considerable torque at starting it is usual to provide compound-wound direct-current motors or phase-wound polyphase induction motors. The series winding of the compound-wound motors is generally weaker than for standard motors, 10 per cent being an average value. The speed control is accomplished by field control for direct-current motors and secondary control for induction motors. Most presses of this type allow of mounting the motor under the bed toward the front of the machine and a belt drive with an idler is almost always used.

**WEB PRESSES** vary greatly in size and come under the head of rotary presses. Different makers have different classifications for the various sizes, such as the number of decks or webs, as 3-deck, 5-deck, 2-web, etc., or according to the number of groups of which they consist, as quadruple, sextuple, octuple, etc. A modern high-speed sextuple press, for example, has three paper rolls and six plate cylinders, each cylinder generally being four plates wide. The plate cylinders revolve at a maximum speed of 300 r.p.m. A wide range of operating speeds must therefore be provided on the controller as the press will often be called upon to operate at speeds as low as one-half of the above.

All of these presses require a slow threading speed, usually about 10 r.p.m. This speed must be steady as the operators have to thread the paper from roll to roll around the cylinder up over the carriers to the folder, and should the press turn by jerks it might mean the loss of a finger, hand or arm. The control must also provide for "jogging" or "inching along" when making the press ready for service, that is turning the cylinders through a small fraction of a revolution so as to bring them to the desired position for putting on the plates. Brakes must

also be provided so that in case of emergency the press may be brought immediately to rest.

**Single-motor Equipment.** — Motor equipments for web presses are of either the single or two-motor type. The former is used with small and medium-size direct-current units but is not practicable above 30 or 35 horse-power. The principal objection to single-motor equipments is the difficulty in maintaining a constant slow speed, due to the wide variation in torque during any given revolution of the press cylinders. The waste of power in the series and shunt resistances is also a disadvantage, particularly for the larger sizes. Compound-wound motors are generally used with the single-motor equipments so as to provide for the comparatively-heavy starting torque. Speed regulation down to 10 per cent is readily accomplished by connecting a resistance in parallel with the armature circuit which, in combination with the series resistance, gives a fixed slow speed.

**Two-motor Equipment.** — The two-motor equipment consists, as the name implies, of two motors, one of small size for driving the press at slow speed through a worm-gear reduction, and a large motor to drive the press at the full-producing speed through ordinary direct gearing. The reduction gearing for the small motor is furthermore provided with an automatic ratchet and pawl clutch, which mechanically disconnects the small motor when the press is being accelerated by the large motor.

Either direct- or alternating-current motors may be used with two-motor equipments. When direct-current is used the small motor should be compound wound to insure sufficient starting torque. It is also a common practice to make the large motor compound wound, so as to accelerate the press more easily. With alternating-current the smaller motor may be of the squirrel-cage type but the larger must be of the phase-wound slip-ring type, as a smooth speed variation from the 10 per cent threading speed to the full running speed is most essential.

The capacity of the motors depends on the size and make of the press, and the accompanying table is only intended to give an approximate idea of the power required:

Type of press	Horse-power	
	Small motor	Large motor
Quadruple	5	35
Sextuple	7	50
Double quadruple	Two $5\frac{1}{2}$	Two 35
Double sextuple	Two $7\frac{1}{2}$	Two 50
Octuple	10	70

**Control of Two-motor Drive.** — Full automatic control in connection with two-motor drive has been almost universally adopted on larger presses. The essentials of this control are the complete automatic control of the press speed from any number of push-button stations located at different points about the press. From any of these stations it is possible to start the press, increase or decrease the speed or stop it. Five buttons are generally provided with each station marked "Fast," "Slow," "Stop," "Safe" and "Run."

Pressure on the "Fast" or "Slow" button causes the press to speed up or slow down until the button is released, when the press will continue to run at the

speed it has then attained. The manipulation of the "Stop" button will immediately stop the press, through the operation of a dynamic brake on direct-current equipments and a solenoid brake on alternating-current equipments. Pressure on the "Safe" button at any station opens the control circuit and renders the equipment inoperative until the "Run" button at that particular station is closed, releasing the "Fast" button. A "Jog" button is frequently also provided, particularly on a-c. equipments, by means of which the cylinders can be inched along to the desired position when plating is done.

(Lond.), 1910, Vol. 46, p. 892.

**PROGRESSION.** — (See also *Series, Mathematical.*) There are two kinds of progression, arithmetical and geometrical.

**ARITHMETICAL PROGRESSION.** — Quantities are said to be in arithmetical progression when they increase or decrease by a common difference.

Let  $a$  = first term of the progression,  
 $d$  = the amount by which any term is greater than the next preceding, i.e., the common difference,  
 $n$  = the number of terms in the progression.

Then the successive terms of the progression are

$$a, a + d, a + 2d, a + 3d, \text{ etc., to } n \text{ terms.}$$

The last term is

$$a + (n - 1)d.$$

The sum of the  $n$  terms is

$$\frac{n}{2} [2a + (n - 1)d].$$

**GEOMETRICAL PROGRESSION.** — Quantities are said to be in geometrical progression when they increase or decrease by a common ratio. Let

$a$  = the first term of the progression,  
 $r$  = the ratio of any term to the next preceding term,  
 $n$  = the number of terms in the progression.

Then the successive terms of the progression are

$$a, ar, ar^2, ar^3, \text{ etc., to } n \text{ terms.}$$

The last term is

$$ar^{n-1}.$$

The sum of the  $n$  terms is

$$\frac{a(1 - r^n)}{1 - r}.$$

**PUMPS AND PUMPING ENGINES.** — (*See also Boilers; Blowers and Compressors; Condensers; Fans; Power Stations; Steam Engines; Steam Turbines.*) Pumps may be classified according to (1) their mode of action as piston, plunger, centrifugal, rotary, jet and direct pressure; (2) their motive power, as engine-driven, turbine-driven, motor-driven, and power-driven (by belt or gearing); (3) the number of cylinders (or their equivalent), as simplex, duplex and triplex; (4) the number of stages or pump elements in series, as single-stage and multi-stage; (5) the mode of connection, as direct-acting, crank-driven and geared. Large steam-driven pumps are usually called pumping engines.

**Piston and Plunger Pumps** are the most common in use. In the single-acting type, water is taken in on one stroke and discharged on the return stroke. In the double-acting pump water is taken in and discharged on both strokes. In the direct-acting piston or plunger pump the steam piston and the water piston or plunger are both secured to the same piston rod and the steam is used non-expansively. Their steam consumption is consequently high, unless special compensating devices, substitutes for a flywheel, are used, as in the Worthington high-duty and the d'Auria pumping engines. Large piston pumps are usually provided with a crank and flywheel, so that the steam may be used expansively.

**Centrifugal Pumps** consist essentially of a rotating impeller which draws water in at its center and a stationary casing which guides the water to the discharge outlet. Centrifugal pumps having stationary guide-vanes inside of the casing are called "turbine" pumps. Centrifugal pumps are especially suited for low heads and large volumes, but are also built multi-stage for high heads. They are not as efficient as high-grade pumping engines, but are considerably cheaper.

**Rotary Pumps.** — Pumps with two parallel geared shafts carrying vanes or impellers which mesh with each other, and other forms of positive-driven apparatus, in which the water is pushed at a moderate velocity, instead of being rotated at a high velocity as in centrifugal pumps, are known as rotary pumps. They have an advantage over reciprocating pumps in being valveless, and over centrifugal pumps in working under widely-varying heads. They are usually not economical, but when carefully designed with the impellers of the correct cycloidal shape, like those used in positive rotary blowers, they give a moderately high efficiency.

**Injectors.** — The injector is a form of steam pump commonly used for feeding boilers. If a cylindrical tube 1 or 2 inches in diameter is reduced to one-half its diameter, or thereabouts, at one portion of its length, by gradual reduction and enlargement, and a smaller tube or nozzle inserted inside of it, so that the end of the smaller tube approaches the reduced section of the larger tube, then if the larger tube be connected to a supply of water and steam at considerable pressure be introduced through the smaller tube or nozzle, the water will be drawn into the larger tube and ejected from its outer end with such force as to cause it to overcome the pressure in the boiler supplying the steam, and thus to feed water into the boiler. The apparent paradox of the injector is explained by the fact that the violent rush of steam into the water gives the latter a high velocity and the momentum thereby induced cannot be overcome in a limited space without the exertion of a force greater than that of the steam in the boiler. As a boiler feeder the injector has a remarkably high efficiency, for so much of the heat energy of the steam as is not converted into mechanical work is carried into the boiler as heat in the water, but as a pump for ordinary purposes its efficiency is very low, since less than 1 per cent of the thermal

energy of the steam is converted into work. The usefulness of the injector as a boiler feeder is limited by the fact that it will not handle hot water.

**Direct-pressure Pumps.** — These are of two types, the pulsometer and the air lift. In the pulsometer the water is raised by suction into the pump chamber by the condensation of steam within it, and is then forced into the delivery pipe by the pressure of a new quantity of steam on the surface of the water. Two chambers are used, which work alternately, one raising while the other is discharging. The air-lift pump consists of a vertical water pipe with its lower end submerged in a well and a smaller pipe delivering air into it at the bottom. The rising column in the pipe consists of air mingled with water, the air being in bubbles of various sizes, and therefore lighter than a column of water of the same height; consequently the water in the pipe is raised above the level of the surrounding water. The pulsometer is used for pumping out pumps, drains, etc., and the air lift for pumping from wells.

**PERFORMANCE.** — The performance of a pump is usually expressed in terms of steam consumption of the steam cylinder or engine driving it, the indicated horse power of the cylinder or engine driving it (or the brake horse power of the motor in case of a motor-driven pump), the mechanical efficiency of the pump, and the slip.

**Useful or Water Horse Power.** — Let  $p$  = difference in pressure in pounds per square inch between inlet and outlet of pump = pressure in pounds per square inch indicated by gauge on force main  $\pm$  pressure in pounds per square inch indicated by gauge on suction main (+ if this reads below atmospheric pressure, - if above) + pressure in pounds per square inch corresponding to the distance between the two gauges;  $H$  = head in ft. corresponding to  $p$ ;  $Q$  = actual discharge\* in cubic feet per minute;  $W$  = pounds per minute discharged;  $w$  = weight of the fluid per cubic foot. For water at 62° F.,  $w$  = 62.36 pounds and is about 0.1 per cent greater at 40° F., and 4 per cent less at 212° F. Then the useful or water horse power is

$$P_w = \frac{144 pQ}{33,000} = \frac{pQ}{229} = \frac{pW}{229w} = \frac{HW}{33,000} = \frac{HwQ}{33,000}$$

For water at 62° F., and approximately at any temperature between 32° and 212° F.,

$$P_w = \frac{pW}{14,300} = \frac{HQ}{529}$$

**Slip.** — By the slip of a pump is meant the ratio of the difference between the piston displacement and the water delivered to the piston displacement.

**Mechanical Efficiency.** — By mechanical efficiency is usually meant the ratio of the useful or water horse power to the indicated horse power of the steam cylinder driving it, or to the brake horse power of the motor in the case of a motor-driven pump. Sometimes the useful or water horse power is figured on the basis of the amount of water corresponding to the piston displacement; the actual water delivered is then equal to the piston displacement multiplied by (1 - slip). The power required to deliver water at a given rate in the first case is equal to the useful or water horse power divided by the mechanical efficiency; in the second case the power required is equal to the useful or water

\*  $Q$  is sometimes taken as equal to the piston displacement, which is greater than the actual water delivered, due to the slip of the water past the piston and valves.

horse power (reckoned on the basis of piston displacement) divided by the product of the mechanical efficiency and  $(1 - \text{slip})$ . (See table below.)

**Duty.**—The performance of a steam-driven pump is also expressed as the number of foot-pounds of useful work done by the pump ( $144 PQ \times \text{time}$  in minutes) per million B.t.u. in the steam supplied to it above the temperature of the boiler feed water. (If the boiler takes water from several sources at different temperatures, the B.t.u. added by the boiler from each source must be reckoned separately.) This ratio is called the "duty" of the pump. Duty is also sometimes expressed as the useful work in foot-pounds done by the pump per 1000 pounds of dry steam supplied to it.

The efficiency of a pump falls off rapidly with use, due to wear of the moving parts, unless it is kept in first-class condition. The figures in the following table are for average full-load conditions at rated speed in ordinary practice:

EFFICIENCY AND DUTY OF PUMPS.

Type of Pump	Pounds steam per hour per h.p. of Useful Work	Mechanical efficiency	Per cent slip	Duty, million ft. lb. per million B.t.u.
<b>Piston pumps:</b>				
Small duplex, direct-acting.....	100 to 200	40 to 60	5 to 20	10 to 20
Compound, direct-acting, non-condensing.....	40 to 80	70 to 90	2 to 20	25 to 50
Ditto with "high duty" attachment.....	20 to 33	60 to 80	2 to 20	60 to 100
Single cylinder, flywheel, non-condensing.....	30 to 50	70 to 90	2 to 20	40 to 60
Multi-cylinder, fly wheel, non-condensing.....	25 to 40	70 to 90	2 to 20	50 to 80
Multi-cylinder, fly wheel, condensing.....	13 to 20	70 to 95	2 to 20	80 to 160
Direct-connected, motor-driven:.....		50 to 80	2 to 20	60 to 80
Gearred pumps.....		50 to 90	2 to 20	30 to 90
<b>Centrifugal pumps:</b>				
Single-stage for low heads.....	22 to 66	40 to 70	.....	30 to 90
Multi-stage for high heads.....	25 to 50	40 to 60	.....	40 to 80
<b>Rotary pumps.....</b>	26 to 50	50 to 80	5 to 20	40 to 75
<b>Pulsometer.....</b>	100 to 400	.....	.....	5 to 20
<b>Air lift.....</b>	.....	10 to 40	.....	10 to 25

**Steam Consumption of Feed Pumps.**—With compound steam ends well lagged and covered 100 pounds of steam per indicated horse-power-hour should be safe consumption for feed pumps of large size, while in small pumps, 200 pounds appears to be nearer the mark. The pump efficiency should not be less than 80 per cent.

**Performance of Injectors.**—Kneass, *Theory of the Injector*, states that the pounds of water delivered ( $w$ ) per pound of steam supplied is equal, very approximately, to the ratio of the B.t.u. per pound in the steam supplied, reckoned from the temperature ( $t$ ) of the discharge water to the difference between the temperature ( $t$ ) of the discharge water, and the temperature ( $t$ )

of the suction water. That is, letting  $r$  = heat of evaporation,  $h$  = heat of liquid, and  $x$  = quality of the steam, then

$$w = (rx + h - t + 32) + (t - t_0).$$

**ELECTRIC DRIVE.** — (See also *Motors, Industrial Applications of.*) Since the reciprocating pump is essentially a low-speed machine, limited to about fifty revolutions per minute or thereabouts, it requires a speed reduction, as by gearing, for connection to the driving motor. The centrifugal pump, on the other hand, is suitable for direct connection to motors operating at speeds of up to 3500 r.p.m.

**Motors for Reciprocating Pumps.** — In starting large reciprocating pumps the water may be delivered through a by-pass until the motor is up to speed, when the by-pass is gradually closed and the water delivered into the system. The load at starting, therefore, only consists of the friction losses, and usually does not exceed 25 per cent of the full-load torque. Small- and medium-size pumps may, however, be required to start under full load.

When direct-current motors are used, the compound-wound type is generally selected for single-acting pumps on account of the rather pulsating load, but for double and triplex pumps having steadier load characteristics the shunt-wound type is used to advantage. Both squirrel-cage and phase-wound induction motors are suitable, the latter, as a rule, being selected where it is desirable to reduce the starting current to a minimum or where a somewhat variable speed is required. Synchronous motors may and are frequently used for driving large pumps. By-pass valves must then, however, be provided for reducing the torque at starting as previously mentioned.

**Motors for Centrifugal Pumps.** — On account of the peculiar characteristics of centrifugal pumps special care is required in the selection of the motor drive. With a reciprocating pump operating at constant speed an increase of the resistance increases the pressure and therefore the load on the motor; but with a centrifugal pump an increase of the resistance reduces the load. The volume of water delivered by a reciprocating pump is not affected by the reduction of the head, but the required power is reduced. A reduction of the head with a centrifugal pump, however, increases the volume of water, and as the efficiency at the same time goes down rapidly, the load increases. It is, therefore, of importance to know what this overload, caused by a reduction of the head, amounts to and the duration of this overload; and the capacity of the motor should as a rule be governed by the low and not the high head conditions.

The condition of starting must also be given careful consideration in selecting the motor. In starting a centrifugal pump the discharge valve may be entirely closed until the motor comes up to speed, so that the motor may start as nearly light as possible. At rest the torque required is small, usually from 15 to 25 per cent of full-load torque, and this drops from 5 to 6 per cent as soon as the machine starts turning over. The pump casing is full of water, however, and as the machine comes up to speed this water is churned around in the casing, causing the motor to load up as it approaches full speed, when with pumps of the usual design it takes from 40 to 50 per cent of full-load torque to drive it even though pumping no water.

Compound-wound direct-current motors, varying-speed brush-shifting motors, and either squirrel-cage or phase-wound induction motors, or synchronous motors are all well adapted for this type of pump and will readily meet the above conditions.

**COST OF FEED PUMPS (Pre-war figures).** — The cost of feed pumps is a small item in the cost of the station, varying from 20 to 50 cents per kilowatt of station capacity, or from 15 cents to \$1 per boiler horsepower the lower prices

applying to the larger station. Duplex direct-acting pumps, of the Worthington type, and suitable for boiler feeding, vary in capacity from the 6 by 4 by 6 in. 100-gallon pump to the larger pot-valved pumps with compound steam ends, 14 and 20 by 10 by 15 in. delivering 500 gallons per minute. The price varies from about \$300 for the small size to around \$2000 for the large size, with the intermediate sizes at proportional prices. Centrifugal feed pumps, turbine-driven, run from 200 to 1000 gallons per minute, in about four sizes, and cost about \$1500 in the 200 gallons size and about \$3200 in the 1000 gallons size. Motor-driven centrifugal pumps are about 10 per cent higher in price, and triplex motor-driven pumps often run from 100 to 200 per cent higher.

**PYROMETERS.** — (See also *Temperature and Thermometers.*) A pyrometer is any device for measuring high temperatures. By high temperature as here used is meant a temperature beyond the range of the ordinary mercury thermometer, say  $350^{\circ}$  C. and up. A great number of pyrometric methods have been proposed, the more important of which will be found treated in detail in Burgess and Le Chatelier's *Measurement of High Temperatures*, New York, 1912. The following brief treatment is adapted from this work.

**CLASSIFICATION OF PYROMETERS.** — The various types of pyrometers may be classified as follows. Some of these are more fully treated in the following sections.

**Gas Pyrometer** (Pouillet, Becquerel, Sainte-Claire-Deville, Barus, Chapuis, Holborn, Callendar, Day). — Utilizes the measurement of change in pressure of a gaseous mass kept at constant volume. Its great volume and its fragility render it unsuitable for ordinary measurements; it serves only to give the definition of temperature and should only be used to standardize other pyrometers.

**Calorimetric Pyrometer** (Regnault, Violle, Le Chatelier, Siemens). — Utilizes the total heat of metals, platinum in the laboratory and nickel in industrial works. It was formerly used for intermittent researches in industrial establishments because its employment demands almost no apprenticeship and because the cost of installation is not great. The cost of a metal ball to withstand over  $1000^{\circ}$  C. prohibits its use above this temperature in industrial works. Other and more convenient types of pyrometers have almost entirely superseded the calorimetric pyrometer.

**Total Radiation Pyrometer** (Rosetti, Langley, Boys, Féry, Thwing). — Utilizes the total heat radiated by warm bodies. Its indications are influenced by the variable emissive power of the different substances. Convenient for the evaluation of very high temperatures which no thermometric substance can withstand (electric arc, sun, very hot furnaces), or when it is not convenient to approach the body whose temperature is wanted. Can be made self-registering.

**Optical Pyrometer** (Becquerel, Le Chatelier, Wanner, Holborn-Kurlbaum, Morse). — Utilizes either the photometric measurement of radiation of a given wave length of a definite portion of the visible spectrum, or the disappearance of a bright filament against an incandescent background. Its indications, as in the preceding case, but to a much less degree, are influenced by variations in emissive power. The intervention of the eye aids greatly the observations, but diminishes notably their precision. This method is mainly employed in industrial works for the determination of the temperatures of bodies difficult of access — for example, of bodies in movement (casting of a metal, the hot metal passing to the rolling mill). Can be used to estimate the highest temperatures and is the best method for use above  $1700^{\circ}$  C. in laboratory and industrial works.

**Electric Resistance Pyrometer** (Siemens, Callendar, Waidner and Burgess). — Utilizes the variations of electric resistance of metals (platinum) with the temperature. This method permits of very precise measurements to  $1000^{\circ}$  C., but requires the employment of fragile apparatus. It merits the preference for very precise investigations in laboratories. As a secondary instrument for the reproduction of a uniform temperature scale throughout the range in which the platinum resistance thermometer can be used, to  $1000^{\circ}$  C. except in very heavy wire, it is unsurpassed in precision and sensibility. It is also now constructed in convenient form for industrial use.

**Thermoelectric Pyrometer** (Bequerel, Barus, Le Chatelier). — Utilizes the measurement of electromotive forces developed by the difference in temperature of two similar thermoelectric junctions opposed one to the other. In employing for this measurement a Deprez-d'Arsonval galvanometer with movable coil or a millivoltmeter one has an apparatus easy to handle and of a precision amply sufficient for industrial and many scientific uses. With a potentiometer an instrument is obtained of the highest precision, available for use to 1600° C., or even to 1750° C. with proper precautions. This pyrometer was used for a good many years in scientific laboratories, before it spread into general industrial use, where it also renders most valuable service.

**Contraction Pyrometer** (Wedgwood). — Utilizes the permanent contraction which clayey materials undergo when submitted to temperatures more or less high. It is employed today only in a few pottery works.

**Fusible Cones** (Seger). — Utilize the unequal fusibility of earthenware blocks of varied composition. Give only discontinuous indications. Such blocks studied by Seger are spaced so as to have fusing points distant about 20° C. In general use in pottery works and in some similar industries.

**Other Pyrometers** (Hobson, Uhling-Steinbart, Job, Fournier). — There are a number of other pyrometers which have been found suitable in special cases or which for one reason or another have been found convenient in some particular line of work. Among these are the various industrial instruments based on the relative expansion of metals or of a metal and graphite used in air blasts and metal baths and pyrometers based on the flow or on the pressure of air or vapor.

**TOTAL-RADIATION PYROMETERS.** — These instruments utilize the radiant heat of all wave lengths given off by the body whose temperature is to be measured or by an auxiliary body at the same temperature. By means of a focusing device the radiant heat from a small portion of the hot surface is caused to fall upon a suitable detector. Various devices have been used as detectors, but in modern radiation pyrometers the thermocouple in conjunction with a galvanometer, millivoltmeter or potentiometer is almost universally employed. Instead of the thermocouple a spiral bi-metallic spring, with a pointer attached, is used in Féry's spiral pyrometer.

Total-radiation pyrometers can be made self-registering by simply substituting for the indicating galvanometer a suitable recording instrument.

**Conditions of Use.** — To obtain accurate results with a radiation pyrometer it should be sighted upon the bottom of a closed-end tube inserted into the furnace or bath. The radiating properties of the bottom of such a tube approach very closely those of a "black body" (see *Heat and Thermal Properties*); i.e., the total energy radiated upon the receiving device is proportional to the difference in the fourth powers of the absolute temperature of the hot body and that of the receiving device. Since the latter temperature is usually low compared with the temperature of the hot body, the radiation is practically proportional to the fourth power of the absolute temperature of the hot body. Hence, if the relation between the absolute temperature  $T_0$  and the deflection  $D_0$  of the galvanometer attached to the thermocouple is known at one temperature, and the deflection is known to be proportional to the amount of heat falling on the thermocouple, then the absolute temperature  $T$  corresponding to any other deflection  $D$  is

$$T = T_0 \sqrt[4]{\frac{D}{D_0}}$$

It should be noted that this law does not apply unless the instrument is focused upon a "black body." If the instrument is focused upon objects in the

open air its readings, if calibrated by the above law, will be too low, due to the selective radiating properties of all materials. However, the instrument may be calibrated by comparison with a standard pyrometer, e.g., a thermoelectric pyrometer, to give true surface temperatures when sighted upon any particular kind of surface, but this calibration will not hold for other surfaces.

**Féry Radiation Pyrometer.** — In this apparatus a concave mirror (gold on glass) is used to focus the rays upon the thermocouple. The gold mirror may be considerably tarnished without seriously influencing the readings; and if the aperture of the furnace sighted upon is of sufficient size and the telescope in focus, the temperature readings are practically independent of the distance. The instrument takes its final reading very promptly with only slight creep.

Foster has also transformed the Féry telescope into a "fixed-focus pyrometer" by putting the thermocouple and the aperture at the *conjugate foci* of the gold mirror. In a similar instrument recently issued by the Brown Pyrometer Company, the sighting of the instrument is facilitated by the use of a finder such as used with photographic cameras. The Féry pyrometer of constant-focus type has been coupled directly to a long closed-end tube by Whipple, so that the closed end may be plunged directly into the hot region or melted metal.

**Thwing Radiation Pyrometer.** — In Thwing's apparatus the reflecting mirror is replaced by a conical cone which by multiple reflection concentrates the radiation at its apex on one or more thermocouples in series with a portable galvanometer.

**OPTICAL PYROMETERS.** — These instruments utilize only the visible portion of the spectrum, and their indications depend on the comparison, by the eye, of the equality of brightness of two images, one of the object whose temperature is sought and the other a standard light source. Such instruments are therefore essentially the same as photometers (*see article on Photometers*). As a rule the comparison is made with approximately monochromatic light, the images being viewed through a colored glass, usually red.

**Temperature and Intensity of Illumination.** — **Wien's Law.** — Wien has shown that the intensity of the light given out by a "black body" (*see Heat and Thermal Properties*) may be expressed by the formula

$$I = Ae^{-\frac{B}{T}},$$

where  $A$  and  $B$  are constants for a given wave length,  $e$  is the base of the natural system of logarithms and  $T$  the absolute temperature. In general, however, the energy of a given wave length radiated by a body in the open air is less than that of a "black body," i.e., its emissive power is less than unity, and the emissive power varies with the temperature. The above law, however, is usually assumed to apply to such bodies, and although the temperature as thus obtained may differ from the true (gas thermometer) temperature by from 50 to 100° C., a consistent scale of temperature is obtained for any particular substance observed.

**"Black Body" Temperature.** — The temperatures indicated by a radiation pyrometer that has been calibrated against a black body, or on the assumption of the laws of "black body" radiation, are known as black-body temperatures. Thus, were a piece of iron and a piece of porcelain both at 1200°, the optical pyrometer, which used the red light emitted by these bodies, would give, as the temperature of these bodies, 1140° and 1100° C. respectively. This means that iron and porcelain at 1200° C. emit red light of the same intensity as is emitted by a black body at 1140° and 1100° C. respectively.

**Féry Absorption Pyrometer (Fig. 1).** — The optical system of this pyrometer is shown in the figure.  $pp'$  are a pair of absorbing-glass wedges,  $G$  is a

mirror with only a narrow central strip silvered over,  $L$  is the standard light source, focused on the mirror  $G$  by the lens  $f$ . The resultant field, when observing a small crucible, is then as shown at  $ab$ .  $r$  is a red glass in the eye-piece. The instrument has a fixed angular aperture, so that no correction has to be made for focusing or for varying distance from furnace. The range of the instrument may be extended by the use of auxiliary absorbing glasses  $A, A'$ . The instrument is movable about a horizontal axis, which is a convenience in sighting.

A setting is made by adjusting the thickness of the absorbing glasses  $pp'$  by moving the wedges together by means of a micrometer screw. Let  $x$  = setting of micrometer screw,  $T$  = absolute temperature, then, assuming Wien's law to apply

$$T = \frac{a}{x + b},$$

where  $a$  and  $b$  are two constants, for a given set of wedges  $pp'$ , and can be obtained by observing two known temperatures.

**Le Chatelier's Optical Pyrometer.** — The Féry pyrometer is a modification of an earlier form devised by Le Chatelier. The latter used an iris diaphragm instead of the wedges, the setting of the instrument being accomplished by changing the aperture. With this arrangement greater sensibility can be obtained, but with the decided disadvantage that the calibration will then hold only for a fixed distance of the instrument from the object viewed.

**Wanner Pyrometer (Fig. 2).** — In this instrument a Nicol prism is used to vary the relative intensities of the light received from the standard lamp and from the object viewed, the angle through which the prism must be turned to give equal illumination being a measure of the relative intensity of the light emitted from the two sources. The principle is the same as that of a König spectrophotometer (see *Photometers*).

The slit  $S_1$  is illuminated by light from the comparison source, a small 4-volt electric lamp not shown in the figure reaching  $S_1$  after diffuse reflection from a right-angled prism placed before  $S_1$ . Light from the object whose temperature is sought enters the slit  $S_2$ . If the analyzer is at an angle of 45 degrees with the plane of polarization of each beam, and if the illumination of  $S_1$  and  $S_2$  is of the same brightness, the eye will see a single red circular field of uniform brightness. If one slit receives more light than the other, one-half of the field will brighten, and the two may be brought to equality again by turning the analyzer carrying a graduated scale, which may be calibrated in terms of temperature. Let  $\phi$  = angle through which prism is turned to establish equal illumination,  $T$  = absolute temperature of furnace or bath; then, assuming Wien's law to apply,

$$T = \frac{a}{\log(\tan \phi) - b},$$

where  $a$  and  $b$  are constants determined by calibration. Only two known tem-

Fig. 1. Féry Absorption Pyrometer

Fig. 2. Wanner Pyrometer

peratures need be observed to obtain these constants, but it is safer to plot a calibration curve from several known temperatures.

In the latest form of this instrument the details of its mechanical construction have been improved, and it has been made direct-reading by providing a second scale on the instrument graduated in temperatures, corresponding, of course, to a definite normal point and for a source approximating a black body.

**Incandescent Lamp Pyrometers.**— In this type of instrument the current through the filament of an incandescent lamp is adjusted until a portion of the filament is of the same color and brightness as the object. When this occurs this part of the filament becomes invisible against the bright background, and the current then becomes a measure of the temperature as given either by a thermocouple or in terms of the intensity of illumination. This principle appears to have been first used by Morse and independently developed by Holborn and Kurlbaum. An absolute match of both color and brightness cannot be made unless monochromatic light is used or unless the lamp filament and viewed object radiate similarly. This instrument is of the Morse type.

**Leeds and Northrup Optical Pyrometer.**— The principle and manner of using the instrument will be understood by reference to Fig. 3, in which *L* is a

Fig. 3. Leeds and Northrup Optical Pyrometer.

lens, through which radiation from the body whose temperature is to be measured is brought to a focus at the point *F*. In the plane of the image produced by the lens is placed a tungsten lamp filament. The lamp filament receives current from a small battery contained in a portable case, also containing a rheostat and an accurate milliammeter. The incandescent filament and the image produced by the lens are observed through the eyepiece.

By means of the rheostat the current through the lamp is adjusted until the brightness of the filament is just equal to the brightness of the image produced by the lens *L*, whereupon the filament blends with or becomes indistinguishable in the background formed by the image of the hot object. This adjustment can be made with great accuracy and certainty, as the effect of radiation upon the eye varies some twenty times faster than does the temperature at 1600° F., and some fourteen times faster at 3400° F. When a balance has been obtained,

the observer notes the reading of the millimeter. The temperature corresponding to the current is then read from a calibration curve supplied with the instrument.

The red glass *R* is in for all temperature measurements. An additional red glass *G* in Fig. 3 is put in when measuring higher temperature where the light emitted becomes dazzling. This also eliminates any question of matching colors or of the observer's ability to distinguish colors. It is further of value in dealing with bodies which do not radiate light in the same composition as that emitted by a black body, since the intensity of radiation of any one color from such bodies increases progressively in a definite manner as the temperature rises. The intensity of this one color can therefore be used as a measure of temperature for the body in question.

**Measurement of Very High Temperatures.** — In observing bodies at very high temperatures, i.e., above 2500° F., the light received through the lens of the telescope is too blinding for direct observation, even through the red glass of the eyepiece. The intensity of the image also becomes greater than that at which it is practicable to burn the filament.

Some method of reducing the intensity of the light from the hot body must therefore be employed at these temperatures. This is done by placing an absorbing screen between the objective lens and the lamp filament so that it reduces the light from the hot body, but does not affect that from the filament. With the proper screen in place, it is possible to make direct observations on the most brilliant light sources, as the electric arc or the surface of the sun.

The screen used in the Leeds and Northrup high-temperature optical pyrometer for cutting off part of the radiation from the hot body can be thrown into or out of the field of view by revolving with the thumb a milled disk projecting through an opening in the barrel of the instrument. With the absorbing screen in use, a different calibration curve is required. Inasmuch, however, as the range of the instrument without the absorbing screen overlaps by several hundred degrees the range with the absorbing screen, the accuracy of the two scales can always be checked by observing a hot body whose temperature lies within this range.

**RESISTANCE PYROMETERS.** — These instruments are based upon the variation of electrical resistance with temperature, and are suitable for measuring temperatures throughout the range from the lowest obtainable temperatures to about 1200° C. Platinum wire is usually employed as the resistor, though nickel may be used for temperatures up to 400° C.

**Platinum Scale of Temperatures.** — The platinum scale of temperatures is defined by the relation

$$t = \frac{R_t - R_0}{R_{100} - R_0} \times 100,$$

where  $R_0$  and  $R_{100}$  are the resistances of the platinum wire at the temperature of ice and boiling water (760 millimeters mercury pressure) respectively, and  $R_t$  is the resistance at any other temperature  $t$ . For this scale to agree with the gas thermometer scale would require that the temperature coefficient of resistance of platinum (on the gas scale) be a constant equal to

$$c = \frac{R_{100} - R_0}{100 R_0}.$$

As a matter of fact the temperature coefficient is not constant but the relation between temperature (on the gas scale) and resistance is

$$R_t = R_0 (1 + at + bt^2)$$

where  $a$  and  $b$  are constants. Consequently the platinum temperature and the gas temperature differ by an amount

$$t - p_t = \delta \left( \frac{t}{100} - 1 \right) \frac{t}{100},$$

where

$$\delta = \frac{10,000 b}{a - 100 b}.$$

The fundamental constants of a platinum thermometer are then  $R_0$ ,  $c$ , and  $\delta$ . These can be determined by measuring the resistance at three known temperatures, viz., melting point of ice, boiling point of water and boiling point of sulphur ( $444.7^\circ \text{C}$ . on the gas scale). For the purest platinum  $\delta = 1.50$  and  $c = 0.0039$ . The value of  $\delta$  increases with the amount of impurity.

#### CORRECTIONS TO $t$ FOR SMALL CHANGES IN $\delta$

Centigrade scale				Centigrade scale			
	$\Delta t$ for $\Delta \delta = 0.01$		$\Delta t$ for $\Delta \delta = 0.01$		$\Delta t$ for $\Delta \delta = 0.01$		$\Delta t$ for $\Delta \delta = 0.01$
50	-0.002	300	+0.060	550	+0.247	800	+0.560
100	.000	350	.087	600	.300	850	.637
150	+ .008	400	.120	650	.357	900	.720
200	.020	450	.157	700	.420	950	.807
250	.037	500	.200	750	.487	1000	.900

Computations of  $t$  from  $p_t$  are made by the table on p. 1238, as if the thermometer had  $\delta = 1.50$ . The above corrections ( $\Delta t$ ) are then applied to the computed values of  $t$  for the value of  $\delta$  proper to the thermometer.

*Example.* Let  $p_t = 470.00$ , whence  $t = 500.00^\circ \text{C}$ , by table on p. 1238. If  $\delta = 1.52$ , the corrected value of  $t$  is  $500.40^\circ \text{C}$ .

For a full discussion of the platinum temperature scale and its relation to the gas-thermometer scale, see Burgess and Le Chatelier, *Measurement of High Temperatures*. The brief discussion given above is adapted from this treatise, from which also the tables are taken.

**Forms of Resistance Thermometers and Pyrometers.**—A complete outfit consists of the thermometer proper or "bulb," the indicating or recording instrument and two or three dry cells for operating the same. Where the indicating or recording instrument is to be in circuit continuously, it is best to operate it from a direct-current lighting circuit or storage-battery system.

With the proper switching device a number of bulbs at widely-separated points may be used with the same indicator or recorder.

**Thermometer Proper or Bulb.**—Since practically every problem in temperature measurement presents different conditions there can be no general type or form of resistance thermometers. The following descriptions are of some of the thermometers now on the market that have proved satisfactory for certain classes of work.

Resistance thermometers for use below  $125^\circ \text{C}$ . are of relatively simple construction, for in this case silk-insulated nickel wire may be used. Such a thermometer is shown in section in Fig. 4. This particular thermometer has an over-all length  $D$  of  $10\frac{1}{4}$  inches, a length of winding  $C$  of  $4\frac{1}{2}$  inches and a

diameter  $A$  of  $\frac{3}{16}$  inch. The same type of thermometer is also made with a number of different lengths from  $3\frac{3}{4}$  inches over-all to  $12\frac{3}{4}$  inches over-all, and one form, designed to be particularly quick acting, is encased in a thin steel tube  $\frac{1}{8}$  inch outside diameter. This type of thermometer is largely used for the measurement of the temperature of air, solids, concrete, water, and grains and fruit in transit. It may also be used as a wet-bulb thermometer.

Fig. 4. Resistance Thermometer for Use up to  $125^\circ\text{C}$ .

The thermometer shown in Fig. 5 is a platinum resistance bulb for measurement of the highest precision. The winding is of pure platinum wound on a mica cross; the protecting tube is of royal Berlin porcelain. For shop use it is well to protect the porcelain tube with a seamless nickel case. Such a case will maintain its mechanical strength after long exposures to high temperatures. Thermometers of this type may be used up to  $1000^\circ\text{C}$ . This type of ther-

nometer is also provided with a special fireproof head and with a steel protecting case in addition to the nickel case. This is necessary where the thermometer is to be used in connection with case hardening.

The Leeds and Northrup Company make a bulb designed especially for measuring the temperature of generators, transformers, etc. The resistance

Fig. 5. Thermometer for Use up to 100° C.

winding of this bulb is about  $\frac{3}{8}$  inches long and is mounted on a flexible stem 30 inches or more in length, the width over-all is  $\frac{1}{4}$  inch and the thickness  $\frac{1}{16}$  inch. This resistance coil is wound non-inductively and is therefore unaffected by neighboring magnetic fields.

**Indicating Devices.**—The application of the various bridge, potentiometer, differential galvanometer and ohmmeter methods (q.v.) to the measurement of the resistance of the platinum coil and the methods of compensating for the resistance of the leads are described in detail in Burgess and Le Chatelier's *Measurement of High Temperatures*. Two types of indicators are employed: (1) the balance type which requires the adjustment of a rheostat to produce zero deflection of the indicating instrument, the temperature then being read in terms of the balancing resistance, current or p.d., and (2) the direct-reading type in which the deflection of the instrument, read on a properly calibrated scale, gives the temperature directly.

**THERMOELECTRIC PYROMETERS.**—These instruments consist of a thermocouple and some device for measuring the e.m.f. generated due to the difference in temperature between the hot and cold junctions of the thermocouple, for which the relation between e.m.f. and temperature difference is known. The thermocouple consists of two parallel wires of different materials joined together at one end but insulated from each other throughout their length. The two ends which are joined form the hot junction and the two open ends are usually referred to as the cold junction, although they are not connected directly to each other. The two cold ends are, however, connected electrically through the device used for measuring the e.m.f. generated, thus forming a closed circuit.

**Thermocouple Circuits.**—The net e.m.f. tending to establish a current in such a circuit as described above is the algebraic sum of all the contact e.m.f.'s (see *Electricity and Magnetism, Principles of*) in the circuit. Wherever there is a change in the chemical nature or physical properties of the conductors forming such a circuit there exists such a contact e.m.f. These various contact e.m.f.'s are functions of the temperature of the transition points, but if the entire circuit is at the same temperature throughout, the net e.m.f. is zero (provided the circuit is formed solely of metallic conductors). If, however, any transition point is at a higher temperature than another, the net e.m.f. will in general not be zero. Consequently, when a thermocouple is used to measure the difference in temperature between the hot and cold junctions of the couple itself, care must be taken to eliminate the e.m.f.'s due to the temperature differences between the various other transition points in the circuit.

Transition points occur (1) at the junction of any two dissimilar metals; (2) wherever there is a change in the homogeneity of the structure of any of the metals in the circuit, and (3) wherever there is a change in the temperature of the metal, although it may be perfectly homogeneous. To avoid errors due to the e.m.f.'s at the transition points other than the hot and cold junctions of the couple itself, it is necessary to use for the latter metals which give a relatively high e.m.f. for a given temperature difference between the two junctions and

which are also *homogeneous* throughout, and to so dispose the rest of the circuit that the e.m.f.'s produced therein as the result of temperature differences neutralize one another.

**Metals for Thermocouples.**—For high-precision thermoelectric pyrometers platinum against platinum-iridium or platinum-rhodium alloys (containing 10 per cent iridium or rhodium) are usually employed. For industrial purposes cheaper metals and alloys are used, such as nickel, copper, iron and alloys of these metals; such couples are usually referred to as *base metal couples*, as contrasted with the *noble* metal couples formed of platinum, iridium, etc.

**Thermocouples for Industrial Use.**—For industrial use cheap and robust couples are required. Such couples may be made either entirely of the

Fig. 6. Base Metal Couple

Fig. 7. Compound Couple

base metals or a base-metal couple may be used in series with a short length of a platinum-alloy couple, the latter only being exposed to the highest temperature. In Fig. 7 is shown one form of compound couple.

In the pipe type couple (Fig. 6) the outside iron pipe is one element of the couple and an alloy wire such as constantan is carried up through the center of this pipe insulated from it throughout the entire length except at the end where it is welded to the pipe forming the hot junction of the couple.

The double wire type couples are usually made of No. 8 wires for temperatures up to 1800° F., and smaller sizes of wires for lower temperatures. The ends are twisted and welded together and porcelain insulators are slipped over the wires. These couples are protected by either a heavy iron pipe or a nichrome pipe. The life of the latter at temperatures above 1800° F. is much greater than that of the iron pipe.

**E.M.F.'s of Thermocouples.**—By the e.m.f. of a thermocouple is meant the e.m.f. developed in a circuit consisting solely of the metals forming the thermocouple itself; i.e., the e.m.f.'s in the external circuit are not considered. If  $E_{sa}$  is the e.m.f. of a couple made of a metal  $a$  against any standard metal  $s$ , and  $E_{sb}$  is the e.m.f. of a couple made of a metal  $b$  against this same standard metal  $s$ , the e.m.f.'s in each case being for the same temperature of the cold junction (standard temperature is 0° C.) and for the same difference in temperature between the hot and cold junctions, then the e.m.f. of a couple made of  $a$  and  $b$  is, for these same temperatures

$$E_{ba} = E_{bs} + E_{sa} = E_{bs} - E_{as}.$$

(In this notation *rises* of potential are considered to be in the direction of the subscripts, that is,  $E_{ba}$  is the rise of potential from  $b$  to  $a$ ). Consequently the insertion of a metal wire of any material in the circuit of a thermocouple does not change the net e.m.f., *provided this wire is of uniform structure and temperature throughout*. Consequently the hot junction may be soldered with any other metal which will not melt at the temperature to which the junction is exposed.

**Electromotive Force Formulas.**—No simple relation exists between the e.m.f. ( $E$ ) of a thermocouple and the temperature difference ( $\theta$ ) between

the hot and cold junctions. A number of approximate formulas, however, has been suggested. The following, due to Holman, is one of the simplest.

$$E = mt^n,$$

where  $m$  and  $n$  are constants, the cold junction being kept at  $0^\circ\text{C}$ . For convenience in plotting and calculation this may be written

$$\log E = n \log t + \log m.$$

Holman's formula when applied to couples made of platinum and its alloys of iridium and rhodium gives results accurate to about  $3^\circ\text{C}$ . for  $t$  between  $200^\circ\text{C}$ . and  $1200^\circ\text{C}$ . Typical values of  $n$  and  $\log m$  are given below (Cambridge Scientific Instrument Company).

	$n$	$\log m$
Pt against (Pt 90%, Ir 10%).....	1.102	0.695
Pt against (Pt 90%, Rh 10%).....	1.169	0.526

The values of these constants, however, differ with different makes of couples, and in any particular case should be obtained from the maker as determined by calibration.

Another formula, due to Holborn and Day, is the following,

$$E = -a + bt + ct^2,$$

where  $a$ ,  $b$  and  $c$  are constants. Between  $300^\circ\text{C}$ . and  $1200^\circ\text{C}$ . this formula gives results accurate to  $1^\circ\text{C}$ . when applied to couples made of platinum and the various platinum alloys.

Ideal wire (*see Wires, Resistance*) and copper form a very satisfactory couple of relatively large e.m.f. suitable for a range of temperature between  $0^\circ$  and  $400^\circ\text{C}$ . With the cold junction at  $0^\circ\text{C}$ . the temperature of the hot junction and the e.m.f. are related as follows:

Temp. Hot Junct., $^\circ\text{C}$ .....	50	100	150	200	250	300	350
E.m.f., microvolts.....	2.3	4.65	7.05	9.45	11.90	14.43	17.08

**Thermoelectric Power (H) of Thermocouples.** — The thermoelectric power of a thermocouple is defined as the increase in the e.m.f. developed per degree increase in the difference in temperature between the hot and cold junctions. This quantity, which is equal to  $b + 2ct$  in Holborn and Day's formula, depends in general upon the temperature ( $t$ ) of the hot junction; the values given in the table on page 1242 are close approximations within the range stated.

**Measurement of E.M.F. of Thermocouples.** — Two methods may be used to measure the electromotive force of a couple: the potentiometer method and the galvanometric method (*see Potentiometers; Galvanometers*). The first is the more accurate and is usually made use of in laboratories. The second method is simpler, but possesses the inconvenience of giving only indirectly the measure of the electromotive force by means of a measurement of current strength.

There are sources of error, however, inherent in the galvanometric method, such as effects of lead resistance and temperature coefficients of leads and galvanometer, which are difficult if not impossible of complete elimination even with the best apparatus available. The potentiometer method, on the other hand, may be made, in so far as the measurements of e.m.f. are concerned, as

## THERMOELECTRIC POWERS OF THERMOCOUPLES

Microvolts per °C. increase in temperature,  $t$  in °C.

Thermocouple	Thermoelectric power	Temperature range, °C.	Authority
Pt and 90% Pt, 10% Rh.....	4.3 + 0.0088 $t$	0-1300	Le Chatelier
Pt and 90% Pt, 10% Ir.....	11.3 + 0.0104 $t$	0-1000	Le Chatelier
Pt and Ni.....	7.8 + 0.01325 $t$	300-1300	Burgess
Cu and Ni.....	24.4 + 0.016 $t$	0-235	Pécheux
Cu and Constantan *.....	42.3 + 0.058 $t$	0-320	Pécheux
Pt and Fe (forged).....	2.5 + 0.0210 $t$	700-1000	Le Chatelier

\* 60% Cu, 40% Ni.

exact as may be desired, or so that the only outstanding uncertainties are inherent in the thermocouple itself. These uncertainties, such as inhomogeneity, conduction along the wires, variable zero and actual change of e.m.f., are sometimes overlooked, giving rise to illusory accuracy.

