"Three of our steamers have been running half a year without superheaters with a coal consumption of 24 to 25 tons. After fitting superheaters the consumption was about 22 tons, making a saving of at least 10 per cent."

In America superheat has, for a number of years, been extensively used in central stations but has not been applied to any extent on ships.

**Superheat and Reversing Turbines.**—Whereas high superheat is beneficial to the operation and life of turbines, it has caused serious trouble in reversing turbines due to expansion strains set up by rapid changes in temperature, and reversing turbines are necessary when mechanical connections between turbine and propeller are adopted. In the case of electrically driven ships, no reversing turbine is needed, the turbine-generator unit revolving continuously in the one direction regardless of the direction of rotation of the propellers.

When steam expands without doing work, its temperature remains nearly constant and, if work is done upon it by a reversed turbine, this temperature is considerably increased. With superheated steam these temperatures may be extreme and might be injurious to the main turbine as well as the reverse turbine, since it also must be used for reversal of direction and since the two often occupy the same casing.

Fig. 4 illustrates the possible steam temperatures which may be reached when maneuvering a ship equipped with reversing turbines. The turbine in this test was first run at full speed in the extremely high vacuum given on the record until a constant temperature was shown by the pyrometer. A little steam was then admitted and a constant temperature was again reached at 825° F. when more steam was admitted and the temperature then rose so quickly that the steam had to be shut off. In the General Electric Company's shops it has been discovered that the reversing wheels of marine turbines turn blue with heat when operated at normal speed in a vacuum of 20 inches.

Fig. 4

When high superheat is used in combination with a reversing turbine, precautions can be adopted to preserve the turbine from damage. Various arrangements have been proposed. One is to reduce the steam temperature before it enters the reversing turbine by injecting a spray of water, or by passing the steam through a cooler. Another method is to install a steam pipe connected between the boiler drum and the superheater—this also requires special maneuvering valves. Precautions must also be taken to prevent the superheater from burning during maneuvering operations. These complications and dangers are, however, entirely eliminated by the adoption of electric drive which abolishes the astern turbine.

**TYPICAL ELECTRICALLY PROPELLED SHIPS.**—The following is list of some of the more important types of electrically propelled ships:

Name	Type	No. of screws	Total S.H.P. at full speed	Type of motors	No. of motors	Reference
"Graeme Stewart" and "Joseph Medill"	Fire-boats	2	500	Direct current	2	1
U. S. S. "Jupiter"	Collier	2	5,600	Induction with external resistors	2	2
The "Mjolner"	Cargo	1	900	Induction with external resistors	2	3
U. S. S. "New Mexico"	Battle-ship	4	31,197	Induction double-squirrel cage type	4	4
The "Mariner"	Trawler	1	400	Direct current	1	5
S. S. "Eclipse"	Cargo	1	3,000	Induction with external resistors	1	None to date
S. S. "Cuba"	Cargo	1	3,000	Synchronous	1	None to date
U. S. S. "Iowa"	Battle-ship	4	60,000	Induction with high and low resistance Rotor windings	4	None to date
U. S. S. "Lexington"	Battle Cruiser	4	180,000	Induction with high and low resistance Rotor windings	8	6

**SHOCK, ELECTRIC.** — The physiological effects of a shock by lightning or by artificially-produced electricity may be classified into two groups, the major effects, cessation of respiration or heart action and the minor effects, fractures and internal injuries due to falls, and burns due to contact with electric arcs.

**Removal of Victim from Circuit.** — If a switch or circuit breaker in the circuit is close at hand, open the circuit at once or cut away the conductors with a wooden-handled hatchet. If the circuit cannot be opened immediately, break the contact of the victim with the conductor by moving the conductor or the victim, using any available dry non-conductor such as a board, rope or clothing. *Do not touch the victim with the bare hands under any circumstances unless insulated thoroughly from the ground.*

**First Aid for Slight Shock.** — If the victim is seen to be breathing, administer heart stimulants such as alcohol, ether or ammonia either by the mouth or hyperdermically, produce external warmth by rubbing the body or by application of hot substance, loosen constricting clothing about the neck and chest and present aromatic spirits to the nostrils to excite consciousness. Give plenty of fresh air.

**Artificial Respiration.** — If the victim does not breathe, send for the nearest doctor, remove any foreign body (tobacco, gum, false teeth, etc.) from his mouth and throat and begin artificial respiration at once, even if the victim appears to be dead. Proceed as follows:\*

(a) Lay the subject on his belly, with arms extended as straightforward as possible and with face to one side, so that nose and mouth are free for breathing; see Fig. 1. Let an assistant draw forward the subject's tongue.

Fig. 1.

(b) Kneel, straddling the subject's thighs and facing his head: rest the palms of your hands on the loins (on the muscles of the small of the back), with fingers spread over the lowest ribs, as in Fig. 1.

(c) With arms held straight swing forward slowly so that the weight of your body is gradually but not violently brought to bear upon the subject, see Fig. 2. This act should take from two to three seconds. Immediately swing backward so as to remove the pressure, thus returning to the position shown in Fig. 1.

\* Report of Commission on Resuscitation from Electric Shock, issued by National Electric Light Association.

(d) Repeat deliberately twelve to fifteen times a minute the swinging forward and back — a complete respiration in four or five seconds.

(e) As soon as this artificial respiration has been started, and while it is being

Fig. 2.

continued, an assistant should loosen any tight clothing about the subject's neck, chest or waist.

(f) Continue the artificial respiration, if necessary at least an hour, without interruption, until natural breathing is restored, or until a physician arrives. If natural breathing stops after being restored, use artificial respiration again.

(g) Do not give any liquid by mouth until the subject is fully conscious.

**Other Methods of Inducing Respiration** are: (1) withdraw the tongue and allow it to recede periodically, the whole manipulation occurring about fifteen times in a minute; (2) dash cold water upon the face; (3) rub spine with ice; (4) massage chest in region of heart; and (5) administer oxygen gas (obtained at drug stores) by placing cone over mouth and nose.

**After Treatment.** — After the victim breathes again, treatment may be administered as outlined above in the case of a slight shock. If any bones have been fractured or if the victim appears to have received internal injuries, do not move the victim any more than is necessary and prepare for removal to the nearest hospital.

**Treatment of Burns and Blisters.** — If the victim has received burns, raw or blistered surfaces should be protected from the air. Blisters should not be opened. Cut around any clothing that sticks and saturate the adhering cloth or cotton dressing with picric acid (0.5 per cent) or a solution of baking soda (one teaspoonful to a pint of water). Wounds may be coated with a paste of flour and water or may be protected with machine, transformer, linseed or olive oil or vaseline. The dressing should be covered with cotton, gauze, lint, clean waste or clean handkerchiefs held tightly in place by bandages. Oil should not be applied to dry charred burns, a light, dry bandage being preferable.

**Indication of Death.** — Efforts to revive the victim should not cease until death is indicated by the following appearances: \* "complete cessation of breathing and heart action, eyelids half-closed and pupils dilated, jaws clenched, tongue appearing between teeth with frothy mucus about mouth and nostrils, fingers semi-contracted with increasing coldness and pallor of surface."

**SHOVELS, ELECTRICAL OPERATION OF.** — (See also *Cranes; Motors, Industrial Applications of.*) The operating cycle of an electrically-operated shovel is about 20 seconds, the component times being: hoist 8 to 10 seconds, thrust 10 seconds and swing 10 to 12 seconds, the thrust being in operation at the same time as the hoist and swing are operating. The motors to meet these requirements must have a sufficiently low armature inertia to permit of rapid acceleration under small power, and are therefore generally of the crane or mill-type construction.

**Hoist Motors.** — In the case of the hoist, considerable advantage may be gained in this respect by using two motors of one-half the capacity each instead of one motor of the full capacity, as the power required for accelerating is much less. For example: Assume a shovel that requires a 225-horse-power, 514 r.p.m. motor for the hoisting operation. Such a motor requires 144 horse-power seconds for bringing up to full speed, whereas if two 112.5-horse-power, 600 r.p.m. motors are substituted in its place, each motor requiring 63.5 horse-power seconds or both 127 horse-power seconds to bring up to speed, there would be a saving of about 12 per cent in the power required to accelerate the motor alone. On the other hand, such an arrangement may require the use of bevel gears and additional shafting.

**Swing Motor.** — This motor, although not subject to the severe overloads and shocks encountered on the hoist motors, is subject to frequent reversals, and, as rapid acceleration is required, a motor of similar design as for the hoist should be used.

**Thrust Motor.** — This motor differs somewhat in its operation in that it is practically stalled during the digging operation, although it may revolve or overhaul according to conditions, and is operated at full speed only after the hoist operation is completed. Its duty is to keep the dipper against the bank, and it must therefore stand still and exert torque most of the time. For this reason its design should be very rugged, and the motor should be able to develop a heavy torque for short intervals of time while standing still, or rotating very slowly.

**Location of Motors.** — The hoist and swinging motors are as a rule located on the car and are geared to the drums through suitable reducing gears, while the thrust motor as a rule is mounted directly on the boom and communicates its motion to the bucket staff through reducing gears connected to a pinion engaging a rack on the staff.