The application of these two methods to the measurement of the e.m.f.'s of thermocouples is described in detail in Burgess and Le Chatelier's *Measurement of High Temperatures*.

**Cold-junction Correction.**—When the galvanometer method is used, it is often not convenient to keep the junctions of the couple to the lead wires of the galvanometer at a definite temperature, although the galvanometer itself may be so far removed from the furnace that its temperature changes are slight. Except in the roughest kind of work, allowance has to be made for the cold-junction temperatures, which may be measured by an auxiliary thermometer.

Calling  $t_c$  the cold-junction temperature for which the instrument reads correctly,  $t$  the observed temperature of the cold junction, the correction to apply to the observed temperature readings of the galvanometer, otherwise supposed to read correctly for a given thermocouple, usually lies between  $\frac{1}{2}(t - t_c)$  and  $(t - t_c)$ , depending on the type of couple and the temperatures of both hot and cold junctions. This question has been treated in detail for several types of couple by C. Offenhaus and E. H. Fischer (*Electrochem. and Met. Ind.*, 1908, Vol. 6, p. 362).

**Elimination of Cold-junction Correction.**—Bristol has also devised an automatic compensator for cold-end temperatures, shown in Fig. 8, consisting of a small glass bulb and capillary tube partially filled with mercury, into which a short loop of fine platinum wire dips. This is inserted in the thermoelectric circuit close to the cold junction. Changes in temperature cause the mercury to expand or contract, cutting in or out resistance in the circuit. This acts in opposition to the change in e.m.f. with temperature at the cold end, so that a balance may be established if the parts are properly designed.

Fig. 8. Bristol's Compensator

In the Thwing instruments the elimination of the temperature variations of the cold ends of the couple, where they can be brought close to the galvanometer, is affected by a device consisting of a compound strip of two metals having unequal coefficients of expansion, so attached to the spring controlling the

pointer that the reading of the galvanometer when no current is flowing is the temperature of the surroundings.

Fig. 9 shows a simplified diagram of connections of the Leeds and Northrup split-circuit potentiometer system with automatic cold-junction compensator.

The current from the battery  $Bt$  divides at  $a$  and  $b$ , one-half passing through the upper branch which includes the slide wire  $S$  and resistances  $G$  and  $B$ . The lower branch includes the nickel coil  $D$  and the resistance  $C$ . All the resistances, except the nickel coil  $D$ , are made of manganin wire having a zero temperature coefficient. The current in the two branches is kept constant by adjusting the rheostat  $R$  until the drop of potential across the coil  $C$  is equal to the e.m.f. of the standard cell  $W$ . The galvanometer  $Gg$  shows when a balance has been obtained. In the recording instrument, this adjustment is made automatically. The resistances  $B$  and  $C$  are high and are so chosen that the resistance in the two branches are equal.

The nickel coil,  $D$ , is located near the cold junction of the thermocouple and has such a value that changes in cold junction temperature are compensated for by changes in the drop of potential across this coil caused by changes in its resistance with temperature.

The value of the resistance of the compensating coil  $D$  is calculated as follows: Let  $R$  = resistance of compensating coil  $D$  at reference temperature;  $c$  = change in e.m.f. of thermocouple per degree change in temperature of cold junction;  $K$  = temperature coefficient of nickel composing compensating coil per ohm per degree;  $i$  = current in branch including nickel coil;  $e$  = change in e.m.f. of thermocouple due to temperature change  $t$  of cold junction;  $e_1$  = change in fall of potential across nickel coil due to temperature change  $t$  of cold junction. In order to have compensation  $c$  must equal  $e_1$ , regardless of changes in temperature of the cold junction, which condition is satisfied when

$$R = \frac{c}{Ki}$$

The value of the resistance  $G$  is so chosen that the scale starts at  $0^\circ$  or at any other desired temperature. For example, suppose the temperature range is from  $0$  to  $1000^\circ$  C. The coil  $G$  will be equal to the nickel coil  $D$  at  $0^\circ$  C. Suppose both the hot junction and the cold junction are at  $0^\circ$  C. The e.m.f. of the thermocouple will be zero and the difference of potential between  $K$  and  $J$  will also be zero because the resistance of  $D$  equals that of  $G$ . If the temperature of the hot junction increases to  $1000^\circ$  C. and the cold junction stays at  $0^\circ$  C., the galvanometer will show a balance when the contact  $K$  is at the extreme right side of the scale (side marked  $H$ ). Now suppose the temperature of the cold junction increases. The e.m.f. of the couple will decrease but the resistance of the nickel coil increases and causes a decrease in the e.m.f. across the points  $J$  and  $K$  that exactly compensates for the decrease in the e.m.f. of the thermocouple. The result is that the contact  $K$  remains at  $1000^\circ$  on the scale, which is the temperature at the hot junction.

FIG. 9.

**CALIBRATION OF PYROMETERS.**—The methods employed are described in detail in Burgess and Le Chatelier's *High Temperature Measurements*. In general, the reading of the pyrometer is observed when the fire end is at the melting or boiling point of some solid or liquid. The melting and boiling points which possess the greatest reliability are given in the article on *Heat and Thermal Properties*.

**COST AND RANGE OF TYPICAL PYROMETERS.**—These items are indicated *approximately* in the table below. The precision stated is on the assumption of proper calibration and careful use.

Type	Range ° C.	Cost,* dollars
Ferry radiation pyrometer.....	800 and up	420-564
Thwing radiation pyrometer.....	800 and up	160-600
Fery absorption pyrometer.....	900 and up	130-150
Wanner pyrometer.....	900 and up	225-300
Leeds & Northrup optical pyrometer.....	650 and up	110-175
Resistance thermometer bulb.....	Up to 125	10-50
Resistance thermometer bulb.....	Up to 1000	40-80
Indicator for resistance thermometer.....	Optional	80-150
Recorder for resistance thermometer.....	Optional	150-700
Platinum Pt. Rh. Couples.....	Up to 1600	10 and up
Base metal couples.....	Up to 1200	5-20
Milli voltmeter indicator.....	Optional	50-200
Milli voltmeter recorder.....	Optional	150-700
Potentiometer indicator.....	Optional	120-200
Potentiometer recorder.....	Optional	200-700

\* As of 1920.

**RADIO COMMUNICATION.**—(See also *Alternating Currents; Capacity and Charging Currents; Electricity and Magnetism, Principles of; Electron Theory; Inductance and Inductive Reactance; Skin Effect; Transient Electric Phenomena.*)

**RADIATION.**—Whenever current flows in an ordinary electric circuit magnetic and electric fields are set up in and around the circuit; the magnetic field is proportional to the current flowing and the electric field is proportional to the difference in electric potential in various parts of the circuit.

These two fields represent a certain amount of energy stored in the space where they exist. The magnetic energy depends upon the self-inductance of the circuit and the current flowing, whereas the electric energy depends upon the capacity (electrostatic) of the parts of the circuit, considered as a condenser, and the potential difference. When the current or potential difference changes the energies change and, if the current and potential difference become zero, the greater part of the magnetic and electric energies are returned to the circuit.

When the current in the circuit is a low-frequency alternating current, practically all the energy which goes out into space is returned when the current and potential become zero. When the frequency is high (and strictly in every case irrespective of the frequency), part of the energy represented by the two fields, is sent out into space and never returns to the circuit. This energy is said to be radiated; as the radiated power varies (for a given circuit) as the square of the frequency, this action may be neglected in circuits where the frequency is less than several thousand; in radio circuits the frequency ranges from 20,000 to 1,000,000 or more, and at these high frequencies the radiated power may constitute the principal loss in the circuit.

**ELECTROMAGNETIC WAVES.**—The radiated energy travels in the form of electromagnetic waves; such a wave has half of its energy magnetic and half electric, and travels with the velocity of light. If the intensity of the magnetic field is  $H$  and that of the electric field is  $E$  (these two intensities being so related that magnetic and electric energies per unit volume are equal) the electromagnetic wave becomes self-sustaining by virtue of the fact that an electric field of intensity  $E$  travelling with the velocity of light generates at right angles to itself, and at right angles to the direction of wave motion, a magnetic field of intensity  $H$ ; or conversely field  $H$ , travelling with the velocity of light sets up, at right angles to itself and the direction of motion, an electric field  $E$ .

The arrangement of electric and magnetic fields around a radiating antenna is indicated in Fig. 1, the magnetic field being shown by dots and the electric

Fig. 1.

field by lines; this arrangement of fields is practically circular around the antenna. The "feet" of the waves slide over the earth's surface (this being considered a conductor) so that in the earth's surface there are around the antenna circular distributions of electric charges, alternately positive and nega-

tive, which bands of charge spread out from the antenna with the velocity of light.

**Wave Length.** — The waves of radiation travel out from the antenna at fixed velocity, so that the distance between the "feet" remains constant; the distance from a band of positive charge in the earth's surface to the next positive band is termed the wave length. In radio practice the wave lengths emitted vary from perhaps 50 meters to as much as 20,000 meters. The longer waves are used in the large stations engaged in transoceanic communication while the shorter may be used in aeroplane radio sets or in small portable field outfits. The standard wave length used for inter-ship communication is 600 meters; occasionally 300 and 450 meters are used in this work.

The wave length and frequency in any wave propagation are related by the equation  $f\lambda = V$ , in which  $f$  is the frequency,  $\lambda$  is the wave length, and  $V$  is the velocity of propagation. For any electromagnetic disturbance, whether light, heat, X rays or radio waves, the velocity of travel is  $3 \times 10^8$  meters per second. Hence the wave length, in meters, is given by

$$\lambda = \frac{300,000,000}{f} \quad \text{meters.}$$

The frequency of currents used in radio antennae lie between 15,000 for the very large stations and 2,000,000 for small portable sets. Ship sets nearly always use a frequency of 500,000 cycles per second.

**Energy in Electromagnetic Wave.** — If  $H$  is the intensity of the magnetic field in gilberts per cm. and  $F$  is the intensity of electric field in e.s. units (statvolts per cm.) at any point in the wave front, the energy per cu. cm., is

$$\frac{H^2}{8\pi} + \frac{F^2}{8\pi} = \frac{H^2}{4\pi} = \frac{F^2}{4\pi},$$

the two energies being equal.

As the two energies have a sinusoidal distribution in the wave disturbance, the average value of the energy density will be one-half the maximum density; if therefore  $F_m$  is the maximum electric gradient in the wave front the average

energy per cu. cm. is  $\frac{F_m^2}{8\pi}$  ergs. The energy passing through one sq. cm. per second

is therefore equal to  $\frac{F_m^2}{8\pi} \times 3 \times 10^{10}$  ergs, or the radiated power associated with one

sq. cm. of wave front is  $\frac{3000}{8\pi} F_m^2$  watts. When the electric gradient  $F_m$  is measured in volts per cm. then

$$\text{Radiated power per sq. cm. of wave front} = \frac{F_m^2}{240\pi} \quad \text{watts.}$$

**Form of Wave Front.** — As the wave travels out from the antenna it gradually increases in height, as indicated in Fig. 1. If the surface of the earth is a good conductor the wave front remains upright; if the atmosphere is highly absorbing (ionization, etc.) the wave front tips backwards, whereas if the atmosphere is non-absorbing and the earth's surface is a poor conductor the wave front tips forwards.

It seems likely that the waves do not extend very high; in the upper rarified atmosphere the ionization is intense, so that the air becomes a fair conductor. Such a conducting layer of air will act as an upper boundary beyond which the waves are able to penetrate with difficulty. Radio communication may there-

fore be regarded as carried on by wave propagation between the earth's surface and this upper layer of conducting air.

**Attenuation.** — As the electromagnetic wave travels over the earth's surface, the intensity of both electric and magnetic fields continually diminish, due to two factors; the wave front becomes larger in area with increasing distance from the transmitting antenna, thus decreasing the energy density in the wave front, and there is also some energy absorbed in the atmosphere and the earth's surface as the wave progresses. Measurements of the attenuation are difficult to make, and experimental results on this effect are meagre. Duddell and Taylor, in 1905, reported the results of tests over comparatively short distances, and L. W. Austin has reported more extensive tests carried out in 1909. Duddell's results indicated that the field strength in the wave front varied inversely with the distance from the sending station, whereas Austin's experiments showed the field strength falling off more rapidly than this. He deduced from his results a formula which is now regarded as the best obtainable. It is

$$I_r = \frac{A}{d} \epsilon^{-\frac{\alpha d}{\lambda}}$$

in which  $I_r$  = current set up in the receiving antenna;  $d$  = distance between transmitting and receiving stations, in km.,  $\lambda$  = wave length in km.;  $\alpha$  = a constant, ordinarily equal to 0.0015;  $A$  = a constant, depending upon heights of the two antennae, current in the transmitting antenna, etc.

The absorption constant,  $\alpha$ , depends upon the amount of ionization present in the air, and condition of the surface over which the wave has travelled, etc. It is least for transmission over sea, at night, and maximum in daytime over mountainous country thickly covered with vegetation.

**Reflection and Refraction.** — Radio waves reflect and refract in the same way as do light waves, allowance being made for the vast difference in wave length; to these two effects many vagaries in radio transmission are undoubtedly due. Thus two ships on opposite sides of a mountainous island are not able to communicate at all, yet if each steams away from the island, thus increasing the distance between them, the transmission becomes normal; such effects are noted by vessels off the shores of Cuba. This effect is probably due to peculiar reflections of the waves by the semi-conducting minerals in the hills over which the waves must travel in crossing the island.

In other cases a very small amount of power may suffice to establish communication over vast distances; it seems quite likely that the upper layers of partly ionized atmosphere concentrate the energy of the electromagnetic waves just as mirrors and lenses concentrate light waves. Of course such effects cannot be relied upon, but they do give at times "silent zones," where the signal disappears, and other zones where the signal may be much more intense than the transmitter power and distance would seem to justify.

**Daily Variation in Transmission.** — There is a very great difference in radio transmission at different times of day, especially if the line of communication runs east and west. This was first noticed at the Marconi stations at Glace Bay and Clifden. The transmission follows a curve about as shown in Fig. 2; when the line of sunset or sunrise was between the two stations the transmission was very poor. It seemed that the line of sunrise or sunset acted as a barrier across which the waves could not easily pass. This effect was more marked on short waves than on long ones, in fact transmission is always more uncertain on short waves than on long ones. Some exceptions to this have, however, been noted, such as those reported by Taylor and Blatterman, who found 500 meters better than 1500 meters in the night time, but not in the daytime.

The variation in signal strength at a receiving station may occur very suddenly, thus at Chelmsford the received current from Clifden would double in 5 minutes. Other instances are on record of even more rapid changes in signal strength, the transmitting station sending out a constant amount of power. Such effects are often spoken of as the "fading" of the signal.

Fig. 2.

**Seasonal Variation.** — L. W. Austin has reported the results of a long series of tests of transmission over distances of about 100 miles, which show that there is a very large variation in the transmission throughout the year. The transmission was over land, with a wave length of 1000 meters. The average signal in the winter showed about 6 times as much energy as the average signal in summer.

**Transmission through Water and Earth.** — Calculation of the attenuation of an electromagnetic wave penetrating water would lead to the belief that the penetration can occur only with great loss, and such proves to be the case. The reception of radio signals by a submerged submarine is only possible if long waves are used, and suitable amplifiers are used with the receiving set. It is possible, however (with a good amplifier), for a submarine submerged 30 to 40 feet to detect signals from a long-wave, high-powered station thousands of miles away. Thus submarines on the Atlantic coast of the U. S. are able to pick up signals from Nauzen, even though submerged.

Experiments have been reported of picking up radio signals with all the receiving apparatus at the bottom of a mine shaft, indicating that the waves penetrate a considerable distance into the earth's surface; not much reliable information on the subject is at hand.

**ANTENNAE.** — The original experiments in radio transmission, by Hertz, used ungrounded sending and receiving systems; this is seldom the case in modern radio sets. Practically the only case of successful ungrounded transmitting antennae is that of air craft. Attached to the upper plane is a network of wires and through the floor of the cockpit of the plane is suspended a wire generally having a weight on the end. This trailing wire and the network on the wing form the two parts of the antenna. Such antenna systems permit communication between two aeroplanes several miles apart, or between a plane and ground station perhaps 50 miles apart. As mentioned below, an ungrounded coil is often used for a receiving station, but practically never as a transmitting antenna.

**Grounded Antenna.**—In Marconi's first successful experiments a single vertical wire was used for antenna, the lower end being connected to ground through the spark gap, as shown in Fig. 3. The high voltage secondary of a spark coil was connected across the gap as indicated by the dotted line. When the coil was operating the antenna was charged to a high voltage by the opening of the interrupter in the primary circuit, thus storing energy in the electric field of the condenser formed by the wire *M* and the earth. When the voltage on *M* rose to a sufficient value, the spark gap broke down, and an oscillatory current was set up in the antenna, the frequency of this current being controlled by the height of the wire *M*. Such a form of antenna radiates very rapidly, so that the oscillatory current for each discharge of the spark gap is of very short duration, perhaps 5 or 10 cycles.

Fig. 3.

**Forms of Voltage and Current Distribution.**

—When a charged antenna is left free to oscillate, the charge on the antenna so flows and rearranges itself that the intensities of potential and current at various parts of the wire follow approximately a sine law distribution. It is evident that in any case the potential of the antenna (with respect to earth) must be zero at the ground end and that the current in the antenna must be zero at the top, or end, of the antenna.

Typical forms of distribution are shown in Fig. 4. At (a) are shown the current and potential curves for a simple vertical wire, similar to the original Mar-

Fig. 4.

coni antenna; such a condition is called *quarter wave length distribution* because one-quarter of a complete wave is developed for each of the curves. In (b) and (c) of Fig. 4 are shown the current and voltage forms when a series inductance has been introduced in the base of the antenna; (b) shows the effect for a small inductance and (c) that for a much larger one. Sometimes it is necessary to use a condenser in the base of the antenna, for which case the current and potential distributions are somewhat as shown in (d) Fig. 4. The node of voltage here shown is not a true node; the phase of the voltage does reverse on the two sides of the point, but the magnitude of the voltage does not go through zero.

**Forms of Antennae.**—There are three ordinary forms of transmitting antennae, as illustrated in Figs. 5, 6, and 7. Fig. 5 represents a *T* antenna which is the type generally used for ship sets, because of the ease of erection from the two ship's masts. It is practically non-directive, sending about the same amount of radiated power in all directions.

The form of antenna shown in Fig. 6, called the inverted *L*, is used for stations

designed to communicate with a fixed receiving station; the large Marconi stations for transoceanic communication are of this type. In the largest stations these antenna may be as much as 500 feet high, 1000 feet wide, and more than a mile long.

High powered stations designed to communicate with stations in various directions, use an umbrella shaped antenna, Fig. 7. This type radiates equally well in all directions, and has the possible mechanical advantage of requiring but one mast. These tall masts are from 600 to 800 feet high, generally made of steel lattice construction. This mast may be in three or four sections jointed flexibly to one another, radial guys running out from these junction points. It is practice to insulate these masts from the ground, the base of the mast being supported on a marble ball, or similar construction. The guys of these high power stations are generally broken up into insulated sections, to keep the induced currents in them low.

Fig. 5.

**Receiving Antennae.** — A few years ago it was customary to use a large antenna for receiving, but to-day such is seldom the case. The present limit on radio reception is the amount of atmospheric disturbance present, this producing a hissing and crackling noise in the operator's telephones, so that the signal is blurred and unreadable. The large receiving antenna "picks up" a stronger signal than a small one, but it also picks up more of the atmospheric disturbances, so that a signal received on the small antenna, after being suitably amplified, is just as readable as that from the large antenna. In fact, with a properly designed amplifier, the signal is amplified more than the disturbing noises, so that the smaller antenna is actually more serviceable in receiving than the large one.

Fig. 6.

**Coil Antenna.** — The coil antenna is a special form of antenna which is never used for transmitting but which is very useful for receiving. It consists of a few turns (sometimes constructed as shown in Fig. 8) and the receiving apparatus is connected to the terminals *a* and *b*, there being no ground connection at all to the receiving circuit. Such a coil must be connected to a powerful amplifier if the

Fig. 7.

receiving apparatus is connected to the terminals *a* and *b*, there being no ground connection at all to the receiving circuit. Such a coil must be connected to a powerful amplifier if the

signals to be received are from a distant station, as the coil picks up but little energy from the radio wave. The size of coil, as well as the number and spacing of turns, depends upon the wave length to be received; for 600 meters a coil 4 feet square of 12 turns spaced  $\frac{1}{4}$  inch from each other is suitable, whereas for 10,000 meters a coil 20 feet square of 50 turns spaced  $1\frac{1}{4}$  inches is about right. The spacing between the turns must be kept sufficiently great, otherwise the capacity between the turns will be so high that tuning with an attached condenser will be poor; in fact if the turns are too close the natural period of the coil will be greater than that of the signalling current, and the reception will then be very poor.

Fig. 8.

**Ground Antenna.** — A long insulated wire laid along the ground, or even better, at the bottom of a shallow body of water, forms a good receiving antenna, if it is opened at its middle point and the receiving apparatus connected in. The wire should be laid in the direction from which the desired signal comes, as this type of antenna is fairly directive. If laid in salt water the wire should not be covered more than a foot or two, whereas in fresh water the depth may be several feet, without too much attenuation of the signal.

**Capacity of an Antenna.** — The electrostatic capacity of an antenna depends upon the area covered by the net work of wires, and upon the height from ground, and to a lesser extent upon the size and number of wires used. For an antenna of the forms shown in Figs. 5 and 6, Austin has found the empirical formula,

$$C = \left( 4 \sqrt{a} + 0.885 \frac{a}{h} \right) \times 10^{-9},$$

in which  $C$  = capacity in microfarads,  $a$  = area of the antenna (width of spreaders multiplied by the distance between them) in square meters;  $h$  = height of the antenna from ground, in meters. If the length,  $l$ , of the antenna is much greater than the width,  $b$ , the value of  $C$  must be multiplied by the factor  $\left( 1 + 0.015 \frac{l}{b} \right)$ .

The ordinary ship's antenna has a capacity\* of about  $0.001 \mu f$ , a small one such as that carried by a submarine about  $0.0005 \mu f$  while those carried by the battleships may have as much as  $0.003 \mu f$ . The large land stations may have a capacity of  $0.01 \mu f$  or more.

The capacity of an antenna, being distributed, is really a function of the frequency, but if the loading coil used has sufficient inductance to increase the wave length to about four times the natural wave length, the antenna capacity may be treated as lumped and thus independent of the frequency.

**Wave-Length Radiated from an Antenna.** — If the antenna is connected directly to the ground (no loading coil used), the wave length radiated is very closely 4 times the distance from the ground, up the lead wire (vertical part of the antenna) and so out to the extreme end of the antenna; actually it may be 10 per cent larger than this value. An antenna of the T-form, having a height of 50 meters, and a length of top part of 150 meters, would have a wave length about  $4 \times \left( 50 + \frac{150}{2} \right) \times 1.1 = 550$  meters. This would be called the "natural wave length" of the antenna. If the lead wire is now attached to the end of the

\* The abbreviation  $\mu f$  is used for microfarad.

top part, thus making an inverted *L* antenna, the natural wave length would be  $4 \times (50 + 150) \times 1.1 = 880$  meters.

**Loading Coil and Condenser.** — It is generally not feasible to use an antenna radiating its natural wave length; generally an antenna is worked at from 2 to 4 times its natural wave length. This is accomplished by putting a suitable inductance (called a loading coil) in the base of the antenna, thus increasing the inductance of the oscillating circuit over that inherent in the antenna itself. For such a case the wave length radiated from the antenna is easily calculated from the formula,

$$\lambda = 1885 \sqrt{LC} \quad \text{meters,}$$

in which *L* is the inductance of the coil in microhenries, and *C* is the capacity of the antenna in microfarads.

By putting a condenser in series with the base of the antenna, and using only a small loading coil (at least a small coil is nearly always necessary to the operation of the average set, as will appear later), it is possible to make the antenna radiate at less than its natural wave length; such operation is carried out only in emergencies.

**Antenna Resistance.** — It is impossible to measure the amount of high frequency power supplied to an antenna by a wattmeter or similar test; the power in the antenna is always calculated from the known resistance of the antenna and the reading of the hot wire ammeter in the antenna circuit. A knowledge of the antenna resistance is thus important; in fact it is probably the most important single factor in the whole radio system.

In Fig. 9 are shown two typical antenna resistance curves; that indicated by *A* being for a ship, and the other *B* for a land station, the two antenna being the same size;  $\lambda_0$  indicates the natural wave length of the antenna. The form of this curve is due to the various components which change in different ways as the wave length is increased. The radiation resistance varies inversely with  $\lambda^2$ , and the principle resistance causing loss of power, due to dielectric hysteresis in the earth's crust and objects in the electric field of the antenna, varies directly with the wave length. This wasteful resistance

Fig. 9.

exists to a greater extent in a land station than in a ship station, hence the higher slope of the curve at the longer wave lengths.

**Importance of Good Ground.** — With a well-grounded antenna at short wave lengths, the greater part of the energy supplied to the antenna is radiated, as indicated by the relative values of the ground resistance and radiation resistance in Fig. 9; at the longer wave lengths, however, the radiation resistance decreases very rapidly, and the ground resistance increases, so that most of the power supplied to the antenna is used up as heat and so wasted. It will thus be realized that the ground resistance must be kept low if the antenna is to be efficient. Elaborate networks of copper wire are often buried in the ground underneath an antenna, and heavy wires carried down to the permanently moist earth to minimize part of the ground resistance effect. From measurements made by J. M. Miller it would appear that wooden posts, trees, etc., close to an antenna absorb a great deal of power.

**Counterpoises.** — Where a good ground connection is not possible, it is found that an insulated network of wires, suspended on insulators a few feet above the ground, serve well as a ground connection. The network should have a spread considerably greater in area than the antenna itself, if possible.

**Radiation Resistance.** — The radiation resistance of an antenna can be obtained from experimental observation, or it can be calculated from the dimensions of the antenna. Various formulæ have been given which differ somewhat among themselves, generally due to different assumptions as to what the height of the antenna is; some formulæ use the "effective" height and others use the actual height. The following formulæ have been given by J. H. Dellinger. For a flat top antenna, of height  $h$ ,

$$R = \left( 39.7 \frac{h}{\lambda} \right)^2 \text{ ohms.}$$

For a square coil of  $N$  turns, length of side,  $a$ ,

$$R = \left( 13.3 \frac{a}{\lambda} \right)^4 N^2 \text{ ohms.}$$

In these formulæ the dimensions must of course all be expressed in the same units.

From the above it is readily seen that a coil is not a good radiator unless its dimensions approach those of the ordinary antenna; it has been used successfully as a transmitter only for very short waves. The above formulæ also give an idea of the comparative amounts of energy the two types of aerial will pick up when used at a receiving station; they do not give an idea of the actual relative merits of the two, however, because the coil aerial may be made with a much lower resistance than the ordinary type, and hence will produce a greater relative response in the detecting device than would be indicated by the above formulæ.

The formulæ show that the maximum radiation resistance which a straight vertical grounded wire can have is about 50 ohms (the value of  $h/\lambda$  for quarter wave length oscillation is about 0.17) and this is the same for all vertical wire antennæ, no matter how high they may be.

**VACUUM TUBES.** — When a metal is heated to a high temperature in a vacuum it gives off free electrons, i.e., particles of negative electricity (*see article on Electron Theory*). When the heated metal is made one electrode, and a second unheated electrode is provided, it is found that the space between the two electrodes becomes a relative good conductor to a current flowing through the tube in the direction from the cold electrode to the hot electrode, but that practically no current will flow in the reverse direction. Such a device is therefore an almost perfect rectifier for alternating currents. The Fleming valve and G. E. kenotron are typical rectifiers of this type.

The electrode to be heated is usually made in the form of a filament, which is heated by sending a current through it from a storage battery or other source of c.m.f. The heated electrode is therefore usually referred to as the "filament" and the other electrode as the "plate." The current from the plate to the filament is called the plate current (and must not be confused with the current passed through the filament to heat it).

**Space Charge.** — Experiment justifies the assumption that for a given temperature of the filament, there is a definite rate at which electrons are given off, or evaporated, from it. When there is no potential difference established between the filament and plate (the plate and filament being insulated from each other), a condition of equilibrium is reached when the number of electrons

evaporated in a given time interval is exactly equal to the number of electrons which are forced back into the filament by the mutual repulsion between the electrons which fill the space in the tube. That is, the tube may be thought of as filled with a negative charge, exerting a pressure tending to prevent a further evaporation of electrons, just as the vapor in a closed vessel partially filled with water exerts a pressure on the water tending to prevent further evaporation of the water. This negative charge is conveniently referred to as the "space charge."

**Two-Electrode Tubes.** — When a difference of potential is established between the plate and the filament, the plate being the anode (positive), the electrons forming this space charge are attracted to the plate, pass through the external circuit and re-enter the filament, and are again evaporated. However, since for a given temperature there is a limit to the rate at which the electrons can be evaporated, it follows that when the potential difference between the plate and the filament is increased to such a value that the plate current is equal to the rate at which negative electricity is evaporated from the filament, then any further increase in this potential difference cannot produce an increase in the value of the current. This limitation to the value of the current is said to be caused by "saturation," and this limiting current is called the "saturation current" for the given filament temperature.

When the applied potential difference is small, and the resulting current is small relative to the rate of evaporation of the electrons, it can be deduced from fundamental principles that the resultant effect of the applied potential difference and the repulsive action of electrons forming the space charge is such as to give a current which depends solely on the applied potential difference and which is independent of the temperature of the filament. Under these conditions the current is said to be limited by the space charge.

Consequently, for high filament temperatures and low potential differences the plate current is the same irrespective of the temperature of the filament

Fig. 10.

Fig. 11.

(current limited by space charge), but for higher potential differences the plate current reaches a maximum value dependent upon the filament temperature only (current limited by saturation); see Fig. 10. Or, looked at from another point of view, for high potential differences and low temperatures the plate current is the same irrespective of the potential difference (current limited by saturation), but for higher temperatures the plate current reaches a maximum value dependent upon the potential difference only (current limited by space charge); see Fig. 11.

The two electrode tube is not used to a great extent to-day; it may be used

as a rectifier in such installations as the Cottrell process for dust precipitation, and during the war was used to some extent as a voltage regulator for small self-excited, variable-speed generators. It seems likely that it may find further application in this field.

**Three Electrode Tube, or Triode.** — The thermionic tube becomes a much more effective device if a third electrode is interposed between the plate and filament, this electrode being in the form of a mesh or grid, so that electrons may flow through it on their way to the plate. Fig. 12 shows diagrammatically the construction of a triode. Such a tube was first put out by DeForest under the trade name of "Audion"; to-day many types of three electrode tubes are in use in both wire and radio communication. Eccles has suggested the name "triode" for a three electrode functioning as a pure electron device, and such a name seems better than the various trade names now used. According to the service for which they are intended these triodes vary in size from a peanut to a bulb 8 inches in diameter or more; the plates and grids are flat in some and cylindrical in others; molybdenum, tungsten and nickel are all used for the construction of grids and plates.

Fig. 12.

**Uses of the Triode.** — The triode is the most important factor in any radio system; it is only due to this device that radio has made such progress during the last few years. It performs the functions of *rectifier*, or *detector*, in every modern receiving station; it is used singly, or several in cascade, as an *amplifier* of radio and other signals; it is used in small transmitting stations as a *converter* or generator of high-frequency power from a continuous current source; and in radio telephone outfits it is used extensively as a *modulator* of the radiated high-frequency power.

**Action of the Grid.** — The feature of fundamental importance in the triode is that under proper conditions a variation in the voltage between grid and filament will produce variations in the plate current *many times greater* than would be produced by equal variations in the voltage between the plate and filament.

The action of the triode is most easily explained by noting that the grid, situated in the space between the filament and the plate, may assist the space charge in limiting the plate current or may nullify the space charge effect and thereby increase the plate current, according as its potential is negative or positive. (In the literature on electron stream devices it is customary to speak of the plate and grid potentials with respect to the negative end of the filament.) The controlling action of the grid depends upon the fineness of its meshes, and upon how completely it surrounds the filament. According to Miller, the grid exerts more control the closer it is to the plate, other things being equal.

**Characteristic Curves of the Triode.** — In Fig. 13 are given typical curves of a triode showing how the plate and grid currents vary as the grid potential is varied, for several values  $E_1$ ,  $E_2$  and  $E_3$  of plate potential. The source of the plate current is connected to *c* and *b* in Fig. 12, and the source of the grid current to *a* and *b*. For small detector tubes the plate current would be less than one milliamperes and the grid current a few microamperes; for telephone repeater tubes, or for small power tubes for radio sets, the plate current is about 50 milliamperes; while for the largest power tubes the plate current

may be an ampere or more, the grid current being perhaps one hundredth as much.

It will be noticed in Fig. 13 that for a given grid potential the grid current increases as the plate potential decreases; this is due to the relatively greater

Fig. 18.

attractive force of the grid on the electrons passing through it, as the plate potential is lowered. For negative potentials the grid of an ordinary triode takes so little current that it requires a sensitive galvanometer to measure it.

The maximum plate current is nearly the same for all plate voltages, it requiring a higher positive grid to reach this maximum current, however, when the plate voltage is low. For very low plate voltage this maximum current is never reached; as the grid is made more and more positive it takes more current, thus depriving the plate of part of the electrons, and it may do this to such an extent that the plate current actually decreases with increasing grid potential, for the highest grid voltages.

**Tungsten Filament and Oxide Coated Filaments.**—In the U. S. practically all the triodes are manufactured either by the G. E. Co. or the W. E. Co. The G. E. tubes go by the trade names of kenotron, pliotron, dynatron, pliodynatron, etc. All of these G. E. tubes use a pure tungsten filament as the electron-emitting element, and tungsten or molybdenum for the grids and plates; the tungsten filament must be at a dazzling white heat before much electron emission occurs and so, of course, considerable power must be used in heating the filament.

For the tungsten filaments Dushman has given the following table of safe operating temperatures, etc., the life of the filament being supposedly 2000 hours.

To get the emission stated in this table the surface of the tungsten must be very clean; there must be no adsorbed gas on the surface.

The tubes made by the W. E. Co. use a platinum ribbon filament coated with certain oxides, a particular cement being used to hold the oxide on; to assist in holding the coating the ribbon is twisted on itself several times per centimeter. The type of emitting surface is frequently called a Wehnelt cathode, as Wehnelt first pointed out the use of the oxide to get more emission

Diameter of filament, cm.	Safe temperature, absolute °C.	Emission in amperes per cm. length	Power to heat filament in watts per cm. length
0.0125	2475	0.03	3.1
0.0175	2500	0.05	4.6
0.0250	2550	0.10	7.2
0.0375	2575	0.20	11.3

at a given temperature. Ordinarily about one milligram of coating is used per square centimeter, but recent experiments seem to indicate that this is much more than necessary.

The advantage of the oxide coated filament is the low temperature at which liberal emission occurs; for a given emission per square centimeter the power required to heat an oxide filament is only about one-half as much as for the pure tungsten filament. An oxide filament is never operated hotter than a bright yellow color; quite appreciable emission occurs when the filament is scarcely visibly hot. The only apparent disadvantage of the oxide filament is the difficulty with which very high vacuum is obtained in the tube without spoiling the filament.

**Effect of Gas in a Tube.** — An electron tube must be freed from gas sufficiently well to make its characteristic curves permanent and reproducible; if appreciable gas is present in the tube this is not so. All sorts of eccentricities were noted in the early, poorly evacuated audions, so that their inventor, DeForest, regarded their action as very mysterious. It is now known that all these peculiarities were due to the kind and amount of residual gas in the tube, and its effect upon the emission of electrons, as well as certain effects produced by ionization of these gases. Certain gases, such as argon, mercury vapor, hydrogen, etc., have very little effect on the electron emission from tungsten, but oxygen or water vapor (in pressures as low as  $10^{-6}$  mm. of Hg) have a marked effect, much reducing the emission. Water vapor may be absorbed in the glass walls of the tube; heating the glass slightly will release this water vapor and it attacks the surface of the filament, changing the emission as much as 20 times when heating the walls only 10 degrees. Mercury vapor as high as  $10^{-1}$  mm. has scarcely any effect on the emission. The best work on the effect of various problems connected with electron emission has been done by Langmuir, who was the first to produce the tube with very pure tungsten parts and very high vacua.

In detector tubes the effect of a slight amount of gas is unimportant; if ionization occurs to an extent sufficient to show the characteristic blue glow, the plate voltage should be reduced until the glow disappears and the tube will generally function as well as before.

In a modern tube there is not sufficient gas to make it erratic in its action. The presence of a gas may be detected by determining the grid current vs. grid potential curve. If such a curve shows an appreciable grid current with reversed grid potential (grid negative with respect to the negative end of filament), it may be concluded that a gas is present.

**Amplification Factor of a Triode.** — As shown in Fig. 13 the plate current depends upon both the plate and grid potentials. For the working range of the tube, the plate current is a function of the sum of the plate voltage  $E_p$  and the product of the grid voltage  $E_g$  and a factor greater than unity, i.e., the plate current is a function of  $(E_p + \mu_0 E_g)$ , where  $\mu_0$  is a factor greater

than 1. This factor  $\mu_0$ , which expresses the relative value of  $E_p$  and  $E_g$  in controlling the plate current, is called the voltage amplification factor of the tube; it is nearly constant throughout the working range of the tube but does depend to some extent upon the filament current and plate and grid potentials. It is greater the finer the grid mesh and in actual tubes may have a value between 1 to 3 (old DeForest audions) to as much as 200. The ordinary value of  $\mu_0$  lies between 3 and 40, the latter value being infrequent. The ordinary detecting and amplifying tube used so much at present has a  $\mu_0$  of about 7.

Langmuir has expressed the relation between the plate current and the plate and grid potentials by the equation,

$$I_p = A(E_p + \mu_0 E_g)^{3/2},$$

where  $A$  is a constant. Van der Bijl, to whom is largely due the development of the W. E. tubes, gives the relation,

$$I_p = A(E_p + \mu_0 E_g + c)^2,$$

where  $c$  is a small quantity determined by the surface characteristics of the three electrodes in the tube (called the contact difference of potential), and other factors. Actually, the exponent of the term in the parentheses is neither  $3/2$  nor 2, but is a variable depending upon the grid and plate voltages.

For small changes in plate current, as occur in the ordinary amplifier circuit the relations of current and potentials may be written,

$$\Delta I_p = K(\Delta E_p + \mu_0 \Delta E_g),$$

where  $K$  is a constant. This relation was first given by Latour. This equation is the one on which practically all tube theory is based; it is not correct for detection, as it neglects the factor upon which detection depends. It also leads to certain vague conclusions when dealing with triodes as power converters.

**Internal Resistance of Tube.** — The circuit to which a tube is connected should always be designed to fit the tube resistance. There are two internal resistances which control the design of the connected circuits, viz., the resistance from the grid to the filament (input circuit), and the resistance from the plate to the filament (output circuit). The input circuit resistance is in nearly all cases very high; if the grid is maintained at some negative potential, as is generally the case, the input circuit may be treated as though it had infinite resistance, except when used with very high frequency, in which case the capacity of the input circuit may be of importance.

The resistance of the output circuit varies with the type of triode and with the voltage used in the plate and grid circuits; it generally lies between 5000 and 100,000 ohms for tubes used to-day. The continuous-current resistance is seldom of importance, the alternating-current resistance being the factor, knowledge of which is necessary. This a-c. resistance is about one-half the c-c. resistance. The c-c. resistance is given by the relation,

$$R_c = \frac{E_p + \mu_0 E_g}{I_p}.$$

The a-c. resistance is,

$$R_a = \frac{\Delta E_p}{\Delta I_p},$$

when  $E_g$  is held constant.

**Triode as a Converter from C-c. to A-c.** — Innumerable circuits have been devised for making the triode function as a converter of c-c. power

to a-c. power, one of the simplest being that shown in Fig. 14. The filament is heated by battery *A* and the plate voltage furnished by generator *B*; a condenser *C* serves as a by-pass for the high-frequency fluctuations in the plate current which occur as soon as the triode starts to function. The coil  $L_1$  and condenser  $C_1$  form an oscillatory circuit of resistance *R*. The grid is connected to the negative end of the filament through an inductance  $L_2$ , which is coupled magnetically to  $L_1$ , the mutual induction being indicated by *M*.

When certain conditions have been satisfied the combination will generate alternating current in circuit  $L_1 - C_1$ , the frequency of the current being fixed by the natural period of this circuit. The plate current itself fluctuates from zero to twice its normal value and in the  $L_1 - C_1$  circuit the magnitude of current is limited (in a suitably designed circuit) only by the resistance *R*. It is to be noted that  $C_1$  and *R* might be the capacity and resistance of an ordinary antenna.

The required conditions for producing oscillations in the oscillatory circuit may be found by assuming a damped oscillatory current to flow in the circuit, and solve for the condition which gives a damping factor of zero; such a condition means of course the continuous generation of alternating current in this circuit. It may be proved in this manner that the condition for oscillations being maintained by the triode is given by the inequality:

$$M \text{ negative and greater in magnitude than } \frac{I}{\mu_0}(L_1 + CRR_p),$$

where  $R_p$  is the alternating current resistance of the plate-filament circuit. The required negative value of *M* means that the coils  $L_1$  and  $L_2$  must be so related that when the plate voltage rises the action of  $L_2$  on  $L_1$  is to make the grid potential fall, in other words, that as the circuit is in oscillation the plate and grid voltages must have opposite polarities with respect to the filament.

**Power Obtainable from a Triode Converter.** — A triode is rated in terms of the power safely dissipated by the plate; if this is too much the plate overheats, drives gas out from itself, and so the vacuum is spoiled. With ordinary adjustments of circuits the amount of power obtainable in the form of alternating-current power is about the same as the safe rating of the plate. For this condition the efficiency of the converter is 50 per cent, neglecting the amount of power required to heat the filament. With suitably designed circuits, however, and with sufficiently high voltage on the plate (that is, high voltage generator in the plate circuit), it is possible to get from the tube about four times as much power as the plate is rated to stand. For such an efficiency the plate circuit generator must be a 2500 volt machine or more.

**Triode as Amplifier.** — The equation for the plate current of a triode shows that the grid is  $\mu_0$  times as effective in controlling this current as is the plate voltage itself. For small changes in grid and plate potentials the change in plate current may be written,

$$\Delta I_p = \frac{I}{R_p}(\Delta E_p + \mu_0 \Delta E_g).$$

Fig. 14.

From this it is seen that the change in plate current for an increment in grid potential is as large as if the grid potential had been held constant and an increment of voltage change in the plate voltage  $\mu_0$  times as large were introduced, so that an alternating e.m.f.,  $E_g$ , introduced in the grid circuit (input circuit) may be regarded, in so far as effect on plate current is concerned, as the equal of a voltage  $\mu_0 E_g$  introduced in the plate circuit.

Neglecting the continuous components of voltages and currents in the tube circuits, and dealing only with the alternating components (r.m.s. values), for a voltage of  $E_g$  in the grid circuit there is produced in the plate circuit a current

$$I_p = \frac{\mu_0 E_g}{R_p}$$

in which  $R_p$  is the a-c. resistance of the plate circuit of the triode. If an external resistance  $R$  is introduced in the plate circuit as indicated in Fig. 15 (heating battery and plate-battery left out as they play no part in the a-c. laws), there are in the plate circuit two resistances in series and the equation for plate current becomes,

$$I_p = \frac{\mu_0 E_g}{R_p + R}$$

$I_p$  will of course be an alternating current of the same form as  $E_g$  (if the distorting effects of the variable  $R_p$  are neglected) so that the drop across the external resistance  $R$  is of the same form as  $E_g$  and equal to

$$E_g \times \frac{\mu_0 R}{R_p + R}$$

Evidently if the fraction  $\mu_0 R / (R_p + R)$  is greater than unity the triode and its attached circuit constitute a voltage amplifier, giving across  $R$  a voltage similar in form to  $E_g$ , and in practice from 2 to 20 times as large.

In case a reactance is used in place of  $R$ , the feasible amplification is somewhat more. Neglecting the resistance of the reactance introduced in the plate circuit, the amplified voltage across the reactance is,

$$E_g \times \frac{\mu_0 X}{\sqrt{X^2 + R_p^2}}$$

If  $X$  is two or three times as large as  $R_p$  the amplified voltage will be sensibly  $\mu_0$  times as large as the input voltage.

Instead of inserting a reactance coil in the plate circuit the primary of a suitably designed transformer may be used. Such a transformer is generally built with a step-up ratio of about 5, so that the possible amplification is thereby increased. These repeating transformers must be built with a very large number of turns to match the resistance of the ordinary amplifying tube; and further, the natural period of the secondary must be kept much lower than that of any frequency to be amplified. It is this fact which keeps down the useful step-up ratio. If the transformer has a ratio of 5 the maximum obtainable amplification of the triode and attached transformer is equal to  $5\mu_0$ .

The output voltage of one triode may be impressed on the input circuit of another triode similarly arranged and the output of this triode impressed on the input of a third, etc. Thus if each stage of amplification (triode and attached circuits) gives a voltage amplification of  $A$ , and  $x$  stages are used, the theoretical

Fig. 15.

amplification is  $A^3$  times in voltage. In practice a voltage amplification of 5000 is possible but seldom used; the amplifier tends to become unstable, and special precautions must be observed in using it if the amplification is more than about 500.

In Fig. 16 is shown a three-stage resistance coupled amplifier using common batteries for all filaments and plates; in this type of circuit the grid of each

Fig. 16.

triode must be insulated from the plate circuit of the preceding one to prevent the high plate voltage from being impressed on the grid. This is the function of the condensers  $C, C$ , etc. The small resistances  $r, r$ , inserted in the negative leg of the filament serve to keep the average potential of the grids negative with respect to all parts of the filament, a necessary condition for efficient amplification.

In Fig. 17 is shown a three-stage transformer coupled amplifier. With tubes having  $\mu_0$  of 7 and transformers having a 5 : 1 step-up ratio three stages is all

Fig. 17.

that could be used without the amplifier being very noisy and possibly not at all workable.

A regenerative coupling is possible and sometimes used with resistance coupled amplifiers; a small variable condenser serves to connect (electrostatically) the last plate to either the grid or plate of the first tube, thus tending to make the effective resistance of the amplifier as a whole zero, that is, tending towards infinite amplification.

**DAMPED-WAVE TELEGRAPHY OR SPARK TELEGRAPHY.**—Up to about 1915, spark telegraphy was the nearly universal method of carrying on radio communication; it is rapidly being superseded by continuous, or undamped, wave telegraphy, because of greater distance obtainable, more freedom from interference, etc. It seems likely that within a few years spark telegraphy will be done away with entirely. At present most of the radio

stations in the world still use the damped wave system; especially is this true of the smaller stations such as those on board ship. A knowledge of the function and operation of a spark station is therefore still essential.

In brief, this system comprises a source of power (generally a motor-driven alternator and step-up transformer to get a power supply of about 15,000 volts; suitable condensers are charged to this high voltage and then are discharged through a few microhenries of inductance, by the breaking down of a spark-gap in the circuit. This discharge is oscillatory, of frequency fixed by the inductance and capacity used. This oscillatory circuit is magnetically coupled to the antenna, and so a high-frequency oscillation is induced in the antenna for every break down of the spark-gap. The average set permits about 1000 sparks a second; therefore 1000 damped, high-frequency wave trains are emitted from the antenna per second.

At the receiving station the circuit is so arranged that the listening operator's telephone is actuated by one pulse of current per wave train arriving at the antenna. Thus the phone diaphragm is impulsed 1000 times per second, so that the operator hears a musical note as long as the transmitting station is sending.