**Type and Size of Motors.** — It is possible to obtain successful operation with a-c. induction motors but it can only be done at the expense of larger capacities and increased power consumption, owing to the characteristic of the motor, which radically differs from that of the steam engine ordinarily used on shovels and from the d-c. series motor.

A careful analysis of the typical steam-shovel engine reveals a characteristics which is not unlike that of the series direct-current motor in that it speeds up under light loads, slows down under heavy loads and possesses a certain elasticity in operation which minimizes mechanical strains on the shovel. Because of these facts it is not only desirable but advisable to adhere to the direct current series motor on the electric shovel. Practically all large power supplies are alternating current, but the smaller capacities in d-c. series motors permit the use of a synchronous motor generator set mounted on the shovel at practically the same cost as the a-c. induction motors with transformers, with the advantages in operating characteristics and power consumption all favorable to the direct-current equipment.

The most recent development in electric shovels has been in connection

with large strippers, which are now being built with differential wound generators and shunt-field control.

The approximate size of motors required for the various operations of a number of different size shovels may be obtained from the following table.

Weight of shovel in tons	Size of dipper in cubic yards	Average cycles of operation per minute	Horsepower of motors			Kw.-hr. per shift
			Hoist	Swing	Crowd	
135	6	2	210	46	40	890
120	5	2	210	46	40	790
105	4	2	150	46	40	725
95	3½	2½	150	37	30	580
80	2½	2½	86	27.5	30	482
65	2	2½	86	27.5	20	381
45	1½	3	55	15	13	292
25	¾	3½	55	9	9	193

**Control Equipment.**—The magnetic contactor control is preferable for all the motors on the shovel. (See *Controllers*.) The hoist and thrust motors are then provided with a notching-back arrangement which will automatically cut resistance into the circuit when the current exceeds a certain limiting value due to the motors becoming stalled by digging too deep or striking rocks or other obstructions, thus protecting the motors from damage. Sometimes the hoist and swing motors are provided with automatic magnet control while the thrust motor is hand controlled, an ordinary drum controller being provided for this motor.

**Brakes** for the different shovel motions are generally of the air-brake type, a small air compressor being provided on the shovel for this purpose.

**BIBLIOGRAPHY.**—Rogers, H. W., *Application of Electric Motors to Shovels*, G. E. Rev., June, 1914; *Electric Shovels*, G. E. Rev., June, 1917; Witt-off, J., *Underground Mining with Electric Shovels*, Coal Age, Dec. 5, 1918.

**SHUNTS.** — (See also *Ammeters; Galvanometers; Voltmeters; Wattmeters*) When heavy currents are to be measured it is impracticable in many cases to pass the entire current through the coils of the instrument proper. In such cases it is necessary therefore to pass the bulk of the current through a parallel circuit or shunt and measure only a known fraction of the total current.

**CONSTRUCTION.** — For laboratory work standard resistance units (*see Resistors, Standard*) are commonly employed as shunts when a high degree of precision is required. Special forms of resistance boxes, usually called *shunt boxes*, are also used. For switchboard work shunts made of sheets of manganin or other high-resistance metal of low temperature coefficient (*see Wires, Resistance*) are usually employed. Several sheets of metal are used in order to provide a large radiating surface. These sheets are brazed into heavy copper terminals for clamping to the bus-bars or other heavy conductors; heavy terminals are necessary to insure a uniform distribution of current in the sheets. The contact surfaces must be kept bright and the bolts tight.

**THEORY OF SHUNTS.** — Fig. 1 shows diagrammatically a simple shunt such as used with an ammeter or galvanometer. The galvanometer (or ammeter) current is

$$I_G = \frac{S}{G+S} \cdot I_B,$$

where  $G$  and  $S$  are the resistances of galvanometer and shunt respectively and  $I_B$  is the total current from the battery or other source.

Fig. 1. Galvanometer and Shunt

For example, if the galvanometer has a resistance of 9900 ohms and the shunt a resistance of 100 ohms, the galvanometer current will be  $\frac{1}{100}$  of the battery current. Shunt boxes made on this principle are usually provided with resistance coils giving a ratio of currents of  $\frac{1}{10}$ ,  $\frac{1}{100}$  and  $\frac{1}{1000}$  when used with a galvanometer having a given resistance. The corresponding readings of the ammeter or galvanometer, multiplied by 10, 100, 1000, or 10,000 will then give the current in the battery circuit.

**"Universal" Galvanometer Shunts.** — Simple shunts such as above described give even ratios of currents only when used with a galvanometer of a certain definite resistance. A set of coils arranged as shown in Fig. 2, when used as described below, will give even ratios when used with a galvanometer of any resistance. A shunt of this kind is known as a universal shunt. The Ayrton and Mather shunt is arranged on this principle.

Fig. 2. Diagram of Ayrton and Mather Universal Shunt

A study of the circuits will show that if the galvanometer is calibrated (*see Galvanometers*) with the terminal  $a$  at  $b$ , that is, with all the resistance  $R$  in parallel with the galvanometer, the same calibration may be used for  $a$  connected to any other terminal  $x$ , provided the current values from the calibration curve are multiplied by the ratio  $R/r_x$ , where  $r_x$  is the resistance in the box between that terminal and  $A$ . The various resistances are usually arranged so that these ratios or "multiplying powers" of 10, 100, 1000, and 10,000 may be obtained. The galvanometer should have a relatively low resistance compared with the total resistance of the shunt.

**Effect of Temperature Changes.** — The resistivity temperature coefficient of a shunt made of manganin is very much lower than the temperature coefficient of the copper circuit of the ammeter or galvanometer. Consequently changes

ture will produce a change in the relative resistances of the shunt meter or galvanometer, thus changing the multiplying power. For measurements a correction should therefore be made in the nominal multiplying power of the shunt. With a universal shunt and a relatively low-galvanometer the effect of temperature changes is less marked, since  $r_x$  and  $R$  are both in the same box and are usually made of manganin metal having a low temperature coefficient.

(Pre-war prices).—A 4-value laboratory shunt box for use with an ammeter and giving multiplying ratios of 10, 100, 1000 and 10,000 costs about \$20. Switchboard shunts cost from \$3 to \$90 depending upon current-carrying capacity, the lower figure applying to a 10-ampere shunt and the higher figure to a 10,000-ampere shunt.

**SIGNALING, RAILWAY.** — Railway signaling is the art of conveying information to the person or persons in immediate charge of the movement of a train. The means for conveying the information are various, including simple movements of the hands and arms, positions or combinations of positions of semaphore arms by day, or colored lights by night, positions or combinations of positions of rows of lights visible both day and night, and colored lights or combinations of colored lights visible both day and night.

**CARDINAL PRINCIPLE OF RAILWAY SIGNALING.** — The cardinal principle of design of all signal circuits, apparatus and systems, is that any failure of any part, such as breaks, open or short circuits, grounds, etc., if having any effect on the signal whatever, shall result in a stop indication.

**CLASSIFICATION OF SIGNALING SYSTEMS.** — The two main divisions of railway signaling are block signaling and interlocking signaling. The former has to do with keeping trains which are running on the same track properly spaced. The latter has to do with the handling of trains over tracks which intersect at points of crossing or divergence, and has for its object the prevention of conflicting movements, the proper routing of trains, and the insurance that the movable parts of the track are in their right positions before the signals governing movement over them can be made to give a proceed indication.

Block signals may be divided into two main classes: non-automatic and automatic. In the United States there are 76,466 miles of track protected by the former as against 60,992 miles of track protected by the latter. Of the non-automatic blocks, those on 72,952 miles of track are operated by telegraph or telephone.\*

**NON-AUTOMATIC BLOCK SIGNALING.** — Systems in this class are of two kinds, non-controlled and controlled.

**Non-controlled Manually Operated System.** — The manually-operated signals used in connection with the telephone or telegraph blocks are located at passenger stations, junctions or other convenient points where operators are available. They are put in the proceed position to permit a train to enter the next block provided information has been received by the operator from the next station in the direction of traffic that the preceding train has passed out of the block. They are placed in the stop position on the passage of the train.

The operators have blanks on which they enter the designation numbers of each train they admit to a block, together with the time of entrance. On the same sheet is checked off the departure of the train from the block as advised by the operator at the leaving end of the block. The train despatcher, located at some central point, is also kept informed of all train movements, so that in case the schedule is deranged for any cause he can give the necessary orders to expedite traffic, such as changing orders for passing points and giving superior rights to certain trains.

**Defects of Non-controlled Manually Operated System.** — The defects of the system are obvious, as misunderstandings may arise between operators, trains may be checked off by mistake as having left a block when such is not the case, or trains may part and the fact not be noted by the block operator because of his failing to note the absence of the tail lights carried by the rear car of a train when the first division passes his station.

**Controlled Manually Operated System.** — These defects are partially overcome by the use of controlled manual block signals. In such systems electric locks are applied to the levers operating the manual signals. The locks are included in circuits running between block stations, and so arranged that when an operator wishes to place a signal in the proceed position he has

\* From tables compiled by the Interstate Commerce Commission, January 1, 1900.

first to ask (by bell signal or otherwise) for an unlock from the next station in the direction of traffic, and cooperate with the operator at that station in the proper manipulation of the circuits to get his unlock. A further check on the operators is sometimes obtained by the use of track circuits at the stations to effect a certain degree of control of the apparatus locking the signal levers by the passage of the trains themselves. These systems, however, are all inferior, in the degree of protection given, to the automatic blocks with signals controlled by continuous track circuits, which are described below.

**Staff System.** — Another form of controlled manual block signal is the staff system in which the possession of a small metal cylinder, or "staff," gives the engineer permission to run through a block. These staffs are normally in one or the other of a pair of instruments called staff instruments, one of a pair being at each end of a block. Only one staff can be taken from a pair of instruments at a time because of their locking features, controlled by circuits between the instruments, requiring the cooperation of two people, one at each instrument, to abstract a staff. Until this staff is replaced in one or the other instrument, no other staff can be withdrawn. Following movements with more than one train in the block can be accomplished by using a divisible staff, made in several sections which must be screwed together in a specified order to permit the insertion of the staff in an instrument when the last train has brought the remainder of the staff through the block.

There is also an automatic staff system in which the cooperation of the second person is not required.

There are about 511 miles of track equipped with the staff system in the United States.\*

**AUTOMATIC BLOCK SIGNALING.** — This subject will be treated under three main headings, in the order stated: Track Circuit, Signals and Their Mechanisms, and Location of Block Signals.

**TRACK CIRCUIT FOR AUTOMATIC BLOCK SIGNALS.** — The standard means of control of automatic block signals is the track circuit. It is the safest means known because the control is continuous and reliable.

**Steam-road Track Circuit (Fig. 1).** — The figure shows the elements of a steam-road track circuit. They are a source of electrical energy, means for limiting the flow of current from the source, a section of the rails of a track

Fig. 1. Elements of a Steam-road Track Circuit

insulated by special rail joints from adjoining rails, the leakage path constituted by the ties and ballast, and an electromagnetic type of relay. The contacts of the relay open and close the circuit which effects the operation of the signal. When there is no train on the track circuit, the contacts of the relay are closed due to the energizing of the relay by current flowing over the rails, which act as conductors from the source of electrical energy. The signal is made to indicate the absence of a train on the track circuit under these conditions. The

\* From tables compiled by the Interstate Commerce Commission, January 1, 1920.

presence of a train on the track circuit, or any other cause depriving the relay of energy, causes the relay to open its contacts, which results in the signal taking the stop position. The use of means for limiting the flow of current is to prevent exceeding the capacity of the source when a train shunts the rails, and at the same time to cause such drop of potential across the rails as will insure the opening of the relay.

**Electric-road Track Circuit.** — The track circuit for a road using electric propulsion, if a direct-current track relay is used, must, in order to avoid false clear signals, have the voltage point at which the relay closes its contacts higher than any voltage which may exist across its terminals, with a train on the track circuit, due to the flow of the propulsion current through the rails. Standard practice, to avoid the possibility of such false closing of the relay contacts, is the use of an alternating-current relay which is not operative to close its contacts under the influence of the propulsion current.

**Single-rail Track Circuit (Fig. 2).** — Fig. 2 shows an arrangement for d-c. propulsion roads where only one rail is used as the main return for the

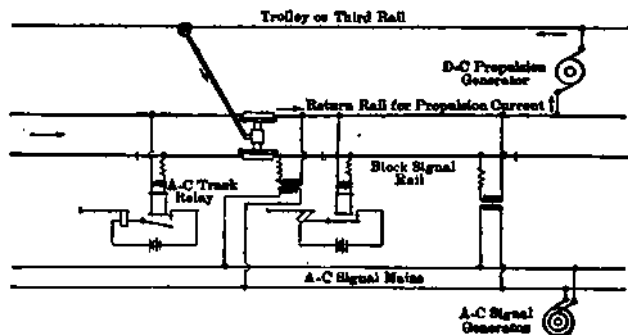

Fig. 2. A-C. Track Circuit, Single-rail System, D-C. Propulsion

propulsion current, the other rail being given up to the signaling current. The resistances used between the rails and the transformer, and between the rails and the relay, limit the flow of propulsion current through those pieces of apparatus. The inductive shunt across the relay serves the same purpose in forming a by-pass for propulsion current. The inductive shunt and the transformer supplying the track circuit have cores with open magnetic circuits to minimize the magnetizing effects of such direct current as may flow through their windings. An arrangement like the above is limited in practical use to those situations where the drop in voltage due to the propulsion current, along the length of continuous rail opposite any section of block rail, is under 50 volts. It finds its greatest application in subway and terminal or interlocking work. Where the number of tracks and shortness of track circuits bring the maximum voltage across the terminals of the relay, due to propulsion current, down to about 5 volts, a relay may be used with resistance enough in its winding to render unnecessary the use of the inductive shunt and resistance between it and the rails.

With a signaling current of higher frequency than the propulsion current and a selective relay, the single-rail track circuit is applicable to a-c. propulsion roads.

**Double-rail Track Circuit (Fig. 3).** — Where the conductivity of the return propulsion circuit is not sufficient to permit giving up one rail to the signaling current, the arrangement shown in Fig. 3 is used. Both rails are sectioned by insulating joints and the return propulsion current is carried around the insulating joints by means of impedance bonds (i.e., coils having a high inductance and low resistance) which are joined electrically at the middle points of their windings. The flow of the propulsion current is opposed

Fig. 3. A-C Track Circuits, Double-rail System, D-C Propulsion

only by the ohmic resistance of the bonds and their connections. The full impedance is, however, offered to the flow of the alternating signaling current from rail to rail, and it is, therefore, possible to maintain a difference in potential across the rails sufficient to operate the track relay.

Where the propulsion current is alternating, a higher frequency is used for the track circuit and the relay made correspondingly selective. 25-cycle current is ordinarily used for the signals on direct-current propulsion roads and 60-cycle current on alternating-current propulsion roads.

**Source of Energy for Track Circuit.** — The source of electrical energy for supplying the track circuit is generally in steam-road practice a primary battery of the caustic potash type with an external resistance. Generally three cells are used in multiple, but where the leakage between rails is high, larger numbers are used in series-multiple combinations. The storage battery is used to a limited extent and is especially advantageous on two- or four-track systems where the number of track circuits and amount of apparatus per unit distance is relatively large.

**Use of Alternating Current.** — Alternating current is rapidly coming into use for signaling on steam roads. Where alternating current is used for track circuits, it is almost universally used to operate the signals and supply the lamps for the night indications. 25- or 60-cycle current is used, the former generally resulting in slightly lower power consumption and being generally favored where the current has to be generated for the signalling system alone and no commercial emergency sources are available. Where such commercial emergency sources are available, as is generally the case in thickly-settled districts, the frequency of such sources being ordinarily 60 cycles, that frequency is often chosen for the signaling system.

**Transformers for Track Circuits.** — The source of alternating current for each block is either a low-voltage (5 to 20 volts) secondary of a transformer whose primary is connected to the transmission line, or a similar secondary

of a small special air-cooled transformer with a 110-volt primary. In the latter case the special transformer may be housed with other signal apparatus and its primary supplied from the 110-volt wires brought from the commercial transformer, whose primary is connected to the transmission line. The same 110-volt wires may be used also to supply the motors, line relays and "hold clear" devices, and carbon lamps used for lighting the signals. If Tungsten lamps are used, they may be supplied from suitable taps on the 110-volt primary of the special transformer or from taps on the low-voltage track secondaries.

Track circuits are generally supplied with current at about one-half the voltage of the source, due to the drop over the intermediate impedance.

**Location of Energy Supply.**—The source of energy (battery or transformer) is usually placed at the end of the block. If, however, the block is long and impedance bonds are used, resulting in large leakage from one rail to the other, the source of energy for the track circuit is sometimes placed at the center, and the control wires for the signal carried through the contacts of the two track relays, one being located at each end of the track circuit. Under these conditions, because of the voltage drop of the signaling current in the rails, there is only a limited distance extending either side of the point of supply in which a train will shunt both track relays simultaneously. This is taken advantage of in some systems of signaling, an example being given in Fig. 7.

**D-C. Track Relay.**—The direct-current track relay most commonly used on steam roads has two or four contacts closed when energized, and has a resistance of four ohms. The working voltage across its terminals is generally 0.4 or 0.5 volt under good weather conditions, but may be as low as 0.35 volt during wet weather.

**A-C. Track Relay.**—There are two types of a-c. track relays called, respectively, "single-energizing-circuit type" and "two-energizing circuit type," according to whether they take all of the energy to operate them from the track, or part from the track and part from a local source. These types are built on either one or both of two distinct principles: (1) on the principle of the electro-dynamometer (q.v.) and (2) on the principle of the induction motor; (see *Motors, Polyphase Induction and Waltham Motors*).

The induction-motor type has the advantage over the electro-dynamometer type, in that, its angular motion being unrestricted, a given pressure at the contact points can be produced with a less expenditure of energy. There is a limitation to this, however, due to the friction of the reduction gearing, which must not be so great that it cannot be overcome by the counterweight provided to open the contacts when the relay is deenergized.