**Typical Transmitting Circuit and Function of Parts.** — In Fig. 18 is shown the general layout of a spark transmitter.

Fig. 18.

**Alternator and Transformer.** — The alternator is generally of the inductor type giving a frequency of 500 cycles per second. It differs from the small alternator for lighting and similar power service in the higher frequency and the very high internal impedance of its armature windings; the short-circuit current of a radio alternator is only slightly in excess of the full-load current. The step-up transformer is of the open or closed core type, more modern sets having the closed core; it steps the voltage up from perhaps 125 to 15,000 volts. *B-B* are high frequency choke coils (generally built in with the transformer) to keep the high-frequency currents from penetrating the secondary winding and breaking down the insulation.

**Spark Gap.** — The spark gap may consist of a couple of discs of non-arcing metal, such as zinc, but, because of the noise and difficulty of maintaining the adjustment of this type of gap, as well as the bad quality of signal radiated, such a gap is seldom used except in emergency sets.

A rotating disc, having studs mounted on its periphery which come close to a couple of stationary studs as the disc revolves, is more often used; it is called a rotating gap. If the rotating studs come in proximity to the stationary studs (so that a spark may pass) once per alternation of the power supply it is called a rotating synchronous gap; otherwise it is called a rotating non-synchronous

gap. The synchronous gap is used more often than the non-synchronous, the rotating disc being mounted on the end of the alternator shaft, thus ensuring synchronism. The disc is so shaped that as it rotates it plays a blast of air on the stationary studs to keep them cool. The U. S. Government station at Arlington from which standard time signals are sent out, uses this type of gap.

**Condensers.** —  $C$  consists of either copper plated glass jars or mica condensers, the latter gradually replacing the jars because of less dielectric loss, more compact structure, and less likelihood of breaking. The copper-plated jars were made of standard size, having 0.002 microfarad capacity. A 1000-cycle spark set requires four of these jars per kw. rated capacity. The mica a-c. condensers are made more generally in units of 0.004 microfarad.

In order to obtain uniform sparking of a set, the reactance of the alternator armature plus the leakage reactance of the transformer must constitute, with condenser  $C$ , a resonant circuit the frequency of which is about 20 per cent lower than the frequency generated by the alternator. In calculating this effect the transformer inductance and condenser capacity must be suitably changed to reduce the circuit to a 1-1 transformer condition.

**Oscillation Transformer and Loading Coil.** — The two coils  $L_1$  and  $L_2$ , placed in proximity to each other constitute the oscillation transformer; the coil  $L_1$  in combination with condenser  $C$  and spark gap make up the closed oscillatory circuit and fix the frequency sent out. The extra coil in the antenna circuit  $L_2$  is called the antenna loading coil. All of these coils  $L_1$ ,  $L_2$ , and  $L_3$ , as well as the mutual inductance between  $L_1$  and  $L_2$  are generally variable either by sliding contacts or taps.

**Ammeter.** — In the base of the antenna, just where it connects to ground, is placed a hot wire ammeter  $A$  to indicate the amount of current flowing in the antenna circuit. For measuring these high-frequency currents in radio circuits only two types of ammeter are available, the hot-wire type and the thermocouple and c-c. millivoltmeter type.

**Safety Devices.** — Various safety devices consisting of high resistances and condensers are placed across the low-voltage lines to keep any high-frequency induced voltages from damaging the insulation of field, armature, etc. A high resistance across the alternator terminals, grounded at its middle point, is shown at  $D$ , in Fig. 18.

**Key.** — Signals are sent in the form of dots and dashes (Continental Morse; see article on *Telegraphy*) by suitably manipulating the key in the transformer primary circuit. In the case of a high-powered station, or station using distant control, this key is of the relay type. Sometimes multiple relays are used putting several gaps in series. The spark gap and relay key are the two parts of a spark transmitter which require the most attention to maintain.

**Coefficient of Coupling.** — The closed oscillating circuit  $L_1-C$  is coupled to the open oscillating circuit (the antenna) by the mutual inductance between  $L_1$  and  $L_2$ . The coefficient of coupling of the two circuits is given by

$$k = \frac{M}{\sqrt{L_1(L_1 + L_2)}}$$

The permissible value of  $k$  varies from perhaps 10 per cent in a rotating gap to 20-25 per cent with a quenched gap (described below).

**Wave-Length Radiated.** — Were the circuit  $L_1-C$  of Fig. 18, not influenced by the circuit  $L_2-L_3$ , it would oscillate at a frequency fixed by the formula,

$$f = \frac{1}{2\pi\sqrt{L_1C}}$$

where  $L_1$  and  $C$  are expressed in henries and farads. When  $L_1$  and  $C$  are expressed in microhenries and microfarads, this formula becomes

$$f = \frac{10^6}{2\pi\sqrt{L_1C}}$$

The corresponding wave-length is then

$$\lambda = 1885\sqrt{L_1C} \quad \text{meters,}$$

when  $L_1$  and  $C$  are expressed in microhenries and microfarads.

In the operation of a set it is necessary to make the natural period of the antenna circuit the same as that of the closed circuit; this is called *tuning* the two circuits. If this has been done it might be supposed that the wave-length radiated from the antenna would be given by the formula  $\lambda = 1885\sqrt{L_1C}$ , but actually such is not the case. By use of a wave meter (described later) it is found that two separate wave-lengths are radiated simultaneously and neither one of them is the same as that expected, one being higher and the other lower. Investigation shows that the values of these two wave-lengths depends upon the coupling, and exact analysis predicts that the wave-lengths should be given by the relations,

$$\lambda' = \lambda\sqrt{1+k},$$

$$\lambda'' = \lambda\sqrt{1-k},$$

in which  $\lambda'$  and  $\lambda''$  are the two radiated waves and  $\lambda$  is the wave-length for which each of the circuits is tuned, and  $k$  is the coefficient of coupling. Thus a set tuned for 600 meters in both the closed and in the open oscillating circuits, and having a coupling coefficient of 20 per cent, would radiate simultaneously 657 meters and 536 meters.

**Quenched Gap.—Elimination of the Double-Wave Radiation.**—The two waves are generated because the transmitting system comprises two more or less independent oscillatory circuits; such a combination will always have two natural periods, and will oscillate at both of them at the same time. The high-frequency energy is first resident in the closed circuit, then by coupling in the oscillation transformer it is transferred to the open circuit, and then again flows back to the closed circuit, and continues this to and fro flow until all the energy is used up, as heat or otherwise. The forms of currents in the two circuits for such a state of affairs are shown in Fig. 19; such a "beating" current is actually made up of two currents of different frequencies.

Fig. 19.

At time  $A$ , Fig. 19, all the energy has left the closed circuit and is in the antenna circuit; if, at this time the circuit  $L_1-C$  should be opened the energy

could not get back into the closed circuit and the antenna would be left free to oscillate at its own natural frequency, and but one wave will be radiated; such an occurrence is shown in Fig. 20. The time available for opening the circuit  $L_1C$  is so short as to make a mechanical break impossible; by suitably designing the spark gap, however, the deionization of the gap, which can take place

Fig. 20.

in perhaps  $10^{-8}$  seconds, serves as a switch to open the circuit at the proper time, and so perform the required operation of preventing the two waves being formed.

A gap built suitably to accomplish this result is called a "quenched" gap; it consists of an assembly of very short gaps connected in series, each gap not more than about 0.02 cm. long. It is generally made up of a series of copper discs, separated by suitable insulating washers, or gaskets, so that the sparking takes place in an air tight cavity. Two sections of such a gap are illustrated in Fig. 21; the sparking surface is of electrolytic copper or silver, let into the faces of the cast copper discs. Ten or fifteen of these discs are clamped together in a frame work of insulated construction to form the ordinary quenched gap. As many of the gaps as desired can be used by clip connections on the flanges. An air blast from a small fan serves to keep the gap cool, the air circulating around the flanges. Small gaps may have liberally designed cooling flanges and so be self-cooled; such a type of gap is used in  $\frac{1}{4}$  kw. sets and smaller.

To maintain the quenching action the insulating gaskets must be made air tight, so after the oxygen, originally in the sparking cavity when the gap is assembled, is once burned out, no more oxygen can get in. If it does, an oxide layer of increasing thickness forms on the sparking surfaces and the gap ceases to quench.

Fig. 21.

**Decrement. — Number of Waves in a Train. —** After the circuit  $L_1C$  opens, the current in the antenna (Fig. 20) dies away, as the energy is radiated and wasted as heat, the decay being in accordance with the exponential law. The antenna current, after the gap has opened the closed oscillating circuit is of the form,

$$i = I_0 e^{-\alpha t} \sin \omega t,$$

in which  $I_0$  is slightly larger than the highest current actually occurring in the antenna; it is equal to the actual maximum current multiplied by  $e^{\frac{\alpha T}{4}}$ , where  $T$  is the natural period of the antenna circuit. The constant  $\alpha$ , called the damping constant, has the value,

$$\alpha = \frac{R}{2L}.$$

The constant  $\omega$ , called the angular frequency, has the value

$$\omega = 2\pi f = \frac{1}{\sqrt{(L_1 + L_2)C}}$$

where  $C$  is the capacity of the antenna.

The current may also be written,

$$i = I_0 e^{-n\delta} \sin \omega t,$$

where

$$\delta = \frac{\alpha}{f},$$

and

$$n = \beta = \frac{1}{T}.$$

The quantity  $n$  is the number of complete periods or oscillations in the time  $t$ . The constant  $\delta$  is called the "decrement" of the wave train, and is equal to the logarithm (to the base  $e$ ) of two successive maxima of current, in the same direction, the ratio being taken greater than unity.

The decrement of a spark station is a very important characteristic; if it is too high the transmitting station causes too much interference with other stations in the vicinity. The upper permissible value of the decrement is fixed by law as 0.2; in a good average spark station it is about 0.1, and in the very large stations it may be as low as 0.02-0.03.

In radio theory it is practice to regard a wave train as ended when the current has decayed to 1 per cent of its original value. Let  $I_N$  be the current at the beginning of the oscillation for which the current has a maximum value equal to  $\frac{I_0}{100}$ . Then,

$$I_N = \frac{I_0}{100} = I_0 e^{-(N-1)\delta}.$$

Then the number of waves in the train is,

$$N = \frac{4.60 + \delta}{\delta}.$$

The larger the decrement the fewer the waves in the train; e.g., for  $\delta = 0.2$ ,  $N = 24$ , and for  $\delta = 0.02$ ,  $N = 231$ .

**Adjustment of a Transmitting Set.** — With the spark gap set to discharge at about one-half normal voltage, and with the antenna circuit open,  $L_1$  is varied until the  $L_1$ - $C$  circuit is generating the desired wave-length, as indicated by a wave meter (described later) held near  $L_1$ . Then with the coupling between  $L_1$  and  $L_2$  very weak the antenna circuit is closed and, with medium value of  $L_2$  connected in the circuit,  $L_2$  is varied until the antenna ammeter indicates maximum current; the antenna is then tuned to the closed circuit, which is generating the desired wave-length. The coupling between  $L_1$  and  $L_2$  should be now increased and the indication of the antenna ammeter noted; this reading will increase rapidly at first (with increasing coupling) and then will increase more slowly. The coupling should not be increased past the point where the rapid increase in antenna current ceases. In case a quenched gap is used the coupling may be increased until, after the current has increased with coupling, it shows a slight decrease with further increase in coupling; the coupling should be left slightly less than that value which shows the decrease in antenna current.

If this procedure is followed, but one wave will be radiated, whereas if tighter

coupling is used the ammeter in the antenna will (or may) show more current yet the radiation at the desired wave-length will actually be less. If too loose coupling is used the set is inefficient, too much of the high-frequency power being used up in heating the closed oscillating circuit, especially the spark gap.

To vary the power output of the set the gap should be changed in length (or, if a quenched gap, the number of active sections reduced), and the field excitation of the alternator suitably reduced to keep the musical note of the set constant. If too much or too little voltage is used with a given length of gap, the note of the set will change from its normal quality, too little voltage dropping the note an octave or two and too much voltage making the note impure, due to several discharges of the condenser per cycle, instead of two, the proper number.

**Receiving Circuit.**— Fig. 22 shows a typical receiving circuit; the antenna circuit is tuned by the variation of  $L_2$  and  $L_1$  and the closed oscillating circuit by varying the condenser  $C_1$ . It

will be noted that there are the same elements in this receiving circuit as there are in the spark-transmitting circuit; the receiving coils and condensers, however, are of much lighter construction than the same parts of the transmitting set, because of the very small currents in the receiving system. In the transmitting station the currents are measured in amperes and potentials in kilovolts, whereas in the receiving system the potentials are less than a volt and the currents measurable in microamperes.

Fig. 22.

Across the tuning condenser  $C_1$  is shunted a pair of head phones in series with some sort of rectifying device. When the two circuits are properly tuned to an incoming signal a musical note is heard in the phones, the pitch being fixed by the number of sparks per second of the transmitting station. The following procedure is followed in tuning the receiving circuit. With the condenser  $C_1$  set at a low value and tight coupling between  $L_2$  and  $L_1$ , the tuning of the antenna circuit is varied until the signal is heard; then, with decreased coupling between  $L_1$  and  $L_2$ ,  $C_1$  is varied until maximum signal is heard. Because of the effect of one circuit on the other, as the coupling is weakened, both circuits must be slightly retuned. Having both circuits properly tuned it will be found that a certain value of coupling gives maximum signal strength; this will generally be quite loose coupling, depending somewhat upon the type of rectifier used and the decrement of the incoming wave.

The sharpness of tuning depends upon three factors, the decrement of the transmitting station, decrement of the receiving station, and the amount of coupling used in the receiving circuit, an increase of any one of these factors generally increasing the broadness of the resonance curve. As coupling is decreased from a high value the tuning increases in sharpness until a certain critical coupling is reached; further decrease in the coupling decrease the signal strength but does not increase the sharpness of tuning.

**Rectifier or Detector.**— The incoming wave train sets up oscillatory currents, of radio frequency, in circuit  $L_1$ - $C_1$ ; if the telephone were connected directly across  $C_1$  nothing would be heard, because neither the phones nor the ear can respond to a radio-frequency current. By interposing the detector  $D$ ,

which permits the passage of current more readily in one direction than in the other, the telephone diaphragm is impaled in one direction (either in or out) for each wave train in the receiving circuit, thus giving a note in the telephone fixed by the number of sparks at the transmitting station; this note, it must be noticed, is entirely independent of the frequency of the radio current, that is, of the wave length used.

**Crystal Rectifiers** were used almost exclusively as detectors up to a few years ago, but since then the three-electrode vacuum tube (triode) has gradually displaced them, until to-day crystal detectors are used only in second-class outfits. Typical curves of carborundum and galena, two of the widely used crystals, are shown in Fig. 23. The rectifying effect depends upon the sharpness of curvature of the volt-ampere characteristic, so that carborundum was generally used, with a polarizing battery of voltage equal to  $O-A$  (Fig. 23) for best results. The crystals were generally used by casting them into a metal box by a low-melting alloy, such as Wood's metal, and making the top contact to a sensitive surface of the crystal by means of a finely pointed spring wire, sometimes called a "cat's whisker." Sometimes the rectifying contact was obtained by using two crystals touching one another, such as zincite and chalcopyrite. In general the more sensitive the crystal rectifier the more easily it gets out of adjustment, or is spoiled at that one contact point by a very intense signal or atmospheric discharge.

**Triode as Detector.**—The triode is immeasurably superior to the crystal detector, due to its reliability and still more to the possibility of suitably arranging the circuits attached to it to magnify the signal strength. The normal connection of

the triode as a detector is shown in Fig. 24; with the connection as given by the full lines the triode is about 5 times as sensitive as an ordinary crystal. But if the plate circuit is opened at  $X$  and the coil  $L_4$  inserted as indicated by the dotted lines, the signal strength may be amplified hundreds of times by the so called "regenerative action" (due to Armstrong). As the coupling between  $L_1$  and  $L_4$  is increased, the signal increases in strength about as indicated in Fig. 25. Beyond a certain value of coupling, the musical quality of the signal disappears and the signal becomes "mushy" or scratchy in sound, although very loud; this region is indicated in Fig. 25 by the dotted portion of the curve. With the critical value of coupling ( $O-A$  in Fig. 25), signals

Fig. 23.

Fig. 24.

which are entirely inaudible with slightly less coupling become quite loud and readable, although not of musical quality.

The coupling between  $L_1$  and  $L_4$  (if of right polarity), tends to produce oscillations in the  $L_1-C_1$  circuit, as pointed out in the section on triodes; in the region shown by the dotted line in Fig. 25 the tube is oscillating and the scratchy quality of the note is due to the irregular interfering action of the continuous oscillations in the  $L_1-C_1$  circuit, and the damped-wave signals induced in this circuit by the signals received by the antenna.

With slightly less than the critical coupling between  $L_1$  and  $L_4$  the decrement of the complete receiving circuit approaches zero, thus very much increasing the selectivity, or sharpness of resonance of the set; the tuning in this condition is limited in sharpness only by the decrement of the transmitting set.

A normal value of the grid condenser  $C_g$  of Fig. 24 is about 200 micro-microfarads, of the grid leak resistance  $R_g$  about 1 megohm, and for the by-pass condenser  $C$  about 3000 micro-microfarads.

Fig. 25.

**CONTINUOUS, OR UNDAMPED TELEGRAPHY.**—Continuous-wave telegraphy (often abbreviated C. W.) is rapidly superseding the older spark-wave system; it is the logical form of power to use for radio communication and the only reason that spark telegraphy gained the field at first was the difficulty of building a high-frequency generator which was reliable and could give several hundred kw. of power. Instead of sending out a group of discontinuous wave trains, as is done in spark telegraphy, the continuous-wave transmitter excites the antenna continuously with high-frequency power as long as the sending key is closed. This is indicated in Fig. 26; at *A* is shown the antenna excitation for a dot by spark telegraphy and at *B* the antenna excitation for a dot by continuous-wave telegraphy. For slow sending a dot might last 0.1 second; this would take 100 wave trains from a 1000-spark transmitter and would require 10,000 cycles of current, of fixed amplitude, for a 3000-meter continuous-wave transmitter.

Fig. 26.

**Advantages of Continuous-Wave Communication.**—For a given radiated power the insulation of an antenna for continuous wave is much simpler than for spark waves, the voltage for which the insulators are built being perhaps  $\frac{1}{10}$  as great; a given amount of power in the form of continuous wave will permit communication over much greater distance than the same amount of damped-wave power, due principally to the receiving circuit used; the interference between continuous-wave stations is much less than that between spark stations.

**Types of Generators Used.**—There are now available three types of generators which will furnish 100 kw. or more of high-frequency power, at frequencies of 40,000 or more; namely, the inductor type of generator, the reflector type, and the Poulsen arc.

**The Inductor Type of Alternator,** first built by Fessenden, and now called the Alexanderson alternator, consists of stationary armature and field

coils, the revolving member being a disc of high-grade steel, carefully machined and balanced. Near its periphery the disc is cut through with closely placed radial slots, the slots being filled in with some non-magnetic alloy to make the disc smooth to cut down the windage loss. The armatures are placed one on either side of the revolving disc, these armatures being built of very finely laminated iron; they are ring shaped, having radial slots in their inner faces, in which the winding (one conductor per slot) is fitted. At the lower frequencies this machine can be built for an output of 100 kw. or more; it has been built to generate directly 100,000 cycles per second with an output of a few hundred watts, but is very inefficient (10 per cent) at these excessive frequencies. At the radio frequencies which these machines generate the iron loss per unit volume of material is very high, so that special means have to be taken to keep the machine from overheating. In the Alexanderson generator water pipes are fitted throughout the structure to keep the material at a safe temperature. The generator is motor driven, the motor being equipped with very sensitive speed controlling devices; this is necessary not only for the sake of efficient reception, but because all these high-frequency alternators require that the attached circuit be accurately tuned if much output is to be obtained, and any speed variations would spoil the adjustment of tuning.

The Reflector Type of Alternator was first suggested as possible by Boucherot in 1893, but no machine of this type proved commercially practicable until the advent of Goldschmidt's generator of this type put out in 1907. The reflector type utilizes the effect of armature reaction in a single-phase generator in inducing in the field winding a current of double the frequency of the armature current. Suppose a single-phase, 60-cycle alternator is loaded, thereby producing armature reaction on the field. It will be found that a 120-cycle e.m.f. has been generated in the field winding and, if a suitable path is provided for it, a 120-cycle current will flow in the field coils. Now an alternator turning at 60-cycle speed and having a field coil excited with 120-cycle current will generate in its armature a 180-cycle e.m.f., and if suitable paths are provided, current of this frequency will flow in the armature. This 180-cycle current will produce, by armature reaction, a 240-cycle e.m.f. in the field coils, which will produce 240-cycle current in the field circuit if suitable low impedance paths are provided. By using this idea of reflecting the frequency back and forth between the armature and the field, each time gaining the frequency of rotation of the machine, the frequency may be effectively quadrupled at least, possibly more.

In Fig. 27 the circuit arrangement of a Goldschmidt alternator connected to an antenna is shown. The key serves to vary the continuous current excitation, through coil  $L_1$ . In the armature coil  $L_2$  is generated a frequency of 10,000, corresponding to the rotational speed of the machine. The combinations  $L_2-C_2$  and  $L_2-C_4$  are each resonant to this frequency. Due to this armature current of 10,000 cycles an e.m.f. of 20,000 is generated in  $L_1$  and as the combinations  $L_1-C_1$  and  $L_2-C_3$  are each resonant to this frequency, a current of 20,000 circulates in the field coil  $L_1$ . This induces an e.m.f. of 30,000 in  $L_2$ , and as circuit  $L_2-C_2-C_4$  is resonant to this frequency, 30,000 cycle current flows in the armature coils. This finally induces a 40,000 e.m.f. in the field coil, and as the circuit  $L_1-C_1$  in series with the antenna capacity is resonant at 40,000 cycles, this frequency flows in the antenna and is used for radiating the signal. The tuning of each of these circuits is somewhat dependent on the tuning of the others, so the final tuning of the various branches has to be done experimentally after the machine is installed. Choke coils in the field-supply circuit prevent this path from short-circuiting the high-frequency currents.

The construction of this machine is a very difficult piece of work; the lami-

cores of field and armature are built of plates 0.002 inch thick with 0.001 inch gap between laminations; the rotor is 3 feet in diameter and weighs

Fig. 27.

turns 4000 r.p.m. with an airgap of about 0.03 inch. In this machine, the Alexanderson machine, it is very essential that the speed be kept constant. To accomplish this a resistance is automatically inserted in the field circuit of the driving motor whenever load is put on the generator. Although reliable figures are not available, it seems likely that the efficiency of these machines is of the order of 50 per cent at full load.

The **Poulsen Arc** is an outgrowth of Duddell's singing arc (see *Arc*, p. 1266). It is shown connected to an antenna in Fig. 28. The commercial

has been made in sizes up to 100 kw. input; the efficiency is somewhat less than 50 per cent; the output of these arcs are of the order of 100 kw. of high-frequency current. The c-c. generator of 600 volts e.m.f. is connected to the arc through a starting resistance and choke coil. After the arc is struck the starting resistance is gradually removed. The current through the arc is unstable, and when it is operating properly the current is nearly zero. The power is twice that supplied by the c-c. generator. The

current from the generator is held nearly constant by the choke coils, so that the variations of the current from the average value flow in the antenna as a high-frequency current, the frequency being determined by the natural period of the antenna circuit.

To operate properly the arc must burn in a light gas, such as hydrogen or acetylene gas; the hollow copper anode must be water cooled, as must the

Fig. 28.

whole chamber in which the arc burns; the carbon cathode must be rotated slowly, the gap length must be proper (about  $\frac{3}{4}$  inch), and the arc must burn in a transverse magnetic field of proper intensity. The action of the arc becomes poorer as the natural period becomes less, the arc in fact is inapplicable for wave-lengths of less than 800 meters. Although the voltage across the arc may be only 50-60 volts when it is not oscillating, the peculiar action of the arc combined with the action of the choke coil results in an average voltage (as read on a c-c. meter) of about 500 volts when normal oscillations are occurring.

The interruption scheme of sending, such as used with the high-frequency generators just described, cannot be used with the arc, because when once it starts to oscillate the operation of the arc must not be stopped, otherwise the starting resistance must be re-inserted and the starting operation be repeated. Because of this condition the transmitting scheme of the arc station is peculiar to this type of transmitter. The arc operates all the time after it is started, the sending key merely changing slightly the natural period of the antenna circuit. Thus when the sending key is not depressed the arc is sending out radiation on a certain wave-length, and when the key is depressed the antenna radiates the same amount of power as before but at a wave-length perhaps 2 per cent higher or lower. The scheme of reception makes it possible to read the signal satisfactorily.

It will be seen that the arc station thus "uses up" two wave-lengths, whereas the two types of machines just described use but that one on which their signal is transmitted; this is one objection against the arc transmitter. Another arises from the fact that, owing to the continuous full load output of the arc (whether sending or not), its operating efficiency may be much lower than that of a generator.

**Saturated Iron Cores** have been used as frequency doublers and triplers to some extent, and the Marconi *multiple timed spark* scheme of generating continuous oscillations are used somewhat by the Marconi Co.; neither of these schemes has much engineering merit as a commercial device.

**The Oscillating Triode** (triode used as a converter; see section on *Triode* above) is used in practically all continuous wave transmitters of small output, say less than 1 kw.; in special tests it has been used in batteries to give several kw. output, but in the present state of its development it cannot be regarded as a competitor of the other schemes outlined, unless the required wave-length is less than about 800 meters, in which case the triode is the only available scheme.

A typical triode circuit is shown in Fig. 29. The oscillations are started and stopped by opening the grid circuit. It is best not to leave the grid "free," as would be the case if the key only were used; a good scheme is to have a battery of small dry cells connected across the key through a high resistance *R*. When the key is open this battery forces the grid to such a high negative potential that the plate current is brought to zero; the resistance *R* prevents short-circuiting the battery when the key is closed.

Sometimes a triode transmitter is used to send *modulated* continuous-wave signals. When the key is pressed it not only starts the triode to oscillate, but closes a buzzer circuit which opens and closes the antenna circuit at buzzer

Fig. 29.

frequency, that is, at an audible frequency. The signals sent out by this method can be received by the ordinary crystal detector set, the transmission being practically the same as a spark station with very low decrement.

**Reception of Continuous-Wave Signals. — Beat Reception.** — As already pointed out, a continuous-wave signal arriving at a spark station receiving set will give no audible response in the telephones because there is no "wave-train frequency" or "spark frequency" to give the audible note. The scheme used universally to make a continuous wave signal audible is one due to Feasenden; it depends upon the creation of a "group," or "wave-train frequency" right at the receiving station, and is known as "beat reception." If a frequency of 100,000 is impressed on the receiving set by the incoming signal, and if there is already in the receiving set a continuous oscillation of 99,000 (or 101,000), these two frequencies together result in the actual current in the receiving circuit having variations in its amplitude, these variations having a frequency equal to the difference in the two frequencies present, in the above case 1000 variations or beats per second.

Originally Feasenden used a small oscillating arc to continually excite the receiving circuit, but to-day an oscillating triode is always used. The circuit is arranged as shown in Fig. 24, the coupling between  $L_1$  and  $L_2$  being adjusted to produce oscillations. The frequency of these oscillations will be fixed by the natural frequency of the  $L_1-C_1$  circuit, and can be varied at will by changing  $C_1$ . Thus the beat frequency can be made just what the individual operator desires.

The triode rectifies this beat frequency just as it does the wave-train frequency from a spark station, and the operator hears the musical note of the beats; the musical note of such a signal is thus not independent of the wavelength of the transmitting station, as it is for a spark station.

This beat method of reception gives a wonderful degree of selectivity, thereby tending to prevent interference between different stations. Suppose one continuous-wave station is sending on 600 meters and another in the vicinity is sending on 605 meters. If the receiving station set is oscillating at 501,000 cycles per second the 600-meter signal will give a note in the phones of 1000, whereas the 605-meter signal will give a musical note of about 5000 per second, practically out of audibility, whereas the desired signal note (1000) is in the most sensitive region of the ear and telephone. From what has already been said of tuning, it is evident that two spark stations sending on 600 meters and 605 meters would interfere very much, one could not be tuned out with tuning-out the other also.

Even if the two continuous-wave stations differed by only one meter in 600 they would still be easily distinguishable. The undesired signal may be made to produce with the local oscillations a beat frequency of zero; that is, the local receiving circuit may be made to oscillate at exactly the same frequency as the transmitter of the undesired signal. The desired signal would then produce a beat frequency of about 1000 per second and the interfering signal be entirely inaudible, no matter with what intensity it is arriving at the receiving antenna.

**Autodyne and Heterodyne Reception.** — When the detecting tube itself is used to produce the local oscillations the scheme is called "autodyne reception," and when another triode, separate from the detecting tube, is used to produce the local oscillations it is called "heterodyne reception." This distinction in names is not widely used in the literature, however, the term heterodyne being used for both methods very frequently. It will be noticed that in autodyne reception the local circuit  $L_1-C_1$  cannot be tuned exactly to the incoming frequency, as the beat frequency for this adjustment would have

zero value and so the signal be inaudible. In the heterodyne scheme the local circuit  $L_1-C_1$ , as well as the antenna circuit, can be exactly tuned to the signal frequency, and furthermore the amount of local oscillation impressed on the detector circuit (generally by mutual induction) can be regulated, and thus maximum response in the detector be obtained.

The amplitude of the local frequency impressed in the detector circuit should be slightly less than that existing when the tube is used for autodyne reception with the minimum value of  $M$  which will sustain oscillations. In other words, the local frequency should carry the plate current variation (Fig. 13) as far as possible without forcing it over the upper and lower knees of the curve, say from  $a$  to  $b$  of curve  $E_2$ .

**RADIO TELEPHONY.** — Radio-telephone conversation may be carried on by means of a suitably *modulated* high-frequency radiation. Some sort of continuous-wave, high-frequency generator is connected to the antenna, and thus radiates continuous-wave power and a receiving station, tuned to this frequency will be excited by it. If now the amplitude of this high-frequency wave is varied by some scheme, in accordance with voice waves, the envelope of the high-frequency radiation will resemble the sound waves of the voice. At the receiving station the ordinary crystal rectifier will give in the phones a sound corresponding to the envelope of the arriving radiation, and so will reproduce the voice actuating the transmitting station. Thus the only additional feature required by a radio-telephone transmitter over those required for a radio-telegraph transmitter, is a scheme which varies the radiated power according to voice sounds, instead of breaking it up into dots and dashes as does the ordinary sending key.

**Microphone in Antenna Circuit.** — The simplest scheme of sending out voice modulated waves is that shown in Fig. 30; the high-frequency generator

Fig. 30.

Fig. 31.

$G$  excites the antenna in series with which is the microphone  $M$ . When spoken into the microphone varies its resistance above and below normal, and so varies the amplitude of current flowing in the antenna, the antenna current thus having a form as shown in Fig. 31. Such a wave arriving at a receiving circuit will give a noise in the phones corresponding to the envelope of the current amplitude,  $A-B-C-D$ , which represents the form of a voice sound wave. This method of modulation is far from perfect, is very inefficient (because of high microphone resistance), and is good for only small amounts of power, at most a few watts. If too much current is allowed to flow through the microphone it overheats and ceases to function.

**Variable Induction Modulation.** — A scheme used in a large radio-telephone station is shown conventionally in Fig. 32; it is due to Alexanderson.

frequency generator *G* is shunted by a path in which there is included more inductance; wound on this core is an extra coil, the current from which is obtained for the plate circuit of the modulator tube. The antenna circuit is connected to the plate circuit of the modulator tube through a battery of tuned triodes (or pentodes or tetrodes or other types of tubes). The microphone circuit is connected to the grid of the modulator tube through a transformer. The microphone circuit is actually a transformer and microphone circuit so that the current of the microphone is controlled by the microphone. The modulation in the antenna circuit is due to the variation in the current of the microphone which acts so as to shunt the path

Fig. 32.

the generator *C-L-C* more or less short-circuits the generator, thus varying the amount of power applied to the antenna more or less in accordance with the voice sounds actuating the microphone. This scheme has been used for high-power outputs of perhaps 50 kw. The actual circuit is more complicated than the one shown, which is designed to give the elementary idea only.

**Modulation by Triode Directly.** — A scheme of modulation due to Heising is shown in Fig. 33. It is by far the best scheme so far used for low-powered

Fig. 33.

less than a few kw. The oscillator tube is connected to the antenna circuit, the plate current being supplied by generator *G* through the iron-core choke coil *L* and the high-frequency choke coil *K*. In small telephone outfits (with tubes with an output of 3-5 watts) *K* is about 2 henries and *L* about 1 henry. The grid excitation for producing oscillation is controlled by the microphone *M* which is about twice the antenna capacity, for tubes having an antenna factor of 4. The wave-length generated is affected somewhat by the value of *C*, but is controlled primarily by the position of tap *A*. To get a wide range of modulation of the wave-length a small variable capacity condenser is usually connected in parallel with the antenna capacity. The position of tap *B* must be chosen to get maximum current in the antenna circuit, this position depending on the resistance of the antenna.

The modulator tube draws its plate current through the same iron-core choke coil *L* as the oscillator, and the amount of current taken by the modulator tube is controlled by the microphone *M* operating on the grid of the modulator tube. Because of the high reactance of coil *K* the current furnished to the two plate

circuits in parallel will be essentially constant, so that as the microphone makes the modulator take more or less current, the oscillator plate circuit is supplied with less or more. The amount of power supplied to the antenna by the oscillator depends upon the oscillator plate current, hence the action of the microphone modulates the antenna output. The choke coil  $L$  is to prevent the high-frequency output of the oscillator tube being partially absorbed by the plate circuit of the modulator.

The modulated high-frequency current in coil  $A-B$  may be used to excite a battery of high-powered tubes, instead of being itself the radiation current; in this case a condenser will replace the antenna in the oscillator circuit. This scheme of using a low-power triode to excite a battery of larger ones makes it possible to successfully modulate several kw. of power.

**Elimination of Distortion of Speech.** — To make the modulation follow closely the voice sounds great care must be used in properly proportioning the various parts of the circuit; the average grid potentials of the two tubes is one of the important factors affecting modulation; generally a suitable battery of small dry cells is inserted in series with the grid of each tube to maintain the average grid potential at its right value. The modulation with a well-designed Heising circuit is so perfect that the voice of the speaking operator is easily distinguishable at the receiving station, the articulation being much better than it is over the ordinary wire line.

**Receiving Circuit for Radio Telephony.** — At the receiving station a triode detector is used, connected as in Fig. 24. The coupling of  $L_1$  and  $L_4$  must not be adjusted as critically (for high amplification of signal) as is possible without having the tube oscillate, because the speech becomes drummy, the consonants being obliterated. As shown previously, the critical coupling of the coils  $L_1$  and  $L_4$  makes the effective resistance of the receiving circuit practically zero, which of course means a very low decrement of the receiving circuit.

The decrement of none of the circuits used in radio telephony can be too low without spoiling the quality of the speech. This statement holds for the transmitter as well as for the receiver. The modulated high-frequency current must be similar to the sound waves; this means that for certain voice sounds the amplitude of the current must change very rapidly, the consonants requiring the most rapid change. If the decrement of a circuit is very low, the current in the circuit cannot be changed in amplitude rapidly, and so cannot follow the voice modulation. Because of this fact the tuning of a good radio-telephone receiver is not as sharp as one designed for the reception of continuous-wave telegraph signals.

**Two-Way Conversation.** — Although the common small radio-telephone outfits require the operator to throw a switch to change from sending to receiving position, it is possible to have this done automatically by a sort of bridge scheme; it is also possible to have two separate antenna systems, one for sending and one for receiving, so interconnected that two-way conversation is obtained as in ordinary wire telephony.

#### ATMOSPHERIC DISTURBANCES AND THEIR ELIMINATION.

— Space is continually agitated by electric disturbances, caused by ionization due to winds or the sun's rays, or by thunder storms with their electric discharges. Especially in the tropical regions are these "atmospherics" or "static" or "strays," as they are variously called, prevalent, probably because of the trade winds. Judging from the effect these electric disturbances have on an antenna it seems that they are radio pulses of very short duration, probably for the most part non-oscillatory. Due to their action all kinds of crackling and hissing noises are heard in the phones of a receiving set. These atmospheric disturb-

ances are the present limit on the utility of radio communication; were it not for these extraneous undesired signals coming into the receiving set, it would be possible to carry on transoceanic communication with one kilowatt of power, or less, instead of several hundred kilowatts as must be used.

Many investigators have put forth solutions of the static problem, but it is still to be solved. Even the very high-powered stations with their wonderful transmitting and receiving circuits have to send their messages slowly, and repeat continually because of the static interference in the receiving station. The partial elimination of static is possible by using a coil antenna, properly combined with a ground antenna, or similar scheme in which it is endeavored to balance out the static picked by the two antennæ and still leave a little of the signal unbalanced; this is then amplified until it is intense enough to read.

**DIRECTIONAL RADIO.**—As radio waves are of exactly the same nature as light waves, and as light waves are directive, can be focussed, bent, etc., it would seem that radio waves could be sent out in one direction only, like the beam of a searchlight. Such is the case theoretically, but it must be remembered that a mirror, or lens, to be effective, must be of dimensions hundreds of times the wave-length to be reflected or focussed. With radio waves thousands of meters long the use of mirrors, etc., is evidently out of the question.

The form of antenna used does give a certain amount of directional effect, as was first pointed out by Marconi. The type of aerial shown in Fig. 34 sends out considerably more power in the direction of its length than it does sideways. The coil antenna is more directive than any other; it sends and receives no power at all in a direction perpendicular to its plane. The distribution of radiated power from an inverted L antenna is as shown in Fig. 34 and that of a

Fig. 34.

Fig. 35.

coil in Fig. 35; in each figure the radius to the locus gives a measure of the radiated power in that direction.

By suitable combinations of two or more antennæ it is possible to get somewhat more directive effects than those shown here. Practically all of the later attempts in this field follow very closely the original work of Bellini and Tosi, who were the pioneers in this branch of radio communication.

**RADIO COMPASS.**—It is now practicable for a ship at sea to get her bearings by radio, an especially useful operation for a ship approaching a harbor in a fog. Suppose the harbor is at *O*, Fig. 36, and the ship at *A*. The ship calls up station *O* and asks for bearings. *A* then sends out a standard signal of some sort for a short time, and by suitable coil antennæ the stations at *C*, *O*, and *B* get her direction simultaneously. The direction as obtained at *C* and *B* is sent in to the central station at *O*; the operator at *O* is thus able to plot accurately the ship's position on his chart, using one of

Fig. 36.

the directions as a check on the other two. Operator at *O* then radios back to the ship her exact position.

A scheme used by aeroplanes for getting their bearings at night or above the clouds utilizes the directive effect of a coil antenna, in this case the coil being on board the plane. A series of land stations send out characteristic signals (each station a different one, of course) and the operator on the plane, by orienting his coil, gets his bearings from two of the stations and so can plot his position. To make the directive effect as sharp as possible, two coils at right angles to each other are used, Fig. 37; they can be connected in series direct or reversed by the double-pole double-throw switch. When the plane of one of the coils is in the direction from which the signals are coming, reversing the switch will have no effect on the signal strength, as the other coil should be getting nothing. By this scheme a plane can get the direction of the waves to within one degree.

**Inaccuracy of the Radio Compass.**—Although the setting of such an antenna as that pictured in Fig. 37 can be carried out to such a wonderful degree of precision, the observation is not as valuable as the precision would seem to justify. Radio

waves are subject to the same laws of refraction as light, and so may be deflected considerably, depending upon the condition of the atmosphere through which they are travelling. This effect has been noticed to a very great extent when the waves are travelling nearly parallel to a shore line, the deflection of the waves from such an obstruction being many degrees. Taylor states that a change of bearing, by wireless compass, of as much as 68 degrees takes place in only 14 minutes, this very large effect occurring during the setting of the sun.

Fig. 37.

**SIMULTANEOUS TRANSMITTING AND RECEIVING.**—It is not practicable to send and receive on the same antenna at the same time, although at present developments are taking place in that direction. It is however, practicable to send from one antenna and receive on another in the vicinity. This is generally accomplished by having at the receiving station two antennae, one of them being used to balance out the intense signal induced in the real receiving antenna by the nearby transmitting antenna. The extra antenna is generally a directive one so oriented that it picks up a maximum signal from the transmitter. By suitably combining, in the coils of the detector set, the signals from this compensating antenna with those from the receiving antenna, the signal from the nearby transmitter may be completely neutralized, leaving the desired signal from the distant transmitter.

In most such stations the transmitter station is operated by remote control from the receiving station; all keys, etc., at the transmitter station being magnetically operated.

**SPEED OF TRANSMITTING.**—A good operator can read 25 to 30 words per minute, when there is not too much interference. This evidently limits the speed of transmission, unless some type of automatic receiver, such as the phonograph, be used at the receiving station. Up to the present none of the many schemes of mechanical reception has proved as efficient as an operator, and they are but infrequently used. Successful experiments have often been conducted, but the fact that practically all of the high-powered stations to-day are sending at slow speed shows that they are not dependable.

When high-speed sending does come into practice another effect, which cannot be analyzed in detail here, must be considered. It has been stated that the tuning of continuous waves is very sharp, so that interference between different stations is reduced to a minimum. This statement does not hold good if the transmitting is done at high speed, the higher the speed the more interference will different stations produce on one another. An antenna does not start to radiate full power the moment the transmitting key is closed, it taking an appreciable time for the antenna to build up to the steady state. With high-speed sending the time for the steady state to be set up becomes comparable with the time the key is closed, and under such conditions the conclusions one reaches from the steady state condition are of no value.

**WAVEMETERS.** — The wavemeter, although a very simple device, is the most important the radio engineer has at his command. It is essentially nothing but a coil and condenser in series, one or both of them variable, with means for telling when the current in the circuit is a maximum. As it is simpler to construct a variable condenser, of wide capacity range, than it is to do the same thing for an inductance, it is the condenser which is generally variable.

Evidently this circuit, coupled to another in which there is a high-frequency current, will have maximum current when it is in resonance with the e.m.f. induced by that circuit, and if the values of the capacity and inductance of the coil are known for all settings, the frequency of the impressed e.m.f. is obtained by adjusting the wavemeter for resonance, and then noting the natural frequency of the circuit for this setting. As the radio engineer generally thinks in terms of wave-length rather than frequency, the meter is calibrated, on the condenser scale, to give wave-length in meters.

As a variable condenser for this purpose is usable from its maximum value to about  $\frac{1}{10}$  of its maximum value, the wave-length range of a meter with a single coil would be only about 3 to 1. To extend the range of the meter several coils, of different inductance, are generally furnished with it. In one type of wavemeter, for example, having a wave-length range from 100 meters to 6000 meters six coils are supplied.

The methods for detecting resonance differ according to the amount of power available. If the test is being made on a transmitting set (plenty of power), a hot-wire ammeter, which is permanently connected in series with the coil and condenser (*A* in Fig. 38) is used to show maximum current. Another scheme is to shunt the condenser with a small glass tube filled with neon (or other easily ionizable gas) at low pressure, as indicated in Fig. 38 by dotted lines; when the wavemeter is in resonance with the circuit being tested, there will be maximum voltage across the condenser and so maximum glow in the tube.

In still another scheme there is a small incandescent lamp connected in series with the coil and condenser, where the ammeter is in Fig. 38; this lamp is brought almost to incandescence by a dry cell in the wavemeter, the circuit to this cell having choke coils to keep out the high frequency. When the wavemeter is in resonance its current flows through the lamp in addition to that already flowing from the cell, and the lamp glows more brightly. This scheme is better than would seem likely, for only a slight increase in current is required to give a perceptible change in the color of the lamp, so that the resonance point can be located quite accurately.

When testing on a low-power set, such as a received signal, there is not enough power available to actuate either a hot-wire meter or a neon tube, so some more delicate means of detection must be used. For such a case the telephone and rectifier are shunted across the condenser as shown in Fig. 39. Sometimes the circuit is opened at the point indicated by *X* in the figure, and an additional

connection made as shown by the dotted line. Such a connection draws less power from the wavemeter, and so does not increase its decrement as much

Fig. 38.

Fig. 39.

as does the other connection, thereby giving sharper resonance. This connection is often called a unilateral connection.

**Uses of the Wavemeter.** — The wavemeter is used principally to measure the wave-length radiated from a transmitter, as the name indicates. In doing this the coil of the wavemeter is held in proximity to the oscillating circuit, and the condenser varied until maximum indication is obtained in the hot-wire meter, phones, or other detector used. To get an accurate indication it is advisable to have the wavemeter coupled to the oscillating circuit as loosely as possible and still get a positive reading on the indicating device. This will make the indication sharp, and also, with loose coupling, there is no danger of the wavemeter changing the frequency of the oscillating circuit.

The wavemeter is also used to measure the decrement of a transmitting set. To do this the meter is brought in proximity to the antenna and adjusted for resonance as indicated by the hot-wire meter; the coupling of the meter to the antenna is then varied so as to get a reading well up on the scale of the ammeter and this reading is noted. The wavemeter is then detuned until the ammeter deflection indicates 0.707 of the current which flows at the resonance setting, and the wave-length for this reduced reading noted. Similarly the wavemeter is detuned on the other side of the resonance point until ammeter again indicates 0.707 of its resonance value and this wave-length noted. It frequently happens that the hot-wire meter used is calibrated in terms of current-squared; thus many German meters are calibrated in current-squared, and the scale values are marked off in watts used in the meter itself. Such meters are labelled "wattmeters," although evidently they are not wattmeters in the ordinary meaning of that term. In getting the two-detuned points with such an indicating instrument, the wavemeter setting is varied until the scale reading is just  $\frac{1}{2}$  of its value at resonance, this being the proper setting for 0.707 of the resonance current.

Fig. 40.

As the setting of the wavemeter condenser is varied the readings of the hot-wire ammeter will follow a curve as indicated in Fig. 40.  $\lambda_r$  corresponds to the resonance setting,  $\lambda_1$  to the detuned condition above resonance, and  $\lambda_2$  to the detuned condition

ce. The value of the decrement is then obtained from the relation (approximate),

$$\delta_m + \delta = 2\pi \frac{\lambda_1 - \lambda_2}{\lambda_1 + \lambda_2} = \pi \frac{\lambda_1 - \lambda_2}{\lambda_f}$$

where  $\delta$  is the decrement desired, and  $\delta_m$  is the decrement of the meter generally given with the meter. If this is not known, it may be determined by performing the same test with a continuous-wave transmitter; as the decrement of the set is in this case zero, the decrement obtained from the meter is the decrement of the meter itself. An oscillating triode is a better source for making this test.

Mr. Kolster has designed a wavemeter with a special scale attached to the condenser with plates properly shaped so that it is possible to read the decrement of the set (plus that of the meter) from the setting on the scale, after carrying out a simple operation; this wavemeter is described in the next section.

**REQUIREMENTS IN RADIO TRANSMISSION.**—The transmission of radio waves is an irregular phenomenon, as previously mentioned, varying throughout the year as well as during the day. The strength of signal received at the receiving station for successful transmission is not a constant, but varies greatly with the amount of atmospheric disturbance present; this variation is probably 100 to 1. Thus it is evident that exact figures cannot be given; the values given in the table below are average values for a spark transmitter transmitting a high musical note (1000 sparks per second). The power rating is the power input to the primary of the power transformer.