With all types of railway signal relays, the addition of "back" contacts to be closed when the relay is deenergized, means the expenditure of more energy to satisfactorily close the "front" contacts, because of the extra counterweighting necessary to develop the necessary pressure on the back contacts.

**Single-energizing-circuit Type of Track Relay.**—Relays of this type are made on the induction motor principle in order to make them selective between the signal and propulsion currents. The following forms of construction are typical:

(1) Segment of sheet aluminum set in motion by the shifting magnetic field due to the "shaded" pole pieces of a laminated "C"-shaped core which carries the winding. This form is very largely used on short track circuits on d-c. propulsion roads.

(2) Double segment of sheet aluminum acted upon differentially on either side of its axis by the two sets of "shaded" poles of a double "C"-shaped

core is so designed that one or the other set of poles is stronger, on the respective amounts of propulsion or signaling current traversing. This form is used on a-c. propulsion roads, being made between 25 and 60 cycles, the latter frequency being used for the current.

Centrifuge driven by split-phase induction motor. This form is used on propulsion roads. It is selective by virtue of the centrifuge being designed to make the contacts when driven at a speed corresponding to the lower of the propulsion current.

Split-phase induction motor with gearing or link connection from rotor to contact supporting member.

Typical power figures at the working points are as follows:

Frequency	Volt-amperes	Volts *	Power factor	Number of contacts closed when energized
25	5.0	3.0	0.55	4
60	8.5	5.0	0.55	4
60	20.0	3.1	0.55	2
60	6.0	2.3	0.70	10
25 } 60 }	10.0	5.0	0.70	6

\* Track windings of relays.

**Two-energizing-circuit Type of Track Relay.**—The following constructions are typical: (1) Electrodynamometer; used on d-c. roads and to some extent on steam roads. (2) Induction motor type; the rotor is a cylindrical shell of copper or aluminum with a laminated core; used on d-c. propulsion roads and very largely on a-c. roads. (3) Centrifuge driven by induction motor; used on a-c. propulsion roads; see also preceding section.

The windings of all two-energizing-circuit relays are generally supplied from 10 to 110 volts. The objection to the higher voltage is the small size and consequently greater liability to damage by lightning.

The following typical power figures are for "two-position" relays, i.e., relays

Frequency	Track			Local		Number of contacts closed when energized
	Volt-amperes	Power factor	Volts	Volt-amperes	Power factor	
25	0.70	0.90	0.35	36	0.70	4
60	1.60	0.80	1.60	33	0.34	4
25	0.038	0.65	0.15	2.4	0.70	10
60	0.024	0.65	0.15	11.0	0.70	10
60	1.30	0.55	0.3	20	0.95	6
25	0.13	0.80	0.35	45	0.35	6
60	0.16	1.00	0.4	44	0.25	6

with one energized and one deenergized position. Relays which are caused to assume two energized positions by reversals of the current in one of the windings are termed "three-position" relays and generally require twice as much power in one of the windings as two-position relays.

The adjustment of the phase relations of the currents in two-energizing-circuit relays has to be carefully cared-for in the choice of the impedance used between transformers and rails, and between local windings and the source of energy supply.

**Single- Versus Two-circuit Types.** — As a track circuit is, from an engineering point of view, nothing but a very inefficient transmission circuit,\* track circuits above a certain length can be worked most economically with a two-energizing-circuit type of relay, as the amount of energy transmitted over the rails can be reduced to a certain point by increasing the amount of energy supplied economically to the second winding from a local source. For track circuits below a certain length, however, the energy supplied to the track circuit for the single-energizing-circuit type of relay is less than the total supplied to the track circuit and the local winding of the two-energizing-circuit type.

The above consideration, taken in conjunction with the fact that a relay with one energizing circuit usually is cheaper than one with two energizing circuits, and does not require the installation of a source of energy supply for a local winding, generally points to the choice of the single-energizing-circuit type for track circuits less than 1500 feet in length. On the other hand, as the single-energizing-circuit type of relay may be falsely energized by current from an adjacent track circuit, due to broken-down insulating joints, it does not give the same degree of protection against this failure as the two-energizing-circuit type, with the source of current supply to adjacent track circuits of opposite instantaneous polarity.

**Impedance Bonds.** — Impedance bonds are wound with strap copper varying from 57,000 cir. mils for 22,000-volt, 25-cycle propulsion to 220,000 cir. mils for ordinary d-c. 600-volt interurban work, and 800,000 cir. mils for heavy 600-volt d-c. traction work. The corresponding resistances across rails are respectively about 0.014, 0.0014 and 0.00045 ohm. The respective continuous propulsion current per rail ratings are 50, 500 and 1500 amperes. Typical impedance values from rail to rail are respectively 10 ohms at 2 volts and 15 ohms at 9.2 volts, 60 cycles; and 0.3 ohm at 1.5 volts, and 0.18 ohm at 15 volts, 25 cycles.

Though the resistance of the connection around an insulating joint formed by an impedance bond may be relatively high as compared with the resistance of the ordinary rail joint bond, the small number of impedance bonds in a system compared to the number of rail joint bonds results in but a very slight percentage increase in the total resistance of the return propulsion circuits.

The impedance bonds for direct-current propulsion roads are provided with an air gap in the magnetic circuit to limit the change in impedance due to un-

\* The inefficiency of the track circuit as a transmission line is due to the drop through the current limiting means between the source of energy and the rails (and in the single-rail system between the relay and the rails), the high reactive drop in the rails, the distributed leakage of ballast and ties, and, in the two-rail system, the concentrated leakage through the impedance bonds. The voltage at which the track winding of a relay is designed to operate is selected first, to obtain safe and reliable operation, and second, to obtain as high a degree of efficiency of the track circuit as is permitted by the characteristics of the track circuit. This generally results, with relays taking a comparatively large amount of energy from the track, in higher voltages for track windings of relays used on steam roads than for those used on electric roads, though the total energy put into the track circuit is less in the former than in the latter case.

equal amounts of propulsion current flowing in the two halves of the winding. Good practice is to provide for satisfactory operation with a maximum difference equal to 20 per cent of twice the rated capacity per rail, e.g., a 1500-ampere per rail bond should operate satisfactorily with a difference of 600 amperes between the currents in the two rails.

**Impedance of Track Circuits.**—The table on page 1415 gives the impedance per 1000 feet of track under various conditions of bonding in common practice and for the values of current commonly used for the energization of the track elements of relays. Where propulsion current is flowing in the rails, the power factor corresponding to the value of the propulsion current should be used to determine the most adverse conditions of drop of potential of signaling current between the point of supply to the track circuit and the relay.

**Resistance of Leakage Path.**—The resistance of the leakage path between rails in ohms per thousand feet of track varies with the nature of the ballast, the condition of the ties and the weather conditions. Two ohms per thousand feet is a low wet weather value for track with gravel ballast.

In connection with the calculations involving the values of rail impedance given in the table on p. 1415 the following values for resistance of ballast and ties between rails may be used. They are given for ballast clear of the rails.

	Ohms per 1000 feet of track
Wet gravel.....	3
Dry gravel.....	6
Wet broken stone.....	6
Dry broken stone.....	16

**Transmission-Line Voltages.**—Transmission-line (between generator and signal transformers) voltages in standard practice vary from 1100 to 4400 volts inclusive, though in some special cases of subway and elevated road work, or where the mains are carried on existing telegraph poles, they may be lower.

**SIGNALS AND THEIR MECHANISMS.**—Signal indications for block and interlocking work are given in standard railroad practice by semaphores. The semaphore consists of a wood, or enameled steel, blade or arm, fastened at its inner end to a "spectacle." The spectacle is a casting, or combination casting and metal stamping, embodying the hub for the shaft on which the semaphore rotates, and the colored glass roundels which change position before a lamp fitted with a clear lens, to give the night indications corresponding with the positions of the semaphore. The lamp is provided with a long-time oil burner (usually seven days) or incandescent bulbs.

**Weight and Torque of Semaphores.**—The weight of the semaphore is

distributed to give a maximum torque (tending to return the semaphore to the stop position) varying with different types of operating mechanisms from about 30 to 100 pound-feet. As the torque curve is necessarily a sine curve, a spectacle moving through  $90^\circ$  is generally designed to have maximum torque at about  $55^\circ$ .

Spectacles operated manually, which can be pulled to the stop position, may be lighter than those which, in returning to the stop position, have to return parts of the mechanism which cause them to assume the proceed position.

In automatic signals gravity is depended on almost universally to return the signal to stop.

**Semaphore Positions and Colors of Lights.** — The three fundamental signal indications are:

1. Stop,\* 2. Proceed with caution, 3. Proceed. The standard method of giving these indications is in the upper right-hand quadrant as indicated in Fig. 4, the respective positions of the semaphore arm being respectively at  $0^\circ$ ,  $45^\circ$ , and  $90^\circ$ . The corresponding colors of the night lights differ with different

Fig. 4. Standard Semaphore Positions

roads; a common practice is to use red for stop, green for proceed with caution and white for proceed, but on account of the danger of a white light being falsely displayed because of the breakage of the colored roundels it is considered best practice to use red, yellow and green, for the respective indications enumerated above.

It is also good (but less up to date) practice to give these indications in the lower right-hand quadrant, the horizontal position of the semaphore arm always indicating stop. Where the view to the right of the signal mast is obscured, as by the poles along a trolley road, or where clearances are small, due to high walls close to the right-of-way, as through a city, the semaphore is sometimes operated in the upper left-hand quadrant.

Two-position semaphores, indicating stop and proceed only, are also largely used, the proceed indication generally being given at from  $60^\circ$  to  $90^\circ$  depending on the individual road.

**Power Mechanisms.** — Power signals are operated by "bottom" or "top post" mechanisms. Electricity, compressed air and gas are used as motive power. Of the track mileage protected by automatic semaphores approximately 90 per cent has electrically-operated mechanisms. Compressed gas and air for automatic blocks are limited in use to very few roads, though these include some of the most important ones. The gas is supplied in tanks. The air is distributed in pipe mains.

**Electrically-operated Bottom-post Mechanism.** — Electric bottom-post mechanisms generally consist of a motor which, by gearing and levers, transmits the movement necessary to clear the semaphore through a vertical rod extending inside the mast between the mechanism and a crank arm on the

\*An automatic signal in the "stop" position may be passed "according to rule" after bringing train to stop. An interlocking signal in the "stop" position may be passed only after bringing train to stop and receiving authority to pass the stop signal from an authorized person.

shore shaft. The type most generally used has interposed in the movement transmission system, as near the connection to the vertical rod as possible, an electric latching device called a *slot*. The operation of the semaphore in maintenance in, a proceed position depends on this latch being energized. The motor cutting out automatically after performing its work. The location of the *slot* in the movement system close to the vertical rod reduces to a minimum number of parts moved by the return of the semaphore to the stop position. The influence of gravity, and, consequently, reduces the possibility of signal sticking in the proceed position due to the development of any friction.

The control of the circuit supplying the motor and slot is effected by the contacts of the track relay.

**Electrically-operated Top-post Mechanism.** — In top-post mechanism the motor acts directly on the semaphore shaft through a train of gears. The semaphore in its return to the stop position has to drive the gear train and the motor. The ratio of gearing in top-post mechanisms is made comparatively low (about 120:1) to diminish friction when going to the stop position. The motors are consequently very slow speed. The latching of the semaphore in the clear position is accomplished by electromechanical means or by electric induction. The latter method obviates the danger of the signaling in the proceed position due to the adhesion of contacting surfaces in the latching device.

**Power Required for Electrically-operated Signal Mechanisms.** — Motors and latching devices are generally supplied with current from local dry or storage batteries at from 8 to 10 volts. With a maximum semaphore weight of between 30 to 50 pound-feet and clearing 90° in about 10 seconds, the motor will consume between 2 and 2½ amperes. The latching device consumes from 0.008 amperes to 0.02 amperes, depending on the voltage and winding resistance.

Under the same conditions as given for d-c. motors, a-c. commutator motors consume slightly less than 1 ampere at 110 volts at about 0.8 power factor. Induction motors will consume between 2.8 and 3.5 amperes at the same rate but at about 0.5 power factor.

The electric latching device consumes approximately from 5 to 10 watts in a-c. mechanisms, the power factor varying widely with the design.

**Pneumatically-operated Signal Mechanisms.** — The pneumatic mechanism is the simplest of those used for operating signals, consisting of merely a 4-inch cylinder with a metal-packed brass piston, a magnet valve controlling the admission of air and suitable mechanical connections to the shore shaft. The electromagnet valve controlling the admission of air is called as the "slot," as its deenergization shuts off the air and exhausts the cylinder to atmosphere. The pneumatic mechanisms are readily adaptable to bottom- or top-post operation. The air pressure carried varies from 40 to 90 pounds. Ninety pounds is a common pressure.

The advantages of the pneumatic mechanisms are their simplicity, reliability and over-load capacity.

**Gas-operated Signal Mechanisms.** — The gas-operated mechanisms are similar in principle to those operated by air, but are complicated by the status incidental to the tank supply being at a very much greater pressure than at which the gas is used in the signal cylinder.

**Light Signals.** — Powerful light signals are sometimes used to give day, as well as night, indications in place of the semaphore. Notable examples of this are the position light signal installations on the Pennsylvania

system, especially in the neighborhood of Philadelphia, and the installation of color day-light light signals on the Chicago, Milwaukee & St. Paul, to say nothing of numerous installations on electric interurban roads.

These light signals are generally hooded to make them more visible in sunlight. They are provided with concentrating lenses, and sometimes with specially-constructed reflectors arranged so that light entering from the exterior through the lens will not be reflected out again and give a false indication when the lamp behind the lens is not lighted.

The candle-power behind the lens varies from 5 to 120, depending upon the type of lamp, the efficiency of the lenses and reflectors, and the color density of the glass. The indication given is sufficiently powerful even in bright sunlight to permit of the satisfactory operation of the highest speed trains.

**LOCATION OF BLOCK SIGNALS.** — Automatic block-signal systems have to take care of such varied fundamental conditions as are found, on the one hand, on single-track roads where the distances between passing sidings may be as great as four miles or more, and the traffic relatively infrequent and, on the other hand, on roads of four tracks, or more, where the traffic is dense, the headway short, and trains of both high- and low-speeds have at times to be handled over parts of the same tracks.

**Home and Distant Signals.** — The signal at the entrance to a block indicating the presence or absence of a train in that block is called the "home signal." In order that a train may be given warning in time to stop at the entrance to an occupied block, a second signal, called the "distant signal," indicating the position of the home signal at the entrance to the block, is located at a point sufficiently distant to enable the runner to act on the indication and bring his train to a standstill with a reasonable factor of safety before passing the stop signal. This distance will vary with the conditions of grade, curvature of track, and character of train equipment and may be from 3500 to 4200 feet or more.

In three-position signaling the semaphore at the beginning of a block is used to give the home signal for that block and the distant signal for the next block ahead. In two-position signaling the position of the home signal is repeated by a semaphore of distinctive shape, displaying a distinctively-colored light at night. This distant signal may, where the blocks are short, be located on the same mast with the preceding home signal. If the blocks are long and the rules of the road require a train to be immediately brought under control when advance information is received that the home signal is at stop, it is best to avoid loss of time by placing the signal giving the advance information on a separate mast at the proper distance from the home signal. This applies also to three-position signaling.

With distant signals it is, therefore, evident that in order to have following trains run continually under clear signals, they must be separated by a distance equal, at least, to the distance run by the preceding train during the time occupied by the clearing of the home and distant signals plus the length of the intervening block plus the distance between the home and distant signals.

The relations stated above give the basis for the theoretical location of automatic block signals to safely obtain maximum traffic capacity. In practice one must consider character of traffic, congested conditions at approaches to terminals, busy passenger stations and junction points, and local conditions such as view and opportunity for suitable foundations, in their effect on signal location.

**Arrangement of Signals on Single-track Road.** — Fig. 5 shows one arrangement of single-track signaling in both directions used by a large western

system. The horizontal lines terminating at one end opposite signals and at the other end opposite insulating joints (the latter indicated by the short marks

Fig. 5. Arrangement of Single-track Signaling in Both Directions

across the lines representing the rails) show the extent of track governing each signal by virtue of the track circuit.

Even where the distance between stations (or sidings) is less than a mile, it is important that intermediate home signals be placed between stations (or sidings) in order to prevent a train on the main track at a station from causing possible detention to an incoming train. It will be noticed by reference to the figure that eight signals are used to protect traffic, six between stations, and two within station limits. This number of signals is necessary to adequately protect all traffic and at the same time to insure proper flexibility, since, with this arrangement, trains can move up to the station limits under full protection from both directions, even though the main line may be occupied within these limits. This is because a train in a station affects only the entrance signals, and consequently does not affect approaching traffic on either side of the station, neither does a train on one side of a station influence traffic on the other side.

Fig. 6 shows the circuits for the system shown in Fig. 5.

Fig. 6. Circuits for System Shown in Fig. 5

Another very typical system of single-track signaling is that which gives station to station protection for opposing moves and signal to signal protection for following moves. It is called the Absolute Permissive Block System or Traffic Direction System, generally abbreviated to A. P. B. System.

**Special Arrangement for Single-track Interurban Road.**— Fig. 7 shows a system of signaling which is particularly applicable to interurban single-track signaling where special conditions sometimes render it extremely desirable to permit more than one car, moving in the same direction, between sidings, and yet give both head-on and rear-end protection.

Because of the impedance of the rails and the characteristics of the voltage supply to the track circuit, track relay at signal "A" is deenergized only by a train between "A" and "X." Similarly, track relay at signal "B" is deenergized only by a train between "B" and "Y." Signals "A" and "B" are

connected so that both will go to "stop" on the entrance of a car at either end of the block, but for following cars the signal at the entering end will clear up after

Fig. 7. System for Single-track Interurban

any preceding car has gone half the distance between sidings plus half the distance  $X-Y$ .  $X-Y$  is generally about 3000 feet where distance  $A-B$  is about 2 miles. If, by any misunderstanding, cars going in opposite directions should enter a stretch of track between sidings, they would be stopped by signals "C" and "D," located sufficiently far apart to allow for a proper factor of safety in stopping.