Power supplied	0.3 kw.	1.0 kw.	5 kw.	30 kw.
Distances in day time..	50-100	125-250	250-500	500-1200

For continuous-wave transmitters the distances successfully covered are much greater than those given above, perhaps two to three times as great. Stations carrying on transoceanic communication all use between 10 and 100 kw. of power, in the antenna itself, the power supplied to the transmitter being nearly twice this figure. Even with this amount of power the transmission is not certain, as they transmit very slowly, often repeating the message during the summer time. During the winter months the transmission is not so certain, and in many cases it is feasible to communicate half way around the world.

**RAILS, TRACK AND THIRD.** — (See also *Bonds, Railway Track, Railways, Electric, Traction Systems for; Third-rail Systems; Trolley Systems*.) The A. E. R. A. Specification says that, unless otherwise specified, the lengths shall be 60 and 62 feet.

The American Electric Railway Association recommends that plain girder rails be used in paved streets except in large cities where the vehicular traffic is largely confined to the pavement area maintained by the railway. In the latter case, grooved rails should be used. The association has standardized the following rail sections which are described fully in its Engineering Manual.

Plain girder rails		Grooved rails	
Height, in.	Weight, lb. per yd.	Height, in.	Weight, lb. per yd.
5½	80	7	122
5¾	90	9	134
7	80 or 91		
6	100		

**RESISTANCE AND CHEMICAL COMPOSITION.** — The chemical composition of steel rails with respect to the impurities or elements other than iron (chiefly carbon, manganese, phosphorus, sulphur and silicon) varies over a considerable range, depending upon the process of manufacture. According to J. A. Capp, the specific resistance of an ordinary \* steel rail may be taken as a rough indication of the total impurities present. Fig. 1 shows the results of tests on a number of samples of different makes, ranging in total impurities:

Fig. 1. (From Trans. A.S.M.E.)

from 0.1 per cent to 1.9 per cent, the specific resistance referred to copper as unity ranging from 6.1 to 13.3. The greater hardness caused by the presence of impurities is an advantage in the case of track rails which offsets the disadvantage of low conductivity, but it is usually economical to employ for the third or contact rail a rail of fairly high conductivity.

\* This does not apply to special forms of rails submitted in the process of roding to extra heavy pressures.

The compositions given in the following tables are recommended by the authorities quoted.

Allowance for Wear in Resistance Calculations. — Resistance calculations should be made for rails worn down to the weight at which they will be rapped. It is usual to scrap rails when they have lost from 10 per cent to 20 per cent of the original weight, depending upon the importance of the line. The

resistances in the following table should therefore be increased from 10 per cent to 20 per cent.

**HISTORICAL DEVELOPMENT.**—The history of electric traction is given briefly by a few salient epoch-making events.

1835. T. Davenport of Vermont built and exhibited a small model electric vehicle operating on a circular track.

1842. Davidson, Edinburgh, Scotland built a seven-ton car operated by primary batteries and electro-magnets.

1851. G. G. Page operated a small locomotive with primary batteries on the Baltimore and Ohio Railroad at Washington.

1877. S. D. Field in San Francisco operated a small car driven from a stationary remote generator.

1882. J. R. Finney first used the over-running trolley at Allegheny, Pa.

1883. Leo Daft equipped a full-sized passenger train running from Saratoga to Mt. McGregor, together with the over-running-trolley construction.

1886. Bently and Knight introduced the first conduit system in Cleveland, O.

1887-8. Several small installations.

1888. Frank Sprague equipped the Richmond Street Railway and demonstrated the practicability of the system. Bently and Knight equipped a road at Allegheny City. Thomson-Houston system installed at Washington, D. C. Van Depoele brought out the under-running trolley. The directors of the Boston West End System decided to adopt electric traction.

1896. Baltimore and Ohio tunnel at Baltimore electrified; the first electrification of a steam road.

For references to the original papers describing these early installations, see Burch, *Electric Traction for Railway Trains*, N. Y., 1911.

**APPLICATIONS OF ELECTRIC TRACTION.**—There are certain well defined fields in which electric traction is superior to other methods, the most important of which are the following:

1. Where the frequency of stops is so great as to require a high rate of acceleration in order to make a good schedule speed. If the service requires trains of several cars, any desired number of these cars can be made motor cars and thus a sufficient weight on the driving wheels can be economically secured to give the required adhesion and tractive effort.

2. Where local conditions prohibit the nuisance of the smoke, exhaust gases and noise of steam locomotives, as in cities and tunnels.

3. In heavy trunk-line service where the density of traffic is so great that a high load factor can be obtained with respect to both the power house and distribution system. The operating cost of an electric train is always less than the operating cost of a steam train but the fixed charges (interest on investment and depreciation) of the electric system are high, for the first cost for the electric equipment, viz., locomotives, motor-car equipment, distribution

system and power house, is much greater than the first cost of steam locomotives, and their accessory equipment. If there are insufficient trains in a system so that the pro rata share of the fixed charges for each train is less than the difference between the operating cost of an equivalent steam equipment and the operating cost of the total electric equipment then electric traction is advantageous.

**SYSTEMS OF ELECTRIC TRACTION.**—Three different types of motors are in use for electric traction, the direct-current motor, the single-phase commutator motor, and the three-phase induction motor; see articles on *Motors*. The trolley or third-rail voltages (i.e., volts between trolley and track rails or between third rail and track rails) and the motor voltages employed are as follows:

**Direct-current Systems.**—Trolley or Third-Rail voltages of 600, 1200, 1500, 2400 and 3000 are in use. The motors for the 600-volt system are designed for operation at full trolley voltage. For all the other systems two motors are permanently connected in series electrically, each designed for half the trolley voltage.

**Single-phase Systems.**—Trolley voltages (third rails are not used) of from 3000 to 11,000 volts and frequencies of 15 and 25 cycles per second are in use. The trolley voltage is stepped down to from 200 to 500 volts, for which voltage the motors are designed.

**Three-phase Systems.**—Two trolley wires for each track are required, the two wires and the track forming the necessary three conductors for the three-phase distribution. The usual frequency is 25 cycles per second. The voltages used between the two trolleys and between each trolley and track range from 6000 to 11,000 volts. Transformers are employed to step this three-phase voltage down to from 400 to 600 volts between motor terminals.

**Comparison of the Various Systems.**—For ordinary street railway service the 600-volt d-c. system is almost universally employed, but for inter-urban and trunk-line service there is a great difference of opinion as to which of the various systems is the most economical when all the factors are taken into account. The factors which must be considered in comparing the three systems in any particular case are the following:

1. For a given weight and length of trolley or third rail the per cent power loss for a given amount of power transmitted varies inversely as the square of the trolley or third-rail voltage.
2. The higher the trolley or third-rail voltage the fewer are the number of substations required for the same efficiency of distribution and weight of conductor.
3. The higher the trolley or third-rail voltage the more costly is the insulation and supporting structure, and also the greater is the cost of maintenance of the distribution system.
4. Both the first cost and the annual expense of the substations are less for the a-c. systems than for the d-c. systems, since for the former static transformers only are required whereas for the latter rotary converters must be used.
5. The relatively low power factor of a-c. motors (80 to 90 per cent) as well as the relatively low power factor of the line (due to the reactance of the trolley wire and track return) gives rise to a greater power loss in the a-c. distribution system for the same power delivered than in the case of the d-c. system, and this great loss and lower power factor makes necessary the employment of generating apparatus of greater k.v.-a. capacity.
6. The 600-volt d-c. motor, for the same horse-power rating and speed,

weighs less and occupies less space than either type of a-c. motor. High-voltage d-c. motors cost more, weigh more and occupy more space than the low-voltage type.

For the a-c. motors transformers are required on the locomotive, and this adds to the cost and weight of the locomotive equipment.

A 600-volt d-c. motor costs less to maintain and is liable to fewer operations than any of the other motors.

In the commutating type of a-c. motor the power lost in the control is practically negligible, since the "potential" type of control can be used on both the d-c. motor and the induction motor a resistance control is used with consequent loss in power (see *Control Systems for Railway Motors*). The induction motor is inherently a constant-speed machine, and the power input varies directly as the opposing resistance. The d-c. motor and the a-c. commutator motor are inherently variable-speed machines, and the power input varies approximately as the square root of the opposing resistance as the speed at the same time falling off.

A three-phase induction motor, when kept connected electrically to the line of power, automatically operates as a generator when the train is on a grade at a speed greater than the synchronous speed of the motor, thus returning power to the line and at the same time acting as a brake. Obtaining any considerable increase in speed. "Regeneration," as this is called, can also be obtained with the other types of motors but only at a considerable expense for the additional control equipment required.

**Examples of the Use of the Various Systems.** — In the following are listed (1) the most notable examples of high voltage d-c. interurban railways in the U. S. A.; (2) the most notable examples of electrified steam railroads in the U. S. A.; and (3) a complete list of single-phase railways in the U. S. A.

**STUDY OF AN ELECTRIC RAILWAY PROJECT.** — In the analytical study of a particular problem the following general line of procedure is followed: (1) determine the number and capacity of cars to supply the service desired; (2) determine the power and energy required to propel these cars at the speed desired; see *Railways, Energy Requirements for*.

(3) determine the motors to correspond to the power determined in 2; see *Railways, Energy Requirements for*.

(4) determine the distribution of cars, by train diagrams if necessary; see *Railways, Energy Requirements for*.

(5) determine the capacity of the low-potential distribution system and of the substations; see *Substations, Railway; Railways, Energy Requirements for; Railways, Energy Requirements for; Trolley Systems*.

(6) determine the capacity of the generating stations and transmission systems; see *Power Stations; Railways, Energy Requirements for; Transmission Systems*.

(7) estimate the first cost of the system; see articles on the various items involved.

(8) estimate the cost of operation; see articles on the various items involved.

(9) estimate the earning power of the system.

In the case of a new road the earning power must exceed the sum of the operating and fixed charges by an amount sufficient to pay dividends.

In the case of the electrification of a steam road it must be possible to

(1) show that the result of electrification has been to reduce the operating charges by an amount more than sufficient to pay the fixed charges on the electrical apparatus, or, (2) that the result of electrification will increase the earning power of the road or attract sufficient new business so that the increased

**RAILWAYS, ENERGY REQUIREMENTS AND MOTOR EQUIPMENT FOR.**—

(See also *Locomotives, Electric; Motors; Power Stations; Railways, Electric, Traction Systems for; Railways, Location and Permanent Way for; Substations, Railway.*) From a consideration of the forces acting on a moving train it is possible to determine the motor capacity and energy required to operate it when the profile and contour of the road, the time table and the characteristics of the available motors are known. The various items are treated in the following sequence:—

Forces Acting on a Train.....	p. 1291

**UNITS AND ABBREVIATIONS.**—Throughout this article the various quantities employed will be expressed in the following units unless specifically stated otherwise: distances in feet, weights in tons of 2000 pounds, forces in pounds, speeds in miles per hour (abbreviated mph.), accelerations in miles per hour per second (abbreviated mphs.), mechanical power in horse power, energy in watt-hours.

**FORCES ACTING ON A TRAIN.**—The forces tending to accelerate a train are the tractive effort developed by the motors and the component of the weight along the track on down grades. The forces which retard the motion of the train are the various frictional forces and the component of the weight along the track on up-grades; also in braking, the frictional force due to the brakes. All the various frictional forces, except the braking resistance, such as track friction, journal friction, air friction, etc., which oppose the motion of a train on a straight track are usually considered together and are referred to as the "train resistance." The extra friction due to track curvature is usually considered as an equivalent up-grade.

**Tractive Effort and Draw-bar Pull.**—The tractive effort of a motor is the force exerted by the motor at the rim of the driving wheel to which the motor is geared. The tractive effort of a locomotive is the force exerted by the locomotive at the rim of the drivers. The draw-bar pull of a locomotive is the force transmitted through the draw-bar of the locomotive,\* and is less than its tractive effort by an amount equal to the resistance due to the rolling friction of the locomotive wheels on the track and the air resistance of the locomotive.

Direct-current motors deliver a uniform tractive effort for a given current; the tractive effort of alternating-current motors pulsates to some extent with the alternations of the current; the tractive effort of a steam locomotive varies

\* In the case of a steam locomotive, the draw-bar pull usually refers to the force transmitted through the coupling between the tender and train; i.e., the tender is considered as a part of the locomotive.

from 28 to 50 per cent above and below its average value during each revolution of the drivers.

**Train Resistance.** — The total train resistance includes the following:

*Rolling friction*, which depends on the stiffness of the rail and the rigidity of the roadbed, and upon the speed and the weight of the train.

*Journal friction*, which depends on the speed, weight of the train, temperature and condition of lubrication.

*Effect of oscillation and concussion*, which depends upon the square of the speed, the weight of the train, and upon the condition of the track and roadbed.

*Air resistance*, which depends upon the square (approximately only) of the speed, the end area and length of train (number of cars), upon the shape of the end surface, and upon the kind of platforms or vestibules, but is independent of the weight of the train.

In view of the numerous factors which affect the train resistance, it is practically impossible to devise a formula for the resistance per ton of train weight which will be applicable to all types of cars and track construction. Numerous formulas have been suggested, most of which are of the form

$$r = A + Bv + Cv^2,$$

where  $r$  = the resistance in pounds per ton,  $v$  = speed in miles per hour and  $A$ ,  $B$  and  $C$  are constants determined by experiment. The values of these constants naturally depend upon the type of cars, nature of roadbed, number of cars in the train, etc.; consequently the values of these constants as obtained from tests on various types of equipment and track construction differ considerably.

Burch (*Electric Traction for Railway Trains, New York, 1911*) gives the following values for these constants under normal conditions of track and weather. In winter the total train resistance may be as much as 60 per cent greater than the values calculated from the above formula, when these values of the constants are used. An electric locomotive is to be treated as a single car, its weight averaged with the weight of the cars. In the case of a steam locomotive and tender, the tender is to be treated as a car, but the locomotive resistance is to be added as a separate item (see below).

**Value of  $A$ .** — This constant depends chiefly upon the average total weight of car and load. Let  $w$  = this average total weight *per car* in tons; then for

$w =$	15	20	25-30	35	40-45	50	70
$A =$	6.0	5.5	5.0	4.5	4.0	3.5	3.0

**Value of  $B$ .** — This constant depends primarily upon the nature of the track and roadbed and also to some extent upon the weight and type of the car. Burch gives the following values:

Passenger cars on excellent track.....	0.06-0.11
Passenger cars on ordinary track.....	0.10-0.15
Freight cars on ordinary track.....	0.05-0.06

The heavier the car the higher the value of this coefficient.

**Value of  $C$ .** — This constant depends primarily upon the air resistance at the head and rear ends of the train and along the sides of the train. It may be expressed approximately by the formula

$$C = \frac{Ks(0.9 + 0.1N)}{Nw},$$

where  $s$  = the cross section of car in square feet,  $N$  = number of cars,  $w$  = average weight of car and load in tons, and  $K = 0.0010$  for parabolic ends,

wedge-shaped ends, 0.0028 for vestibule cars, 0.0030 for open-plate ends, 0.0033 for freight cars and 0.0040 for flat fronts.

Tests on three-car trains in the Boston-Cambridge subway gave a value of approximately 0.0050 for the constant  $K$ , the higher value being due to the resistance in the tunnel. (See *Elec. Ry. Jour.*, 1912, Vol. 40, p. 280.)

**Table of Train Resistance.** — Using the above values of the constants, the author has calculated the following table for train resistance.

**TRAIN RESISTANCE FOR ELECTRIC TRAINS**

- $N$  = number of cars (including electric locomotive, if any);
- $W$  = average weight of car loaded, in tons (= total weight of train divided by  $N$ );
- $r$  = resistance in pounds per ton;
- $V$  = speed in miles per hour;
- $A$  = cross-section of car in square feet;
- $B$  = constants in the formula;  $K$  taken as 0.0030 throughout.

$$r = A + Bv + \frac{Ka(0.9 + 0.1N)v^2}{Nw} \quad (1)$$

**Other Formulas for Train Resistance.**—Of the numerous other formulas which have been proposed for train resistance the two most commonly employed are Armstrong's formula

$$r = \frac{50}{\sqrt{Nw}} + 0.03v + \frac{0.002a(0.9 + 0.1N)v^2}{Nw}$$

and Mailloux's formula

$$r = 3.5 + 0.15v + \frac{(0.25 + 0.02N)v^2}{Nw}$$

The symbols have the same meaning as above. Armstrong's formula gives considerably lower values than those given by Burch, except for heavy trains; Mailloux's formula gives lower values than those given by Burch except for heavy trains at low speeds, but the difference in most cases is not very great. For other formulas proposed from time to time see Burch, *Electric Traction for Railway Trains*. See also an excellent paper on the resistance of freight trains by E. C. Schmidt in *Trans. A.S.M.E.*, May, 1910.

**Resistance of Steam Locomotives.**—The American Railway Engineering Association recommend the formula for the resistance of a steam locomotive

$$r_1 = 18.7 + \frac{80X}{w_1}$$

where  $r_1$  is the resistance (between cylinder and rim of drivers) per ton weight on the drivers,  $X$  is the number of driving axles and  $w_1$  the total weight in tons on all the drivers. Tests by the American Locomotive Company showed that the resistance per ton weight on the drivers is 22.2 pounds.

**Train Resistance at Starting.**—The formulas given above are not applicable to speeds below about 10 mph. The New York Central tests on electric trains show that the train resistance decreases with decrease in speed to 10 mph., but that as the speed still further decreases the resistance per ton increases. The resistance at starting may be from 6 to 18 pounds per ton, depending upon the condition of the bearings, track, etc., and upon the duration of the stop preceding the starting. These figures also apply to freight trains. Tests on the Rock Island system showed that in the case of a train which had stood overnight in cold weather (i.e., which had become "frozen up"), the starting resistance was 30 pounds per ton. The slack in the car couplings, however, renders it unnecessary for a locomotive to exert sufficient effort to start all the cars at once.

**Grades and Curvature.**—(See *Railways, Location and Permanent Way* for.) An actual up-grade of  $G$  per cent produces a retarding force of  $20G$  pounds per

down-grade of  $G$  per cent produces an accelerating force of  $20G$  pounds per ton. An upward curve gives rise to a retarding force which may be represented by

$$r = 0.058 SC,$$

(excess) curve resistance in lb. per ton,  
 $S$  = speed, m.p.h.,  
 $C$  = degree of curvature.

(See Schmidt and H. H. Dunn, Univ. of Illinois, Bulletin, No. 92.)  
 For angles of curvature up to 12 degrees the angle in degrees may be taken as  $5730 + R$  where  $R$  is the radius of curvature in feet.

**ACCELERATION AND BRAKING.** — The permissible rate of acceleration depends upon a number of factors.

It depends upon the size of the motors; the larger the motors the higher the tractive effort they can develop and therefore the greater the acceleration.

It depends upon the weight on the driving wheels of the car or locomotive; the maximum tractive effort that a motor car can exert without slipping the wheels is from 10 to 15 per cent of the weight on the drivers (see below under *Adhesion Coefficient*).

It depends upon the comfort of the passengers; the higher the acceleration rate the more difficult it is for a passenger to maintain his equilibrium. This also depends to a great extent upon the uniformity of the acceleration.

It depends upon the schedule speed with the least amount of energy the schedule rate should be as high as possible. Very high rates of acceleration, especially in freight service, are not in general justified on this score, as the increase in the size of the motors required may more than offset the saving of energy. The following rates of acceleration represent common practice:

TABLE II.—ACCELERATION RATES

Service	Miles per hour per second
Locomotive, freight service.....	0.1 to 0.2
Locomotive, passenger service.....	0.2 to 0.5
Locomotive, passenger service.....	0.3 to 0.6
Motor cars, interurban service.....	0.8 to 1.3
Motor cars, city service.....	1.5 to 2.0
Motor cars, rapid transit service.....	1.5 to 2.0
Practical rate.....	2.0 to 2.5

— The maximum retardation in braking is limited by the comfort of the passengers, and injury to equipment, a retardation of 1.5 miles per hour per second being the usual practical limit for electric or steam passenger trains, and 2.5 miles per hour per second is sometimes attained. For freight trains the maximum braking retardation is from 0.7 to 0.8 miles per hour per second. The lower the rate of braking the less the energy consumption for a given distance.

**Acceleration Constant.** — The tractive effort required to give to one ton (2,240 pounds) a linear acceleration of one mphps. is 91.2 pounds. To accelerate a train of  $W$  tons requires a tractive effort of  $91.2 aW$  pounds to produce an acceleration of  $a$  mphps., but on account of the accompanying inertia of the rotating parts an additional force is required. This

additional force is proportional to the linear acceleration  $a$  and also depends upon the radius of gyration (*see Mechanics, Principles of*) of all rotating parts, and upon the gear ratio of the motors (i.e., ratio of number of teeth in gear to number of teeth in pinion). The effect of the moment of inertia may be looked upon either as increasing the effective weight  $W$  or as increasing the acceleration constant, the acceleration constant being defined as the quotient of total accelerating force divided by the product of weight and linear acceleration.

The increase in effective weight (in tons) due to any rotating axle or wheel is  $\frac{M}{2000} \left(\frac{K}{r}\right)^2$ , where  $M$  is the weight in pounds of the part in question,  $K$  its radius of gyration (*see Inertia, Moment of*) and  $r$  its actual radius, both in feet. Each motor armature adds to the effective weight  $\frac{M}{2000} \left(\frac{\rho K}{r}\right)^2$  tons, where  $M$  is the weight of the armature in pounds,  $K$  the radius of gyration of the armature in feet;  $r$  the radius in feet of the wheel to which it is geared and  $\rho$  is the gear ratio. The total additional weight  $W_r$  is the sum of the above items for all the rotating parts. The total force in pounds required to produce the acceleration of  $a$  mphs. is then  $CaW$ , where  $W$  is the actual weight of the train in tons and  $C = 91.2 \left(1 + \frac{W_r}{W}\right)$ . This quantity  $C$  is the corrected acceleration constant, and this corrected value should be used in all calculations.

The acceleration constant is raised by the flywheel effect discussed above by about 5 per cent (i.e.,  $W_r/W = 0.05$ ) for heavy cars and locomotives, and between 5 per cent and 10 per cent for light low-speed cars, 8 per cent being an average figure. However,  $C$  is usually taken as 100, corresponding to an increase in effective weight of about 10 per cent. A given linear acceleration of  $a$  mphs. then requires an accelerating force of 100s pounds per ton.

#### TRACTION EFFORT REQUIRED. — Let

$F$  = tractive effort, in pounds per ton, exerted by motors,

$G$  = per cent actual grade (+ for up-grade),

$g$  = degrees of curvature,

$r$  = train resistance, in pounds per ton,

$a$  = acceleration in mphs (- for retardation).

Then the tractive effort required per ton of total train weight is

$$F = 100a + r + 20G + g. \quad (1)$$

**Example.** — Given a train of three 45-ton cars moving with a speed of 20 mph. and accelerating at a rate of 1.5 mphs. up a 1 per cent grade on a straight track; what is the total tractive effort required?

Answer:  $(100 \times 1.5 + 7.8 + 20 \times 1) 3 \times 45 = 24,000$  pounds.

**GEAR RATIO AND SPEED.** — By gear ratio is meant the ratio of the number of teeth in the gear on the wheel axle to the number of teeth in the pinion on the motor shaft. A gear ratio greater than 6:1 is seldom used for railway motors. For a given torque developed by the driving motor, the tractive effort at the wheel rim and the linear speed for a given current depend upon the gear ratio and wheel diameter. Let  $D$  = the diameter of the wheel in inches,  $K$  = the gear ratio,  $F$  = the tractive effort for a given current input; then the tractive effort  $F_1$  for this same current input but for a wheel diameter  $D_1$  and gear ratio  $K_1$  is

$$F_1 = \frac{DK_1}{D_1K} F.$$

If  $V$  is the speed corresponding to the tractive effort  $F$  for a given motor voltage,

then the speed  $V_1$  corresponding to the tractive effort  $F_1$  for the same motor voltage and current is

$$V_1 = \frac{DK_1}{D_1K} V.$$

If the gear ratio is low, the maximum speed will be high and the rate of acceleration low; if the gear ratio is high, the maximum speed will be low and the rate of acceleration high.

For a given motor equipment, train weight, schedule, and profile the energy consumption and temperature rise of the motors depend upon the gear ratio selected, since this in turn determines the amount of coasting; see section below on *Importance of Coasting*. The proper gear ratio can be found only by trial calculation, plotting speed-time and distance-time curves from motor curves based upon different gear ratios, and calculating the energy consumption and temperature rise in the motors as described below.

**MAXIMUM POSSIBLE TRACTIVE EFFORT — ADHESION COEFFICIENT.** — The adhesion or "tractive" coefficient is the quotient (expressed usually as per cent) of the tractive effort in pounds which will slip the drivers, divided by the weight in pounds on the drivers. Burch gives the values in the following table. The maximum possible tractive effort is the product of the adhesion coefficient (as a decimal fraction) by the weight (in pounds) on the drivers.

TABLE III. — ADHESION COEFFICIENTS

Condition of track	Without sand	With sand
Most favorable condition.....	35	40
Clean, dry rail.....	28	30
Thoroughly wet rail.....	18	24
Greasy moist rail.....	15	25
Sleet-covered rail.....	15	20
Dry-snow-covered rail.....	11	15

**Maximum Grade Train can Ascend.** — Let

$W$  = total weight of train in tons,

$W_d$  = total weight on all drivers in tons,

$\rho$  = adhesion coefficient in per cent,

$r$  = train resistance in pounds per ton of total weight,

$G$  = per cent grade,

$g$  = degree of curvature,

$a$  = acceleration in miles per hour per second.

Then the maximum tractive effort which the drivers can exert is  $20 \rho W_d$  pounds, and therefore  $(r + 20 G + g + 100 a) W$  must be less than  $20 \rho W_d$ , or the maximum per cent grade which the train can ascend is\*

$$G = \frac{\rho W_d}{W} - \frac{(r + g + 100 a)}{20}. \quad (3)$$

\*To be exact  $W_d$  should be multiplied by  $\sqrt{1 - (G/100)^2}$ , but except for very heavy grades this correction is negligible.

This grade is greater the less the acceleration, or the greater the retardation. The greater the speed before the train strikes the grade, the greater may the retardation be without bringing the train to rest on the grade, and therefore the steeper the grade it may ascend.

**Example.** — Assume no acceleration or retardation and no curvature, a train resistance of 8 pounds per ton, an adhesive coefficient of 15 per cent, and 25 per cent of total weight of train on drivers. Then the maximum grade the train can ascend is  $G = 15 \times 0.25 - 9\% = 3.35$  per cent.

The highest permissible grade is when all the weight is on the drivers, e.g., single cars or trains of motor cars with all axles equipped with motors. On steam freight roads the maximum grade seldom exceeds 2 per cent, and is usually considerably less, except in very mountainous country.

**Weight of Locomotive.** — The weight of locomotive required to accelerate a train weighing  $W$  tons at the rate of  $a$  miles per hour per second up a grade of  $G$  per cent on a  $g$  degree curve against a frictional resistance of  $r$  pounds per ton, when the  $q$  per cent of the weight is on the drivers and the coefficient of adhesion is  $p$  per cent, is given by the following formula:

$$\text{Weight of locomotive} = \frac{5W}{pq} (100a + r + 20G + g).$$

**Example:** What weight of locomotive is required to accelerate a 400-ton train at the rate of 0.5 mile per hour per second up a 0.1% grade against a frictional resistance of 8 lb. per ton, when 80% of the weight is on the drivers and the coefficient of adhesion is 20%?

$$\text{Weight of locomotive} = \frac{5 \times 400}{20 \times 80} (50 + 8 + 2) = 75 \text{ tons.}$$

#### POWER REQUIRED AT GIVEN SPEED. — Let

$r$  = train resistance in pounds per ton of total train weight,

$G$  = per cent grade,

$g$  = degree of curvature,

$a$  = acceleration in mphps.,

$v$  = speed in mph.,

$W$  = total weight of train in tons.

Then the power required at the rims of the drivers is  $1.99 v (r + 20G + g + 100a)$  watts per ton, or  $p_0 = 2.67 \times 10^{-8} vW (r + 20G + g + 100a)$  horse power, total. (4)

The power input  $p_i$  to the car or locomotive is equal to the power at the rims of the drivers divided by the over-all efficiency  $\epsilon$  of the controller, motors and gears, i.e.,

$$p_i = \frac{1.99 Wv (r + 20G + g + 100a)}{1000 \epsilon} \quad \text{kilowatts} \quad (5)$$

**Efficiency of Motors.** — The over-all efficiency of the motors and gears when the motor is operating at full line voltage does not vary considerably for loads ranging from 50 to 150 per cent of rated load. The maximum efficiency is usually at about rated load, and has the values given in Table IV. At 50 and 150 per cent load, the efficiency may be from 3 to 10 per cent less, depending upon the design and the type of motor. The variation in efficiency with load is usually greater with alternating-current series than with direct-current motors.

**Average Over-all Efficiency During Controller Period.** — The over-all efficiency of the motors and controller depends upon the type of control employed and upon the resistance inserted or the connections made by the controller. Most modern controllers for interurban cars are provided with a

TABLE IV. — MAXIMUM OVER-ALL EFFICIENCY OF MOTORS AND GEARS AT RATED VOLTAGE.

Horse power, 1-hour rating	Kind of motor	Max. eff., per cent
30-100	D.C. geared.....	83-85
100-250	D.C. geared.....	80-83
250-500	D.C. geared.....	91-93
50-200	A.C. series geared.....	70-80*
200-500	3-phase induction geared.....	85-89

\* Including step-down transformers.

current-limiting device which limits the current to a given value, usually the value of the current corresponding to the 1-hour rating of the motor. Under these conditions the average over-all efficiency of the motors and controller over the whole of the controller period (i.e., from time of starting until full line voltage is established across each motor or until all resistance is cut out) may be expressed as follows, on the assumption (which is very nearly exact) that the speed of the motor varies directly as the voltage impressed across its terminals:

Let  $\epsilon$  = the over-all efficiency of the motors and gears at end of controller period. Then for straight resistance control with direct-current or induction motors the average efficiency during the controller period is  $\epsilon/3$ ; for series-parallel control with 2 direct-current motors the average efficiency during the controller period is  $2\epsilon/3$ ; with 4 direct-current motors first all in series, then 2 series sets in parallel, and then all 4 motors in parallel the average efficiency during the controller period is  $8\epsilon/11$ ; for alternating-current series motors with voltage control the average efficiency during the controller period (including losses in step-down transformers) is about  $0.90\epsilon$ . Hence for a motor having an 85 per cent efficiency at the 1-hour rating and the starting current limited to the corresponding current rating, the average over-all efficiency of the controller, motors and gear during the controller period is

For straight resistance control.....	43 per cent
For series-parallel control, direct-current motors.....	57 per cent
For series-series-parallel control, direct-current motors..	62 per cent

Example. — Given a train of three 45-ton cars each car equipped with two 200-horse-power direct-current motors. What is the input to each motor if the speed is 30 mph. and the train is accelerating at 1.0 mph/s. up a 2-per-cent grade, the track being straight, and full line voltage being across each motor?

Answer: From Table I the train resistance is  $r = 10.5$ , and from equation (4) the total power output is

$$P = 2.67 \times 10^{-6} \times 30 \times 135 (10.5 + 20 \times 2 + 100 \times 1) \\ = 1627 \text{ horse-power,}$$

or  $1627/6 = 271$  horse power per motor. Assuming an efficiency of 87 per cent, the input to each motor is  $271 \times 0.746/0.87 = 232$  kilowatts, and the total input to the train  $6 \times 232 = 1392$  kilowatts.

If the train accelerates at this same rate from rest to a speed of 30 mph. at the end of the controller period (series multiple control) the grade being 2 per cent throughout, the average output of the motor would be the output corresponding to half speed or 15 mph., or 136 horse power per motor, requiring an

average input of  $136 \times 0.748/0.57 = 178$  kilowatts, and the average input to the train during the controller period would be  $6 \times 178 = 1068$  kilowatts.

**SPEED-TIME AND DISTANCE-TIME CURVES.** — To determine the energy required to propel a car or train a given distance over a given track in a given time requires the consideration of a number of factors which can best be taken into account by the construction of various kinds of time curves. Such curves may be constructed with practically any degree of accuracy desired when the profile of the track, the weight of the train, the various resistances, schedule speed, time of stops, etc., are accurately known. Such data are, however, seldom known with any great precision, and consequently elaborate methods of plotting and calculation are seldom justified. Below will be given (1) some results of actual tests, (2) a rough but simple method of approximating the energy requirements, (3) a step-by-step method, which, though tedious in application, is susceptible of any degree of accuracy desired, provided the given data are accurately known, and (4) an analytical method by which the effect of changes in the time of coasting, rates of acceleration and braking, etc., may be predetermined.

The following terminology will be employed:

**Speed-time Curve.** — A curve showing the speed (in mph.) plotted as ordinates against elapsed time (in seconds) as abscissas; e.g., the curve *ABCE* in Fig. 1. A speed-time curve may be conveniently divided into four parts, namely:

Fig. 1.

**Controller Period.** — The period from starting until full line-voltage is established across each motor; i.e., the portion *AB* of the curve in Fig. 1.

**Motor-Curve Period.** — The period during which the motor is operating on full line voltage; i.e., the portion *BC* in Fig. 1. The relation between speed and tractive effort during this portion of the run is fixed by the motor characteristics; specifically by the speed-torque curve of the motor and the gear ratio.

**Coasting Period.** — The period during which the car or train is coasting; i.e., the portion *CE* in Fig. 1.

**Braking Period.** — The period during which the brakes are applied; i.e., the portion *EF* in Fig. 1.

**Distance-time Curve.**—A curve showing the distance covered (in feet) plotted as ordinates against elapsed time (in seconds) as abscissas; e.g., the curve *AG* in Fig. 1.

**Current-time Curve.**—A curve showing the line current (in amperes) plotted as ordinates against elapsed time (in seconds) as abscissas; e.g., the curve marked "Amperes" in Fig. 1.

**Voltage-time and Power-time Curves.**—Curves showing respectively the voltage per motor (or the line voltage) and the power input to the motor (or train) plotted as ordinates against elapsed time (in seconds) as abscissas.

**Average Speed and Schedule Speed.**—The average speed *V* is the total distance run *L'* (in miles) divided by the time (in hours) the train is actually running. The schedule speed *S* is the total distance run (in miles) divided by the total time (in hours) of the run from one end of the road to the other, including time of all stops at intermediate stations. If the total time of all the intermediate stops is *T<sub>s</sub>'* seconds, then

$$V = \frac{S}{1 - \frac{T_s'S}{3600 L'}} \quad (6)$$

where *V* and *S* are in miles per hour and *L'* is the total length of route in miles.

**Duration and Frequency of Station Stops.**—The duration of each stop for surface cars ranges from 5 to 10 seconds, for elevated and subway trains from 10 to 30 seconds, for interurban trains from 10 to 40 seconds. The stops per mile are the reciprocal of the average distance in miles between stops. For the six most important elevated and subway lines in Europe and America, the stops per mile average 2.5.

**Average Equivalent Grade (*G*).**—Grades may be taken into consideration by calculating the sum *H<sub>1</sub>* of all the rises on upgrades and the sum *H<sub>2</sub>* of all the drops on down grades, and taking for the average "equivalent" upgrade in per cent

$$G = \frac{100(H_1 - 0.5 H_2)}{L} \quad (7)$$

where *H<sub>1</sub>* and *H<sub>2</sub>* are in feet and *L* is the total length of the route in feet. On a round trip *H<sub>1</sub>* = *H<sub>2</sub>*, and the "equivalent" grade in per cent is

$$G = \frac{50H_1}{L}$$

This method of dealing with grades is equivalent to assuming that half the kinetic energy stored in the train on down grades is utilized in taking the train up the following upgrade. The amount of energy thus rendered available of course will depend upon the amount of braking necessary on down grades to prevent excessive speeds and also upon the location of the stops with respect to the grades. The figure  $\frac{1}{2}$  is taken as an approximate average; this figure may be varied as seems reasonable in view of the actual profile.

**Average Angle of Curvature (*g*).**—Curves may be taken into account by finding the average curvature, i.e., finding for each curve the product of the degree of curvature by the length of the curve, adding all these products and dividing by the length of the route.

**ENERGY CONSUMPTION FROM TESTS.**—The table on p. 1302 gives the energy consumption, as found by tests, for a number of typical services. This table will be found useful as a rough check on any calculations made for a specific service. Methods of making such calculations are given below.

**APPROXIMATE METHOD OF CALCULATING ENERGY CONSUMPTION.**—The following method is based upon simple kinetic principles, and, if certain characteristics of the run are known, gives the actual energy output at the wheel rims. This fact makes the method useful, not only for rough calculations, but also to check calculations made by the step-by-step method.

When the method is applied to checking purposes, the column of Table VI. headed "Actual energy output" should be used, and the input calculated from the known efficiencies. When applied to rough calculations, the column headed "Approximate electrical energy input" should be used. In the latter case the maximum speed and length of run with power on are not known, but it is possible to assume certain values, based upon experience, which will give a rough approximation to the energy required. Let

$V$  = average running speed in miles per hour,

$V_m$  = maximum speed in miles per hour,

$L$  = length of run in miles,

$L_p$  = distance traveled, with power on, in miles,

$n = 1/L$  = number of stops per mile including one terminus,

$r$  = average train resistance, in lb. per ton (Say that corresponding to a speed from 10 to 20 per cent greater than the average speed),

$G$  = average equivalent grade, in per cent,

$g$  = average curvature in degrees,

$K = \frac{V_m}{V}$  = ratio of maximum to average speed; see Table VII,

$Q = \frac{L}{L_p}$  = ratio of length of run to distance traveled with power on; see Table VII.

TABLE VI.—OUTPUT AT WHEEL RIM AND INPUT TO CAR  
IN WATT-HOURS PER TON-MILE

Energy for	Actual energy output at wheel rims of cars	Approx. electrical energy input to cars
Acceleration.....	$\frac{V_m^3}{36.2L}$	$\frac{K^3 n V^3}{25}$
Train resistance.....	$\frac{1.99 r L_p}{L}$	$\frac{2.9 r}{Q}$
Grades.....	$\frac{39.8 G L_p}{L}$	$\frac{57 G}{Q}$
Curves.....	$\frac{1.99 g L_p}{L}$	$\frac{2.9 g}{Q}$
Total.....	Sum	Sum

NOTE.—25 = 36.2  $\epsilon$ , 57 = 39.8  $\epsilon$ , and 2.9 = 1.99  $\epsilon$ , where  $\epsilon$  is the efficiency, taken as 0.7. The formula for energy due to curves assumes each degree of curvature to be equivalent to a train resistance of one pound per ton, which is probably high.

TABLE VII.—VALUES OF K AND Q

over 5.0	2.00	2.00	3.00

(The above method was worked out by D. C. Woodbury and W. A. Del Mar, the table being based upon a large number of actual and calculated runs.)

**Example.**—A multiple-unit train has a speed (excluding stops) of 25 miles per hour and makes 0.8 stops per mile. It ascends an average grade of 0.143 per cent. What will be its energy consumption in watt-hours per ton-mile?

From Table VII we find for  $s = 0.8$ , that  $K = 1.47$  and  $Q = 1.99$ . Then using the formulas in Table VI, the results in the table on the next page are obtained, assuming 6.5 pounds per ton for friction.

**Efficiency of Run.**—The formulas given above enable one to judge the effect upon the energy consumption, of altering any of the principal physical elements upon which the run is based.

From the formulas for kinetic energy it is obvious that a low value of  $K$  means a low energy consumption. A low value of  $K$ , however, means a "square" speed-time curve; i.e. for low energy consumption the controller, acceleration and braking periods should be as short as possible, or in other words, the rate of acceleration and braking should be as great as practicable.

The quantitative effect of changing any of these variables may be estimated by the analytical method given further on.

Energy for	Watt-hours per ton-mile	
Acceleration.....	$\frac{1.47^2 \times 0.9 \times 25^2}{25}$	48.5
Train resistance.....	$\frac{2.9 \times 6.5}{1.99}$	9.5
Grades.....	$\frac{57 \times 0.143}{1.99}$	4.1
Total.....		62.1

This example worked out by the step-by-step method gave 60.5 watt-hours per ton-mile.

#### STEP-BY-STEP METHOD OF PLOTTING SPEED-TIME CURVES.

— There is no way of exactly predetermining a speed-time curve except by a number of successive trials. That is to say, the time the current is kept on, the time of coasting and the time of braking must each be guessed and it is usually necessary to make a number of trials, by varying the proportion of motor run, coasting and braking, before the given distance is traversed in the desired time.

If the characteristics of the train and its equipment are expressed numerically, the principles of mechanics enable such trial runs to be plotted on paper and the proper proportion of motor run, coasting and braking, selected to make the train travel the desired distance in the given time. For a given motor equipment on a given route it is possible to plot by a step-by-step method these speed-time curves, and then from these curves and the characteristic curves of the motors the various characteristics, such as energy consumption, root-mean-square current, etc., may be determined. The accuracy of this method depends solely upon the accuracy with which the assumed data are known. The necessary data are:

Profile and alignment of road.

Characteristic curves of the motors.

$W$  = total weight of train in tons,

$T$  = the time of run in seconds between successive stops,

$I_0$  = the permissible starting current, or

$a$  = the acceleration in miles per hour per second during the controller period,

$b$  = the braking rate in miles per hour per second,

$r$  = the train resistance in pounds per ton at any speed.

**Determination of Acceleration and Retardation Rates.** — From the motor characteristics, which are usually given in the form indicated in Fig. 2, determine the tractive effort and speed corresponding to the permissible starting current. This is usually taken as the current corresponding to the 1-hour rating; in the case of the motor whose characteristics are shown in Fig. 2, this current is 315 amperes, the speed 19.6 mph. and the tractive effort 4,300 pounds. If each car is equipped with two motors, the weight corresponding to each motor is half the weight of the car. If the cars weigh 44 tons each, then the tractive effort per ton developed by the motors at this speed is  $4,300/22 = 195$  pounds per ton. At the point where the motors are changed from series to parallel the speed

will be approximately one-half the speed at rated voltage or 9.8 mph. If the average line voltage is less than the rated voltage, these speeds should be reduced in proportion to the ratio of the actual to the rated voltage. In the case selected the average line-voltage is 571 volts; hence the speeds corresponding to the parallel and series points are 18.6 and 9.3 mph respectively. These speeds and the corresponding tractive efforts are entered into Table VIII.

From the motor characteristics determine the tractive effort ( $f$ ) in pounds per ton and the corresponding speeds ( $v$ ), corrected for line voltage, up to the maximum permissible speed, and enter these in Table VIII. Also enter into this table the train resistance corresponding to the various speeds. In the table given, the train resistance is calculated from Burch's formula for three 44-ton cars, the cross section of each car being 120 square feet, and the constant  $K$  is taken equal to 0.0050 (subway service). The formula is then

$$r = 4.0 + 0.13v + 0.0055v^2,$$

where  $v$  is the speed in miles per hour.

The available tractive effort in pounds per ton for acceleration on any grade is then  $f - r - 20G$ , and the acceleration rate is (assuming an acceleration constant of 100)

$$a = \frac{f - r - 20G}{100},$$

where  $G$  is the "equivalent" grade (including curvature, see above), in per cent. The value of  $a$  is calculated for grades of 0, 1, 2, 3, etc., per cent, both up and down, including the largest up and down grade. These values are entered into Table VIII. The maximum speeds are the speeds for which the acceleration becomes zero. These can be obtained by plotting the accelerations against speed, and finding the speed at which the curves cross the speed axis.

Similar calculations should also be made for the retardation on up-grades when the train strikes such a grade, with power on, at a higher speed than the free running speed on the grade, and also for the coasting period when no power is on. When power is on, the friction of the gears and motors is allowed for in the motor tractive effort curve, the tractive effort curve being the gross tractive effort less these losses. The friction of the gears and motors may be taken as approximately 5 per cent of the rated tractive effort, which, in the special case under consideration is  $0.05 \times 195 = 10$  pounds per ton. The total train resistance in coasting is then the normal train resistance plus the resistance of gears and motors.

In the Tables  $a +$  acceleration signifies an actual increase in velocity,  $a -$  acceleration a retardation, or decrease in velocity.

The braking rate is assumed constant, usually  $b = 1.5$  mph/s.

Fig. 2.

TABLE VIII.—ACCELERATION RATES

	Motor tractive effort, pounds per ton	Train resistance, pounds per ton	Acceleration rates, mphs., = $a$						
			Per cent equivalent grade given in first line

	27	15	-0.48	-0.28	-0.08	.....	.....	.....	.....
	45	13	-0.28	-0.08	.....	.....	.....	.....	.....
	0	34	-0.94	-0.74	-0.54	-0.34	-0.14	+0.06	+0.26
	0	31	-0.91	-0.71	-0.51	-0.31	-0.11	+0.09	+0.29
	0	28	-0.88	-0.68	-0.48	-0.28	-0.08	+0.12	+0.32
	0	25	-0.85	-0.65	-0.45	-0.25	-0.05	+0.15	+0.35
	0	23	-0.83	-0.63	-0.43	-0.23	-0.03	+0.17	+0.37
	0	21	-0.81	-0.61	-0.41	-0.21	-0.01	+0.19	+0.39
	0	19	-0.79	-0.59	-0.39	-0.19	+0.01	+0.21	+0.41

The train resistance is assumed to be 6 lb. per ton from zero speed to 9.3 mph.

**Construction of Acceleration and Retardation Time Curves.**—The method is to construct a set of acceleration speed-time and distance-time curves, a set of coasting speed-time and distance-time curves, and a braking speed-time and distance-time curve. The construction of these curves is based on the following relations:

$v_1$  = the speed in miles per hour at time  $t_1$ ,

$v_2$  = the speed in mph. at time  $t_2$ ,

$$\frac{v_1 + v_2}{2} = \text{average speed during the interval } t_2 - t_1,$$

$a_1$  = the acceleration in miles per hour per second at time  $t_1$ ,

$a_2$  = the acceleration in miles per hour per second at time  $t_2$ ,

$$\frac{a_1 + a_2}{2} = \text{average acceleration during the interval } t_2 - t_1; \text{ (for the first interval, } a_1 \text{ is the acceleration corresponding to half the speed at end of controller period),}$$

$s_1$  = the distance in feet from the starting point at time  $t_1$ ,

$s_2$  = the distance in feet from the starting point at time  $t_2$ .

A small change in speed,

$$t_2 - t_1 = \frac{v_2 - v_1}{a} \quad \text{seconds} \quad (8)$$

and the distance covered in this interval is

$$x_2 - x_1 = 1.466 v (t_2 - t_1)$$

or, when the speed is plotted against time,

$$x_2 - x_1 = 1.466 \times (\text{Area of speed-time curve between } t_1 \text{ and } t_2)$$

From equation (8), using the values of  $a$  given in Table which any speed is reached may be calculated. The calculations for the special case under consideration are given in Figs. 3, 4 and 5. The distance-time curves are plotted in Figs. 3, 4 and 5. The distance-time curves are obtained by integrating the speed-time curves and multiplying by 1.466 (see also Figs. 3, 4 and 5).

TABLE IX.—DATA FOR ACCELERATING, COASTING, AND RETARDING SPEED TIME CURVES

Speed $v$		Total time in seconds to accelerate from 0 to $v$				
		Per cent equivalent grade

20 0E

The speed during the braking period  $t$  seconds before the train stops is  $v = w$  and the distance to travel to come to rest is  $x = \frac{1}{2} wt^2$ .

In the special case of a braking rate of 1.5 mphps.,

$$v = 1.5 t \text{ miles per hour,}$$

and the distance to travel to come to rest is

$$x = \frac{1.466 \times 1.5 t^2}{2}.$$

The corresponding curves are given in Fig. 6.