**Trolley Wheel Operated Signals.** — Block signals controlled from a contactor operated by the trolley wheel do not meet the requirements of high-speed signaling as to reliability, and are of value principally in preventing the loss of time due to two cars moving in opposite directions entering the same stretch of track, where conditions of vision and speed are such that there is small chance of harm resulting from a collision.

**Arrangement of Signals on Double-track Road.** — Fig. 8 shows a typical a-c. automatic block-signaling system with circuits for a two-track road. It will be noted that the control of the third position of the signals is obtained by the use of line wires running between the signals and supplied with current by circuit controllers operated by the signals.

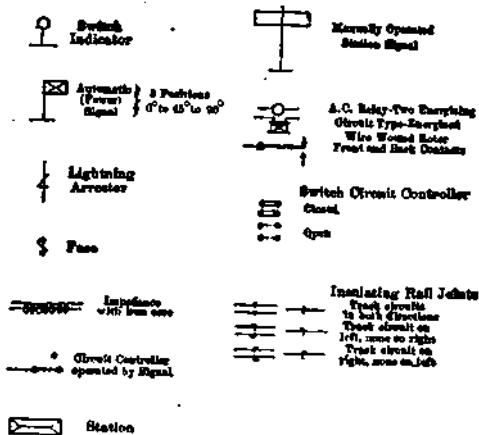

Fig. 8a. Key to Fig. 8

Fig. 8b. Details of Transformer Shown in Fig. 8

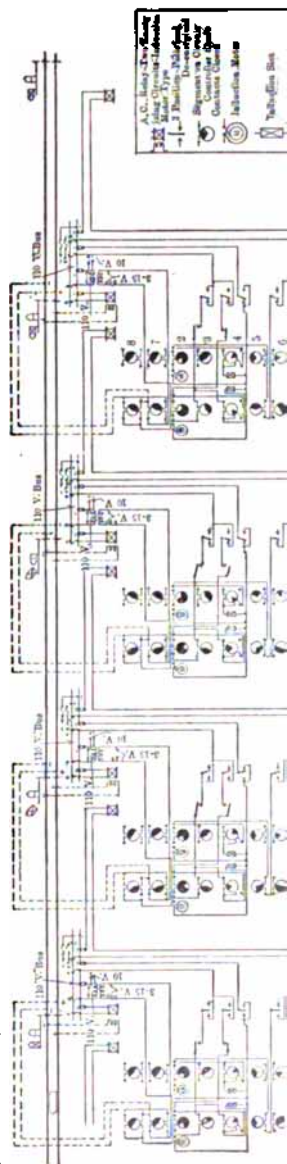

The use of two-energizing-circuit track relays as *polarised* relays permits *dispensing* with control line wires, in obtaining the control of the third position of three-position signals. The polarized relays close contacts in two positions according to direction of current in track winding and open them when deenergized, as by the presence of a train on the track circuit. The polarity of the current supplied to the track circuit in the rear of any signal depends on the position of that signal and the circuit controllers attached to it. This method is known as *polarised wireless control* and has its counterpart in direct-current signaling.

**Maximum Capacity Arrangement.**—Fig. 9 shows the latest development of signaling to give maximum capacity where high- and low-speed trains are run on close headway. The main idea is to make possible proper *speed control*. It will be noted that the high-speed trains receive sufficient warning to stop at the proper point in spite of the spacing of signals being made close to get maximum capacity with low-speed trains, which may run for short distances on the high-speed tracks.

Beginning with the first signal behind the occupied block at the left, the indications are respectively "Stop, then proceed according to rule," "Proceed, prepared to stop at next signal," "Proceed, prepared to pass next signal at medium speed," "Proceed."

**INTERLOCKINGS AT CROSSINGS, JUNCTIONS AND TERMINALS.**—All interlockings are designed with the view of insuring that signals governing traffic over any movable track must be in the stop position before the track parts can be shifted, that the track parts cannot be moved under a train, that they must be locked in the proper position before the signals governing over them can be placed in the proceed position, and that conflicting signals cannot be given.

The apparatus at an "interlocking" consists of the signals and movable

track parts with their operating mechanisms and intermediate apparatus, the central-controlling interlocking machine (sometimes called an "interlocker") located in a signal tower or station, and auxiliary apparatus. Three types of interlockings are used: (1) mechanical interlocking, in which movement is transmitted to the signals and track parts by means of wire and pipe connections to the levers in the interlocking machine; (2) electric interlocking in which the signals and track parts are moved by electric motors controlled through the interlocking machine; and (3), electro-pneumatic interlocking in which the signals and track parts are moved by compressed air controlled electrically through the interlocking machine. The last two types are called power interlockings as contrasted with the mechanical interlockings.

Almost all large terminals in the United States use electro-pneumatic interlockings. On the smallest power interlocking installations, "all electric" predominates. For installations of intermediate size there are many factors governing the wisdom of the choice.

**Signal Apparatus.**—Interlocking signals differ from automatic signals in external appearance only in such details as are necessary to enable the runner to differentiate them. The differences are generally confined to shapes and markings of arms, locations on masts, etc., and call attention to modifications in the significance of some of the aspects of interlocking signals as distinguished from automatics, e.g., see section above on *Semaphore Positions*. In mechanical interlockings signals are operated by wire or pipe connections to the mechanical levers in the interlocking machine. Sometimes a low voltage electric operating mechanism is used, though the switches remain mechanically operated. In such cases the signals are controlled through contacts operated directly from the mechanical lever or from contacts on a small auxiliary lever properly interlocked with the other levers of the machine.

In power interlockings the signal-operating mechanisms are essentially the same as those used for automatic block signals and are described above in the section on *Power Mechanisms*. Their control and operating circuits replace the mechanically operated pipe and wire connections of the mechanical interlocking signals.

**Track Apparatus.**—The track apparatus comprises switches, movable point frogs, detector bars, derails, bolt locks, drawbridge locks, etc., with their operating mechanisms.

The detector bar is a piece of steel  $\frac{3}{8}$  inch or  $\frac{1}{2}$  inch thick,  $2\frac{1}{2}$  inches wide and varying in length up to 55 feet. It is supported beside the head of the rail in the vicinity of a movable part of the track, so that it is capable of vertical motion above the head of the rail when no car is present over it.

On account of the fact that with power interlocking and a wide head of rail a mechanical detector bar is likely to be forced up outside the wheels of a car over a switch, mechanical bars are being supplanted by short track circuits, called detector track circuits, which are utilized to lock the switch-control lever in the interlocking machine against being thrown under a train while a train is over a movable track part.

In all types of interlocking the movable part of the track is locked in position by connecting to it a horizontal bar, called the lock rod, which moves with the track part at right angles to the track. The lock rod is provided with holes or notches into which a bar, moving in guides parallel to the track, may be moved when the switch, or other moving part, is in its correct position. This

\* Combinations of (1) and (2) are rapidly coming into use, and are of great advantage when the tower space is restricted and a change of track layout calls for an increase of capacity over that of the existing "mechanical" machine. The combination is called "Electro-mechanical."

which engages the lock rod, receives its motion from the connection at the detector bar. The sequence of movements at the switch is: (1) the raising of the detector bars; (2) the withdrawal of the bar engaging the switch, the latter operation not being capable of completion unless it has been able to raise the detector bar to the full extent of its travel); (3) the lowering of the switch, or other track part; (4) the lowering of the detector bar into the entrance of the locking bar into the hole or notch in the lock rod, the moving part has made its full travel and is in its correct position.

**Intermediate Apparatus.** — The movements enumerated in the above paragraph are generally effected in mechanical interlockings by pipe connections between the parts and their locking devices to corresponding levers in the interlocking machine. Bell cranks are used in the pipe connections to change the direction of motion. Sometimes all the movements enumerated above are effected in proper order by a device located beside the track, called a "lock and lock movement," which may be operated by one pipe connection to the interlocking machine lever. In power interlockings switch and lock movements are always used, power apparatus at the track and electric circuits are used to operate the mechanically-operated pipe connections.

**Power Apparatus for Electric Interlockings.** — The power supply for electric interlockings is derived from storage batteries, used in duplicate sets to allow for charging, or in single sets charged while in service or floated on the circuit. The nominal voltage is 110, but exceeds this figure if the battery is recharged in operation, or floated, or if, as is sometimes the case, 55 cells are used. A 120-ampere-hour cell is a common size for interlockings. At such plants the charging is generally done two or three times a week by a gas-driven generator. A switch motor operating a single switch takes about 2 amperes. A mechanical detector bar in two seconds takes an average current of 2 amperes. With about 200 feet of detector bar the corresponding current is about  $4\frac{1}{2}$  amperes. A motor signal operating in the same time takes about 10 amperes to clear and one-tenth ampere to hold. Solenoid dwarf signals are quite commonly used, operate almost instantaneously and require a resistance of about 12 ohms and require 0.3 ampere to hold, resistance is increased when the signal clears.