Fig. 3. Accelerating

Fig. 5. Retarding, Power Off

Fig. 6. Braking

**Time Curves for Given Profile and Alignment.** — With these four sets of curves the speed-time curve for any given run with this particular equipment may be rapidly constructed. For intermediate grades interpolation may be readily made. In Fig. 7 is given a profile and alignment between two stops. The first step is to make up a table like Table X, dividing the route into sections such that the "equivalent" grade (= actual grade plus, say, 0.05 per cent for each degree of curvature, assuming a resistance of 1 pound per ton per degree of curvature) is the same throughout each section.

TABLE X. — "EQUIVALENT" GRADES

Stop	Distance between stops, feet	Length of section in feet	Per cent grade = $G$	Radius of curvature in feet	Degree of curvature = $S$	"Equivalent" grade $G' = G + 0.05 S$
A	....	505	.....	....	...	.....
	....	145	.....	1130	5.0	+0.95
	....	908	+0.70	1130	5.0	+0.95
	....	77	+0.50	1130	5.0	+0.75
	....	633	+0.50	....	...	+0.50
	....	273	+3.00	....	...	+3.00
	....	273	+3.00	800	7.2	+3.36
	....	347	.....	800	7.2	+0.36
	....	94	.....	....	...	.....
	....	308	-2.95	....	...	-2.95
	....	800	+3.00	....	...	+3.00
	....	1862	-3.00	....	...	-3.00
	....	192	-3.00	5000	1.2	-2.94
	....	234	+0.12	5000	1.2	+0.18
	....	178	+0.12	....	...	+0.12
....	69	+0.12	5000	1.2	+0.18	
B	....	358	.....	5000	1.2	+0.06
	7321	165	.....	....	...	.....

For a complete round trip over the entire route the time curves must be plotted for the entire route in both directions. The run in one direction between two stations only will be considered in the numerical calculations given below.

Next lay off on a piece of tracing cloth, see upper part of Fig. 7, a distance equal to the time of run between the two stations (156 seconds in the example), to the same scale as Figs. 3 to 6. The braking speed-time curve can be laid off directly at the far end of the run by placing Fig. 6 under the tracing cloth and tracing the curve. Similarly, by placing Figs. 3 and 4 under the tracing cloth and tracing for the proper distance the curve corresponding to the proper grade, an acceleration curve can be built up until this curve intersects the braking curve. If the total distance, as read off from the corresponding distance-time curve, is greater than the actual distance, it will be necessary to introduce a coasting period of proper duration to make the total distance as read off from the distance-time curves equal to the actual distance. This can be done by placing Fig. 5 under the tracing cloth, and by cut and try finding the proper amount of coasting.

A more accurate, but tedious method, is to plot a power-time curve by multiplying the total current per train at successive intervals of time by the average line voltage during this interval, and then integrating this curve to find the total watt-seconds. This area, in watt-seconds, divided by (3600  $W/L$ ) will give the watt-hours per ton-mile. In making such a calculation note that during the series part of the controller period the current per train is equal to the current per motor multiplied by half the number of motors.

**Root-mean-square Current per Motor.**—This may be found by squaring the ordinates of the current-time curve (current per motor), plotted as described above, and dividing by the time of run including stops and taking the square root of the quotient. Or, the current-time curve may be plotted in polar co-ordinates, taking time in seconds as the angle in degrees and current in amperes as the radius vector. See Fig. 8. Calling  $B$  the area of this curve, the unit of area being the square whose side has a length corresponding to 1 ampere, then the root-mean-square current is

$$I_e = 10.7 \sqrt{\frac{B}{T + T_s}}$$

where  $T$  is the time that the train is moving and  $T_s$  the standing time, both in seconds.

**Average Motor Voltage.**—For a simple run, such as shown in Fig. 1, average motor voltage during the controller period is equal to approximately 55 per cent of the line voltage, assuming 10 per cent of line voltage across the motors at the instant of starting. Let

- $E$  = average line voltage,
- $T_1$  = time of controller period, from speed-time curve,
- $T_2$  = time motor is running on full line voltage,
- $T$  = total time that the train is moving,
- $T_s$  = total standing time.

Then average motor voltage for the entire run is

$$E_m = \frac{0.55ET_1 + ET_2}{T + T_s}$$

For a complex run, where the controller is shut off and put on again during the run, a voltage-time curve may be plotted and the average ordinate obtained by integration.

**MOTOR CAPACITY.**—A railway motor is usually rated in terms of the output in kilowatts or horse-power which it will give when run for 1 hour at rated voltage with a temperature rise above the surrounding air not exceeding 75° C. in any part of the motor, other than the commutator (see *Standards of the A. I. E. E.*).

The size of motor required for any particular service (i.e. for a given route, schedule, weight of car, line voltage and per cent coasting) depends upon two factors, (1) the motor must be of such a size that the maximum current required will not produce harmful sparking at the brushes or dangerous mechanical stresses in any part of the motor, and (2) the temperature must not rise to a value which will cause the insulation to deteriorate.

**Size of Motor Limited by Commutation and Mechanical Stresses**—The maximum current is usually that required at starting, and since the start-

Fig. 8.

ing current remains practically constant up to the point where full line voltage is impressed across the motor, the corresponding maximum horse-power output of the motor can be calculated directly from equation (4), when  $v$  is taken as the speed at the end of the controller period and  $W$  as the weight of the train per motor, i.e.,  $W$  is taken equal to the total weight of train divided by the number of motors. A safe rule for non-interpole motors in single-car or multiple-unit service is to limit the starting current to a value equal to the rated current. For interpole motors in like service the starting current may safely be 25 to 50 per cent in excess of the rated current.

In locomotive work a heavier starting current is sometimes demanded, and due to the low acceleration rate during the starting period the motor must carry this current for a longer interval than in the case of single-car or multiple-unit service. In selecting a motor for such service, information should be obtained from the manufacturer as to the maximum current which the motor can safely carry during a limited period, say for 5 minutes. This maximum current may be limited by sparking at the commutator, by mechanical stresses, or by local heating of the windings. See also section below on *Size of Motor Limited by Short-time Heating*.

TABLE XI.—RATED AND CONTINUOUS CAPACITY OF WESTINGHOUSE RAILWAY MOTORS

	Type, Westing- house	Rated H.P.	Rated voltage	Rated amperes	Continuous current capacity		Weight in pounds
					At 300 volts	At 450 volts

	300	200	550	310	150	130	6475

**Size of Motor Limited by Heating.**—The heat developed in a railway motor is carried partly by conduction through the several parts and partly by

convection through the air to the motor frame, whence it is distributed to the outside air. As the temperature of the several parts is thus dependent not only upon their own internal losses, but also upon the temperature of the neighboring parts, it becomes necessary to determine the actual value and distribution of losses in a railway motor for a given service in order to determine with precision what the temperature rise will be; or, *vice versa*, to determine what size of motor will be required to avoid too great a temperature rise.

For ordinary electric railway calculations, however, in view of the other uncertain elements which enter, it is usually sufficiently accurate to assume that the *relative* temperatures in the different parts of the motor are independent of the *relative* values of the copper and core losses. The copper loss, i.e., the rate at which heat is developed in the windings, is proportional to the square of the current, and the core loss, i.e., the rate at which heat is developed in the core, due to hysteresis and eddy currents, may be taken as proportional to the first power of the voltage across the motor terminals (this latter relation being approximate only). When the motor reaches a constant temperature under a constant load, the temperature of any part will then be proportional (approximately) to the total power (kilowatts) lost in the windings and core. Similarly, under a fluctuating load continuing over a long period during which there are no excessively long breaks or excessive overloads, the temperature becomes fairly constant and the rise is proportional to the average power (kilowatts) lost during this period. There will be times at which the temperature rise will exceed this average and times at which it will be less, but on account of the heat storage capacity (or thermal capacity) of the materials of which the motor is made the fluctuations in temperature will be very much less than the fluctuations in the load.

**Size of Motor Limited by Average Temperature Rise.**—The manufacturers supply information as to the current which any motor will carry continuously (on stand test) without overheating, at various voltages from one-half to full voltage; see Table XI. From this information, making the assumptions noted in the preceding paragraph, it is possible to determine the approximate temperature of the motor for any given run or series of runs. The process is to calculate the root-mean-square current per motor and the average motor voltage for the particular service contemplated, using the methods given above in the paragraphs headed *Root-Mean-Square Current per Motor* and *Average Motor Voltage*. Call these values of the r.m.s. service current and average motor voltage  $I_s$  and  $E_m$  respectively. Let  $J_c$  be the continuous-current capacity at a given voltage  $E_c$ , as given by the manufacturer (see Table XI), and let  $T_c$  be temperature rise corresponding to this continuous rating. (Motors having ordinary fibrous insulation are rated on the basis of a  $75^\circ\text{C}$ . temperature rise on stand test, which corresponds to about  $65^\circ\text{C}$ . rise in actual service, due to better ventilation; see *Standardisation Rules of the A.I.E.E.*; hence for ordinary motors  $T_c$  is  $65^\circ\text{C}$ .) Let  $J_e$  be the corresponding core loss and  $K_e$  the corresponding copper loss and  $L_e = J_e + K_e$  be the corresponding total electrical losses. Then the total electrical losses corresponding to the average load are

$$L_a = \frac{E_m}{E_c} J_c + \left(\frac{I_s}{I_c}\right)^2 K_e$$

and the average temperature attained by the motor in service will be approximately

$$T_a = \frac{L_a}{L_e} \cdot T_c$$

For safe operation the average temperature rise  $T_a$  should never exceed the value  $T_c$ , which for motors with ordinary fibrous insulation is  $65^\circ\text{C}$ .

**Approximate Values of  $J_c$  and  $K_c$ .** — When the core loss and copper loss are not given separately, a rough estimate of  $J_c$  and  $K_c$  may be made by assuming that at rated load (one-hour rating and line voltage) the core loss is, say,  $\frac{1}{4}$ th of the total electrical losses. The total electrical losses  $L_r$  in kw. at rated load may be found from the characteristic curves of the motor by using the formula

$$L_r = P \left( \frac{0.97}{\epsilon} - 1 \right),$$

where  $P$  is the one-hour rating in kilowatts,  $\epsilon$  the efficiency of the motor with gears, and the 0.97 takes into account the frictional losses in the motor and the gears. Let  $I_r$  be the rated current and  $E_r$  the rated voltage; then

$$J_c = \frac{L_r E_c}{4 E_r} \quad \text{and} \quad K_c = \frac{3 L_r \left( \frac{I_c}{I_r} \right)^2}{4}$$

**Size of Motor Limited by Short-time Temperature Rise.** — When the service is such that the motor must take a heavy current for a comparatively long interval (e.g., a long starting period or a heavy grade for a considerable distance) followed by a like period of light load or no load, the average temperature for the run, as calculated above, may be within the required limits, but the short-time temperature rise may be excessive. This short-time temperature rise depends upon the heat-storage capacity of the motor, i.e., upon the energy loss (number of kilowatt-hours of heat developed in it) required to raise its temperature one degree, say, assuming no radiation of heat from its surface. The one-hour rating of a motor is an indirect measure of this heat-storage or thermal capacity.

The temperature-time curve during the first hour's application of a load is practically a straight line whose slope is proportional to the load. The rise in temperature of the motor due to a short-time load may then be assumed to be proportional to the energy (kilowatt-hour) input during this time, and the factor of proportionality may be obtained from the one-hour rating as follows: Let  $T_r$  = the temperature rise at the end of one hour due to a load equal to the one-hour rating of the motor (rated current and rated voltage),  $L_r$  = the total electrical losses in kilowatts corresponding to the rated load,  $L_a$  = the total electrical losses in kilowatts corresponding to the average load in service ( $L_r$  and  $L_a$  may be estimated by the method given in the preceding section),  $L_p$  = the total electrical losses in kilowatts corresponding to any given short-time or peak load,  $t_p$  = the number of minutes' duration of this peak load. Then during this interval  $t_p$  the rise of temperature above the average value  $T_a$  is

$$T_p - T_a = \frac{t_p T_r}{60 L_r} \cdot (L_p - L_a).$$

$T_p$  as calculated from this formula gives approximately the maximum temperature rise during the run. For safe operation this maximum temperature rise  $T_p$  should not exceed the safe limit stated by the manufacturer. For motors with ordinary fibrous insulation  $T_p$  should not exceed  $75^\circ \text{C}$ .

**Final Choice of Motor.** — No motor should be employed for a given service which does not meet the above requirements regarding the maximum current and heating limits. A larger motor than that fixed by these requirements may prove the cheaper in the long run, if by using such a motor the energy consumption can be materially reduced by increasing the amount of coasting during the run. In any event the motor should be of sufficient capacity to permit of a reasonable amount of coasting under normal conditions, so that there will be a sufficient margin in which to make up for lost time, due to unexpected slow-downs or extra stops.

**ANALYTICAL METHOD OF PREDETERMINING ENERGY AND MOTOR EQUIPMENT.**—The following method was suggested by that developed by Cary T. Hutchinson, in two papers in the *A.I.E.E. Trans.*, Vol. 19, p. 120, 1902, and Vol. 22, p. 657, 1903. In this method a speed-time curve similar in shape to the curve *ABCEP* in Fig. 1 is assumed. That is, the acceleration during the controller period, the train resistance and the braking retardation are all assumed constant, but a "motor-curve" period (*BC* in Fig. 1) is also taken into account, this latter constituting the essential difference between this method and the "straight-line" speed-time curve method frequently employed for approximate calculations. The introduction of this motor-curve period in the calculations enables one to approximate much more closely actual working conditions, and the results are much more accurate. In addition this method enables one to predetermine, without choosing any particular equipment, the effect of rate of acceleration, rate of braking, per cent of coasting, etc.

TABLE XII.—AVERAGE MOTOR CHARACTERISTICS

$y$ —ratio of any given speed to speed at rated input	$f$ —ratio of tractive effort at this speed to rated tractive effort	$\beta$ —ratio of power input at this speed to rated input
0.80	2.06	1.82
0.85	1.67	1.54
0.90	1.38	1.30
0.95	1.19	1.14
1.00	1.00	1.00
1.05	0.83	0.87
1.10	0.71	0.78
1.15	0.61	0.70
1.20	0.53	0.625
1.25	0.46	0.57
1.30	0.41	0.525
1.35	0.365	0.48

1.85	0.14	0.28
1.90	0.13	0.265
1.95	0.125	0.26
2.00	0.12	0.25

**Average Motor Characteristics.**—To take into account the motor-curve portion of the speed-time curve it is necessary to consider the speed,

tractive effort and current input characteristics of the motors. However, instead of using the motor characteristics for any specific motor, the average characteristic curves of direct-current motors\* given by Mr. Hutchinson are employed, see Table XII. These average characteristics were calculated by plotting the characteristic curves for the various sizes of direct-current motors manufactured by the General Electric and Westinghouse Companies, expressing the various quantities (current, speed, and tractive effort) as fractions of their values at rated load. Such curves are found to lie very close together, which justifies the use of a single set of curves representing the averages for the various motors. Mr. Hutchinson's curves were calculated from the characteristics of non-interpole motors, but have been found to check also quite closely with the curves for interpole motors. It is also found that these curves have practically the same shape irrespective of what point, between 75% and 125% of rated load, on the curves is taken as unity.

**Method of Calculation.** — The following symbols are employed:

$n$  = number of stops per mile = total number of stops including one terminus divided by the distance between termini in miles,

$V$  = average running speed in miles per hour,

$T = \frac{3600}{nV}$  = average running time between stops in seconds,

$a$  = acceleration in miles per hour per second,†

$b$  = braking rate in miles per hour per second,

$r$  = train resistance in pounds per ton corresponding to a speed from 10 to 20% greater than the average speed  $V$ ,

$G$  = "equivalent" grade in per cent (see above),

$g$  = average curvature, in degrees (see above),

$c = \frac{r + 20G + g}{100}$  = average "effective" coasting retardation in miles per hour per second,

$e$  = over-all efficiency (expressed as a fraction) of motors and gears at rated load;  $e$  is about 0.85 for direct-current motors and about 0.75 for alternating-current motors, the latter figure including step-down transformer losses,

$s$  = ratio of total standing time (including stops and lay overs) to total time that the train is moving,

$W$  = total weight of train in tons,

$M$  = total number of motors for the entire train,

$E$  = average line voltage.

\* The method is also applicable to alternating-current motors, but average characteristic curves for such motors are not available. They may, however, be readily constructed, or the characteristic curves given for direct-current motors may be used as an approximation.

† When the starting tractive effort is given, then  $a$  is to be calculated from the formula  $a = (F - r) + 100$ , where  $F$  is the tractive effort in pounds per ton and  $r$  the train resistance corresponding to a speed from 10 to 20% greater than  $V$ . The actual starting acceleration will be greater than this, due to the lower train resistance at low speeds. Vice versa, if the starting acceleration is given, then the calculated tractive effort (and therefore the starting current and horse-power) at end of the controller period will produce a starting acceleration in excess of the assumed value. As far as the energy consumption and heating are concerned, however, these differences in the actual and assumed accelerations will be balanced by the higher train resistance at the higher speeds.

Calculate

$$\beta = \frac{a}{c},$$

$$A = \frac{V}{T} = \frac{\pi V^2}{3600},$$

$$m = 2A \left( \frac{1}{c} - \frac{1}{b} \right),$$

$$q = \frac{a}{A} (1 + m).$$

Select a value of the ratio

$$x = \frac{\text{time power is applied}}{\text{time of controller period}}.$$

A run of specified distance can be made in a given time with various values of this ratio  $x$ , since this ratio depends upon the proportion of the time that the train coasts; i.e., the greater the coasting time the smaller the value of  $x$ , see Fig. 1. The less the value of this ratio, however, the greater will be the starting current required, and therefore the larger the motor capacity in order to avoid sparking. By carrying through the calculations for several values of  $x$  one can determine the relation between energy consumption, time of coasting and starting current, and, by plotting, find the minimum value of the energy consumption corresponding to the data assumed, see Fig. 9. In typical rapid-transit service (1 or more stops per mile) minimum energy consumption usually corresponds to a value of  $x$  between 2 and 5, i.e., for the controller period lasting from 50 to 20 per cent of the total time power is on.

From Tables *A* to *D*, pp. 1196 and 1197, find the values of  $y$ ,  $\lambda$ ,  $u$  and  $i^*$  corresponding to the selected value of  $x$  and the ratio  $\beta$ . Using these values calculate

$$J = \frac{x + \beta y}{q}, \quad \text{and} \quad H = \frac{\lambda + \beta y^2}{2q}.$$

Then calculate the quantities listed in the following table.

\* The analytical expressions for  $x$ ,  $\lambda$ ,  $u$  and  $i$  in terms of  $y$ ,  $f$  and  $\beta$  (see column headings of Table XII for definitions) are

$$x = 1 + \int_1^y \frac{\beta dy}{(1 + \beta)f - 1}$$

$$\lambda = 1 + 2 \int_1^x y dx$$

$$u = \frac{1 + \beta}{18.1\beta} \left[ 0.75 + \int_1^x \beta dx \right]$$

$$i = 199 \left( 1 + \frac{1}{\beta} \right) \sqrt{1 + \int_1^x \beta^2 dx}.$$

In the expression for  $u$  the constant 0.75 is for series-parallel control. For straight resistance control change 0.75 to 1.00 and for series-series-parallel control change 0.75 to 0.69. For a-c. commutator motors change 0.75 to 0.56. Tables *A* to *D* were made up by calculating the value of the above expressions graphically, using for  $y$ ,  $f$  and  $\beta$  the values given in Table XII. Similar tables may readily be calculated for a-c. commutator motors, or for any other type of motor whose "percentages" characteristics differ from Table XII.

Speed at end of controller period in miles per hour....	$V_1 =$
Maximum speed in miles per hour.....	$V_m =$
Watt-hours per ton-mile .....	$U =$
Ratio of total running time to time on controller.....	$X =$
Ratio of coasting time to running time.....	$C =$
Horsepower output at end of controller period.....	$P_0 =$
Starting current per motor *.....	$I_0 =$
Root-mean-square current per motor (including stops) *.....	$I_e =$
Average voltage across motor terminals (including stops).....	$E_m =$

\* For alternating-current series motors insert the power factor denominator of the formula.

**Example.** — Consider the following example:

Number of stops per mile.....
Average running speed.....
Acceleration rate.....
Braking rate.....
Train resistance at 34.4 mph.....
Average equivalent grade.....
Average curvature.....
Average effective coasting retardation.....
Efficiency of motors and gears at rated load.....
Ratio of standing to running time (20 sec. stops).....
Total weight of train in tons.....
Total number of motors.....
Average line voltage.....

Then

$$\beta = \frac{1.84}{0.21} = 8.76,$$

$$A = \frac{0.938 (28.7)^2}{3600} = 0.214,$$

$$m = 2 \times 0.214 \left( \frac{1}{0.21} - \frac{1}{1.60} \right) = 1.77$$

$$q = \frac{1.84 (1 + 1.77)}{0.214} = 23.8.$$

Then (see above for meaning of symbols)

#### Importance of Coasting and Selection of Gear Ratio

Fig. 9 shows that a much less energy consumption would be obtained with a coasting period of 50 per cent instead of the actual coasting period of 72 per cent, namely 72 watt-hours instead of 88 watt-hours. The starting current in order to obtain this higher coasting time is 406 amperes instead of 370 amperes, or an increase in the starting current of 10 per cent. If no change in the motor were made, this would require approximately the same increase in the gear ratio. The root-mean-square current would increase from 132 to 150, but the average motor voltage would drop from 350 to 170. The motor could therefore probably operate at this higher gear ratio without seriously overheating, but it would be safer to use a larger size motor, particularly as the starting current of 406 amperes is also close to the safe commutating limit.

#### TRAIN AND LOAD DIAGRAMS.

—The current-time curve for a train making a number of stops may be represented as shown by (a) in Fig. 10. On a railway line where there are several trains, the total current may be obtained by placing the current curve for each train at its proper place in the time scale, and adding the ordinates of the curves. Such a process is very tedious and unnecessary where there are many trains. In such cases the high and low parts of the curves be compared with respect to one another more or less according to the law of probability, so that each current curve may be replaced by a rectangle of the same area extending over the entire running time as shown by

Fig. 10

When this is done the kilowatts and amperes per train are derived from the watt-hours per ton-mile by the following formulas:

$$\text{kilowatts} = \frac{WV}{1000} \times (\text{watt-hours per ton-mile}),$$

$$\text{amperes} = \frac{WV}{E} \times (\text{watt-hours per ton-mile}),$$

where

$W$  = weight of train in tons,

$V$  = average running speed (excluding stops) in miles per hour,

$E$  = line voltage.

The time when the current is cut off is indicated by 1, and that when the train stops, by 2, in Fig. 10.

Another approximation, which is even more often used, is to replace the series of rectangles shown at *b*, by a single rectangle as shown at *c* in Fig. 10. The area of this rectangle will be equal to the sum of the areas of the smaller rectangles or current curves. Using this approximation, kilowatts or amperes may be obtained from the above formulas, taking, however,  $V$  to be the schedule speed (i.e., speed including stops). The procedure is to plot a train diagram showing

when each train comes on and off the line, neglecting intermediate stops, as shown for a simple case in Fig. 11. Each time a train comes on or off, the corresponding kilowatts or amperes are added to, or subtracted from, the load diagram.

**Power Required for Car Heating and Lighting.**—In addition to the energy required for propelling the cars, a very appreciable amount is also required in the winter, for heating them, and a small amount at night for lighting. In making up a load diagram this energy should be included.

The average power for car heating varies, of course, with the climate and time of year. The following figures represent usual requirements in the northern parts of the United States:

TABLE XIII.—HEATING AND LIGHTING OF CARS

Length of car, feet	Average* kw. for lighting	Average† kilowatts for heating	
		Average conditions	Severe conditions
14-20	0.25	3.5	4
20-28	0.35	4.5	5.5
28-34	0.55	5.5	7.5
34-40	0.70	7.5	10.5

\* During the hours lights are on, using Tungsten lamps.

† During the time car is in service.

**Substation and Power-station Loads.**—The load diagram obtained as described above gives the total load at the trains. To obtain the load at a sub-

Fig. 11.

station, the kilowatts or amperes must be increased by a factor to allow for the losses in the distribution system. The load distribution should allow for all transmission and distribution losses, power house and substation (see *Power Stations; Substations; Trolley Systems*), and also for all auxiliary power, such as station lighting, shop machinery, etc.

**RAILWAYS, LOCATION AND PERMANENT WAY FOR. —**

(See also *Railways, Energy Requirements and Motor Capacity for; Railways, Electric, Traction Systems for; Third-rail Systems; Trolley Systems.*) There are four general steps in the determination of the location of a railway, (1) the reconnoissance, which is a personal examination by the locating engineer of the country through which the railway is to run, (2) a preliminary survey and investigation more particularly of the topographic features of the proposed road, (3) office study of the data obtained in (1) and (2), and (4) the field location and the preparation of final location plans.

**RECONNOISSANCE.** — First a careful examination of the country should be made, with a view not only of obtaining a line which will be reasonably straight and as free from grades as possible, but also with a view of selecting a line or lines which will earn a suitable revenue. An electric railway reconnoissance calls for a much more detailed study of the country than a steam railroad location and a very much more detailed study of the amount of population, its growth, and the likelihood of the population making use of the proposed line. The adapting of an electric line to take in the various intermediate centers of population is practically a necessity if the income of the line is to be sufficient to take care of the investment. The engineer should therefore realize fully that the commercial and financial matters relating to the road are more important than the engineering problems, and should always bear in mind that the road is constructed for the purpose of selling transportation.

Electric railway locations are divided in general into two classes: those which are operated on the public highways, and those which are operated upon their own private rights of way, where they are free to make the fastest practicable schedules. Speed and comfort must be considered. Both of them are, as a rule, better obtained on private locations. It is essential in this reconnoissance for the engineer to make a careful estimate of the probable gross income of the road, as well as to choose two or three lines which will later on be investigated by preliminary surveys.

**PRELIMINARY SURVEY.** — After the favorable lines have been determined by the locating engineer in his reconnoissance, a party is sent into the field to make a preliminary survey. This is usually a linear traverse run by transit and tape. After this a level party determines the profile of this line, this party being followed by a topographical party which sketches in the 5-foot contours, the locations of brooks, highway crossings, the number and kinds of industries located within say a mile or so of the line, the location of existing recreation points and picnic grounds, as well as the possible location and development of those which do not now exist. The engineer running the preliminary line should keep in mind that the railroad is built for the convenience of the public and that any inconvenient detail of the road will have a material effect upon its gross income.

The topographical party should note the character and property value of buildings or other structures which the line may affect, the character of soil (whether rock or gravel), the location of possible borrow pits, etc. In some locations the topographical features should extend a considerable distance from the transit line; in other locations, where, for example, the line is passing through a narrow valley, the topographical features need not be taken very far from the transit line. While the line should be as straight as possible, some curves are necessary. In locating curves consideration should be taken of the fact that electric traction permits of very rapid acceleration and retardation, and therefore sharper curves are permissible than in steam railroad practice because of the shorter time required to pass around it, even at the

slower speed rendered necessary because of its greater curvature. The time lost in passing around the curve as well as the permissible speed are factors which should be taken into consideration. Roughly speaking, a safe rule is that the speed on curves in miles per hour can be equal to the square root of the radius in feet.

**OFFICE STUDY.** — On the preliminary map an accurate paper location is drawn and an estimate is made of the cost of the road and of the probable gross earnings, as well as of the fixed charges and the cost of operating and maintaining. This study is one of great importance and if the reconnaissance and preliminary survey are not thoroughly accomplished, errors in judgment may very easily creep into this part of the work. The office study shows the final alignment and the proposed grades of the road.

**FIELD LOCATION.** — After the completion of the office study the line is finally located in the field. Field location requires running out the line by straight lines and curves, using easement curves at the beginning and end of all changes in direction; the preparation of property maps showing the location required for the railway and all parcels of property affected by actual takings for slope easements; as well as studies of grade crossing eliminations where they are necessary. At this time soundings or borings are taken for bridges or other structures. Cross sections are made of the line, from which careful estimates are made. These cross sections are used in computing the final payment for the work of construction.

**Locations in Existing Highways.** — Such locations usually have the great advantage of easy grades which frequently cannot be so cheaply obtained upon private land. Locations in highways have the disadvantage of requiring much slower speed. Where such locations are made it is necessary to survey the highways as laid out by the proper officials, and not infrequently it is necessary to consider the widening of such highways by takings on either side. The electric road, for example, may be a 2-track road laid out in the center of the roadway, in which case the road would possibly occupy nearly the full width of the existing highway. In this case the electric road would be required to purchase additional property on either side and probably to build roadways for other vehicles in lieu of the portion which the electric line occupies. When this is done high speeds can sometimes be maintained. Where the electric road occupies one side of an existing highway, the speed often has to be reduced to a relatively low rate. This affects the amount of traffic which the road will attract and thereby reduces the gross earnings.

**DEFINITIONS OF TERMS USED ON RAILWAY MAPS AND PROFILES.** — Some of the more common terms are defined below.

**Curves.** — A curve is generally composed of successive arcs of circles joining two straight lines or tangents. When these arcs are of varying radii decreasing with the distance from the tangents the curve is said to be compounded or spiralled. To insure smooth riding the curve should begin with a large radius and gradually grow sharper until the circular part is reached. At the same time the outer rail should be gradually raised (see below) until it reaches its maximum elevation. A curve so built is called an easement curve. Curves, if properly eased, may be run at full speed. On high-speed lines curves sharper than 10 degrees should be avoided.

The following terms are in general use:

The point of curvature (P. C.) is the beginning of the curve, and the point of tangency (P. T.) is the end of the curve, going in the direction of the surveyor's stationing on the line.

The point of intersection (P. I.) is the point where the two tangents through P. C. and P. T. intersect.

The tangent distance is the distance between the P. C. or P. T. and P. I.

The degree of curvature is the angle subtended at the center of a curve by a chord 100 ft. long. Up to a curvature of 12 degrees the radius of curvature may be found to a close approximation by dividing 5730 by the degree of curvature. The exact relation between the degree of curvature  $C$  and the radius  $R$  is

$$R = \frac{5730}{C \sin \frac{C}{2}}$$

The middle ordinate is the perpendicular distance from the center of a chord to the curve.

**Elevation of Outer Rail on Curves.**—The outer rail on curves is raised above the inner an amount depending upon the velocity of cars and the degree of the curve. This elevation must be gradually attained. The amount of elevation required in order to make the weight of the car just balance the centrifugal force on the curve is

$$E = \frac{DV^2}{32.2 R} \text{ feet,}$$

where  $D$  is the distance between center lines of the two rails (not the track gage),  $V$  the speed of car in feet per second, and  $R$  the radius of curvature in feet. For standard track gage, viz., 4 feet 8½ inches from inside edge of the head of one rail to the inside head of the other rail, and taking  $R = 5730/C$ , where  $C$  is the curvature in degrees, the above expression for the elevation becomes

$$E = 0.000325 V^2 C \text{ inches.}$$

**Grades.**—A railroad grade is expressed in per cent, this per cent being the number of feet vertical rise in a horizontal distance of 100 feet; i. e., a 4 per cent grade means a rise of 4 feet in a horizontal distance of 100 feet. Calling  $L$  the distance in feet along the track and  $H$  the vertical rise in feet in this distance, the per cent grade may also be expressed as

$$G = \frac{100 H}{\sqrt{L^2 - H^2}},$$

which for a grade less than 10 per cent is equal to  $100 H/L$  with an error of less than 1 part in 100.

Grades should be as small as financially practicable. It may be cheaper to operate over a grade than to pay interest on the sum needed to reduce it. Some steam road grades are as steep as 4 per cent, but such grades are extremely costly to operate. Two per cent is about the limit for steam roads and most roads try to keep grades down to about 0.5 per cent. On electric lines operating single trolley cars grades as steep as 10 per cent exist, but no grade over 6 per cent ought to be used unless it is absolutely unavoidable.

**Virtual and Momentum Grades.**—A driving force or tractive effort is required to accelerate a train, and a driving force or tractive effort is required to cause a train to ascend a grade at constant speed; hence an increase of the speed of the train may be considered, as far as the motive power is concerned, as equivalent to an up-grade. *Vice-versa*, a decrease of speed may be considered as equivalent to a down-grade. The energy required to give the train a speed of  $v$  miles per hour is the same as the energy required to raise it a height of  $0.0334 v^2$  feet. Hence, if to the actual elevation of the profile at each point is added a height of  $0.0334 v^2$  feet, where  $v$  is the velocity of the train at this

point, and a line is drawn showing the sum of the actual elevation and this velocity head at each point, this line may be looked upon as the "virtual profile" of the road, and the slope of this virtual profile, at any point, i.e., the change in its elevation per hundred feet, is called the "virtual grade" at this point.

The virtual grade at any point on an actual up-grade will be less than the actual grade, if the speed of the train is decreasing as it passes this point; the grade in this case is sometimes called a "momentum grade." That is, if the train has a high speed when it strikes an up-grade, and the operating requirements of the division will permit of a slowing down of the train as it ascends the grade, then the effective or virtual grade will be less than the actual grade. Under such circumstances a given locomotive can pull a given train up a short steep grade on which it could neither start this train nor pull it at constant velocity. A momentum grade must be comparatively short.

**Ruling Grade.**—The limiting or ruling grade on a division is that grade which limits the weight of the train which can be hauled over this division by the regular motive-power unit. Ordinarily, it is the maximum grade on the division, but if momentum grades are relied upon, the ruling grade might be the maximum virtual grade. Reliance upon momentum grades is not always considered good practice, since a heavy train which might get over this grade if it strikes the grade with sufficient momentum, cannot start on this grade if it should have to stop on the grade due to some emergency. When steep grades occur at only one or two places in a division it is sometimes economical to use helper engines on these steep grades, thus making possible the hauling of heavier trains, the weight of train then usually being limited by maximum grade on the remainder of the division.

**Switches, Frogs, Cross-overs, Etc.**—A switch is an arrangement of rails, which permits a car or train to pass from one track to another. A cross-over consists of a pair of switches connected by a short piece of track in such a way as to allow a car or train to pass or cross over from one track to another parallel one. A turn-out or siding is a short length of track parallel to the main track and connected thereto by a switch at each end; when used as a means of passing cars or trains it is usually called a turn-out, and when used primarily for storing cars or loading it is called a siding.

A frog, Fig. 1, is that part of the switch where the two inner rails cross each other, and is so designed as to allow the flange of the wheel to pass over without "riding up" on the rail. A guard rail is set close to the switch rail opposite the frog. The lead of a frog is the distance of a frog from the frog point *P*, see Fig. 1, to the point of the switch. The point of the switch is the tip end of the movable rail of the switch which is planed down to fit closely against the main rail. The number of a frog is equal to the quotient of the distance from *P* to the line *AB* divided by the length of the line *AB*.

Fig. 1.

**Turn-outs.**—Turn-outs are short sidings used on single-track roads to permit cars running in opposite directions to pass each other. The proper location of turn-outs is governed to a certain extent by topography. They can be readily located by drawing up a train diagram; see *Railways, Energy Requirements and Motor Capacity for*. To keep the number of turn-outs at a minimum the time intervals between cars (headway) should all be multiples of the shortest time interval. For accurate results the diagram should be carefully drawn to a scale large enough so that locations can be measured with an error not to exceed 100 feet for distance and one minute for time.

**CONSTRUCTION OF PERMANENT WAY.**—In the preparation of the roadbed for ballast, ties and track, it should be noted that rails settle more or less and allowance must be made for this when grading is in progress. The surface of the roadbed should be flat, from 14 to 20 feet wide for a single-track road, and from 9 to 10 feet wider for a double-track road, with a ditch at each side for drainage. On this the ballast of broken stone, gravel or cinders is laid varying from 6 to 12 inches thick under the ties. The ballast should ultimately be brought up level with the tops of the ties.

**Ballast.**—Broken stone is best but most expensive in first cost and maintenance. It is clean and dustless. Gravel is cheaper and very satisfactory from a maintenance standpoint. It is apt to be very dusty. Cinders are fairly satisfactory but are very dirty.

**Ties.**—Ties are of the following materials in the order named: Oaks, southern pine, Douglas fir, cedar, chestnut, cypress, western pine, tamarack, hemlock, redwood, lodge-pole pine and white pine; see article on *Timber*. The average cost is about \$1.00. Treated ties cost about \$1.25. With the rapidly increasing cost of ties, preservative treatment is becoming important. Creosoting is best. Zinc chloride treatment is satisfactory in arid regions only. The average life of an untreated tie is 5 years for hemlock, 7 to 12 years for white oak, and 15 years for cedar ties. Treated ties may last 30 years, but must be protected from mechanical injury by rails and spikes. For this purpose tie-plates and screw spikes should be used. Ties are spaced about 7 feet between centers.

**Rails.**—See article on *Rails, Track and Third*.

**Grade Crossings.**—On high-speed lines grade crossings should be avoided wherever practicable. It costs less to avoid them in the beginning than to eliminate them afterwards. To eliminate an existing grade crossing costs from \$40,000 up unless the topography is usually favorable.

**COST OF PERMANENT WAY.**—The following costs are based on pre-war prices. When tracks are laid in paved streets the railway usually has to pay for paving 18 inches of the street outside the rails. The total cost of such track, excluding overhead construction, and using 8- or 9-inch girder rails is about \$5 per foot of single track. When the track is constructed with a light T-rail, as may be the case when laid on a private right of way or at the side of a street where there is no paving, the cost may be as low as \$1 per foot, exclusive of ballast, bonding, and overhead construction. Ballast will cost from \$1000 for cheap gravel to \$3000 for thin rock, per mile of track. Thick rock ballasting as used on steam railroads may go as high as \$5000 per mile.

**Maintenance Costs.**—Maintenance of way costs will depend largely on the character of the original construction and also upon the character and amount of traffic. On typical Massachusetts street and interurban railways maintenance of way expenses are reported as from \$200 to over \$500 per mile of track. \$200 per mile is not sufficient to maintain the road and track in an adequate manner, but from \$350 to \$380 is probably a fair figure.

**BIBLIOGRAPHY.**—Herrick, A. B., *Practical Electric Handbook*, N. Y., 1906; Herrick and Boynton, *American Electric Railway Practice*, N. Y., 1907; Gouzenbach, *Engineering Preliminaries for an Interurban Electric Railway*, N. Y., 1903; Merriman, M., *American Civil Engineers' Handbook*, N. Y.

**REACTANCE COILS OR REACTORS.**—(See also *Alternating Currents; Inductances and Inductive Reactance.*) Coils designed particularly for the purpose of introducing reactance (see *Inductance and Inductive Reactance*) into a circuit, when connected therein, are called "reactance coils" or "reactors."

**APPLICATIONS.**—Reactance coils are used wherever (1) it is desired to produce a voltage drop in an a-c. circuit without producing a proportionate loss in power (see *Controllers*); (2) to introduce inductance into a circuit where a compounding effect is to be obtained by passing a leading current through the coils (see *Converters, Synchronous*); (3) in large power stations to limit the short-circuit current; and (4) as "choke coils" in connection with lightning arresters (see *Lightning Protectors*).

**RATING OF REACTANCE COILS.**—It is common practice to rate a reactance coil in terms of the kilo-volt-amperes absorbed by it when carrying such a current (of the given frequency) as will produce a temperature rise of 50° C., or 70° C., respectively, above the room temperature, depending upon the type or class of insulation used in accordance with the Standards of the A. I. E. E. on temperature limits. Usually the resistance is negligible compared with the reactance and under this condition the k.-va. rating is  $I^2x$ .

**Per cent Reactance.**—A reactance coil having a reactance of  $x$  ohms is said to have a "per cent reactance" equal to  $(100xI) \div V$ , where  $I$  is the normal or full-load current through it and  $V$  the total normal voltage across the circuit in which it is placed; i.e., the percentage reactance is the percentage ratio of the reactance drop at normal current to the total voltage impressed on the circuit in which it is inserted. When the coil is to be inserted in one branch of a  $Y$ , the voltage  $V$  is the volts to neutral.

In the case of a three-phase generator, three-phase transformer or bank of transformers, or set of three single-phase reactance coils, the  $Y$  reactance,  $x$ , (see *Alternating Currents*) is related to the per cent reactance,  $p$ , by the formula

$$x = \frac{10 p E^2}{(k\tau - \sigma)}, \quad (1)$$

where  $E$  is the kilovolts between phases (i.e., between the terminals of the  $Y$ ) and  $(k\tau - \sigma)$  stands for the total kilovolt-ampere rating of the three phases.

**DESIGN OF IRON-CORE REACTANCES.**—When a high inductance is required the coils are usually wound on an iron core, which usually contains an air gap, for the inductance of a coil on a completely closed iron core is by no means a constant, due to the variation of the permeability of the iron with the magnetizing current, and a straight-line relation between voltage and current does not hold. When a relatively low inductance is required the iron core may be omitted entirely. Reactance coils for use in connection with synchronous converters have an iron core.

In iron-core reactances the air gap is usually of such a length that practically all of the reluctance of the circuit is in the air gap. Hence in calculating the reactance of the coil the reluctance of the iron portion of the path may be neglected without materially affecting the results, provided normal magnetic densities exist in the iron (60,000 to 80,000 lines per square inch, maximum values). As the gap is made adjustable such errors as result from this approximation are allowed for by adjusting the gap afterwards.

The inductance  $L$  in henries and the reactance  $x$  in ohms are given approximately (neglecting effect of iron) by the equations

$$L = \frac{3.2 S^2 A}{10^9 l} \quad \text{and} \quad x = 2\pi f L, \quad (2)$$

where  $S$  = number of turns in coil;  $A$  = cross section of path in gap, in square inches;  $l$  = length of gap, in inches;  $f$  = frequency in cycles per second. This must, however, be checked to see that the magnetic density  $B$  is not too great at the maximum current to be used, thus,  $B = (3.2 \times \sqrt{2} SI) / l$ , where  $I$  = the effective value of current;  $B$  = maximum value of flux density = 60,000 to 80,000 lines per sq. in.

The losses in such a coil are the core-loss in the iron and the  $R I^2$  in the copper. See article on *Magnetic Properties of Materials* for the method of calculating the core-loss. The procedure in proportioning the various parts is similar to that employed in the design of transformers (q.v.).

**POWER-LIMITING REACTANCES.\*** — (See also *Power Stations*.) In order to avoid the prohibitive expense of high-voltage insulation, power-limiting reactances are always designed to be installed in the low-tension circuits. From the standpoint of economy, this requirement prohibits the use of a magnetic core. When power-limiting reactances are installed at a distance greater than one-half their diameter from any iron or steel structure, no appreciable eddy current or hysteresis losses will be produced in such structures.

The inductance and reactance of the coils can be calculated from the formula for a short solenoid given in the article on *Inductances and Inductive Reactance*.

It is desirable to reduce the size of reactance coils as much as possible, and they are therefore now usually designed for a temperature rise of 70° C. As to the dielectric test, the A.I.E.E. rules recommend  $2\frac{1}{2}$  times the line voltage plus 2000 for one minute, from conductor to ground.

**Location of Reactance Coils.** — As noted above the reactance coils may be inserted in the leads from the generator, between sections of the low-tension bus-bars, or in the low-tension leads of the transformers. Which one of these locations or combinations is preferable depends on a number of conditions. Modern water-wheel-driven generators are now designed for a very high inherent reactance and external power-limiting reactances are usually inserted between the bus-bar sections or in the low-tension transformer leads.

**Reactances in Generator Leads.** — With reactances in the generator leads the current flowing in the armature winding is limited, and this method therefore affords an excellent protection for the generator itself. An objection to generator reactances is the fact that a short-circuit on or near the bus-bars will cause a voltage drop on all the feeder circuits connected thereto.

**Reactances between Bus-bar Sections.** — With reactance inserted between the bus-bar sections the trouble is confined to the particular section on which short-circuit takes place. Bus-section reactances afford no protection to the generators connected to the bus to which the faulty line is connected, but they give added protection to the generators on the other sections.

**Reactances in Low-tension Leads of Transformers.** — Reactances in the low-tension leads of the transformer banks are of considerable value for protecting against short-circuits in the lines, where they, of course, mostly take place. They are, however, not of value if the short-circuit should occur on the low-tension bus or in the generators or in their leads. There is also a constant loss of power in the reactance coils when they are inserted in the transformer leads, as is also the case when they are installed in the generator leads. For large systems this may reach a considerable value and must not be ignored when the selection of reactances is made.

**Calculation of Short-circuit Kilovolt-amperes.** — The short-circuit current for any arrangement of reactances and for a short at any point can be found

\* By D. B. Rushmore.

with sufficient accuracy by neglecting the resistances of the apparatus and connections and calculating the resultant reactance by applying successively the formulas for two reactances in series or in parallel, as the case may be. Note that the resultant reactance  $X_s$  of two reactances,  $x_1$  and  $x_2$  in series, and the resultant reactance  $X_p$  of two reactances,  $x_1$  and  $x_2$  in parallel, are respectively

$$X_s = x_1 + x_2, X_p = \frac{x_1 x_2}{x_1 + x_2} \quad (3)$$

provided the resistances of the circuits are negligible. The reactances,  $x_1$ ,  $x_2$ , etc., of the various circuits can be calculated from the percentage reactance by formula (1). Let  $X_r$  be the resultant reactance of all the circuits feeding into the short circuit, and let  $E$  be the kilovolt rating of the generators, then

$$\text{Total short-circuit kv-a.} = \frac{1000 E^2}{X_r} \quad (4)$$

For example, consider the case of four, 12,000 kv-a., three-phase, 11,000-volt generators feeding into a bus which is divided into two sections, *A* and *B*, with two generators feeding into each section, and one transmission line from each section, each line fed through a bank of transformers. A set of reactance coils, having 6 per cent reactance, connects the two bus sections. The inherent reactance of each transformer bank is 8 per cent, and the inherent reactance of each generator is 20 per cent. The reactance of each generator is then 2.0 ohms; of each transformer bank 0.4 ohm, and of each set of reactance coils 0.6 ohm. Let a short circuit occur between the three wires of the line connected to the bus section *B*. We then have  $2.0/2 = 1.00$  ohm in series with 0.6 ohm, or a total of 1.6 ohms, which total is in parallel with the other two generators, i.e., in parallel with 1.0 ohm, giving a resultant reactance up to the transformer bank of 0.6 ohm; this is in series with the transformer bank, giving a final resultant reactance,  $X_r = 0.6 + 0.4 = 1.0$  ohm. Hence the total kilovolt-amperes, from formula (4), is 121,000, or about 10 times the rating of each generator.

**DIMENSIONS, WEIGHT AND COST.**—Iron-core reactances with air gap occupy from 0.30 to 0.50 cubic foot per rated kv-a., weigh from 20 to 50 pounds per rated kv-a. and cost from \$3 to \$5 per rated kv-a., the first figure in each case applying to air-blast reactances and the latter figure to oil-cooled reactances. Power-limiting reactances occupy from 0.3 to 0.6 cubic foot per rated kv-a., weigh from 20 to 30 lbs. per-rated kv-a. and cost from \$4 to \$12 per rated kv-a. The first figure in each case applies to reactances having a rating of approximately 500 kv-a. and the latter for ratings of approximately 50 kv-a. These figures apply to 60-cycle reactances and should be increased from 10 to 15 per cent for 25-cycle reactances. (1920 prices.)

**RECTIFIERS.** — (See also *Arc, Electric; Converters; Motor-Generators.*) The term rectifier is applied to any stationary apparatus or rotating commutator for transforming alternating into direct current, or vice versa. Three types of rectifiers are in commercial use, viz., the mercury-arc rectifier, the electrolytic rectifier and the rotating commutator driven by a synchronous motor, but only the first type is at present of much importance commercially.

**MERCURY-ARC OR MERCURY-VAPOR RECTIFIER.** — The operation of this rectifier depends upon the fact that a tube containing mercury vapor under a low pressure and having one electrode of mercury, and the other of some other conductor, offers a very high resistance to a current tending to flow through the tube from the mercury to the other electrode, but has a very low resistance to a current flowing in the opposite direction, provided the current is once started by forming an arc in the tube, e.g., by tilting the tube so that the mercury touches for an instant the other electrode. See article on *Arc, Electric*.

**Application.** — Mercury-arc rectifiers find their chief application as a means of charging storage batteries and supplying a certain series type of d-c. arc lamp (see *Lamps, Electric*) from an a-c. supply. In the latter case the rectifier receives its current from a constant-current transformer and delivers a direct current of constant value. Mercury-arc rectifiers have also been tried out experimentally on electric cars and locomotives, power being supplied to the car or locomotive from a high-voltage a-c. trolley, stepped down to a lower voltage by transformers and converted into low-voltage direct current by means of the rectifiers. Although this scheme has not yet proved satisfactory commercially, it seems to be particularly promising when used in connection with high voltage (1200-volt) railway motors. The difficulty lies chiefly in producing a tube of rugged and lasting qualities.

**Connections for Single-phase Operation.** — The connections employed in practice are shown in Fig. 1. The complete equipment consists of a source of alternating current *HG*, the rectifier tube *AA'*, two reactances *E* and *F* and the load represented as a storage battery *J*. The rectifier tube is an exhausted glass vessel in which are two graphite electrodes (anodes *AA'*) and one mercury cathode *B*. Each anode is connected to a separate side of the a-c. supply, and also through one-half of the main reactance to the negative side of the load. The cathode *B* is connected to the positive side. There is also a small starting electrode *C* connected to one side of the a-c. circuit through a resistance and used for starting the arc. When the rectifier tube is rocked so as to form and break a bridge of mercury between the cathode *B* and starting anode *C* a small arc is formed. This produces mercury vapor in the tube and the arc immediately jumps to one or the other of the main anodes and alternates on these during regular operation.

Fig. 1. Mercury-vapor Rectifier

**Mode of Operation.** — To analyze the operation, assume an instant when the terminal *G* is positive and *H* negative. The positive current will then flow from anode *A'* to cathode *B*, through the load *J* to *D* and through reactance *F* back to *H*. The current cannot jump from *A'* to *A* on account of the high

counter electromotive force of the arc. The small arrows surrounded by circles show the path of the current during this half cycle. During the next half cycle the terminal *B* is positive and the current flows to *A* through the tube to *B*, through the load *J*, reactance *E* and back to *G*. The small arrows show the path of the current during this half cycle. Hence during a whole cycle the cathode *B* is continuously negative but first one anode is active and then the other. If the voltage and current should become zero coincidentally the arc would become extinguished and operation cease. Hence the reactances *E* and *F* are introduced. At the end of the first half cycle described, when the line voltage drops to zero, the inductance of *F* maintains the current and a local circuit is formed through *A*, *B* and *F*, which maintains the arc until the voltage at *G* has risen to a value which will maintain the arc.

The rectifier thus makes use of both half waves, or the entire alternating current, and the result is a uniform pulsating uni-directional current. On account of the reactance in the circuit, this current in the load never falls to zero and, in fact, with sufficient reactance, may be made very nearly constant. But this extreme is not always desirable, as it distorts the current wave in the a-c. supply circuit.

**Arc Rectifiers on Polyphase Circuits.** — Rectifiers may be arranged on two-phase and three-phase circuits, and in fact there is an advantage in the arrangement of the reactances in these cases.

**Efficiency of Mercury-arc Rectifier.** — The losses in the rectifier correspond to a constant counter e.m.f. of about 14 or 15 volts, thus the efficiency of the tube is constant at all loads and at high voltages is very high; the higher the voltage the higher the efficiency. In fact, for high voltages the losses in the transformer and reactance coils form the major part of the total losses. On account of the small losses in the tube itself, there is very little heat to be dissipated, and rectifier tubes of large capacity are very small in bulk.

**Kilowatt Capacity of Mercury-arc Rectifier.** — Rectifiers have been built for voltages up to 6000. The tubes may be of glass or steel. The glass tubes have a capacity of about 40 amperes and the steel tubes from 200 to 300 amperes. Several rectifiers may be operated in parallel for large currents. The power factor of the combination of tube and controlling devices is about 90 per cent. Rectifiers have been built of a capacity sufficient to operate motor cars and locomotives.

**Dimensions, Weights and Costs of Mercury-arc Rectifier Outfits.** — A standard outfit consisting of rectifier tube, transformer, reactance, switch-board panel, switches and instruments to supply a load of 30 amperes at 110 volts d.c. would occupy a floor space 16 × 19 in., have a height of about 64 in., and weigh complete about 600 pounds. The first cost of the outfit would be between \$200 and \$250 and the cost of renewing the tube about \$20. The net efficiency would be about 78 per cent. Such an equipment is frequently used for charging the batteries of electric vehicles from a-c. supply circuits.

**ELECTROLYTIC RECTIFIERS.** — (See also *Condensers; Lightning Protectors.*) The operation of this type of rectifier is in a general way the same as that of the mercury-arc rectifier, being based on the fact that a certain electrolytic cell having electrodes of different metals (e.g., aluminum and steel electrodes in a solution of ammonium phosphate) have the property of allowing a current to pass in only one direction. By suitably combining two of these cells both the half waves of an alternating current may be rectified. Such rectifiers have a low efficiency and due to the large losses in them heat very rapidly. They are therefore applicable only to the rectification of small currents. Examples are the electrolytic rectifier of Nodon described at the International Electric Congress of 1904.

**TUNGAR RECTIFIER.** — This rectifier acts on the principle of the Fleming valve (see *Radio Communication*), and consists of a heated tungsten filament for one electrode, and a tungsten plate for the other, both placed in a high vacuum in a glass bulb. If the plate is made positive to the filament a thermionic current will flow across the intervening space in the vacuum, but if the filament is positive to the plate no current will flow. By combining two tungar rectifiers with an auto-transformer, as is done with the two halves of the mercury-vapor rectifier, both half waves may be rectified. This rectifier is limited to small current (7.5 amp.) and is used chiefly for charging small groups of storage batteries at 15 volts or less.

**MECHANICAL RECTIFIERS.** — These usually consist of a commutator driven by a synchronous motor. Each commutator has as many live segments as there are poles on the synchronous motor. Alternate segments are connected to the source of alternating currents, and brushes properly spaced and bearing on the commutator collect the direct current. The objections to these devices are that if there is much inductance in the d-c. circuit (e.g., a motor) there will be a great deal of sparking, or if the load has a constant counter e.m.f. (e.g., a storage battery) there will be sparking. By alternating live and dead segments, this trouble can be obviated, provided the current to be rectified is not too large and the proportions of the live and dead segments are properly chosen. Commutator rectifiers of this type capable of rectifying currents up to 50 amperes at 200 volts have been constructed. The principal losses are in the driving motor; the efficiency is poor at light loads.

Many attempts have been made to produce a satisfactory rectifier by various schemes for interchanging the connections to the a-c. circuit at the end of every half wave, but none of them have as yet proved satisfactory for rectifying currents of any considerable magnitude. The difficulty lies chiefly in providing a means of preventing the formation of a spark when the circuit is interrupted or commutated.

**REGULATORS.** — (See also *Batteries, Storage, Applications of; Controllers; Rheostats; Starters. Motor; Switchgear Equipment for Power Stations.*) Devices for adjusting and controlling the voltage in an electric circuit are called regulators. They may be divided into two classes, depending on whether they operate directly on the circuit or indirectly by means of the excitation of the generator.

**FEEDER OR POTENTIAL REGULATORS**, as the name implies, operate to raise or lower the feeder voltage. Where a feeder circuit is operated from a constant potential bus and it is desirable to compensate for the drop in the feeder, there is usually installed a regulator which adjusts the voltage impressed upon the feeder so as to maintain proper voltage at the point of distribution.

With d-c. circuits the only way to raise the voltage of the feeder above that of the bus is to connect a booster or a storage battery (q.v.) in series. The feeder voltage may be lowered by connecting in resistance. Owing to the inefficiency of resistance control and the complication of providing boosters or batteries, feeder control of d-c. circuits is used only in special cases, such as for the distribution system of a direct-current railway.

Feeder control for a-c. circuits is accomplished by transformer action. Feeder regulation for such circuits can be made in various ways, the most common being the "induction" type and the "step" type.

**Induction Regulators**, also called "induction potential regulators," are used on either single-phase or three-phase circuits and are arranged for hand operation, motor operation with distant control, or for full automatic operation by means of relays. An induction regulator is a special type of transformer, built like an induction motor (q.v.) with a coil-wound secondary. The primary is permanently connected across the feeder circuit, and the secondary which is connected in series with the feeder is normally stationary, but is movable at will for the purpose of adjusting the voltage. In comparison with the step-type regulator (see below) the induction regulator possesses the advantage of being operated without short-circuiting any transformer coils. It has the disadvantages of a large magnetic leakage and a high value of exciting current.

**Single-phase Induction Regulator.** — This regulator has a secondary induced voltage whose value depends on the relative angular position of the primary and secondary coils, but which is always in time phase with the primary voltage. This induced voltage is a maximum when the axes of the coils coincide and it is zero when the coils are at right angles to one another. The resultant feeder voltage is equal to the arithmetical sum (or difference) of the primary and secondary voltages.

**Polyphase Induction Regulator.** — This regulator has a rotating flux of constant value, set up by the primary current. Thus the secondary induced voltage is also constant in value but differs in phase from the normal line voltage depending on the angular relation between the primary and secondary windings. The resultant delivered voltage is the vector sum of the primary and secondary voltages, and its value varies with the position of the movable member.

**Step-type Regulators**, also called "contact-voltage regulators," consist essentially of a stationary transformer provided with a large number of secondary taps for cutting in and out sections of the transformer windings. The taps are connected with a dial or drum so that any pair of taps can be connected to the feeder circuit according to the voltage required.

The moving arm on the dial-type regulator is usually arranged so that in passing from the position of maximum boost the number of secondary turns in series with the circuit is reduced in equal steps until the turns are all cut out. Further rotation in the same direction throws over the reversing switch and

then cuts in the same secondary turns in opposition to the main voltage until the position of maximum bucking is reached, when a stop prevents any further rotation in that direction. A similar stop prevents overtravel in the position of the maximum boost.

**Automatic Operation of Feeder Regulators** with either single- or three-phase circuits is obtained by the action of a voltage relay, which may or may not have a compensating device. This relay acts in conjunction with the motor on the regulator so that, as the load comes on or as the bus-voltage drops, the motor will turn the regulator in such a direction as to increase the voltage. By means of a compensator which can be set for a certain resistance and a certain inductive drop, the voltage at the point of distribution can be maintained constant independent of the amount and power factor of the load, provided the total drop is within the range of the regulator.

**OUTDOOR INDUCTION REGULATORS.**—During the last few years a number of induction regulators, both of the single-phase type and the poly-phase type have been developed for outdoor service. The smaller regulators are arranged for mounting on a pole or pole platform while the larger ones, usually employed in connection with outdoor transforming stations, are located on the ground level. To secure satisfactory cooling the smaller size regulators are mounted in corrugated sheet-steel cases, while the larger ones are provided with radiators similar to the large outdoor self-cooling transformers.

Outdoor induction regulators have been built as large as 1750 kv.-a., three-phase, 60 cycle, 13,600 volts, and larger regulators can be built whenever needed.

**FIELD REGULATORS.**—In order to maintain practically constant voltage on a-c. and d-c. generators, or to have these machines compound automatically to take care of feeder drop, field regulators of either non-automatic or automatic types are employed. The former are hand-controlled rheostats (see *Rheostats*), the latter are made in various forms of which the regulator originally known as the "Tirill" type is the best known in America. These generator-voltage regulators are made in two forms, one using a d-c. magnet and the other using an a-c. vibrating magnet relay as the anti-hunting control device.

Either design of regulator depends for its operation on the rapid opening and closing of a circuit that shunts the field rheostats and thus changes the resistance in the field circuit of the generator to be regulated. For d-c. service the regulator usually works upon the main generator field and for a-c. service upon the field of the exciter. In both cases the rheostat is so adjusted that when in circuit it tends to lower the voltage considerably below normal, and when the rheostat is short circuited the generator voltage rises. The regulator automatically closes the shunt circuit and the voltage drops to a predetermined value and opens the shunt circuit when the voltage rises above that value.

The main features of the regulator with the d-c. vibrating magnet are: 1st, the method of control by shunting the rheostat; 2nd, that with the total range of regulation from no load to full load the maximum travel of the only moving part (the vibrating contact) is only  $\frac{1}{2}$  inch; 3rd, the use of the exciter voltage as one of the main control circuits which prevents the generator voltage from overshooting. The vibrations are so rapid that the time factor is reduced to a minimum and there are no retarding effects due to dash pots or other damping devices.

**Regulator for Direct-current Generator (Fig. 1).**—This consists essentially of a main control magnet whose winding is connected across the generator terminals, and a differentially-wound relay magnet. When the effect of the potential winding increases, due to a rise in the generator voltage, the contact of the main control magnet is opened and in turn one winding of the relay

magnet is deenergized. Thus the relay contact is opened and the short-circuit removed from the generator rheostat. When the generator voltage drops, the main contact is closed and the differentially-wound relay magnet acts to short-circuit the field rheostat. The relay contacts are shunted by a condenser to reduce sparking.

In case the generator is to overcompound for line drop a current winding is added to the main control magnet and is connected across a shunt in one of the local mains. The action of this current winding opposes the action of the potential winding in the control magnet end, and thus makes the generator overcompound for line drop. Regulators of this type can be adjusted for a line drop up to 15 per cent.

Where the generators are shunt wound a separate regulator is required for each machine which is operating at any time. Where several small compound machines are operating in parallel and all of the regulating is done by one machine, the others trailing after, provision is made for connecting any machine to the regulator. For field currents in excess of about 3 amperes at 250 volts, it is found that one relay contact is not sufficient, and for such cases regulators are built with as many as 10 relays, all being operated by a single main control magnet. For still larger d-c. generators whose field current could not be handled by a multiple-contact regulator, it is necessary to supply a separate exciter or exciters and the regulator then controls the field circuit of the exciter as described below for a-c. generators.

Fig. 1. Connections for Direct-current Tirrill Regulator

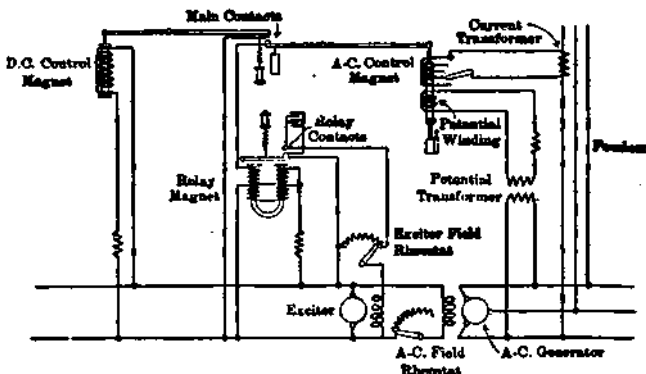

Fig. 2. Connections for Alternating-current Tirrill Regulator

**Regulator with D-C. Vibrating Magnet (Fig. 2).**— This works on the exciter field. The main contacts with this type of regulator are acted on by

two sets of control magnets, one connected across the exciter bus and tending to move the main contacts farther apart as the exciter voltage rises, and the other acted upon by a-c. potential and current coils. Suitable springs and counterweights allow the proper adjustment to be made. When the main contact closes, it energizes the relay magnet, thus closing the relay contact, short-circuiting the exciter rheostat and raising the exciter voltage and consequently the generator voltage. The use of the exciter voltage as one of the main control circuits prevents the generator voltage "overshooting," for as the exciter voltage rises to bring up the a-c. voltage the d-c. control tends to keep the main contacts apart and so reduce the voltage again.

The compensating current winding of the a-c. solenoid is provided with a dial switch to give any amount of compensation required for the feeder circuit

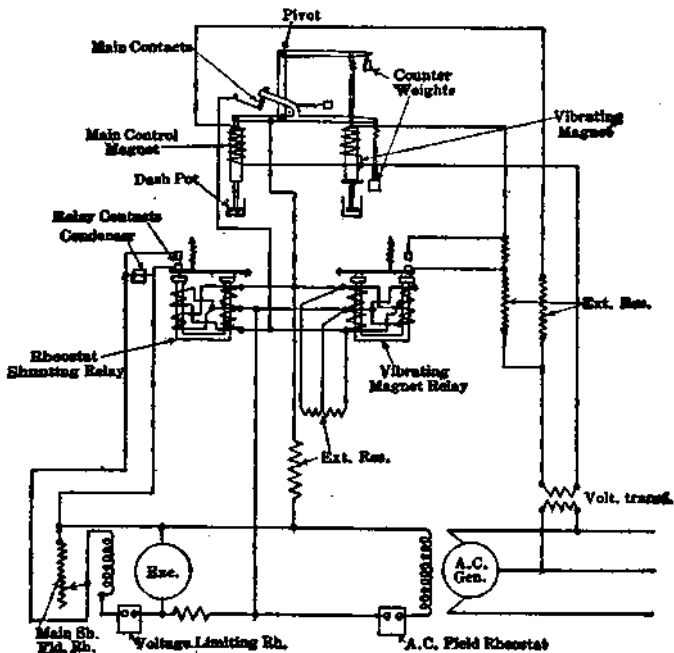

Fig. 2. Regulator with A-C. Vibrating Relay Control.

in which the current transformer is located. Where it is desired to compensate for both resistance and inductive drop under varying power factors a special compensator is provided. A modification of the regulator to take care of the large exciters has a number of relay contacts all operated at the same time from the one set of control contacts, the various relays being shunted by condensers to reduce the sparking. A single regulator may serve a number of alternators if they are operated in parallel and if all use the same exciter. If two or more exciters are operated in multiple, a single regulator will suffice; if not operated in multiple, a separate regulator is usually installed for each exciter.

**Regulator with A-C. Vibrating Magnet.** — This type of generator voltage regulator does not employ any d-c. main control magnets, but uses an a-c. vibrating magnet relay and its general connections are indicated in Fig. 3. The main control magnet has its core attracted upwards and its core stem connected to the floating lever which is pivoted to the bell crank of the vibrating magnet. The two magnets are energized from the same voltage transformer and actuates the main contacts into and out of engagement with the fixed contact. The opening of the main contacts open all relay contacts and inserts the full resistance into the vibrating magnet circuit, weakening the pull and closing the main contacts again. This system comprising the main control magnet, the vibrating magnet, levers, rheostats, shunting and vibrating relays, constitutes a vibrating system when the circuits are properly energized and the control elements balanced. For a given line voltage there is a definite upward pull of the vibrating magnet core when the vibrating relay contacts are open, and a definite pull of greater value when the relay contacts are closed. When the regulator is connected to the system the rheostat shunting relays open and close the circuit across the shunt field or regulating rheostat of the exciter, and the effective resistance of this rheostat is determined by the time of contact engagement.

Regulators for d-c. service are built for pressures up to 550 volts and for a-c. service they can be made so that by means of master relays they may control as many as 60 rheostat shunting relays, each rheostat shunting relay being capable of handling between 2000 and 2500 watts where the total current of any exciter field winding does not exceed about 15 or 16 amperes. The regulator with the main d-c. control is usually intended for a 2 : 1 range with no load to full load excitation current. With the vibrating relay control a broad range system of regulator can be adopted securing a 10 : 1 or greater voltage range by energizing the relays from a separate source of direct current, such as a small motor generator set or storage battery.

**REGULATOR APPLICATION.** — The following conditions should be approached as nearly as possible in order to obtain satisfactory results:

(1) Prime movers must be provided with proper automatic governors that will respond instantly to changes in load and keep the speed reasonably constant, within 3 per cent to 4 per cent, from no load to full load.

(2) Alternating-current generators should have as nearly as possible the same percentage range of excitation from no load to full load.

(3) Exciters must be capable of delivering sufficient voltage to take care of the alternating-current generator field under the full load conditions, 80 per cent power factor plus a certain additional voltage. This additional voltage above the steady exciter voltage required to maintain constant bus voltage under full load conditions is necessary in order that the regulator will continue to vibrate and thereby have control of the exciter.

(4) Where more than one exciter are to be considered, they must be adjusted to operate in parallel under all loads, with any point on the saturation curve.

(5) Exciters for 125-volt service should be able to build voltage up or down between the limits of 30 and 125 volts in five seconds or less under load consisting of generator field circuits. The time constant should be the same for exciters of other rated voltages over proportional changes. Exciters with greater time constants than this may not permit the regulator to maintain constant voltage with rapidly fluctuating load.

(6) Interpole exciters for 125-volt service must be able to develop at least 135 volts with series windings disconnected and should be so operated. Series windings must be out of circuit in order to secure a satisfactory time constant. In general, the exciter must be capable of developing a voltage 10 to 15 per

cent in excess of that required by the a-c. generator at full load, 80 per cent power factor, the a-c. generator field rheostat being adjusted so that with 60 volts on a 125-volt exciter, the a-c. generator develops normal voltage at no load.

Regulators can be arranged for satisfactory parallel control where generators are in parallel and the exciters operating independently.

**EXCESS VOLTAGE PROTECTION.**— Unless special devices are furnished with the generator voltage regulator, when a short circuit on the system is cleared away, a dangerous voltage rise is inevitable. On the occurrence of a short circuit on a system without some protective device, the main contacts of the regulators close, causing the exciter voltage to build up to the maximum value. When the short is cleared away, high voltage results from the high exciter voltage and the consequent high generator field current which lasts until the regulator has had time to again become operative. This condition of excessive voltage can, however, be prevented by means of excess-voltage protective devices arranged so that the exciter voltage can never rise above a predetermined point, which is usually a little above the no-load excitation value required by the a-c. generators. Different types of regulators require slightly different excess-voltage protective devices to accomplish this result.

**COSTS.**— The cost of regulators varies considerably due to the character of installation and varies between about \$1200.00 for a one-relay regulator and \$2715.00 for a ten-relay regulator.

**RELAYS.** — (See also *Circuit Breakers; Telegraphy; Telephony; Regulators; Signaling, Railway.*) A relay is a device which opens or closes a local circuit under predetermined electrical conditions of the main circuit. There are three general classes of relays as determined by their respective functions of (1) protecting the main circuit, (2) regulating the current in the main circuit, or (3) signaling the condition of the main circuit.

**PROTECTIVE RELAYS** are auxiliary devices supplied for use with circuit breakers on systems that require protection more selective and flexible than that afforded by the usual control features of automatic circuit breakers (q.v.). The closing of a local circuit through the action of the relay causes in turn the tripping of the circuit breaker.

**Types of Protective Relays.** — The types which are most commonly employed are given in the following table, together with the apparatus with which each type is applied and the protection furnished by the operation of the relay.

Relays are built to furnish protection against overvoltage, no voltage, overload, no load, reverse power and reverse phase. They may operate either directly

TYPES OF RELAYS

Type of relay	Application	Operations	Approximate cost per relay*
D-C. overvoltage	Storage batteries d-c. apparatus	Prevents overcharging Prevents damage from excess voltage	\$25.00
D-C. reverse current	Storage batteries rotary converters	Prevents discharging into charging source Protects against re- versal of flow of energy	94.00
D-C. low-voltage release	D-C. motors	Operates if voltage falls below given value	25.00
D-C. underload	Storage batteries	Disconnects on com- pletion of charge	25.00
A-C. overload	Feeders, motors, ro- tary converters, transformers	Protects against over- load	33.80
A-C. reverse power	Feeders, generators	Protects against re- versal of flow of energy	80.00
A-C. low-voltage	Induction motors	Protects against fall in line voltage	37.60
A-C. reverse phase	Synchronous appara- tus, elevators and cranes	Protects against re- versal of phase pro- gression	42.25

\* Costs do not include shunts for d-c. relays or current and potential transformers for a-c. relays, as the cost of these varies greatly with current and voltage. Costs are for 1921.

or in connection with other relays, and may be made instantaneous or provided with a time limit either of definite duration (time-limit relay) or inversely proportional to the extent of overload (inverse-time-limit relay).

**Definite Minimum Inverse Time-limit Overload Relays.** — Where the time-limit relays are wanted for the protection of a-c. circuits, it is practically universal American practice to furnish relays that have an adjustable definite minimum time setting and an inverse time setting combined. With one type, there is a definite time setting of two seconds with the maximum adjustment so that, independent of the intensity of a short circuit, the breaker will not trip out until two seconds have elapsed. This definite time is, however, adjustable between practically any limits between 0.1 second and 2 seconds. Beyond the definite time there is an inverse time feature which gives selective action whereby the time of operation varies inversely with the load. With this type of relay the faulty line carrying the heavier load usually will have its breaker tripped out before the other breakers are affected.

**Example of Use of Relays.** — The various types of relays that may be used to advantage in a system are shown diagrammatically in Fig. 1, where

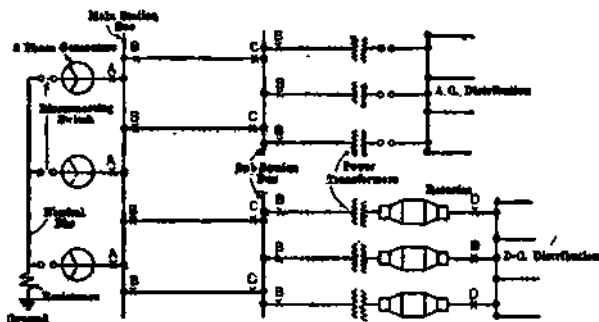

Fig. 1. Diagram Illustrating Use of Various Types of Relays.]

three a-c. generators operate in parallel with their neutral points grounded through a resistance and feed a common bus supplying current to power transformers, rotaries, etc., for a-c. and d-c. distribution. Relays for the operation of circuit breakers are inserted as follows:

- At A — a-c. overload and reverse power relays.
- B — a-c. overload time-limit relays.
- C — a-c. reverse power, time-limit relays.
- D — d-c. reverse current, inverse time-limit relays.

**The Principle of Operation** of a protective relay depends somewhat on the duty to be performed. The actuating mechanism usually involves such a motive device as a solenoid and core, or a rotating motor. The mechanisms described below are those most frequently used for the respective types of service.

**D-C. Overvoltage Relay.** — One design consists of a permanent magnet which forms a base and two iron cores mounted parallel to the base and attached to it at one end with an eccentrically-pivoted armature carrying a suitable contact. With no current flowing the two cores exert an equal pull (due to the magnetic field of the permanent magnet) on the pivoted armature, which, due to its eccentric mounting, is pulled up against one core. When voltage is impressed on the coils wound on the iron cores the magnetism in one pole is strengthened and in the other weakened. At the predetermined over-

voltage the position of the armature is reversed, notwithstanding its eccentric mounting, and the contact is closed, tripping the breaker.

**D-C. Reverse-current Relays** for instantaneous operation are similar in construction to overvoltage relays (*see preceding paragraph*). The solenoids, however, are operated from a shunt in such a way that with the current in the normal direction the contact is held open, but when the current reverses in direction the contact is closed, thus tripping the breaker.

**Reverse-current Time-limit Relays** are built on the principle of a permanent-magnet d-c. ammeter operated from a shunt. In normal operation the armature of the relay tends to turn in one direction but is restrained by a stop; in the case of current reversal the armature turns in the opposite direction, its rate of movement being proportional to the strength of the current. The angle through which the armature has to turn to close the contacts is adjustable by moving the stationary contact.

**A-C. Overload Relays** are usually built in single pole units and are nearly always made to give a definite minimum inverse time element. These relays are of the induction type and have practically superseded the solenoid design. This definite minimum feature is obtained by the use of a torque compensator or a small current transformer that saturates at practically 5 amperes. The primary side of this torque compensator is connected to the current transformer in the main circuit while the secondary side goes to the relay operating coils. Independent of the severity of the short circuit and consequently the current furnished to the primary of the torque compensator, the current supplied by the torque compensator to the relay coils does not materially exceed 5 amperes so that the speed with which the contacts are moved is practically fixed. The damping is so arranged that normally two seconds are required for the contact arm to move through its entire length of travel. By shortening the distance through which the contact arm has to move, this definite minimum time can be adjusted down to approximately 0.1 second. Relays of this kind are usually operated from current transformers having a normal secondary current of 5 amperes.

**A-C. Reverse Power Relays.**— These are made in various types and one kind frequently employed practically combines the features of the definite minimum overload relay and a selective wattmeter element. The overload element closes its contacts on excess current in either direction but the selective wattmeter element does not allow it to complete the tripping circuit unless power is flowing in the reverse direction. A momentary surge which may reverse the power will cause the selective wattmeter element to close its contacts, but the relay will not operate to trip out the breaker unless the current in the reverse direction exceeds the relay setting and is maintained for two seconds or longer.

**Relay Switch.**— Where, as frequently happens, the tripping contacts of a relay will not carry enough current to trip the circuit breaker, a relay switch is employed. In this case the relay merely energizes the operating coil of the relay switch whose contacts can be made suitable for any reasonable amount of current.

**Rating of Protective Relays** for overload service is given usually in terms of maximum current in the main circuit (secondary of transformer with a-c.). For reverse-load relays the rating is expressed as the percentage of reverse load on which they will operate. For relays which are not instantaneous in their action a time rating in seconds is usually given.

**REGULATING RELAYS.**— See article on *Regulators*.

**ING RELAYS.** — See articles on *Telegraphy; Telephony; Signaling*.

— See table above.

**RESISTANCE AND CONDUCTANCE, ELECTRIC.** — (See also *Alternating Currents; Bridges for Electrical Measurements; Electricity and Magnetism, Principles of; Resistors, Standard; Skin Effect; Wires and Cables; Wires, Resistor.*) The general definition of the resistance  $R'$  of a substance between any two equipotential surfaces intersecting the path of a current  $I$  is

$$R' = \frac{P_h}{I^2}, \quad (1)$$

where  $P_h$  is the power dissipated as heat between the two equipotential surfaces and  $I$  is the *effective* value of the *total* current from one surface to the other. In the case of a varying current this dissipation of heat may occur in four different ways, viz., (1) as heat due to the conduction current through the substance, (2) as heat due to dielectric hysteresis accompanying the displacement current through the substance (when the latter is an insulator), (3) as heat due to magnetic hysteresis accompanying the varying magnetic flux produced by the current and (4) as heat due to eddy currents induced in neighboring conductors.

In the case of a continuous (non-varying) current the last three effects do not occur, and the heat is that due to the conduction current only. The resistance offered by a substance to a continuous current is called the "true," "ohmic," "continuous-current" or "direct-current" resistance, as distinguished from the "effective" resistance offered by the substance to a varying current. The effective resistance, even when there are no losses due to dielectric or magnetic hysteresis, is in general greater than the ohmic resistance, due to the skin effect; see *Skin Effect*.

Similarly, the general definition of conductance is

$$G' = \frac{P_h}{V^2}, \quad (2)$$

where  $P_h$  has the same meaning as above and  $V$  is the *effective* value of the potential difference between the two equipotential surfaces. When the voltage is non-varying the conductance is called the "true," "ohmic," "continuous-current" or "direct-current" conductance as distinguished from the "effective" conductance to a varying current.

In the case of a *continuous*, or constant current  $I$ , the above expressions for resistance and conductance reduce to

$$R = \frac{V}{I}, \quad \text{and} \quad G = \frac{I}{V}, \quad (3)$$

provided there is no source of e.m.f. between these two surfaces. The ohmic resistance and conductance, given by equations (3), are reciprocals of each other, but this is not true for the effective resistance and conductance.

**RESISTIVITY AND CONDUCTIVITY.** — When the current stream lines from one equipotential surface to the other are straight and parallel and uniformly distributed, and  $l$  is the distance between the two surfaces and  $A$  the area of each, the ohmic resistance and conductance of the prism or cylinder of the substance thus formed are respectively

$$R = \rho \frac{l}{A}, \quad \text{and} \quad G = \gamma \frac{A}{l}, \quad (4)$$

where  $\rho$  and  $\gamma$  (which are reciprocals) are called the resistivity\* and conductivity\* of the substance respectively. For a given material at constant temperature throughout  $\rho$  and  $\gamma$  are constants.

\* Also called specific resistance and specific conductance.

**Units of Resistivity and Conductivity.** — From (4) it is evident that  $\rho$  is the resistance of a cube of the substance of unit length on each edge when the current stream lines are uniformly distributed and parallel to four of the edges of the cube; similarly,  $\gamma$  is the conductivity of such a unit cube. Resistivity is therefore frequently expressed as ohms or microhms per centimeter cube or per inch cube, and conductivity as mhos or mega-mhos per centimeter or inch cube. Note that a resistivity of  $x$  microhms per centimeter (or inch) cube is equivalent to a conductivity of  $\frac{1}{x}$  mega-mhos per centimeter (or inch) cube.

**Ohms per Mil-foot.** — It is frequently convenient in dealing with wires to express lengths in feet and cross sections in circular mils. The corresponding value of the resistivity  $\rho$  is then expressed in ohms per mil foot.

**Ohms per Meter-gram.** — The cross section of a bar or wire of uniform cross-section is equal to the volume of the bar divided by its length, and the volume of the bar is in turn equal to its mass divided by the density of the material of which it is made. Hence, using the same symbols as above, and in addition calling  $m$  the mass of the conductor and  $\delta$  its specific gravity,

$$R = \rho \delta \frac{l^3}{m} \quad (5)$$

For a given material at a given temperature  $\rho \delta$  is also constant, hence

$$R = k \frac{l^3}{m} \quad (5a)$$

where  $k$  is a constant (equal to  $\rho \delta$ ) for a given material at a given temperature; this factor  $k$  is then called the specific resistance of the conductor in "ohms per meter-gram" when  $l$  is in meters and  $m$  in grams.

**Pounds per Mile-ohm.** — In telephone and telegraph practice the specific resistance of a conductor is also expressed as the weight  $w$ , in pounds, of a wire one mile long having a resistance of one ohm. This weight  $w$  is sometimes called the "mile-ohm equivalent" of the wire.

**"Annealed Copper Standard." — Matthiessen's Standard.** — In 1862 Matthiessen published the results of a number of determinations of the resistivity of copper. Recent determinations of the conductivity of a number of samples of commercial annealed copper wire at the Bureau of Standards (*Bull. Bur. Stand.*, 1911, Vol. 7, p. 103) gave a mean value of the resistivity very close to Matthiessen's value. A conductivity corresponding to 0.15328 ohm per meter-gram at 20° C. has been adopted (1912) by the Bureau and by the American Institute of Electrical Engineers (1914)\* as the "standard" of conductivity, the name "Annealed Copper Standard" being suggested for it. (*See Standardization Rules of the A. I. E. E.*) Matthiessen's Standard, formerly used by the American Institute of Electrical Engineers as the basis for their wire tables corresponded to 0.141729 ohm per meter-gram at 0° C.

To reduce the value of the Annealed Copper Standard to resistivity and conductivity in volume units the value of 8.96 has been adopted as the density of copper in grams per cubic centimeter at 20° C. which corresponds to 8.90 grams per cubic centimeter at 0° C.

**Per cent Conductivity.** — The Bureau of Standards recommends that whenever the conductivity of a sample is expressed as a percentage, the measured resistivity or conductivity be corrected to reduce it to the value it would have

\* Also adopted by the national electrical engineering societies in Germany and France.

at 20° C.; see section on *Temperature Coefficient of Resistance*, below. A conductivity of  $P$  per cent is equivalent to

$$15.328 + P \text{ ohms per meter-gram at } 20^\circ \text{ C.}$$

$$172.41 + P \text{ microhms per centimeter cube at } 20^\circ \text{ C.}$$

$$67.87 + P \text{ microhms per inch cube at } 20^\circ \text{ C.}$$

$$1037.1 + P \text{ ohms per mil-foot at } 20^\circ \text{ C.}$$

For example, a conductivity of 60 per cent is equivalent to a resistance of 17.255 ohms per mil-foot.

**CALCULATION OF THE OHMIC RESISTANCE OF A CONDUCTOR.** — Values of the resistivity of various materials are given in the table below. Experiment shows that the resistance of a given length of wire of uniform cross section is independent of the shape into which the wire is bent, provided the diameter of the wire is small compared to the radius of curvature of the curve into which it may be bent. This condition is almost always realized in practice, and consequently formulas (4) and (5a) are in general directly applicable to the calculation of the resistance of a wire whether the wire be straight or curved or wound into a coil of any shape. These formulas are also applicable to the calculation of the resistance of a rod or bar, provided the rod or bar is not bent into a sharp curve, and the distance between its points of connection to the circuit is large compared to the linear dimensions of its cross section. Care should be taken, however, to express all quantities in the proper units; for example, the resistance in *ohms* of a wire which has a specific resistance of 1.6 microhms per centimeter cube, a length of 1000 feet and a cross section of  $\frac{1}{4}$  square inch, is

$$R = 1.6 \times 10^{-6} \frac{1000 \times 12 \times 2.54}{0.25 \times (2.54)^2} = 0.0302 \text{ ohm.}$$

**Resistance Formulas When the Stream Lines are Not Parallel and Uniformly Distributed.** — When the stream lines of the current are not all of the same length, as, for example, when a current is established in a heavy short bar bent into a sharp curve, the resistance of the bar can be calculated only when the distribution of these stream lines is known. Again, when the stream lines of the current are not parallel, e.g., the leakage current through the insulation of a cable, these formulas are not applicable. However, when the formula for the capacity between any two conductors is known (see *Capacity and Charging Current*), the resistance of the insulation, if uniform throughout, may be found by multiplying the *reciprocal* of the capacity, viz.,  $\frac{1}{C}$ , by  $\frac{K\rho}{4\pi}$ , where  $\rho$  is the resistivity of the insulation and  $K$  the specific inductive capacity in the capacity formula. See articles on *Rheostats* and *Wires and Cables, Insulated*.

**TEMPERATURE COEFFICIENT OF ELECTRIC RESISTANCE.** — The resistance temperature coefficient  $\beta_t$  of a substance at any temperature  $t$  is defined as the rate of change of the resistance at this temperature, viz.  $\left(\frac{dR}{dt}\right)_t$ , divided by the resistance  $R_t$  at this temperature, i.e.,

$$\beta_t = \frac{1}{R_t} \left(\frac{dR}{dt}\right)_t \quad (6)$$

The *mean* temperature coefficient  $\alpha_t$  between any two temperatures  $t$  and  $t_1$  referred to the temperature  $t$  is defined as the *average* change in the resistance in this interval per degree change of temperature, divided by the resistance at the lower temperature, viz.,

$$\alpha_t = \frac{R_{t_1} - R_t}{R_t (t_1 - t)} \quad (7)$$

**General Expression for Change of Resistance with Temperature.** — In general, the relation between the resistance  $R_t$  of a given mass of a substance at any temperature  $t$  may be expressed in terms of its resistance  $R_0$  at zero degrees as follows:

$$R_t = R_0 (1 + at + bt^2 + \dots), \quad (8)$$

here  $a$ ,  $b$ , etc., are constant coefficients.

**Linear Relation Between Resistance and Temperature.** — When all the coefficients except the first one,  $a$ , are of negligible magnitude, i.e., when the relation between the resistance and temperature is a *linear* one, then, from the above definitions, the mean temperature coefficient ( $\alpha_t$ ) referred to a given temperature  $t$  is equal to the temperature coefficient ( $\beta_t$ ) at that temperature, and the zero degree temperature coefficient ( $\alpha_0 = \beta_0 = a$ ) and the  $t'$  degree temperature coefficient  $\alpha_{t'}$  are related as follows:

$$\alpha_{t'} = \frac{\alpha_0}{1 + \alpha_0 t'} \quad (9)$$

$$\text{and} \quad R_t = R_0 (1 + \alpha_0 t) = R_{t'} [1 + \alpha_{t'} (t - t')], \quad (10)$$

where  $R_0$  is the resistance at zero degrees,  $R_{t'}$  the resistance at  $t'$  degrees and  $R_t$  the resistance at  $t$  degrees.

For most metals the simple linear relation expressed by equation (10) represents the experimental facts within practical limits of accuracy and for ordinary temperature ranges; values of  $\alpha_0$  are given in the table below. For dielectrics, however, the relation between the resistance and temperature is by no means linear, and several terms in such an expression as equation (8) are needed to represent the facts; see *Insulating Materials, Properties of*, particularly the sub-headings *Cambric, Paper and Rubber*.

**Calculation of Change in Resistance With Temperature.** — Equation (10) may be conveniently expressed in the form

$$\frac{R_{t'}}{R_t} = \frac{T_0 + t'}{T_0 + t}, \quad (11)$$

where  $T_0$  is written for the reciprocal of  $\alpha_0$ , viz.,  $T_0 = \frac{1}{\alpha_0}$ . (11a)

Equation (11) will be found very convenient for calculating the change of resistance with temperature and the change of temperature corresponding to two measured resistances, particularly when a slide rule is used.

$T_0$  is approximately equal to the number expressing the absolute zero on the mercury thermometer scale (except for magnetic metals) and is sometimes called the "inferred absolute zero" for the particular metal in question.

**MEASUREMENT OF RESISTANCE, RESISTIVITY AND TEMPERATURE COEFFICIENT.** — The simplest method of measuring a resistance in ordinary engineering work is to send a direct current through the conductor and measure this current by means of an ammeter (q.v.) and measure the potential difference across it by means of a voltmeter (q.v.). For measuring very low resistances, however, and for high-precision measurements, a bridge method should be used; see *Bridges for Electrical Measurements*.

**VALUES OF RESISTIVITY AND TEMPERATURE COEFFICIENT.** — The resistivity and temperature coefficient of the more common metals and alloys are given in the tables below.

## RESISTIVITY AND TEMPERATURE COEFFICIENT

$$1 \text{ microhm per centimeter cube} = \frac{1}{2.5400} \text{ microhms}$$

$$= 6.0153 \text{ ohms per}$$

$$= 0.01 \delta \text{ ohms per}$$

$$\text{specific gravit}$$

$$= 57.08 \delta \text{ pounds.}$$

$$\rho \text{ microhms per cm. cube at } 20^{\circ}\text{C.} = \frac{172.4}{\rho} \text{ per cent c}$$

The zero degree Fahrenheit temperature coefficient

$$\frac{5\alpha_0}{9 - 160\alpha_0}$$

(4) Herman Boker and Co. (5) Thomas Prosser and Son. (6) Dr. Frink, Trans. Am. Electro-chem Soc., 1910, Vol. 17. (7) *Copper Wire Tables*, Circ. No. 31, Bureau of Standards, 1914. (8) Electrical Alloy Co.

**Resistivity and Temperature Coefficient of Some Common Solutions.** — (See also *Electrochemistry, Principles of*.) The table on p. 1357 is based on data given by Kohlrausch and Holborn (*Leitvermögen der Elektrolyse*, Leipzig, 1898). The temperature coefficient given is that corresponding to an increase of temperature from 18° C. to 19° C., and is a negative quantity, i.e., for an increase of temperature the resistance decreases. The resistivity temperature coefficient of aqueous solutions diminishes rapidly with increase of temperature, i.e., the higher the temperature the less is the decrease in resistance for each degree increase in temperature.

**Resistivity and Temperature Coefficient of Ordinary Water.** — The resistivity of ordinary tap or river water ranges from 1200 to 12,000 ohms per centimeter cube, ordinarily being between the limits 2000 and 5000 ohms per centimeter cube. The change of the resistance of such water with temperature between the limits 0° C. and 100° C. may be represented to a fair degree of approximation by the formula

$$R_t = \frac{40 R_{20}}{20 + t},$$

where  $R_{20}$  is the resistance at 20° C. and  $t$  is any other temperature between 0° C. and 100° C. (From *Tests by Applequist and McKenny*, Mass. Inst. of Tech., 1912.)

## RESISTIVITY OF SOLUTIONS AND THEIR TEMPERATURE COEFFICIENT OF RESISTANCE

$$1 \text{ ohm per centimeter cube} = \frac{1}{2.540} \text{ ohm per inch cube.}$$

Percent solution is meant the weight of the dissolved salt or acid expressed as a percent of the weight of the solution.

For a solution less than 5% the resistivity is approximately inversely as the percent of salt or acid, i.e., a 2 per cent solution of common salt has a resistivity of approximately  $14.9 \times 5/2 = 37$  ohms per centimeter cube. As noted above the resistivity of ordinary tap water ranges from 1200 to 12,000 ohms per centimeter cube; a sample made from such water can not of course have a resistivity greater than that of

GRAPHY. — See references in text.

**RESISTORS, STANDARD, AND RESISTANCE BOXES.**—

(See also *Bridges for Electrical Measurements; Resistance and Conductance; Wires, Resistance; Rheostats.*) The primary standard of resistance is a mercury column of certain specified dimensions (see below). Secondary or commercial standards are made in two forms, viz.: (1) resistance standards each consisting of a single coil, carefully calibrated, mounted in a metal case, and (2) the ordinary resistance box, which contains a group of coils of known resistance.

The ultimate or primary standard of resistance, when measured in the international units, is the resistance of a column of mercury at 0° C. having a length of 106.300 centimeters and having a mass of 14.4521 grams (see *Units, Practical Electrical*).

**STANDARD MERCURY RESISTANCE.**—For the practical realization of such a standard, the International Conference on Electrical Units held in London in 1908 adopted the following specifications:

The glass tubes used for mercury standards of resistance must be made of a glass such that the dimensions may remain as constant as possible. The tubes must be well annealed and straight. The bore must be as nearly as possible uniform and circular, and the area of cross-section of the bore must be approximately one square millimeter. The mercury must have a resistance of approximately one ohm.

Each of the tubes must be accurately calibrated. The correction to be applied, to allow for the area of the cross-section of the bore not being exactly the same at all parts of the tube, must not exceed 5 parts in 10,000.

The mercury filling the tube must be considered as bounded by plane surfaces placed in contact with the ends of the tube.

The length of the axis of the tube, the mass of mercury the tube contains and the electrical resistance of the mercury are to be determined at a temperature as near to 0° C. as possible. The measurements are to be corrected to 0° C.

For the purpose of the electrical measurements, end vessels carrying connections for the current and potential terminals are to be fitted on to the tube. These end vessels are to be spherical in shape (of a diameter of approximately four centimeters) and should have cylindrical pieces attached to make connections with the tubes. The outside edge of each end of the tube is to be coincident with the inner surface of the corresponding spherical end vessel. The leads which make contact with the mercury are to be of thin platinum wire fused into glass. The point of entry of the current lead and the end of the tube are to be at opposite ends of a diameter of the bulb; the potential lead is to be midway between these two points. All the leads must be so thin that no error in the resistance is introduced through conduction of heat to the mercury. The filling of the tube with mercury for the purpose of the resistance measurements must be carried out under the same conditions as the filling for the determination of the mass.

The resistance which has to be added to the resistance of the tube to allow for the effect of the end vessels is to be calculated by the formula

$$A = \frac{0.80}{1063\pi} \left( \frac{1}{r_1} + \frac{1}{r_2} \right) \text{ ohm,}$$

where  $r_1$  and  $r_2$  are the radii in millimeters of the end sections of the bore of the tube.

The mean of the calculated resistances of at least five tubes shall be taken to determine the value of the unit of resistance.

For the purpose of the comparison of resistances with a mercury tube, the measurements shall be made with at least three separate fillings of the tube.