**Power Apparatus for Electro-pneumatic Interlocking.** — Each signal cylinder in electro-pneumatic interlocking is provided with an electromagnetic piston fastened directly to the cylinder. The piston is metal-packed, single-acting, self-sealing at the end of its stroke under pressure. The cylinder diameter is 2 inches and the stroke 4 inches except where two cylinders act jointly to operate the three positions of the semaphore. Admission of air is obtained by the opening of the magnet valve, and exhaust by the deenergization, the piston returning under the influence of the counterweight of the semaphore. Each cylinder is double acting, and vary from four inches to seven inches in diameter, depending on the character of the load, and have a stroke varying from a length equal to the throw of the switch up to 10 inches. In some cases cylinders are used to act directly on the switch points without bars, but in most cases they are used to operate (through the medium of a switch and lock movement) the heavier movable-point frogs in connection with one end of a double-acting complement of bars. The stroke of the larger cylinders is generally 4 inches. Air is admitted to the cylinder by a slide valve. The latter is actuated by two small single-acting pistons, the admission of air to which is controlled by two electromagnetic pin valves similar to those used on the signal cylinders. The slide valve is locked in its extreme positions by a pin actuated by a piston controlled by a third electromagnetic valve whose energiza-

tion must precede the operation of either of the pistons which shift the slide valve.

The control of the various magnet valves is effected by contacts operated by the interlocking machine levers. Storage battery to give about four teen volts is generally used and the individual currents may vary from  $\frac{1}{10}$  to  $\frac{1}{2}$  of an ampere. From 75 to 100 pounds air pressure is generally carried.

**Interlocking Machine for Mechanical Interlocking.** — The interlocking machine comprises the levers, or controller handles, corresponding to the apparatus governed, and the mechanical, or mechanical and electrical, interlocking devices between the levers themselves, and between the levers and the apparatus governed by them.

The mechanical locking between levers is effected in the "locking bed." This is an iron plate, with two sets of parallel grooves. One set of grooves contains cold-rolled steel bars of rectangular cross section connected to and moved by the levers. The other set of grooves, at right angles to the first, contains shorter bars with ends shaped to engage with projections or depressions on the bars connected to the levers. The cross bars engage with the lever bars in such a manner that a lever cannot be moved unless the lever bar affecting the other end of the cross bar is in a definite position.

In a mechanical interlocking the operation of the detector bar and locking bar operating in conjunction with a movable track part, is generally effected by a separate lever in the interlocking machine, called the lock lever. This lever is interlocked with the proper signal levers so that the latter must have been operated to put the corresponding signals to stop before the lock lever can be operated to raise the detector bar and unlock the switch. The switch lever is in turn, interlocked with the lock lever so that if the lock lever cannot make its full stroke, due, for example, to a train being over the detector bars, the switch lever cannot be thrown. If, after the switch lever is thrown, the lock lever cannot be thrown fully back to its original position, due, for example, to the switch not having made full travel, and the locking bar not being able to properly engage the lock rod, the interlocking between the lock and signal levers prevents the latter from being operated to put the signals in the proceed position. In mechanical interlocking plants rods connected to the signals are also often made to engage with the lock rod of the switch.

Further protection is often obtained in mechanical machines by attaching to moving parts connected to the levers circuit controllers and electromagnetic locks. The electric locks act by gravity when deenergized to engage with a moving part connected to the lever. The circuit which energizes them may be carried through circuit controllers attached to the signal or track mechanism, or through the circuit controllers on other levers.

**Interlocking Machine for Power Interlockings.** — In power interlockings the levers are small as they have to operate only the mechanical locking in the machine and contacts for controlling the various circuits. The strain which can be brought on the mechanical locking is thereby reduced, and it is made correspondingly smaller than in mechanical interlocking machines. In these types of machines where the levers give a rotary motion to the circuit controllers it is possible, by the use of the two extreme positions of the levers, to control signals governing over the same route in opposing directions by the same lever. Only circuits for signals in one direction are closed in an extreme position and the indication referred to below being received before the lever can be returned to the middle position, where it releases the mechanical lock. This insures against signals being placed in the proceed position if opposing signals controlled by the same lever have not returned to stop.

ing on the type, a power interlocking machine may occupy less than of the space taken by a mechanical machine, and require but one operator. Space is also saved on the ground, as the pipe connections are replaced by wires.

In interlockings the completion of the stroke of a movable-track part per locking is "indicated" on the machine by the energization of an electric lock which allows the lever to complete its full stroke, thereby effecting the proper mechanical locking in the machine. The circuit for the lock is completed through contacts on the moving mechanism on the ground. The signal to the stop position is indicated in a similar manner.

**Control of Current for Electric Interlockings.** — The supply of current for signals, switches, etc., may be effected directly by the controller of the interlocking machine, or by simple or polarized secondary controllers. In the various signals and switches, the windings of the secondary controller being in turn supplied in whole or in part with current from the lever contacts. The use of the secondary controllers permits the size of the interlocking machine to be small, the power for the signals, switches, etc., being supplied through contacts operated by the secondary controller from mains running through the plant.

Because of the small amount of current used to operate the secondary controllers compared to the amount used by the apparatus they supply, the size of the interlocking machine may be as small and compact as in an automatic interlocking machine, and therefore offer the same excellent economy for intercontrol of circuits in the machine itself. This is particularly important, for instance, where it is desired to effect *route locking* (see below) where it may be necessary to have certain signals and switches enter into a variety of combinations.

**Indication Current for Power Interlockings.** — Among the various methods of providing the current for "indication" may be mentioned: (1) the use of the same current as is used for control and operation, called "battery current"; (2) the use of polarized apparatus in connection with the preceding method; (3) the use of current of a different character from the operating current, utilizing the momentum of the operating electric motor to generate the indication current after the motor has completed the movement of the apparatus; (4) the operation of the electric motor as a motor generator after it has completed the movement of the apparatus, the generated current being distinctive in character, viz., alternating or of greater frequency than the operating current and of such direction as to selectively operate the magnets.

**Emergency Apparatus.** — Various relays, indicators, annunciators, emergency lever releases and special circuits are used in connection with or in addition to the essential interlocking apparatus to expedite the handling of signals to meet special conditions.

**Emergency Locking.** — Where electric locking is effective while a train is passing a signal which has been set for it to proceed, to prevent manipulations or devices which would endanger that train, it is termed *emergency locking*.

**Route Locking.** — When electric locking is so arranged that it takes effect when a train passes a signal to prevent manipulation of levers which would endanger the train while it is within the limits of the route entered, it is termed *route locking*.

**Sectional Route Locking.** — To minimize the limitation of trackage which results from route locking, especially when the route lies across several tracks, *sectional route locking* is used. This is route locking so

arranged that a train in clearing each section of a route releases the locking affecting that section. The detector track circuits are used to accomplish this type of locking. When *route locking* is not used it is necessary, in order to safely obtain full trackage capacity, to space the signals so close that no considerable amount of track is locked by the clearing of any one signal. Where the track layout and traffic conditions are such that short switching moves predominate over through routing this latter method is superior in giving greater capacity and flexibility.

**AUTOMATIC STOPS.** — Automatic stops have been in use for a number of years in connection with elevated and subway roads. They have been operated by direct mechanical connection to the signals or by separate mechanisms working in conjunction with the signals, and have consisted of arms located on the roadbed so that when elevated they were in position to engage with and operate a connection to the brake system on the car. It is evident that as a train may travel a considerable distance after the brakes are applied, and as the engineman or runner is dependent on the signals for the knowledge necessary to the proper control of his train, the relation of signal and stop locations must be such that in case the signals are properly observed the brakes will not be automatically applied, while if the contrary is the case, the space intervening between the train causing the display of the danger signal and the automatic stop protecting it must be sufficient to allow a following train being brought to rest without a collision.

This may be accomplished in two ways: (1) by using an overlap (i. e., extending the control of a signal to a point sufficiently beyond the next succeeding signal), which increases the spacing of trains and diminishes the capacity of the road; (2) by giving the runner an advance indication of the position of the signal at which it may be necessary to make a stop, so that if necessary he may bring his train under control in time to stop at the proper point. In the latter case the automatic stop is located to bring the train to rest at the stop signal, in case the speed has not been properly reduced. Up to the present (1921) automatic stop installations have been almost universally on the overlap system.

On account of clearances and atmospheric conditions, the automatic stop problem for steam roads is very difficult of solution. The problem is further complicated by the fact that there are involved the different conditions affecting freight and passenger traffic, a differentiation between the absolute stop indication of an interlocking signal and the permissive stop indication of an automatic block signal, and a differentiation between the speeds permissible over different routes, as indicated by an interlocking signal, with two or more arms, located at a point of divergence.

The above considerations indicate that the satisfactory solution of the automatic-stop problem for the majority of roads must follow the trend of modern signaling, and be based on speed control.