**STANDARD SINGLE-COIL RESISTANCES.** — The mercury standard resistance is cumbersome to work with and must be kept at constant zero temperature. Secondary standards, made of wire having a low temperature coefficient, are therefore universally employed in ordinary testing laboratories. The unit is provided with suitable heavy copper terminals so arranged that it may be hung from mercury cups and dipped into an oil bath. The object of the oil bath is to keep the temperature constant. Very low-resistance units, designed to carry large currents, are kept cool by means of water circulating in a coil of pipe within the case itself. Low-resistance units are also provided with "potential terminals," see Fig. 1, the stated resistance being the resistance between these terminals.

**Reichsanstalt and N.B.S. Types.** — There are at present two recognized types of resistance standards, the Reichsanstalt type and the National Bureau of Standards (or N. B. S.) type. Fig. 1 shows a 0.1-ohm standard of the first type, and Fig. 2 a 1-ohm standard of the N. B. S. type.

Fig. 1. Reichsanstalt Type Resistance Standard

Fig. 2. N. B. S. Type Resistance Standard

The Reichsanstalt type and the N. B. S. type standards are insulated and baked in much the same manner as the coils in ordinary resistance boxes, though of course more carefully calibrated. The chief difference between the two types of standards is that the N. B. S. type is hermetically sealed in an oil-filled brass case, the oil having previously been freed from air by boiling. It is claimed that the N. B. S. units hold their calibration better than the Reichsanstalt units, the latter being subject to slight variations of resistance in climates where wide changes of humidity occur. (See *Bulletin Bureau of Standards*, Vol. 5, p. 413.)

**Precision and Current-carrying Capacity of Standard Resistances.** — The makers of standard units usually guarantee their accuracy as given below. The current-carrying capacity of the units is also given.

**REICHSANSTALT TYPE, STANDARD RESISTANCE**

Size of unit	Max. amp.	Error not greater than	Size of unit	Max. amp.	Error not greater than
0.0001	100	$\frac{1}{2}$ %	10	.3	$\frac{1}{100}$ %
0.001	30	$\frac{1}{2}$ %	100	.1	$\frac{1}{100}$
0.01	10	$\frac{1}{2}$ %	1,000	.03	$\frac{1}{100}$
0.1	3	$\frac{1}{2}$ %	10,000	.01	$\frac{1}{100}$
1	1	$\frac{1}{100}$	.....	.....	.....

The National Bureau of Standards will calibrate any of these units and guarantee their accuracy of calibration to the above degree of precision, the charge being \$4 to \$6 per unit according to the value of the resistance.

**RESISTANCE BOXES.**—A brief description of the construction and arrangement of the coils in ordinary resistance boxes is given below.

**Construction of Coils.**—The coils are always wound non-inductively, that is, there are as many turns carrying the current in the right-handed direction as in the left-handed direction; this construction is illustrated in Fig. 3. Manganin wire (*see Wires, Resistor*) is usually employed. This wire is double-silk or enamel insulated, and is wound on wood or metal spools. Metal spools do not change in shape as wooden spools are liable to do, and since they more readily conduct the heat away, they may be safely used with larger currents.

The wound spools are then dipped in shellac and baked from 10 to 15 hours at a temperature of 140° C. This baking removes the tension from the wire due to the winding and the resistance is rendered constant, whereas coils not treated in this manner will change their resistance to some extent long after being wound. The resistance coils are adjusted to the desired values by varying the length of the wire, and copper terminals are silver soldered to the ends of the resistance wire. The coils are then ready for soldering in place in resistance boxes.

**Arrangement of Coils.**—The principal arrangements employed at the present time in the construction of resistance boxes are the 1, 2, 3, 4 plan, the 1, 2, 2, 5 plan and the four-coil and five-coil decade plans. Nine- and ten-coil decades are also extensively used, particularly when a telephone receiver is used as a detector. With four- or five-coil decades there is a disagreeable sound in passing from step to step.

**The 1, 2, 3, 4, and the 1, 2, 2, 5 Plans.**—Resistance boxes built on the 1, 2, 3, 4 plan have coils of the following resistances: 1, 2, 3, 4, 10, 20, 30, 40, 100, 200, 300, 400, 1000, 2000, 3000, 4000 ohms. These coils are all in series and each block on the top of the box is connected to a junction between successive coils. Inserting a plug therefore short-circuits a coil, *see Fig. 3*. In the 1, 2, 2, 5 plan the construction is similar, but the coils of any group have resistances in the ratio 1 : 2 : 2 : 5. Any resistance from 1 to 10,000 ohms can be obtained by either of these plans. On account of the large

number of plugs to be manipulated the large number of plug contacts and the necessity of making a mental summation of the values unplugged, these arrangements are being superseded in modern resistance boxes by the decade plan described below.

Fig. 4. 10-coil Decade

Fig. 5. 4-coil Decade

Fig. 6. 4-coil Dial Decade

Fig. 3. Resistance Coil Construction

**Decade Plan.** — The name decade arises from the use of 10 plug holes or 10 sectors in a dial arrangement, for each group of coils, each hole or sector corresponding to a given number of units, tens, hundreds, etc.

There may be either 10, 9, 5 or 4 coils per set. The 10-coil arrangement is shown in Fig. 4, a 4-coil plug decade arrangement in Fig. 5, and a 4-coil dial decade arrangement in Fig. 6, and a 5-coil decade arrangement in Fig. 7. The 9-coil decade differs from the 10-coil decade only in the omission of the tenth coil.

The only gain in having the tenth coil is to make it possible to check the total resistance of the 10 coils of one decade against any one coil of the next higher decade. The 4-coil and 5-coil arrangement possesses all the advantages of the 9-coil decade, and has the added feature of fewer coils to get out of adjustment.

**Precision of Resistance Boxes.** — The precision to which the various coils in a resistance box are adjusted depends on the design and use to which the box is to be put. In the cheaper boxes the actual resistance of any coil may differ from the stated resistance by as much as  $\frac{1}{4}$  per cent, whereas higher grades of boxes can be had having an accuracy of  $\frac{1}{48}$  per cent.

**Precautions to be Taken. Care of Resistance Boxes.** — The directions under these same headings given in the article on *Bridges for Electrical Measurements* also apply to the use and care of resistance boxes.

**COSTS (Pre-war prices).** — An ordinary 10,000-ohm resistance box (with coils for obtaining all resistances from 1 to 10,000 ohms) with the coils accurate to  $\frac{1}{4}$  per cent costs about \$30. A high-grade 10,000-ohm resistance box with coils accurate to  $\frac{1}{48}$  per cent costs about \$90. The costs of Reichsanstalt standard resistances are approximately as follows:

0.0001 ohm.....	\$40	1 to 1000 ohms.....	\$20
0.001 ohm.....	30	10,000 ohms.....	25
0.01 and 0.1 ohm.....	30		

**BIBLIOGRAPHY.** — See *Bridges for Electrical Measurements*.

Fig. 7. 5-coil Dial Decade.

**RHEOSTATS AND RESISTORS.** — (See also *Controllers; Control Systems for Railway Motors; Motors; Regulators; Resistors, Standard; Starters, Motor.*) A rheostat is a resistance device, usually adjustable, placed in a circuit for the purpose of regulating the current in that circuit. If used in connection with a machine, it may serve for regulating the speed, input, output, voltage or power factor. The name resistor is also used synonymously with rheostat, but is sometimes limited to mean a non-adjustable resistance device. This article treats primarily of the design of the resistance units, or resistors, used in the various controlling and starting devices employed commercially and in the laboratory; for their application, connections, etc., see the articles listed at the head of this article.

**General Principles of Design.** — Rheostats used for starting motors or for other intermittent work are usually designed on the assumption that no heat is radiated by them during the period (usually from 15 to 30 seconds) that they are carrying current. On this assumption the maximum allowable current  $I$  which a resistor can carry for  $t$  seconds without exceeding a temperature rise of  $T$  degrees is proportional to the square root of the ratio of  $T$  to  $t$ , the factor of proportionality depending upon the specific resistance and size of the current conductor, and the specific heats, weights and volumes of the materials heated, including the insulating material in which the resistors are embedded; see *Heat and Thermal Properties*. However, since there are so many variables entering into this factor  $K$ , the usual method employed in designing a rheostat is to determine experimentally the relations between current, temperature rise and time for a series of resistance units and to plot these relations in a set of curves. See also below under *Commercial Forms of Rheostats*.

The maximum temperature rise in the case of rheostats designed to carry a continuous load will occur when the heat radiated equals the heat generated. The proper resistance units for any service are determined from capacity curves for a variety of units subject to various conditions. Capacity curves are obtained by plotting as ordinates degrees of final rise of temperature against watts dissipated as abscissas. See also below under *Commercial Forms of Rheostats*. Natural draught is usually depended on for ventilation. For very large capacities forced ventilation is occasionally applied, if the space available is limited, but little is saved on the initial investment, and the maintenance expense is increased.

**COMMERCIAL RHEOSTATS.** — The term "commercial rheostat" is commonly meant to include besides the resistance elements the complete switching and control mechanism which serves to vary the resistance in the circuit for any particular kind of regulation.

**Forms of Resistance Elements for Commercial Rheostats.** — The more common forms of resistance elements are described below.

**Standard "Unit" Type of Resistance Element.** — Units of this type are made in either a flat or cylindrical form. One form of flat unit consists of a moulded flat core of vitreous material on which the resistance wire is wound; the surface is then coated with a special cement and baked. Thus the resistance material is protected from injury and made proof against moisture.

Standard cylindrical units usually have a core of asbestos tubing, or sometimes of metal tube coated with a suitable insulating material, such as enamel. A wire of low temperature coefficient is used; see *Wires, Resistance*. The tube with winding is covered with a suitable insulating compound, and porcelain bushings or metal rings (the latter for the clip type) are placed on the ends. The units are then thoroughly baked and mounted rigidly on a frame or in a suitable case. The coating protects the resistance material from mechanical injury,

l conductor of heat, and in case of a burn-out prevents appreciable unwinding of the wire. As a further protection, a sheet metal sometimes placed around the cement.

and capacities of cylindrical units cover the following ranges approximately capacity, from 30 to 350 watts; current capacity, from 0.06 to resistance, from 0.1 to 10,000 ohms; length, from 4 to 22 inches; from 1 to 2.5 inches. The watt capacity for these resistance units approximately 1.5 to 3.5 watts per square inch of surface for con- ice, when assembled in frames affording good ventilation. This stat is rarely employed when currents of more than 50 amperes are

**Type of Resistance Element.** — In this type the resistance coils to a circular base of insulating material. The coils are either an insulating, heat-conducting cement and baked, or are enclosed ed iron case. Suitable contacts and a switch arm are provided. her than 60 amperes are rarely handled by this type of rheostat. a sizes of plates range from 9 to 15 inches in diameter.

**Type of Resistance Element.** — This type of rheostat consists grids assembled on horizontal rods bolted to pressed steel end-plates. pe generally used for large currents. The rods are covered with a ng sleeve. If mounted on a frame affording good ventilation, the apacity of the standard grids is approximately 700 amperes per f cross-section for a maximum rise of 240° C.

**Operating and Control Mechanism for Rheostats.** — (See also *Starters*, h those rheostats which contain distinct resistance elements, or rminals of the elements are brought out to metal contacts usually circle on an insulating, fireproof plate. The contact of the switch l currents up to 25 amperes per contact arm consists of an ordinary er contact brush; for currents up to 350 amperes, solid sliding evenly-faced surfaces held by springs against the contact segments e switch-arms. For higher currents the laminated brush has been satisfactory because of the more uniform contact obtained. Most used on the rule that for maximum current, 20° C. rise of temperature nding air should not be exceeded for contacts and face parts. operated rheostats cannot be mounted on the panel, chain and ve is usually employed. Gear control is also occasionally used. ats are frequently operated by solenoids or motors. Motor- ostats are usually employed for currents in excess of 350 amperes.

**Forms of Commercial Rheostats.** — For any particular class of ature of the regulation desired, and the kind of circuit to which the be connected will determine the arrangement, size and number of e steps necessary as well as the proper type of switching mechanism See also *Motors, Industrial Application of*.

**Rheostats.** — The number of steps for a field rheostat depends ess with which adjustments of field current are to be made and on sired. For ordinary conditions a rheostat resistance equal to the e the generator field is satisfactory. Machines which are regulated e voltage regulators frequently require a rheostat resistance of from that of the generator field. Field rheostats for currents up to 60 usually in form of the plate type or unit type. For higher capacities e is employed. Field rheostats commonly have from 30 to 70 resistance. Double this number may be obtained in case of two or if the plates have the levers staggered. Field rheostats are either led or solenoid- or motor-operated.

**Field Discharge Resistors.** — These resistances are used in the field of motor or generator whenever the main-line switch is closed for the purpose of providing a gradual dissipation of the electromotive force in the field, thus limiting the arc on opening and reducing the force due to the inductance of the field circuit. They are used for 15-second duty. In general, a resistance equivalent to that recommended is recommended. They are frequently included with the field rheostat.

**Starting Rheostats.** — See *Starters, Motor*.

**LABORATORY RHEOSTATS AND RESISTORS.** (See *Standard*.) On account of the extreme variety of the requirements in a laboratory, there are but few standard forms of rheostats in use on the market. Therefore, most laboratory rheostats are custom-made.

A good form of laboratory rheostat for moderately-large currents consists of a thin metal tube, on which enameled resistance wire sliders should carry two or more laminated brushes, below which is scraped off. For fixed resistors the slider is omitted. The capacity of this form of resistor of diameter from 1 inch to 2 inches is 4 to 6 watts per square inch of surface, if ventilation is good. Grooved porcelain tubes or rectangular slate slabs wound with resistance wire will carry on an average from 2 to 4 watts per square inch.

Resistance wire (see *Wires, Resistance*) wound on open cores is frequently used for laboratory rheostats.

**Data on Galvanized Iron Wire.** — Iron wire, although it has a lower resistance than the various forms of resistance wire, is much cheaper and is therefore sometimes used. The following data are found useful in designing iron wire rheostats.

DATA ON GALVANIZED IRON WIRE

B. & S. gage	Circular mils	Maximum* allowable current	Feet per pound

**Carbon Rheostats.** — This type of rheostat consists of carbon plates stacked in a suitable frame and provided with an adjustable pressure that the pressure between the plates may be varied. All different sizes are sometimes used in large rheostats to secure

These rheostats are very useful when continuous variation of resist-  
relatively small ranges is desired; they are also very durable and cheap.

**Data for the Design of Carbon Rheostats.**—The following data  
from an article by C. R. Moore in the *Elec. Rev. and West. Elec.*, 1912,  
p. 672. Carbon plates, either circular or square, varying in thickness  
to  $\frac{1}{4}$  inch are satisfactory, the sizes from  $\frac{1}{8}$  to  $\frac{3}{16}$  inch being preferable  
of the more uniform contact obtained between the plates. Since prac-  
d of the resistance is in the contacts between successive plates the  
aces must be ground very smooth. The current-carrying capacity for  
stats varies from 5 to 12 amperes per square inch with an average of  
5 per square inch. For temperature rises ranging from 40 to 85° C.  
ing coefficient is from 0.002 to 0.005 watt per square inch of radiating  
er degree centigrade rise. For pressures ranging from 7.5 to 180 lb. per  
e variation in resistance per square inch per contact based on average  
shown in the following table:

RESISTANCE OF CARBON-PLATE RHEOSTATS

Resistance, ohms per sq. in. per contact	Pressure, lb. per sq. inch	Resistance, ohms per sq. in. per contact	Pressure, lb. per sq. inch	Resistance, ohms per sq. in. per contact
0.0230	35	0.0063	90	0.0029
0.0185	40	0.0057	100	0.0027
0.0145	45	0.0052	120	0.0024
0.0125	50	0.0047	140	0.0021
0.0100	60	0.0041	160	0.0018
0.0082	70	0.0036	180	0.0015
0.0071	80	0.0032		

**Example for Design of Carbon Rheostats.**—Given a circuit of  
sistance connected to constant potential mains of 110 volts, the current  
adjusted between the limit of 17 and 21.5 amperes by means of a series

Hence the corresponding voltage drops through the rheostat are  
5 volts respectively, which calls for a resistance ranging from 1.47  
0.116 ohm. For a current-carrying capacity of 7 amperes per square  
plates must have an area of  $21.5 \div 7 = 3$  sq. in. approximately; square  
5 by 1.75 in. may therefore be used. A convenient thickness for plates  
is  $\frac{1}{8}$  in. With 8 lb. per sq. in. as the minimum pressure, the resistance  
is  $0.022 \div 3 = 0.0073$  ohm (from table and area of plates as computed  
Hence the number of plates for 1.47 ohms resistance is  $1.47 \div 0.0073 =$   
s the length of the rheostat is approximately  $200 \times 0.125 = 25$  in.  
imum resistance of 0.116 ohm requires  $0.116 \div 200 = 0.00058$  ohm  
, which is equivalent to  $3 \times 0.00058 = 0.00174$  ohm per square inch  
ct. Hence, from the table the maximum pressure must be 165 lb. per  
hich is equivalent to a total pressure of  $3 \times 165 = 495$  lb. acting on  
supporting the carbon blocks.

ing surface must be provided for a maximum of  $25 \times 17 = 425$  watts.  
radiating constant of 0.004 watts per square inch per degree centigrade  
emperature, a maximum rise of temperature of 75° C. will require a  
of  $0.004 \times 75 = 0.30$  watts per square inch. Hence a radiating sur-  
 $425 \div 0.30 = 1420$  sq. in. must be provided. Since the 200 plates rep-  
radiating surface (edges only) of only  $200 \times 4 \times 0.125 \times 1.75 = 175$  sq.

in., every other plate must be of a larger size. This may be secured by using 100 small plates 1½ by 1½ by ¼ inch, having a total radiating surface (edges only) of 87.5 sq. in., and 100 plates 3 by 3 by ¼ inch, having a total edge surface of  $3 \times 0.125 \times 4 \times 100 = 150$  sq. in.; the total area of their projecting sides represents  $(3 \times 3 - 3) \times 2 \times 100 = 1200$  sq. in. Thus the total radiating surface is  $87.5 + 150 + 1200 = 1437.5$  sq. in.

**SUBMERGED WIRE RHEOSTATS.** — Steady loads for temporary work may be obtained from galvanized iron resistors placed in a river or tailrace or in a barrel continuously fed with supply water. The proper diameter and length of wire for any set of requirements may be calculated from the following formulas:

$$d = KI^{2/3}, \quad l = \frac{d^3 E}{112 I^2}$$

in which  $d$  = diameter of wire in mils,  $I$  = the current in amperes,  $E$  = the impressed voltage,  $l$  = length of wire in feet, 112 = average value of ohms per mil-foot of galvanized iron wire. Values of  $K$  for barrels or tanks range from 3.25 to 2.75, for tailraces or rivers of moderate flow, 2.75 to 2.25, for conditions of rapid flow, 2.25 to 2.0. Wooden sticks with fairly-sharp edges will make reliable supports for the wire. For more careful work the wires may be held by porcelain cleats screwed to wooden frames. The heating of these wires in water is so great that there must be no obstructions to a free circulation of the cooling water, otherwise failure may occur due to the formation of gaseous envelopes surrounding the wire. The water used must be clean to prevent rapid destruction by electrolysis. When tanks or barrels are used, it is preferable to raise the container above the ground (on wooden blocks about two feet high) so as to avoid seriously grounding the circuit through the stream of cooling water.

**DATA FOR SUBMERGED RHEOSTATS OF GALVANIZED IRON WIRE**

From *Rheostats for Dynamo Load Tests*, Am. Elec., 1903, Vol. 15, p. 512.

Size of wire, B. & S. Gage	Safe carrying capacity, amperes	Minimum length in feet for safe carrying capacity at different voltages			Feet per ohm, hot

**WATER RHEOSTATS.**—A water rheostat serves as a simple, cheap and satisfactory means of dissipating large amounts of energy. It is extensively used in the commercial testing of apparatus and for other purposes where an adjustable, high-power-capacity resistance is required. Permanent installations are sometimes made in hydroelectric stations to improve hydraulic or electric regulation and to furnish an artificial load.

**Resistivity of Water and Common Solutions.**—The resistivity of ordinary water at 20° C. (= 68° F.), taken from streams, wells or reservoirs, usually ranges from about 800 to 2000 ohms per inch cube (2000 to 5000 ohms per centimeter cube) though extremes may be found as low as 500 and as high as 5000 ohms per inch cube (1200 and 12,000 ohms per centimeter cube respectively). In water rheostats designed for less than 1000 volts it is usually desirable to increase the conductivity of the water by adding a salt (common salt, copper sulphate or other cheap salt) or an acid (usually sulphuric). For example, the resistivity of a 5 per cent solution of common salt at 18° C. is 14.9 ohms per inch cube (38 ohms per centimeter cube). The resistivity of various solutions of different strengths is given in the article on *Resistance and Conductance*.

As noted in the article just referred to, the resistance of ordinary water and of salt and acid solutions diminishes rapidly with increase of temperature. To a close approximation the resistance of ordinary clean water between 0° C. and 100° C. may be calculated from the formulas

$$R_t = \frac{40 R_{20}}{20 + t}, \quad \text{or} \quad R_t' = \frac{72 R_{68}}{4 + t'}$$

where  $R_{20}$  is the resistance at 20° C. =  $R_{68}$ , the resistance at 68° F., and  $t$  is any other temperature centigrade and  $t'$  any other temperature Fahrenheit.

Before designing a large high-voltage rheostat it is desirable to determine both the resistivity and temperature coefficient of a sample of the water which will be used. The sample should be tested in a miniature, low-voltage rheostat. If the large rheostat is to be operated on alternating current, the test with the miniature rheostat should also be made with alternating current, in order to avoid the effects of polarization. Determinations for a direct-current rheostat should be made with direct current, using a miniature rheostat of the same materials as are to be used in the large rheostat, and operated at the same current density and voltage. In designing a rheostat for permanent use data should also be obtained on the variations in the resistivity of the water throughout the year, for these variations are very marked in some cases.

**Low-voltage Water Rheostats.**—A simple form of water rheostat for direct-current or single-phase low-voltage work can be made of an oil barrel and two iron plates. One plate is placed on the bottom of the barrel. An insulated copper wire is connected to this plate and brought up along the side of the barrel and out through the top, or it may be attached to the underside of the barrel by means of a bolt passing through the plate and the bottom of the barrel. The other terminal is attached to a movable plate which is held by a window cord strung over two pulleys, the plate being held in position by a suitable counterweight at the free end of the cord. The barrel is filled with water, to which a relatively strong solution of common salt (NaCl), sal ammoniac (NH<sub>4</sub>Cl) or washing soda (Na<sub>2</sub>CO<sub>3</sub>) is added in sufficient amount to give the required conductivity. It is essential that the substance should be dissolved before it is added to the water barrel and that the solution should be poured in very carefully, because a very small amount of a salt solution will add considerably to the conductivity of the water. A single-phase load of 100 amperes at 100 volts may be carried continuously in a 40-gallon barrel without causing the water to boil. The plates should have a surface (one side only) of at least 1 square inch per ampere.

For low-voltage three-phase work a barrel with three pipes, suitably mounted and arranged to be raised or lowered by means of a cord and pulleys, is sometimes used. The pipes should have an immersed surface (outside surface only) of at least 1 square inch per ampere.

A serious objection to the use of a water rheostat containing a salt or acid is that the resistance for a given setting of the electrodes does not remain constant, due to the evaporation of the water, rendering the solution more concentrated. The increase in the temperature of the solution also causes very appreciable changes in resistance. When direct current is used the change in the concentration of the solution at the two electrodes (polarization) also causes a variation in the resistance with time.

**High-voltage Water Rheostats.**—For voltages above 1000 the conductivity of the tap or river water available is usually ample, without having recourse to the use of salts or acids. The use of ordinary water also makes it possible to keep a continuous flow of water through the rheostat and thus maintain a practically constant temperature. The discussion of such high-voltage rheostats given below is adapted from an excellent paper on this subject by E. A. Ekern in the *Stons and Webster Public Service Journal* for Nov., 1911.

Fig. 1. Open-column Type

Fig. 2. Closed-column Type

Fig. 3. Open Type, Three-phase Rheostat

Fig. 4. Mixed Type, Three-phase

**Types of High-voltage Water Rheostats.**—Fig. 1 illustrates a simple form of such a rheostat, and will be referred to as the "open-column" type, and Fig. 2 illustrates another simple form which will be referred to as the "closed-column" type. The illustrations are for single-phase rheostats; three-phase rheostats are made by combining three single-phase elements with the neutral point grounded. Fig. 3 illustrates a three-phase type suitable for immersion

in an open body of water; this type will be referred to as the "open type." The type shown in Fig. 4, which is a combination of the column type and open type, will be referred to as the "mixed type;" the illustration shows a three-phase rheostat with three plates for terminal electrodes sandwiched between four neutral electrodes. The plates should preferably have rounded edges.

**Calculation of Resistance.**—The resistance of the column type of rheostat (Figs. 1 and 2) is computed by the formula

$$R = \rho \frac{L}{A}, \quad (1)$$

where  $\rho$  = the resistivity of the water in ohms per inch cube (as noted above  $\rho$  is usually between 800 and 2000 ohms per inch cube),  $L$  = the length of the column in inches, and  $A$  = the area of the cross section of the column in sq. in.

For the open type (Fig. 3) the resistance between any cylindrical electrode and the neutral is given by the formula

$$R = \frac{\rho}{2.73 l} \log_{10} \left( \frac{2D}{d} \right), \quad (2)$$

where  $\rho$  = the resistivity of the water in ohms per inch cube,  $l$  = the wetted length of cylinder in inches,  $D$  = distance between cylinders in inches (center to center), and  $d$  = external diameter of each cylinder in inches. The equation is sufficiently accurate for all practical purposes when  $2D + d$  is greater than 80 and may be used with but small error when this ratio is as low as 40. (See also the article on Resistance and Conductance.)

The resistance to neutral of the mixed type (Fig. 4) is computed by the formula

$$R = \frac{R_1 R_2}{R_1 + R_2}, \quad (3)$$

where

$$R_1 = \rho \frac{S}{2A} \quad \text{and} \quad R_2 = \frac{\rho}{2.37 \lambda} \log_{10} \left( \frac{4S}{t} \right), \quad (4)$$

$R_1$  is the resistance between the face of any one terminal plate and the two neutral plates between which it is placed and  $R_2$  is the resistance between the wetted edge (assumed rounded) of the terminal plate and the two plates between which it is placed. The letters in the expressions for  $R_1$  and  $R_2$  have the following meanings:  $\rho$  = resistivity of the water in ohms per inch cube,  $S$  = the distance between adjacent plates (terminal plate to neutral plate) in inches,  $A$  = area in square inches (one side only) of terminal plate,  $t$  = thickness of each terminal plate in inches,  $\lambda$  = total length in inches of wetted edge (perimeter) of one terminal plate. The expression for  $R_2$  is a rough approximation, but as  $R_2$  is small compared with  $R_1$ , the error in the resultant resistance  $R$  due to an error in  $R_2$  is relatively small.

**Allowable Current Density.**—A current density at the electrodes in excess of 4 amperes per square inch is accompanied by a "spitting" or arcing and there is danger of short circuit. This limiting current density applies to clean water, but as there is always a likelihood of foreign materials getting into the water, it is not advisable to use a current density between flat plates in excess of 1 ampere per square inch, but at the edges of the plates or where there is a free and large circulation of water a current density as high as 3 amperes per square inch may be safely used.

**Minimum Distance between Electrodes.**—Calling  $\sigma$  the maximum allowable current density and  $v$  the voltage to neutral, then in terms of the notation defined above, the minimum spacing of the electrode is:

$$\text{For column type (Figs. 1 and 2)} \quad L = \frac{v}{\rho \sigma}. \quad (5)$$

$$\text{For open type (Fig. 3)} \quad D = \frac{d}{2} \log^{-1} \left( \frac{0.869 v}{\rho d \sigma} \right) \quad (6)$$

In the mixed type the limiting current density is usually at the edge of the plates, and the minimum spacing in this case is given by the relation:

$$\text{For mixed type (Fig. 4)} \quad S = \frac{l}{4} \log^{-1} \left( \frac{0.869 v}{\rho l \sigma} \right) \quad (7)$$

The logarithms are all common logarithms (i.e., to the base 10).

**Minimum Size of Electrodes.**—Using the same symbols as above, and in addition calling  $I$  the current per phase (terminal to neutral), the minimum area of each plate in the column type (Figs. 1 and 2) is  $A = I + \sigma$  square inches, and in the open type (Fig. 3) the minimum diameter of the electrodes is  $d = I + (\pi l \sigma)$  inches. In the mixed type the total area of the terminal plate (both sides and the edges) is approximately  $(\rho S) + R$ , where  $R$  is the total required resistance. The area of the flat surface of the plate (one side only) may be taken from 10 to 15 per cent less than half of this total surface, to allow for the edges. The actual division of current between the edges and the flat surfaces will be inversely as the resistances  $R_1$  and  $R_2$  given by equations (4).

**Example of Calculation of Dimensions.**—The more complicated case of a mixed type of rheostat is chosen, to illustrate the use of both types of formulas. Power to be dissipated 3000 kw. at 2300 volts, three-phase. Then voltage to neutral is  $V = 1328$  volts, current per phase  $I = 753$  amperes, corresponding to a resistance of 1.762 ohms. Assume the plates to be  $\frac{3}{8}$  inch thick, then  $l = 0.25$ . Allowing a maximum current density of 3 amperes per sq. in. at the edges, and taking  $\rho = 800$ , the minimum spacing is then, from equation (7),  $S = 5.27$  inches.

The total surface (both sides and edges) of each terminal plate, assuming  $\rho = 1200$ , to allow for an increase in the assumed resistivity of the water, will be  $(1200 \times 5.27) + 1.762 = 3580$  sq. in., and the area of the plate should then be say 15 per cent less than  $3580 + 2$ , or 1500 sq. in. approximately. A plate 60 by 25 inches will be a suitable size. The two resistances  $R_1$  and  $R_2$  are then from equation (4),  $R_1 = 2.1$  ohms and  $R_2 = 11.6$  ohms, and from equation (3)  $R = 1.775$ , which practically agrees with the required value of 1.762 ohms.

**Supply of Water.**—Due to the change in the resistivity of water with increase in temperature it is preferable to supply the rheostat with sufficient water to prevent much of an increase of temperature. At a hydroelectric station it is usually possible to use an open-type rheostat (Fig. 3) placed in a running stream or in a large body of water. When the water supply is limited it is sometimes necessary to allow the water to heat or even boil in extreme cases. Even in the case of limited water supply, however, a small steady overflow should be allowed, in order to prevent an accumulation in the rheostat of the salts contained in the water.

For an increase of  $T^\circ$  F. in temperature the water required to carry off  $P$  kilowatts, assuming no radiation or evaporation, is

$$\frac{0.91 P}{T} \text{ cu. ft. per min.} = \frac{6.8 P}{T} \text{ gallons per min.} \quad (8)$$

If only  $G$  gallons of water per minute are available and the water is allowed to boil, then calling  $T$  the difference between the boiling point and the temperature of the supply water in degrees Fahrenheit, the water evaporated when  $P$  kilowatts are supplied to the rheostat would be

$$G_e = \frac{P}{143} - \frac{GT}{970} \text{ gallons per min.} \quad (9)$$

*Example.* — To dissipate 3000 kw. with a  $10^{\circ}$  F. rise in the temperature of the water would require  $(6.8 \times 3000) + 10 = 2040$  gallons per min. If only 60 gallons per minute are available at  $62^{\circ}$  F.,  $G_e = 3000 + 143 - 60 \times (212 - 62) + 970 = 11.7$  gallons per min. will be evaporated, leaving 48.3 gallons per minute for the overflow.

**Notes on Design of Water Rheostats.** — The column type of rheostat may be used for any capacity and voltage. For voltages up to 23,000, the mixed type is usually preferable for large loads. For higher voltages, the open type may then be employed to advantage. Common iron pipe or steel plates are satisfactory materials for electrodes. Rheostats designed for permanent use should have galvanized electrodes. For voltages of 2300 volts and less, well-oiled and shellacked wooden containing vessels for the water have been found satisfactory. Open-or mixed-types of rheostats may be put in any tank or body of water where the clearance to sides or bottom is greater than one-half the spacing of electrodes. Column type rheostats up to 44,000 volts having columns built of vitrified glazed tile cemented together with Portland cement shellacked over have been operated successfully. Open-type rheostats made of iron pipes insulated and held securely above the water surface are very satisfactory. Mixed-type rheostats having plates separated by common porcelain line insulators and all clamped into a wooden frame have been used very successfully. Plates or electrodes should always be so arranged and located as to obtain free circulation of water. Where insulating material may be partially or intermittently in and out of the water, material may be deposited from the water and sufficient leakage surface must be provided. Innumerable arrangements and contrivances for the operation of rheostats may be designed but the important considerations are sufficient insulation to protect the operator, and positive movements to obtain the required degree of adjustment. Water rheostats are practically non-inductive. A slightly-leading current is obtained due to electrostatic capacity, but it is often more than offset by the inductive reactance of the conductors.

M., *Submerged Wire Rheostats*, Elec. World, 1909, Vol. 53, p. 1091; Davies, F. H., *Artificial Loads for the Dissipation of Electric Power*, Elec. World, 1911, Vol. 57, p. 549; Ekern, E. A., *The Water Rheostat as Artificial Load for Electrical Installations*, Stone & Webster Pub. Ser. Jour., 1912, Vol. 9, p. 312; Moore, C. R., *Carbon-plate Rheostats*, Elec. Rev. and West. Elec., 1912, Vol. 60, p. 672.

**ROOTS AND POWERS.** — The symbol  $a^n$  where  $n$  is a positive whole number means  $a$  multiplied by itself  $n$  times;  $n$  is called the exponent of  $a$ . The conception of an exponent is also extended to include negative and fractional exponents as follows: Let  $m$  be a positive whole number and let  $n = -m$ ; then the expression  $a^n = a^{-m}$  is defined as equivalent to  $\frac{1}{a^m}$ ; that is,  $a^{-m}$  is taken as equivalent to the reciprocal of  $a^m$ . Again, let  $n$  be a whole number and let  $n = \frac{1}{m}$ ; then the expression  $a^n$  is defined as equivalent to  $a^{\frac{1}{m}} = \sqrt[m]{a}$ ; that is,  $a^{\frac{1}{m}}$  is taken to represent the  $m$  root of  $a$ . In general, then, the properties of exponents are the following, where  $m$  and  $n$  may be positive or negative whole numbers or fractions:

$$\begin{array}{ll}
 a^{-m} = \frac{1}{a^m} & (a^m)^n = a^{mn} \\
 a^{\frac{1}{m}} = \sqrt[m]{a} & \sqrt[n]{a^m} = a^{\frac{m}{n}} \\
 a^m a^n = a^{m+n} & a^0 = 1 \\
 \frac{a^m}{a^n} = a^{m-n} &
 \end{array}$$

The calculation of roots and powers can be conveniently carried out by means of logarithms (q. v.); for the highest accuracy, a seven or nine place table should be used. Note that

$$\begin{array}{l}
 \log a^n = n \log a \\
 \log \sqrt[n]{a} = \frac{1}{n} \log a
 \end{array}$$

## MANILA ROPE

(From Blue Book of Amer. Mfg. Co., N. Y.)

Diameter of rope, inches	Approx. pounds per foot	Breaking strength, pounds	Diameter of rope, inches	Approx. pounds per foot	Breaking strength, pounds
½	0.085	1,750	1¾	0.65	13,200
¾	0.13	2,730	1½	0.77	15,700
¾	0.20	3,950	1¾	0.90	18,500
¾	0.26	5,400	1¾	1.04	21,400
1	0.34	7,000	2	1.36	28,000
1¼	0.43	8,900	2½	1.73	35,400
1½	0.53	10,900	2¾	2.13	43,700

**Factor of Safety.**—For ordinary purposes the maximum safe stress in wire ropes should be about one-third the ultimate, and for shafts and elevators about one-fourth the ultimate. In estimating the stress due to the load for shafts and elevators, allowance should be made for the additional stress due to acceleration in starting. For short inclined planes not used for passengers a factor of safety as low as 2½ is sometimes used, and for derricks in which large sheaves cannot be used and long life of the rope is not expected, the factor of safety may be as low as 2.

For power transmission by hemp ropes a factor of safety of 36 (referred to the nominal strength of the rope) is usually employed (*C. W. Hunt, Trans. A.S.M.E., Vol. 12, p. 230*).

**Splicing and Knots.**—See *Ken's Mechanical Engineers' Pocket-Book*.

**ROPE DRIVING.**—There are two methods of putting ropes on the pulleys, the multiple-rope and the single-rope systems. In the multiple-rope system several endless ropes are employed, and therefore there are as many splices as there are single ropes. In the single-rope system one endless rope is used, making several turns around the pulleys or sheaves, and therefore with but a single splice. In the first case the individual ropes are spliced in place, being made very taut at first, and less so as the rope lengthens, stretching until it slips, when it is respliced. In the second method tension pulley must be used to give the necessary adhesion and also to take up the wear.

**Power Transmitted by a Rope.**—The formulas given in the article on *Belts and Belling* are directly applicable to rope transmission, but may be put in a more convenient form as follows. Let

$V$  = velocity of rope, in feet per minute,

$d$  = diameter of rope, in inches,

$w$  = weight, in pounds, of 1 foot of rope 1 inch in diameter,

$T_1$  = actual tension in driving side of rope, in pounds per circular inch (i.e., the tension in pounds in a rope 1 inch in diameter),

$f$  = coefficient of friction between rope and pulley,

$n$  = number of half-turns the rope makes around pulley,

$C = 1 - e^{-nf}$ , where the value of  $e^{-nf}$  is taken from the table of  $e^{-x}$  in the article on *Exponential Functions*, putting  $x = nfr$ .

Then horse-power transmitted by each taut rope from one pulley to the other is

$$P = \frac{CT_1 d^2 V}{33,000} \left( 1 - \frac{wV^2}{116,000 T_1} \right) \quad (1)$$

**Power Transmitted by Hemp Rope.**—A formula developed by C. W. Hunt (*Trans. A.S.M.E., Vol. 12, p. 230*) is frequently employed. This formula may be written

$$P = \frac{d^2 V}{248} \left[ 1 - \left( \frac{V}{8500} \right)^2 \right], \quad (2)$$

which is the same as formula (1) when  $n = 1$ ,  $f = 0.35$ ,  $C = 0.67$ ,  $m = 0.32$  and  $T_1 = 200$ . The following table is calculated from Hunt's formula. For temporary work a rope of given diameter may be used with safety to transmit twice the horse power given in the table.

### HORSE POWER TRANSMITTED BY HEMP ROPE AT VARIOUS SPEEDS

*Computed from formula (2) given above*

Diam. of ropes, inches	Speed of the rope in feet per minute									
	1500	2000	2500	3000	3500	4000	4500	5000	6000	7000
$\frac{3}{8}$	1.45	1.9	2.3	2.7	3.0	3.2	3.4	3.4	3.1	3.2
$\frac{5}{8}$	2.3	3.2	3.6	4.2	4.6	5.0	5.3	5.3	4.9	3.4
$\frac{3}{4}$	3.3	4.3	5.2	5.8	6.7	7.2	7.7	7.7	7.1	4.9
$\frac{7}{8}$	4.5	5.9	7.0	8.2	9.1	9.8	10.8	10.8	9.3	6.9
1	5.8	7.7	9.2	10.7	11.9	12.8	13.6	13.7	12.5	8.8

**Power Transmitted by Iron and Steel Ropes.**—Wm. Hewitt of the Trenton Iron Company gives the following formula for the power transmitted by a steel rope, excluding the losses due to journal friction of the sheaves,

$$P = Bv^3, \quad (3)$$

where  $v$  is the velocity of the rope in feet per second and  $B$  has the following values.

$B$ for steel rope on	Number of half turns around sheave = $n$					
	1	2	3	4	5	6
Iron.....	5.61	8.81	10.62	11.65	12.16	12.56
Wood.....	6.70	9.93	11.51	12.26	12.66	12.83
Rubber or leather.....	9.29	11.95	12.70	12.91	12.97	13.00

For iron rope take for  $B$  one-half the figures given in the above table.

Hewitt's formula (3) is equivalent to (1) when the centrifugal force of the rope is neglected and  $T_1$  and  $f$  are as follows:

Kind of rope	Working tension $T_1$ in lbs. per circ. inch		Coeff. of friction = $f$
	Iron	Steel	
Iron.....	3600	7200	0.16
Wood.....	3600	7200	0.23
Rubber or leather.....	3600	7200	0.40

It should be noted that the coefficient of friction decreases rapidly with moisture or grease on the rope and sheaves, and consequently to transmit a given amount of power the tension must then be increased.

In the following table is given the horse-power that may be transmitted by a steel rope making a single half turn ( $n = 1$ ) on wood-filled sheaves. This table agrees approximately with formula (3). The transmission of more than 250 h.p. by a single steel rope making a single half turn on filled sheaves is impracticable, as the filling would be rapidly cut out due to the increased tension (i.e., total tension =  $T_1 d^2$ ) and high velocities required. If the rope makes several half turns around the sheave, however, a greater amount of power can be transmitted at a given speed and tension than when only a single half turn is used.

#### HORSE-POWER TRANSMITTED BY A STEEL ROPE ON WOOD-FILLED SHEAVES

Diameter of rope, in.	Velocity of rope in feet per second									
	10	20	30	40	50	60	70	80	90	100
$\frac{1}{4}$	4	8	13	17	21	25	28	32	37	40
$\frac{5}{16}$	7	13	20	26	33	40	44	51	57	62
$\frac{3}{8}$	10	19	28	38	47	56	64	73	80	89
$\frac{7}{16}$	13	26	38	51	63	75	88	99	109	121
$\frac{1}{2}$	17	34	51	67	83	99	115	130	144	159
$\frac{9}{16}$	22	43	65	86	106	128	147	167	184	203
$\frac{5}{8}$	27	53	79	104	130	155	179	203	225	247
$1\frac{1}{16}$	32	63	95	126	157	186	217	245	...	...
$\frac{3}{4}$	38	76	103	150	186	223	...	...	...	...
$\frac{7}{8}$	52	104	156	206	...	...	...	...	...	...
1	68	135	202	...	...	...	...	...	...	...

The horse-power that may be transmitted by iron ropes is one-half of the above.

**Power Lost Due to Friction of Sheaves and Shafts.**—In the above formula no allowance is made for the friction of the sheaves and shafts. Wm. Hewitt of the Trenton Iron Company gives the following expression for the horse-power lost in friction

$$6 \times 10^{-4} (W + G_1 + G_2) v,$$

where  $W$  = total weight of rope,  $G_1$  = total weight of terminal sheaves and shafts,  $G_2$  = total weight of intermediate sheaves and shafts, all in pounds, and  $v$  = velocity of rope in feet per second.

**Sheaves of Ropes.** — The following table gives the minimum diameter recommended by Hunt for hemp ropes and by Hewitt for steel and iron ropes. The larger the diameter of the sheaves the greater the life of the rope.

MINIMUM DIAMETER OF SHEAVES

Hemp	Steel			Iron		
	7-wire	12-wire	19-wire	7-wire	12-wire	19-wire

**Measured by Sag.** — (See also article on *Transmission Lines*.) Let

$T$  = weight of rope per foot, in pounds,

$S$  = distance between centers of sheaves in feet,

$s$  = distance in feet midway between sheaves.

The tension at the sheaves, corresponding to the sag  $S$ , is approximately

$$T = \frac{wL^2}{8S} + wS \quad \text{pounds}$$

for the driving or the slack rope.

**RUBBER.** — (See also *Gutta-Percha; Insulating Materials; Wires and Cables Insulated.*) Rubber is derived from the milky secretion or latex of certain tropical trees, creepers and shrubs found chiefly in America, Africa, Ceylon and Malacca. When these plants are tapped, a thick milky-looking fluid or latex exudes from them. This latex is composed of very minute oil-like refractive globules, varying in size, which are in a state of rapid Brownian movement in a clear transparent liquid, called the serum. Besides these caoutchouc globules, or rubber-gum proper, the serum contains resins, protein, enzymes and various organic and inorganic compounds. Rubber or India rubber is the dried-up or coagulated latex. The best rubber is from a tree known as the *Hevea Brasiliensis*, and is known as *Hevea* rubber. It grows wild in Brazil and is cultivated in Ceylon and the Malay Peninsula. In Brazil coagulation is effected principally by dry heat or smoking. A wooden paddle is dipped in the latex and held over a smoky fire until the latex has coagulated. This process is repeated until the caoutchouc layers have become sufficiently thick, when the lump of raw rubber is cut off, dried for several days and despatched usually as "fine Para biscuits" to a trading center. The plantation rubber is coagulated in sheets by means of acetic acid. If subsequently smoked it is known as "smoked sheets." Para enterfine, Negro Heads and Sernamby are usually prepared from fine Para rubber which adheres to the tree during tapping or to the vessels containing the latex.

**IMPURITIES IN COMMERCIAL RUBBER.** — Commercial rubber contains, in addition to the caoutchouc, a number of foreign substances, such as sand, bark, etc., which can be removed by mechanical washing, followed by drying.

**Acetone Extract.** — In addition to the pure rubber gum, washed rubber contains resins and proteins which are soluble in acetone and are therefore often known as "acetone extract."

The accompanying table shows the loss in washing and the percentage of acetone extract in the best brands of raw rubber.

#### IMPURITIES IN COMMERCIAL RUBBER

(Abstracted from a very comprehensive table in "Lectures on India Rubber,"  
Edited by D. Spence.)

##### Brazilian Rubber

Trade name	Geographical origin	Mean loss on washing, per cent	Acetone extract in washed dry rubber, per cent
Para, fine Island, soft cure	Brazil, the islands of the lower Amazon and its delta, and also other parts of the State of Para	17-20	1.9-2.1
Para estrefine, Islands estrefine		18-25	Varies
Negro Heads, or Islands Coarse Sernamby		35-40	2-6
Fine Para, upriver, hard cure	Amazon district. Also the districts drained by its large tributaries	15-20	1.9-2.9
Upriver estrefine, hard estrefine		18-25	Varies
Upriver coarse or Manaus Scrappy Negroheads		18-25	1.5-1.8
Cameta Negroheads	Southwestern Para	37-42	1.2-2.2

IMPURITIES IN COMMERCIAL RUBBER — *Continued*Brazilian Rubber — *Continued*

Trade name	Geographical origin	Mean loss on washing, per cent	Acetone extract in washed dry rubber, per cent
Caucho Balls	Amazon district and its lower tributaries	25-35	3.6-4
Caucho Slabs and Strips		35-42	4-8
Ceará Scraps Manicoba	Ceará, Piauí and Rio del Norte	29	2.1
Matto-Grosso, Virgin sheets, white Para	Matto-Grosso	15-30	2.5-3.5
Matto-Grosso, Negroheads	Matto-Grosso	25-35	2.5-6

## Miscellaneous South and Central American Rubber

Kasai, fine	" "	7-10	3.3

**MANUFACTURE OF RUBBER INSULATION.** — The washed, dried rubber is passed between heavy rollers and flattened into thin sheets. It is then cut into small pieces and again passed through the rollers with a large proportion of fine powder consisting usually of inert mineral substances, waxy hydrocarbons and sulphur. The mixture is thus masticated until all its constituents are thoroughly mixed and a smooth homogeneous paste obtained. This process is known as compounding.

**Fillers Used in Compounding.** — Experience has shown that 60 or 70 per cent of mineral filler, or even a greater proportion of rubber substitute, may be added to rubber gum, before the essential qualities of the rubber

cease to predominate. The majority of commercial 30 per cent insulating compounds have compositions which fall within the following limits.

Ingredient	Per cent
Rubber.....	30-33
Whiting.....	0-30
Zinc oxide.....	25-67
Litharge.....	1-12
Ozokerite or paraffin.....	2-4

In addition to the above fillers, from 2 per cent to 4 per cent of sulphur is added to the compound, the greater part of which combines with the rubber in the vulcanizing process (see below).

Barium sulphate, sublimed white lead, lead carbonate, lamp-black, talc, magnesium carbonate, red lead, barium carbonate and other substances are also used in small quantities. Talc is often objected to, as making the compound porous, and lampblack, as rendering analysis difficult.

**Applying the Compound to Wires.**—The rubber compound is applied to the wire by "tubing" machines, or is applied in strips, and the wire thus covered with the compound is coiled up ready for vulcanizing. See article on *Wires and Cables, Insulated*.

**Vulcanizing.**—If exposed for a long time to air and sunlight, rubber loses its elasticity and finally oxidizes completely into resinous matter soluble in acetone. By vulcanization, however, rubber is rendered more or less immune from deterioration by weathering. Vulcanization is the chemical union of rubber gum with sulphur. It takes place at a temperature of from 248° to 302° F.

The coils of wire, covered with the compound as above described, are placed in a suitable chamber to which steam at the proper temperature is admitted. The time required for vulcanization depends upon the thickness of the insulation, the nature of the compound, the temperature and pressure of the steam, etc., ranging from 2 to 8 hours.

**Sulphur Required for Vulcanization.**—The amount of sulphur required to produce vulcanization varies with the brand of rubber and the nature of the adulterants with which it is mixed. The ratio of the weight of combined sulphur to the weight of caoutchouc, which is insoluble in acetone, is called the vulcanization coefficient. The highest grades of 30 per cent hevea insulation usually have a coefficient between 5 per cent and 10 per cent.

The vulcanization of some brands of rubber cannot be accomplished without either an excess of sulphur or the presence of excessive quantities of some mineral accelerator, such as red lead. Such rubber is to be avoided where permanency is an important consideration. It does not follow from this that red lead is a detrimental ingredient.

**SPECIFIC RESISTANCE.**—The specific resistance of 30 per cent hevea rubber compounds is exceedingly variable, depending largely upon the success with which steam is prevented from condensing in the insulation during vulcanization. The megohm-miles are usually computed from the following formula:

$$M = K \log_{10} \frac{D}{d}$$

here

$M$  = insulation resistance of a cable, megohm-miles,  
 $d$  = diameter of cylindrical conductor,  
 $D$  = diameter of cable over its insulation,  
 $K$  =  $5.8 \times$  (millions of megohms per inch cube at  $60^\circ \text{F}$ ).

The value of  $K$  varies from 3000 to 7000, the usual specification value being 5000 for 30% hevea compounds.

The specific resistance is not an indication of the quality of rubber insulation as it depends more upon the dryness, the proportion of mineral wax, and the degree of vulcanization, than upon the quality of the ingredients. When the megohms are low they can almost invariably be raised by drying the insulation in a desiccator. The specific resistance of very poor quality rubber compounds, however, sometimes so low that when a cable lies in damp earth, sufficient leakage current may flow to permit the passage of water by endosmose, when the conductor is negative to the ground (see article on *Endosmose*).

**DIELECTRIC STRENGTH.** — The disruptive strength of rubber insulation is generally given as between 350 and 450 kilovolts per inch or about 140 to 180 kilovolts per centimeter effective a-c. values. The pressures which should be used in commercial testing do not depend entirely upon the dielectric strength of the rubber, as air in the rubber or between the rubber and conductor or between the rubber and ground becomes ionized at a pressure of about 30 kilovolts per centimeter with consequent generation of ozone, which rapidly oxidizes and destroys the rubber. This does not occur with paper insulation because the impregnating oil precludes the possibility of air spaces; and no harm results in the case of varnished cambric because it is not seriously attacked by ozone. Hence test pressures for rubber insulation must be based upon experience rather than upon theory and if sufficiently high to permit ionization of the air, should not last long enough to permit the formation of an appreciable amount of ozone.

**SPECIFIC INDUCTIVE CAPACITY.** — The specific inductive capacity of pure rubber is about 2.3 (*Floy*), but the vulcanized compounds used for insulation have specific capacities ranging between 3 and 5, the latter value being nearer the average. The specific capacities of several compounds of stated composition are given by E. Jona (*St. Louis, 1904*), but they cannot be considered as representative of American practice.

**SPECIFICATIONS.** — Specifications for rubber insulation for wires and cables will be found under *Wires and Cables, Insulated*.

**SECOHMMETER.** — (See also *Bridges for Electrical Measurements.*) The secohmmeter is an instrument used in connection with a Wheatstone bridge for changing the direct current from a battery to an alternating current, by commutating the portion of this current that flows in the galvanometer circuit to a direct current. The secohmmeter may be used in the measurement and comparison of self- and mutual inductances and in the measurement of the resistance of electrolytes.

Fig. 1 shows the relative position of the commutators and brushes of a secohmmeter when connected in a bridge circuit. *A* is the commutator to which the galvanometer is connected and *B* the one to which the battery is connected. They are on the same shaft and turn together.

The secohmmeter is not an altogether satisfactory instrument, due to the variation in the various contact resistances when used for any length of time. Whenever possible some other method of accomplishing the desired results should be employed, e.g., the use of alternating current with some sort of a-c. detector, such as a telephone receiver, electro-dynamometer or a-c. galvanometer.

Fig. 1. Connections for Secohmmeter

**M.** — Selenium, an element of rare occurrence in nature, is found in as a selenide in combination with various metals. Vitreous selenium which has been fused, is dark brown in color and has a specific 28. Its melting and boiling points are  $217^{\circ}$  C. and  $700^{\circ}$  C. respectively. Selenium is a very poor conductor of electricity, its resistance 60,000 ohms per centimeter-cube at room temperature. When selenium is annealed it assumes a crystalline form sometimes called selenium. As a result of the annealing process, the electrical resistance is greatly reduced (the amount depending upon the thoroughness of the annealing) and becomes a function of the intensity of illumination, a property not possessed to a lesser degree by tellurium and carbon. Sensitive selenium is said to be light-positive or light-negative depending upon whether its resistance decreases or increases respectively when carried from light to dark. Sensitive selenium is usually light-positive. The resistance of selenium is usually less than that of light-positive selenium.

**SELENIUM LIGHT-CELLS.** — A selenium cell or unit is made by connecting narrow strips of light-sensitive selenium in parallel between the two brass plates. The higher the resistance the higher the sensibility of the cell, that is, the greater the ratio of its conductivity in the light to its conductivity in the dark. The conductivity of a cell made of high-resistance selenium shows a change in conductivity of 20,000 per cent (200 times) when carried from direct sunlight to a dark room. Cells made of low-resistance selenium (light-negative) show a much smaller change in conductivity, seldom more than 10 per cent for a change from direct sunlight to dark.

**Intensity of Illumination.** — The resistance of the cell when illuminated depends upon the time of exposure and the intensity of the light. If a strong light is suddenly thrown upon a high-resistance cell in a dark room, the resistance of the cell decreases to its minimum value in a few seconds and then begins slowly to increase again. If the illumination is not so great or the cell has a comparatively low resistance the time taken to reach a minimum resistance may be several minutes. The majority of experimenters on this subject agree that the change of resistance is proportional to the square root of the intensity of illumination.

**Wave Length of Light, Temperature, etc.** — It is found that the yellow rays are the most effective. The sensibility of most cells increases with the temperature increases. In certain selenium cells a large difference impressed across the terminals of the cell produces a variation in the cell similar to that caused by an exposure to light.

**Selenium Cells.** — The light-sensitive property of selenium has been used in the photophone and in connection with the electrical transmission of pictures. In the photophone a beam of light reflected from a mirror on the vibrating disk of a telephone transmitter is made to play across a selenium cell connected in series with a battery and a telephone receiver. In the transmission of speech may be transmitted through space by means of light waves. In the transmission of pictures a large number of selenium cells are usually used to reproduce the light and shade of the picture. The light reflected from the picture is then represented at the distant point by a corresponding intensity of current, which may reproduce again electrochemically the picture of the reflected light at each point.

**SEPARATORS, STEAM.** — (See also *Boilers*)  
 boilers, without superheaters, generally deliver steam  
 1.5 per cent of moisture. When the water level rises  
 the water contains substances which cause foaming  
 in the steam may be much higher. Condensation  
 also increases the moisture, and for this reason it is  
 pipe line near the engines one or more steam separa-  
 by suddenly changing the direction of the flowing  
 of water are by their momentum carried out of the  
 jected against a baffle or bend in the pipe or separa-  
 collected and removed through a trap. Separators  
 in the exhaust steam piping to eliminate the cylinder  
 steam.

Although absurdly high efficiencies are claimed  
 separators, efficiencies which cannot be realized in  
 separator should be retained in service that does  
 cent of the water carried by the steam approaching

**BIBLIOGRAPHY.** — Gebhardt, G. F., *Steam  
 Catalogues of Manufacturers.*

**SERIES, MATHEMATICAL.** — (See also *Equations, Differential; Wave Analysis.*) In calculating the numerical values of a function for given numerical values of the variable, it is frequently convenient to express the function as a sum of a series of terms each of which is a simple algebraic function of the variable. The simplest form of such a series is the

**Binomial Theorem.** —

$$(x + a)^n = x^n + nax^{n-1} + \frac{n(n-1)}{2!} a^2 x^{n-2} + \frac{n(n-1)(n-2)}{3!} a^3 x^{n-3} + \dots + a^n$$

Where  $2!$  means  $1 \times 2$ ,  $3!$  means  $1 \times 2 \times 3$ , etc.

A particular case of this series is when  $x = 1$ ,  $a = \frac{1}{n}$  and  $n$  is taken infinitely

large. The expression  $\left(1 + \frac{1}{n}\right)^n$  is not unity, but has the value

$$e = 1 + 1 + \frac{1}{2!} + \frac{1}{3!} + \frac{1}{4!} + \dots$$

This is the base of the natural system of logarithms and is numerically equal to 2.718281.

**Taylor's Series.** — Let  $f(x)$  be any function of  $x$ , and for brevity write

$$f'(x) \text{ for } \frac{df(x)}{dx}, f''(x) \text{ for } \frac{d^2f(x)}{dx^2}, \text{ etc.}$$

Then  $f(x+h) = f(x) + hf'(x) + \frac{h^2}{2!} f''(x) + \frac{h^3}{3!} f'''(x) + \dots$

This expression is known as Taylor's series. Such a series is a useful expression for  $f(x+h)$  only when the terms of the higher order are negligibly small, in which case the series is said to be convergent.

**Maclaurin's Series** is the special case of Taylor's Series when the  $x$  in the latter is taken equal to 0 and the  $h$  in the latter is put equal to  $x$ . In this case

$$f(x) = f(0) + xf'(0) + \frac{x^2}{2!} f''(0) + \frac{x^3}{3!} f'''(0) + \dots$$

Where by  $f(0)$  is meant the value of  $f(x)$  for  $x = 0$ , by  $f'(0)$  is meant the value of  $f'(x)$  when  $x = 0$ , etc.

The following are useful expressions derived from the above relations:

$$e^x = 1 + x + \frac{x^2}{2!} + \frac{x^3}{3!} + \dots$$

$$\log(x+1) = x - \frac{x^2}{2} + \frac{x^3}{3} - \frac{x^4}{4} + \dots$$

$$\sin x = x - \frac{x^3}{3!} + \frac{x^5}{5!} - \frac{x^7}{7!} + \dots$$

$$\cos x = 1 - \frac{x^2}{2!} + \frac{x^4}{4!} - \frac{x^6}{6!} + \dots$$

$$\sinh x = x + \frac{x^3}{3!} + \frac{x^5}{5!} + \frac{x^7}{7!} + \dots$$

$$\cosh x = 1 + \frac{x^2}{2!} + \frac{x^4}{4!} + \frac{x^6}{6!} + \dots$$

**SHAFTING.** — (See also *Bearings; Belts and Belting.*) Ordinary shafting for mill work is usually made of solid steel rods, although hollow shafting is sometimes used.

**Diameter of Shaft.** — The proper size of shafting to use to transmit a given amount of power may be expressed by the formula

$$d = \sqrt[3]{\frac{CP}{N}}$$

where  $d$  is the diameter in inches,  $P$  the horse-power transmitted,  $N$  the speed in revolutions per minute, and  $C$  a constant depending upon the desired factor of safety, the number and location of pulleys or gears, the weight of pulleys or gears and belting, etc. Various authorities assign different values to  $C$ , ranging from 40 to 125, the lower value for short shafts used simply for transmitting power, a higher value for line shafts (carrying several pulleys), and the highest value for head shafts carrying the main driving pulley.

**Distance Between Bearings.** — The distance between bearings may be expressed by the formula

$$L = \sqrt[3]{Bd^3}$$

where  $L$  is in feet,  $d$  in inches and  $B$  is a constant dependent upon the elasticity of the shaft, the load on the shaft and the allowable deflection. The latter is usually taken as  $\frac{1}{100}$  of an inch per foot of length. The Pencoyd Iron Works take  $B = 720$  for bare shafts, and  $B = 140$  for shafts carrying pulleys.

**Speed of Shafting.** — The following represents average practice.

Machine shops.....	120-240 revolutions per minute.
Wood-working.....	250-300 revolutions per minute.
Cotton and woolen mills.....	300-400 revolutions per minute.

**Efficiency of Shafting.** — Experiments made by various engineers have shown losses between engine and machine in ordinary machine shops of from 50 to 60 per cent of the total power transmitted by the engine. This loss is greatest in shops where large machines are employed, located at some distance from each other, and it is here that other kinds of transmission can be used to advantage.

**Cost of Shafting (Pre-war figures).** — The cost of shafting, including the necessary hangers, couplings and pulleys will vary according to size between \$2 and \$6 per linear foot. A rough rule which may be used in preliminary work is to allow \$1 per linear foot per inch of diameter.

**BIBLIOGRAPHY.** — See Kent's *Mechanical Engineers' Pocket-Book* and the various works on *Machine Design* listed in the Bibliography at the end of article on *Bearings*.

**ELECTRIC PROPULSION OF.**—The relative light weight, and high steam economy of high-speed steam turbines, compared with reciprocating engines, naturally suggest the use of such turbines for the propulsion of ships. The most efficient speed of a ship's propeller, however, is that of a steam turbine. Consequently, to obtain the best over-all means for speed reduction must be provided. At present no means available, namely, high-speed tooth-gearing and "electric" gear, high-speed generators direct-connected to the turbines and electrically connected to low-speed motors which in turn are direct-connected to the shafts. By these two methods speed reductions as high as approximately 20 to 1 are being obtained. Ships equipped with electric gearing are referred to as electrically propelled.

The development of the turbine and these two methods of speed reduction make the reciprocating engine relatively undesirable for ship propulsion, especially for quite small boats. The electric propulsion of ships is now being used and more into favor. There are still, however, opponents to this method among ship owners and others. The more obvious application is for small boats, such as warships and ocean liners. The many very great advantages of electric propulsion for large warships is now fully recognized by the Navy, as all the many battleships and battle cruisers which are being built and those which have been built during the last four years, are equipped with the electric method of propulsion.

The first two fire-boats, "Graeme Stewart" and "Joseph Medill" were propelled by electric propulsion in 1908. The first large ship equipped with electric propulsion for the United States Navy was the collier "Jupiter," which has been in continuous service since 1913. During the Great War the equipment was many times heavily overloaded. The Navy Department reports that practically no expense has been caused by the electric equipment during the war period.

Low-pressure turbines, which in comparison with high-speed machines, are less efficient, have been used for a number of years for driving ships. They are either directly connected to their propellers or are connected through a gear reduction gearing. In some large ships a combination of high-speed steam engines and a low-pressure turbine have been installed.

**Electric Propulsion versus Reciprocating Steam Engines.**—Aside from questions of initial cost, the higher steam economy of high-speed turbines is of itself sufficient in most cases to justify the adoption of the turbine for ship propulsion. The steam engine of the triple or quadruple-expansion type, due to the limitation of the low-pressure cylinder, cannot be made having a steam ratio greater than about 16 to 1, or 20 to 1. The steam turbine has no such limitation and is capable of using efficiently steam expanded to any extent. Where turbines are used, a vacuum of 28.5 inches is quite common. A vacuum of 29.5 inches is being recorded in some central stations during winter months. The economy due to large expansions is indicated by a comparison of the available energy of a pound of steam when expanded from boiler pressure to various degrees of vacuum, viz.:

100 pounds pressure to 24-inch vacuum = 220,000 foot-pounds  
 100 pounds pressure to 26-inch vacuum = 238,000 foot-pounds  
 100 pounds pressure to 28-inch vacuum = 265,000 foot-pounds  
 100 pounds pressure to 29-inch vacuum = 289,000 foot-pounds

These figures give an indication of the saving that can be expected by the use of a turbine which can use efficiently steam expanded to a low degree. Little

advantage, however, is gained with a reciprocating engine when the expansion is carried below 24 inches. This not only means a saving of fuel, but also the size of boilers, auxiliaries, etc.

**Application of Internal Combustion Engines to Ship Propulsion.** — Electric gearing not only serves as a means whereby high-speed steam turbines may be effectively used for ship propulsion, but also makes possible the adaptation of relatively simple internal-combustion engines for this purpose. Some years ago two or three vessels in Europe were equipped with electric transmission gear between internal-combustion engines and propellers with partial success. Recently in America some low-powered boats have been equipped in a similar manner using direct current apparatus; for example, the trawler "Mariner," which has been in successful operation for about two years. The apparatus on this boat consists of two 165 kw.-125 volt generators, each direct-coupled to an eight-cylinder, four-cycle, 350 r.p.m. Diesel engine. These two self-excited generators are normally connected in series and supply current to a 440 horsepower, 250 volt, 300 r.p.m. motor which is direct coupled to the propeller shaft. For slow speeds of the ship, one engine can be shut down and the motor supplied with current at 125 volts. Two master controllers are provided, one in the pilot house and the other in the engine room. For emergency manual operation is also provided in the engine room.

**FUNDAMENTAL REQUIREMENTS OF SHIP PROPELLING MACHINERY.** — A ship may be equipped with 1, 2, 3, or 4 propellers. The most favorable propeller speed is generally from 75 to 300 r.p.m., depending upon the size and speed of vessel. Destroyers and similar vessels have higher speed propellers. The following are considered desirable turbine speeds (for the impulse type of turbine) for the corresponding output:

Horsepower	R.P.M.	Poles of generator	Cycles per second
7,000	3600	2 poles	60
10,000	3000	2 poles	50
16,000	2400	2 poles	40
29,000	1800	4 poles	60
65,000	1200	4 poles	40

To secure the most favorable speeds for both propellers and turbines, a high-speed reduction is required, the amount depending upon the size of the turbine and the design of the propeller. For example, for a twin-screw ship having a propeller speed of 100 r.p.m. and a total horsepower of 18,000 equipped with two main turbines, a speed reduction of 30 to 1 should be adopted.

**Loss due to Incorrect Turbine and Propeller Speeds.** — In many turbine-gearred equipments it has been considered advisable to depart from the most desirable propeller and turbine speeds so as to reduce the speed ratio of turbine and propeller and thus obtain a simple gearing. This sacrifice of turbine and propeller efficiency in some cases has caused an increase of fuel consumption amounting to from 25 to 30 per cent. With electric propulsion the most favorable turbine and propeller speeds can be generally adopted and a speed ratio as high as 40 to 1 can be used if desired.

**Reversing.** — The propelling machinery of a ship must of course, be capable of backing the ship as well as driving it forward. With reciprocating steam

engines there is of course no difficulty in this respect. A steam turbine, however, cannot be reversed. Consequently, when a ship is equipped with turbines directly connected to the propeller shafts, or connected thereto through mechanical gearing, each shaft must be equipped not only with a forward-driving turbine, but also with a turbine whose normal direction of rotation is opposite to that of the forward driving turbine. Such turbines are called "reversing turbines" or "astern turbines." When the ship is driven forward the reversing turbine is driven backward, no steam being admitted to it. To reverse the direction of motion of the ship, the steam supply is cut off from the main turbine and admitted to the reversing turbine, the main turbine then being driven backward.

With electric gearing, reversing turbines are of course unnecessary, since the direction of rotation of the motors connected to the propeller shafts can be reversed merely by operating suitable switches. This is a decided advantage of electric propulsion over direct-connected or mechanically geared turbines.

**Losses in Reversing Turbines.** — Experiment has shown that a turbine forced in a direction opposite to its normal direction of rotation has about 10 times as much friction loss as when driven in its normal direction. This friction loss in a reversing turbine, which is always present when the ship is in motion, may amount to more than 1 per cent of the shaft horsepower of the propeller.

**Two Efficient Speeds.** — The propelling machinery of a war vessel should be capable of driving the ship efficiently not only at full speed, but also at cruising speeds, which are usually from 50 to 70 per cent of full speed. The same is also desirable in certain passenger ships. As the power required to propel a ship varies approximately as the cube of the speed, this means that at cruising speeds the propelling machinery will be running at less than one-third of its maximum load. Since a steam turbine is most efficient at or near maximum load and at full speed, it follows that when directly connected or mechanically geared turbines are employed, there must of necessity be a sacrifice in efficiency at cruising speed, which, in the case of a warship, is the speed at which the ship is driven by far the greater part of the time.

**Cruising Turbines.** — To avoid this difficulty, it is possible to provide, in addition to the main turbines, auxiliary high-speed turbines geared to the propeller shafts, the speed reduction being such as to give the desired cruising speed. Provision has to be made in this case for disconnecting the auxiliary turbines when the ship is driven at full speed by the main turbines. These auxiliary turbines are usually referred to as "cruising turbines." The two U. S. battleships "Idaho" and "Mississippi" are equipped in this manner. The full speed of these ships is 21 knots. The cruising turbines are used for speeds up to 17 knots for the "Idaho" and up to 15 knots for the "Mississippi."

With electric propulsion two efficient speeds are readily obtained without any such complication. All that is necessary is to change the ratio of the number of poles of the motors to the number of poles of the generators, which is readily accomplished by a simple switching operation. Since the propeller torque required at half speed is only about one-quarter that required at full speed, the voltage applied to the motors at cruising speed can also be reduced, thus keeping the motors operating at relatively high efficiency at reduced speed. The equipment of the U. S. battleship "New Mexico," which was the first electrically propelled battleship, being put into commission in 1918, is arranged in this manner. This ship is a sister ship to turbine-driven ships "Idaho" and "Mississippi."

**Comparison of the "New Mexico" and the "Idaho" and "Mississippi."** — During the period from 1918 to 1920 the relative maneuvering

qualities and the relative fuel economy of these three ships observed when operating together. The electrically propelled proven decidedly superior with regard to maneuvering quality superior in fuel economy. The fuel consumption of the "Ida" "Mississippi" exceeds that of the "New Mexico" by the following

At 10 knots.....	20.0 per cent
At 13 knots.....	42.7
At 16 knots.....	47.8
At 19 knots.....	40.1
At 21 knots (full speed).....	32.3

At 19 knots, and also at full power, the "New Mexico" uses about 1.1 pound of oil per shaft horsepower per hour, and at 15 knots 1.1 pound of oil per shaft horsepower per hour. These figures include the total oil used for the engine and the propeller.

With reference to the "New Mexico," Commander S. M. Engineer of the Pacific Fleet, states:

"In conclusion, it may be said that the performance of the electric propulsion since commissioning has been entirely satisfactory in every way, and that the expectations of those who were responsible for its installation have been more than realized."

**Propeller Characteristics.** — Fig. 1 shows the relation between the speed and torque of a propeller when the ship is being driven at constant speed in smooth water, and also when the ship is held stationary in the water. It will be noted that the running propeller torque increases approximately as the square of the speed. The power to drive a ship therefore increases approximately as the cube of the speed.

**Torque Required to Stop and Reverse.** — When the driving power is removed from a propeller with the ship traveling at a high speed, the propeller will continue to revolve in the same direction, being driven by the water. In order to stop the ship in the shortest time, or to maneuver quickly, it is necessary, not only to stop the propeller against the action of the water, but also to drive it in the reverse direction.

An experimental determination of the relation between the speed and torque of the propeller while being stopped and reversed with the ship traveling at constant speeds was made in the model tank at the Naval Academy, Washington, and later these data were found to approximately agree with tests taken on the U. S. S. "Jupiter" and the U. S. S. "New Mexico." Figure 2 shows such a propeller characteristic as obtained in the model tank.

Directly the power is removed, the propeller begins to slow down to approximately 73 per cent of its original speed and, if power is now applied to the shaft, tending to stop the propeller, the torque of the propeller mounts up to approximately 100 per cent of the forward driving torque.

Fig. 1

Fig. 2

This maximum torque is attained at between 35 per cent and 40 per cent of normal propeller speed.

From this point on less torque is needed to bring the propeller to rest. If the propeller is now reversed, with the ship at full speed, 100 per cent torque is attained at a speed of about 30 per cent of normal. From this curve, therefore, it will be noted that it takes approximately 100 per cent torque to break the propeller away from the water, but only requires about 40 per cent torque to hold the propeller stationary after being stopped.

From experience obtained to date, it would seem that machinery for high-speed ships, having two or more propellers, should give 100 per cent reversing torque to quickly bring the propellers to rest when reversing from full speed. On lower speed ships, indications are that the maximum stopping torque is considerably less than 100 per cent. On single screw cargo boats, the stopping torque is probably quite low.

**Variation of Propeller Torque with Pitching of Ship.** — The General Electric Company has taken a number of elaborate tests with reliable apparatus to determine the variation of the propeller torque when the ship is in a sea-way. An illustration of the variation which may be expected in moderately rough sea is shown on Fig. 3. Although the ship was only pitching  $4^\circ$ , the increase in torque varied from no load to 175 per cent of normal load.

These results were obtained on a cargo ship equipped with double reduction gearing. This turbine equipment did not have a governor

and the variation in torque may, in part, be due to the variation in speed of the propelling machinery, but was mostly due to the different conditions of wake at different depths below the surface of the water.

Under worse conditions of sea, it may be expected that this variation in torque would be considerably increased.

It was observed that, when the propeller approached the surface of the water, the load was quickly released and was again gradually increased as the propeller went deeper into the water. The record was taken with the ship in ballast and it was observed that the propeller did not break water. This variable condition of torque has been confirmed on electrically driven ships by observing the variation of load by electrical instruments.

The electric motor is an ideal piece of machinery for absorbing these shocks without deterioration. As there is no mechanical connection between the turbine and the propeller, this shock is absorbed in the air gap of the motor; it being necessary only to give the electrical machinery a sufficiently strong magnetic bond to hold the generator and motor together. This bond is increased by simply increasing the degree of excitation. If the motors drop out of step with the generators, then to bring them in step again it is necessary only to reduce the turbine speed and increase the excitation. Then the turbine speed can again be increased to normal. No harm is done if these motors are left out of step for short periods as the generator is so proportioned that the increase in current cannot greatly exceed the normal.

**EQUIPMENT FOR ELECTRIC DRIVE.** — The essential elements required for electric transmission between the turbines and the propellers of a ship are the generators, the motors, the cables connecting these two, and the switching and control devices.

**Relative Weights of Electric Drive and Gear Drive.** — When properly designed, the weight of the machinery required for electric drive is but little,

Fig. 3.

If any, in excess of the weight required for gear drive, except high-speed boats as destroyers, scout cruisers and pleasure yachts, in certain cases the weight of the electric drive may be actually less than that of a gear drive. For example, in the case of a 3000 horsepower single turbine drive having a propeller speed of 100 r.p.m., assuming that the turbine is installed at the center of the ship and, in both cases, the turbine is installed in the hull and in the case of the electric drive the motor is installed in the hull of the boat, the electric propelling machinery, including the propeller shaft, is 10 per cent less than the geared propelling machinery.

**Alternating versus Direct Current.** — Alternating-current drive is usually adopted for ship propulsion in preference to direct current drive, but there are, however, a few cases where direct current is used when steam engines are involved, and also when Diesel engines are used as prime movers.

Alternating current has many advantages over direct current drive which may be stated as follows:

1. The combined transmission losses of the generator and motor when alternating-current apparatus is used, is from 5 to 8 per cent less than that of direct-current apparatus.

2. High-speed prime movers and generators can be used with alternating current, whereas with direct current, when a high-speed steam engine is used, it is necessary to have a reduction gear between this and the low-speed direct-current generator. High-speed apparatus is cheaper and lighter than low-speed apparatus.

3. Alternating-current apparatus is, generally speaking, more reliable than direct current. As the distance between the generator and the motor on board is short, there is no advantage in using high-voltage transmission in the case on land. Lower voltages, therefore, are usually adopted for ship propulsion. The voltage of voltage on cargo boats is from 1100 to 2300. The General Electric Company's records, over long periods of years and covering such a large apparatus as is used on cargo ships, show that only about  $\frac{1}{10}$  of 1 per cent of such voltage give any electrical trouble in a period of ten years. The electrical apparatus includes all motors and generators installed in a ship.

In warships, machines designed for 5000 volts are being used.

**Types of Motors Suitable for Electric Drive.** — Five types of direct-current motors have been used for ship propulsion:

1. Induction motors equipped with slip rings and external resistance.

2. Induction motors without slip rings, but with two squirrel-cage windings. A high-resistance rotor winding is placed in the slot near the periphery of the rotor and beneath this a low-resistance winding. When running, when the current alternates slowly in the rotor, the high-resistance winding carries the current. When, however, there is a high-frequency self-induction in the rotor, as is the case during reversals of the rotor, the self-induction of the low-resistance winding forces current through the high-resistance winding, and this produces a high torque.

3. Induction motors without slip rings but with one squirrel-cage winding, consisting of deep, narrow bars. The action of this winding during reversal is similar to the double squirrel-cage motor.

4. Induction motors equipped with slip rings but no external resistance. The rotor is wound with a low-resistance winding near the periphery of the rotor and beneath this a high-resistance squirrel-cage winding. The high-resistance winding is connected to the slip rings. To make the low-resistance winding carry the current during reversal of propeller, the high-resistance rotor winding is opened by means of contactor switch across the slip rings. If this motor is wound to give two di-

The slip rings can be made neutral for high-speed running, and thus need not carry heavy current. All reversals are accomplished with low-speed connection.

5. Synchronous motors, the periphery of the poles being equipped with a low-resistance bar winding. With this type of motor the propeller is brought to rest during reversal by reversing the phases with the circuit "dead," and then applying a strong field on the motor, leaving the field off the generator. The propeller thus drives the synchronous motor as a generator, being loaded on the turbine generator. Sufficient torque is developed to bring the propeller approximately to rest. Field is now applied to the main generator and removed from the synchronous motor. If the turbine governor has previously been set for a slow speed, the synchronous motor will now reverse and quickly reach approximate synchronous speed at which time the field is again applied. A small and simple air cooled resistor can be switched in multiple with the generator during the stopping period. If this is done a higher torque can be developed with less excitation and with lower current flowing between the machines.

The following advantages are claimed for the synchronous motor over the induction motor:

1. A higher transmission efficiency due to operating at unity power factor.
2. Larger air gaps can be provided.
3. The generator and motor are lighter and cheaper.

The induction motor is more suited to cases where two different numbers of poles are desired for running at different speeds, such as is desired for war-ships.

**Efficiency of Electric Transmission.**— Opponents of electric propulsion have made claims that the transmission efficiency of this type of drive is low compared to other forms of speed-reducing machinery. However, when all the losses incident to the transmission by mechanical gearing are taken into account, the difference in efficiency of the two types of drive is by no means so great as is frequently stated, the advantage in favor of the mechanical gearing being less than 2 per cent. The following comparison for a low-powered cargo ship of 2500 shaft horsepower, driven by a single screw running at 100 r.p.m., is quoted from a paper by Mr. W. L. R. Emmet. (Read as a paper before the *Society of Naval Architects and Marine Engineers*, New York City, Nov. 13, 1919; also published by the *General Electric Review*, Jan., 1920).

"The selection for comparison of a ship of low power is unfavorable to electric drive in the matter of transmission efficiency, the conditions being better for this method in ships of higher power. The generator designed for this case has an efficiency of 95.6 per cent and the motor 95.9 per cent, making the transmission efficiency, including cable loss, etc., 91.6 per cent. In machinery designed for certain high-power ships, the efficiency is as high as 94 per cent.

"To determine the efficiency of gear transmission as compared with the figures just given, very careful tests have been made at Schenectady. A 2400-horsepower ship turbine was connected through two sets of double-reduction gearing to a generator, and the steam consumption was tested at various degrees of load and speed; then the same turbine was connected to the same generator without gearing, and tests were run with the same conditions and the same degree of steam flow. All this was done on a testing stand where conditions are uniform and accurate, the gears ran with perfect smoothness and all conditions were favorable. Since the comparison gives the loss of two gears, the differences are considerable and the determination should be very close to the correct value. This test showed that the performance of a single gear is as follows:

Shaft horsepower	R.P.M.	Loss of gearing, horsepower	Efficiency of gears, per cent
2400	87	125	95.0
1420	77	80	94.7

"In addition to these gear losses, we must also consider the loss in friction of the reversing turbine, which is estimated from reliable data to be 28 horsepower, and we must also consider the bearing losses on about 100 feet of shaft, which in perfect alignment will be 8.5 horsepower. These additional losses reduce the transmission efficiency to 93.5 per cent, leaving only 1.9 per cent advantage to the gearing. With the shaft more or less out of line and the gears operating under sea conditions, it is probable that the losses given would be greatly increased. Noise is an indication of loss, and most marine gears are at times noisy, while the gears in this test were almost silent. The gears tested in this case were of the General Electric Alquist type, and it might be claimed that other kinds of gears would be more efficient but it is obvious that, under fixed load and with similar gear speeds and diameters, there could be no advantage in any other type even if it ran with equal smoothness."

**Gain in Efficiency at Low Speeds by Operating at Reduced Voltage.** — Electric motors for shore purposes usually operate at approximately constant voltage regardless of the load carried. At light loads, therefore, they are relatively inefficient due to the iron losses remaining approximately constant. Motors, however, used for propelling ships usually obtain their power from a generator whose voltage can be varied to suit the motor's load. At reduced speeds, therefore, in an electrically driven ship, the voltage can be reduced; this reduction has the effect of materially reducing the losses in the iron laminations of both motor and generator. Thus, at reduced loads, the percentage of power lost is nearly the same as at full load. Whereas with gear, the transmission loss remains quite high at reduced speeds. Also the percentage loss of power in the gears increases when the gears have become worn.

**Location of Propelling Machinery.** — When vessels are equipped with turbine electric propulsion, the driving motors can be placed as far aft as convenient, thus shortening the propeller shafting. This also gives a larger and better disposition of cargo space and eliminates the long shaft tunnels. The turbine-generator units can be placed near the boilers at any desired level, reducing to a minimum the length of steam piping and other piping systems. The controlling mechanism, as in an electric locomotive, can be placed at one or more convenient positions.

**Ventilation of Electrical Apparatus.** — It is very important to ventilate the electrical apparatus in such a way that it will not collect moisture when shut down or running under light loads. To prevent this the temperature of the apparatus must not be lower than that of the surrounding air. The ventilating air should, therefore, be taken from the same room in which the apparatus is placed. This air, after passing through the machines, can be used under the boilers. Suitable dampers can be provided to prevent the engine room from becoming uncomfortably cold during the winter weather.

In some cases the air after leaving the generator and motors is passed between cooling tubes through which water is circulated. After passing between the tubes, the air enters the room in which the apparatus is placed and again cir-

ulates through the generators or motors. Thus the same air is used continually.

This method eliminates the large ducts leading from the upper decks of the ship and also ensures clean air being always used. These coolers can be made quite small for this purpose.

**Electric Drive for Auxiliaries.**—A source of considerable loss in the operation of many ships is due to the use of steam driven auxiliaries. With electric drive it is necessary to maintain a direct current electrical supply independent of the main generators for purposes of excitation and lighting. This same source can be used for driving electrical auxiliaries. If turbine units are chosen for this auxiliary power, the steam from these units can be exhausted into a suitable stage of the main turbine and, by automatic means, exhausted into the main condenser when the load is removed from the main turbine. A more simple method is to design the auxiliary turbines as condensing units and connect their exhaust directly into the main condenser. An auxiliary condenser should, however, be provided for use in port. In certain cases it may be desirable to use a few steam-driven auxiliaries, such as boiler-feed pumps and the exhaust from these can be utilized for feed heating. If necessary, this steam can be supplemented by either "bleeding" the main turbine or using part of the exhaust from the auxiliary units.

In some cases these d-c. auxiliaries can be equipped with slip rings from which alternating current could be taken for driving the main motor in cases of emergency at reduced speed.

Some European cargo ships are equipped with auxiliaries driven by alternating-current motors from the main generating unit. In such cases reduced speeds of the ship are obtained by running the turbine generator at approximately full speed and reducing the motor speed by means of an external resistance. The fuel consumption during these reduced speeds is greater with this method than when the turbine speed can be reduced as there is a large loss of power in the external resistance.

**Operating Force.**—The following is quoted from a paper by Mr. W. L. R. Emmet. (Read as a paper before the *Society of Naval Architects and Marine Engineers*, New York City, Nov. 13, 1919; also published by the *General Electric Review*, Jan., 1920.)

"The history of the electrical industry has repeatedly shown that persons who have not used electrical apparatus assume that its operation requires a high order of skill and expert knowledge, and of this assumption we have already heard much in connection with electric drive for ships. A vast amount of experience has repeatedly shown that this assumption is the direct reverse of the truth, and a little thought as to the conditions in electrical apparatus should make the reason obvious. Conductor circuits are much simpler mechanically than pipes and mechanical motions, and electrical machinery is simply a combination of electric circuits with motion of rotation. The connections are easily shown by diagrams, and little mechanical skill is required to make them. The work of insulation can be so done that, under such conditions as exist in ship installations troubles which might involve difficulty of repair by unskilled persons are very improbable. In all the extensive uses of electricity in mills, mines, railways, and other industries, it has seldom failed to become popular immediately with the operating forces. In no case has this been more marked than in the ships which have been driven electrically. Large electrical apparatus is generally simpler than small, and the machinery used to propel a ship is in many respects simpler than that which is used to light it. Instead of introducing difficulties to the operating force, the adoption of electric drive will eliminate them and make ships much less dependent upon the skill and resourcefulness in their crews."

**ADVANTAGES OF ELECTRIC PROPULSION.** — tages of electric propulsion have already been noted. They are very fully treated by Mr. W. L. R. Emmet in numerous papers from which much of the following is quoted.

**Ease of Disconnection and Repair of Propelling** — The following is quoted from Mr. Emmet: "In a geared engine has a system of turbines, gears, bearings, thrust-balancing and balancing systems all mechanically locked together. With him any kind of trouble with any of these parts will almost result in the immediate stoppage of the whole system. To keep a ship running out of balance or with bearing trouble is impossible. Any part would present almost equal difficulty. In the event of an emergency of such character a ship would have to be stopped until the trouble is cleared. The work necessary to uncouple and disconnect a very heavy apparatus would be a serious matter involving much of the time required to stop the ship.

"If it was found impracticable to make this disconnection, it was such that the shaft could not be allowed to revolve, it would be necessary to lock the shaft to hold the propeller. A dragging propeller would create a serious drag on a vessel travelling at even moderate speed. A dragging screw may add 20 per cent to the horsepower and would materially reduce the maneuvering qualities of the vessel.

"In the electrically-driven ship there is no mechanical connection between the shaft to anything but the rotors of motors. These are self-contained structures and cannot by any possibility be subject to mechanical trouble. The shafts are subject to the same possibilities of bearing trouble as shafts in other ships, but the presence of the motors does not increase the danger, and the speed being low it is remote in any case. Any one motor, generator or turbine, if in any kind of trouble, can be disconnected without stopping the ship and with only a slight loss of the highest speed capacity. Such a disconnection is made by a switch.

Referring specifically to 180,000-horsepower, 33.5-knot (1920) being built for the U. S. Navy, Mr. Emmet continues: "The interchangeability as this power of disconnection gives constitutes one of the important advantages of electric drive in such a ship. In the event of eight in trouble, only one-eighth of the maximum capacity of the ship's maximum speed is impaired by only about 1 knot. If one turbine is in trouble, the maximum speed is reduced only a few per cent. If two generating units and four motors out the ship can make 20 knots. If three generators and four motors out she can make 19 knots. If four in trouble, they are simply cut out and repaired at leisure or during the voyage. The value of this interchangeability in a warship can hardly be overestimated. It largely overcomes the military danger incident to accident to the main power, a danger which has always been of primary importance.

**Mud in Condensers.** — In addition to the foregoing advantages is the advantage when maneuvering an electrically propelled ship in muddy water in and around harbors, provided the ship is provided with more than one turbine and condenser. Under these conditions if one generator is needed to drive the ship and, in case the condenser is plugged with mud, it can be immediately switched off and another switched on to the driving motors.

In cases where turbines are mechanically connected to the propellers, under similar conditions of operation, it would be necessary to disconnect the turbines together with their condensers. If such a ship

condensers might become plugged at once but, if only one became plugged, the maneuvering qualities of the ship would be dangerously impaired. Commander Robinson states:

"As an actual experience the 'New Mexico' while entering New York harbor had to shift main generators twice owing to the plugging of her condensers with mud, and these shifts were made so quickly that they did not affect the operation of the ship at all."

**Backing Power.** — Again quoting Mr. Emmet: "In turbine-driven ships, not electric, it is necessary to provide backing turbines which must run idle in the reverse direction when the ship is going ahead. These backing turbines involve complications which are very objectionable, and if these are reduced to a desirable minimum the backing power will be greatly inferior to that easily provided with electric drive. Experiment has shown that a turbine forced in an opposite direction involves about ten times as much friction loss as when driven in its normal direction. This loss, therefore, is very appreciable in the backing turbines of ships. There are also serious difficulties and dangers in high-speed apparatus incident to the abrupt and wide changes of temperature where steam is suddenly admitted to a cold reversing or ahead turbine. With electric drive the turbine never need be stopped when the ship is under way, and its operation is easier than in a power station because the load is steadier; with modern high-speed turbines superheat affords large gains in fuel economy, and the ability to safely use high degrees of superheat may constitute one of the important reasons for adopting electric drive.

**Efficiency of Transmission.** — "Various statements and estimates have been published concerning losses in high-speed gearing for which the authority is not known by the writer. Tests at Schenectady have shown losses about double those generally estimated, with rapid diminution of efficiency as load falls.

"With the electric drive in these battle cruisers (the 180,000-horsepower vessels now building for the U. S. Navy) the losses from turbines to propeller shaft at full speed will amount to 6 per cent, and by adjustment of voltage the transmission efficiency can be kept nearly as good at all speeds. Considering gearing losses, reversing turbine losses, losses incident to necessary subdivisions of the turbine and additional packings, it is believed that the actual transmission from turbine blades to shaft at full speed cannot be made more than 2 per cent better in the geared equipment than it is in the electric. At reduced loads the geared equipment will be much less efficient. The normal cruising speed of these ships will require less than one-tenth of full load, and the drag of gearing, bearings, reversing turbines and idle parts of main turbines will be very serious."

**Cruising Economy.** — "With the electric design, the number of motors and turbines used can be adapted to the demand for power, while with the other all parts must be kept running. This gives very important gain in economy at all speeds below the maximum. At 19 knots (in the case of the 180,000-horsepower battle cruisers for the U. S. Navy), only one turbine is required to drive the ship, and electrical arrangements are made by which it can be run at full speed instead of running at half speed, as it would if the ratio was fixed as by gearing. Thus the steam efficiency at 19 knots, a desirable cruising speed, is equal to the best attainable at any speed. Assertions which have been made by ship builders and others that equal cruising results can be obtained by the use of cruising turbines are obviously absurd. The cruising turbines themselves would be greatly inferior to the single main turbine so used, and they would be burdened with all the drags which are mentioned above. Cruising economy gives increased cruising radius without renewal of fuel supply. This

has always been considered a matter of the greatest importance in warship it is a feature in respect to which electric drive can have no rival."

**Flexibility of Installation.**—A military advantage of great importance in connection with electric propulsion is the "flexibility of installation." The following is quoted from Commander Robinson (*General Electric Review*, April, 1919):

"The tendency in building modern capital ships is to provide for more and more torpedo protection and it becomes necessary to crowd the machinery away from the sides of the ship as much as possible. This arrangement is also desirable from the point of protection against gunfire for a similar reason. In this respect, electric drive has an enormous advantage over any other type of machinery in which the prime mover is mechanically connected to the propelling shaft. The main turbine-generators may be placed in any part of the ship that is most desirable; they may be placed in compartments forward of each other and they may be raised up enough to place the main condenser underneath them—in fact, there is practically no limit, other than the heat room, as to the position of the main turbine-generator in the ship. This gives an enormous advantage to electric drive over all other types of machinery and enables the Naval Constructor to give far more adequate protection to the ship and machinery against damage by torpedo and gunfire. Those parts of the machinery—the main motors—which it is necessary to connect mechanically to the shafts, are comparatively small and take up only a small space so that they can be placed in small isolated compartments which will not menace the ship in case of flooding; since no main auxiliaries are required for the motors, the flooding of a motor room will not entail any loss in that respect. Also, the motors may be placed very much farther aft than can steam-driven turbines and therefore the length of the main shafting can be very materially reduced. This constitutes a big advantage; both on account of less liability to derangement of the shafting itself, due to injury to the ship, and also of less danger to the ship itself because of the shafting not having to pierce a number of watertight bulkheads. These advantages of installation constitute the real and main reason for the adoption of electric drive for capital ships and any other advantages are minor compared with them. Utilizing these advantages to the fullest extent makes it possible to build capital ships which are far superior to any others fitted with any other form of machinery. In addition to advantages from the point of view of protection, there are also the advantages from an engineering standpoint. The shorter lengths of shafting make it easier to keep the shafts in line; the grouping of boilers around the machinery makes short and direct steam pipes with a consequent reduction in weight and complication and a smaller drop in steam pressure. The same may be said of practically all the other piping systems of the ship, such as feed lines, oil lines, exhaust lines, etc."

**Use of Superheated Steam.**—As is well known, superheat greatly improves the efficiency of steam turbines by reducing the friction and windage loss of turbine blades and disks. There is also a considerable gain due to increase in the available energy of the steam incident to increase in temperature. It is generally conceded that the steam consumption is reduced at least 1 per cent for every 12.5° F. of superheat. With some installations there is also a gain in boiler efficiency caused by increased heating surface exposed to the flue gases. Superheated steam also increases the life of the turbine blades and nozzles.

In Europe superheat for ships has been used for some years and great saving in fuel has been realized. In 1912, Mr. Ljungstrom in Sweden equipped the "Mjolner," a small coastwise vessel with electric drive. This ship is only 85 feet long, 36 feet beam, and 15 feet draught, requiring 200 SHP. The

steam conditions are 218 pounds pressure, 200° F. superheat. This ship uses 12.3 per cent less fuel than a sister-ship, the "Mimer," which is equipped with a triple-expansion engine. Since that date larger cargo ships have been equipped in a similar manner, using still higher degrees of superheat.

Superheat has also been used successfully for a number of years in Europe with engine-driven ships. The following extract from a letter from Van Nievelt, Joudriaan & Co., Rotterdam, Holland, illustrates the superheat possibilities in engine-driven ships:

"We are using during the last five years, in our multi-tubular boilers 3 1/2-inch tubes, very high funnels and Diamond blowers, and have no trouble at all in getting sufficient steam. We have practically no leakage at the connections of the pipes and boxes. The original pipes are still in use. The capacity of a 10-ton evaporator is sufficient for supplying feed water.