**SKIN EFFECT.** — (See also *Electricity and Magnetism, Principles of; Resistance and Conductance, Electric.*) A conductor of finite cross-section may be looked upon as made up of separate filaments, just as a beam may be looked upon as made up of separate fibers. The inductances of the various filaments which make up such a conductor are different, due to the fact that the exterior filaments are linked by fewer flux lines than the interior filaments; see *Electricity and Magnetism, Principles of, and Inductance and Inductive Reactance.* Consequently, when the same potential gradient (varying with time, however) is established through all the filaments of such a conductor, by connecting it to some external source of alternating or varying e.m.f., the self-induced back e.m.f. in the interior filaments will be greater than in those filaments nearer the surface, and therefore the resistance drop in the interior filaments must be less than in the surface filaments. This can be brought about only by the current distributing itself over the cross-section of the conductor in such a manner that the current density in the interior of the wire will be less than at the surface, i.e., the current is forced toward the surface filaments or "skin" of the wire; hence the term "skin-effect" for this phenomenon.

**Factors upon which the Skin Effect Depends.** — The self-induced e.m.f. depends not only upon the amount of flux set up but also upon the rapidity of its variation; hence the skin effect becomes more pronounced the greater the frequency of the impressed e.m.f. It is also greater the larger the cross section of the conductor, the greater the conductivity of the conductor and the greater its magnetic permeability. It also depends slightly upon temperature since the conductivity changes with temperature.

**Change in Resistance and Inductance due to Skin Effect.** — As a consequence of the skin-effect the effective resistance of a conductor to alternating currents is greater than to direct currents, but the *internal* inductance decreases with the frequency; the external inductance is not altered; see *Inductance and Inductive Reactance.* Whereas, however, the internal inductance with increasing frequency approaches a limiting value, the resistance increases indefinitely as the frequency approaches an infinite value. The change of resistance is always relatively much larger than the change in the total inductance.

The effects just described are, for the most part, negligible at low frequencies, except in the case of heavy conductors and in coils wound with stout wire in several layers. In the latter case, however, the diminution of the inductance, due to the irregular distribution of the current, is masked, to a greater or less degree, by the effect of the capacity between the windings of the coil, which gives rise to an *increase* of the inductance with the frequency. For the same reason the resistance is increased more than it would be by the eddy currents alone.

Unfortunately, the rigorous or approximate solution of the problem at high frequencies for the various cases which arise in practice is in many instances very difficult, if not impossible.

**SKIN EFFECT IN STRAIGHT ROUND WIRES.** — An accurate solution for the case of straight *solid*<sup>9</sup> wires of circular cross-section has been given in a number of different forms by various scientists. A summary of the formulas is given in a paper by Rosa and Grover, *Bull. Bur. Sids., 1912, Vol.*

<sup>9</sup> Tests at the Massachusetts Institute of Technology (*Proc. A.I.E.E., Sept., 1915*), indicate that the formulas for solid wires also apply to round *stranded* wires of the same cross-section of metal, not the same over-all diameter, for frequencies up to 1200, but above this frequency there is an increase in the skin effect, due to the spiraling of the component wires of the cable.

8, p. 172. The calculations are most conveniently made by the use of the tables given in Rosa and Grover's paper, which are given in a condensed form below. Let

$f$  = frequency in cycles per second,

$\mu$  = permeability of the wire, assumed constant,

$R$  = direct-current resistance, in ohms, of 1000 feet of the wire; see tables in the article on *Wires and Cables, Bare*.

$L$  = direct-current inductance, in millihenries per 1000 feet, of a non-magnetic wire of the same cross section as that of the given wire, and at the given spacing between wires, taken from the tables in the article on *Inductance and Inductive Reactance*.

Calculate the quantity

$$x = 0.02768 \sqrt{\frac{\mu f}{R}}, \quad (1)$$

and take from the following table the corresponding values of  $K_1$  and  $K_2$ . Then the alternating-current resistance at the frequency  $f$  is

$$R' = K_1 R \quad \text{ohms per 1000 ft.} \quad (2)$$

and the alternating-current inductance of the given wire at the frequency  $f$  is

$$L' = L + 0.01524 (\mu K_2 - 1) \quad \text{millihenries per 1000 ft.} \quad (3)$$

For  $x$  greater than 7 the following relations hold to within less than 1 per cent, the error being less the greater the value of  $x$ :

$$R' = \left( \frac{x}{2.828} + 0.25 \right) R, \quad (4)$$

$$L' = L + 0.01524 \left( \frac{2.828 \mu}{x} - 1 \right). \quad (5)$$

**Example.**—Take the case of a 1,000,000-circular-mil copper cable (assumed equivalent to a solid wire of the same cross section; see footnote on preceding page), frequency 60 cycles, and return wire 10 ft. away. Then at 25° C.,  $R = 0.0108$  ohm per 1000 ft. of wire,  $L = 0.3494$  millihenry per 1000 ft., for direct current. The value of  $x$  is

$$x = 0.02768 \sqrt{\frac{1 \times 60}{0.0108}} = 2.06.$$

From the table below  $K_1 = 1.088$  and  $K_2 = 0.957$ , and the alternating-current resistance at 25° C. is therefore  $R' = 1.088 \times 0.0108 = 0.0118$  ohm per 1000 ft., and the alternating-current inductance is  $L' = 0.3494 + 0.01524 (1 \times 0.957 - 1) = 0.3487$  millihenry per 1000 ft.

**EFFECT IN THIN STRIPS AND TUBES.** — The following are exact for a flat strip of infinite width and at an infinite distance from another conductor carrying a current; they also apply with a close degree of approximation to a tube which has a circumference 10 or more times its thickness. If no other conductor carrying a current is closer than a distance equal to the thickness of the strip or tube.

$x$  = thickness of strip, or twice the thickness of the wall of a tube, in centimeters,

- $w$  = width of strip or half the mean circumference of tube, in centimeters,  
 $l$  = length of strip or tube in centimeters,  
 $\rho$  = specific resistance of conductor, in microhms per centimeter cube, at the given temperature,  
 $\mu$  = magnetic permeability of conductor in absolute units,  
 $f$  = frequency in cycles per second,

$$x = 0.1987 l \sqrt{\frac{\mu f}{\rho}}$$

Then d-c. resistance is

$$R = \frac{10^{-9} \rho l}{wt} \text{ ohms.}$$

The d-c. internal \* inductance is

$$L_i = 1.047 \times 10^{-9} l \frac{\mu l}{w} \text{ millihenries.}$$

The ratio of the a-c. to the d-c. resistance is

$$\frac{R'}{R} = \frac{x}{2} \left( \frac{\sinh x + \sin(57.3 x)^\circ}{\cosh x - \cos(57.3 x)^\circ} \right)$$

and the ratio of the a-c. to the d-c. internal inductance is

$$\frac{L_i'}{L_i} = \frac{3}{x} \left( \frac{\sinh x - \sin(57.3 x)^\circ}{\cosh x - \cos(57.3 x)^\circ} \right)$$

For  $x$  less than unity these ratios are unity to within 0.6% and 0.2% respectively, i.e., the a-c. resistance is practically equal to the d-c. resistance and the a-c. internal inductance is practically equal to the d-c. internal inductance. For  $x$  greater than 6 the following formulas are accurate to within 0.5%:

$$\frac{R'}{R} = \frac{x}{2} \quad \text{and} \quad \frac{L_i'}{L_i} = \frac{3}{x}$$

To a very rough degree of approximation the skin effect in a conductor of any shaped cross section may be approximated by using the above formulas for a strip, taking for the effective width  $w$  one-half the perimeter of the section (in centimeters) and for its effective thickness twice the area of the section (in square centimeters) divided by its perimeter. In general, then, for the same area the skin effect will be less the greater the perimeter of the section. If the section approaches more nearly that of a solid circle than that of an elongated rectangle, the formulas for a solid round wire will give more accurate results.

#### Skin Effect in Bus-bars (Strips of Finite Width).—

The formulas given above are for strips of infinite width; the skin effect in narrow strips, such as used for bus-bars, is much greater than the theoretical value for infinite strips, due to the crowding of the current to the edge of the strip. This latter effect has been called the "edge effect." Experimental results obtained by Kennelly, Laws

Fig. 1

e (Proc. A.I.E.E., Sept., 1915), for strip conductors, outgoing and inductor 60 cm. apart, are given in Fig. 1. For other spacings the paper should be consulted.

*Journal of the Franklin Institute* for March, 1918, are reported tests on bus-bars 4 inches by  $\frac{1}{4}$ -inch, showing a ratio of a-c. to d-c. resistance of 1.6 at 60 cycles and 1.1 at 24 cycles. It is stated that this increase in resistance is due chiefly to the crowding of the current toward the edge of the bars and not to the sides. Three such bars in parallel with an air space of 1 inch between them gave a ratio of a-c. to d-c. resistance of 2.2 at 60 cycles.

**EFFECT IN WIRES, STRIPS AND TUBES AT HIGH FREQUENCIES.**—Kennelly and Afel, from a series of tests at frequencies up to 100,000 cycles per second, reported in the *Proceedings of the Institute of Radio Engineers* (May, 1916), draw the following conclusions:

The skin-effect resistance ratio of round copper wires has been found to conform to the standard Heaviside-Kelvin Bessel-function formulas, within the limits of experimental error.

The skin-effect resistance ratio of a copper conductor formed of seven parallel round bare strands (six surrounding a central seventh), was found to be the same as that of the equisectional solid round wire up to 100,000 cycles per second, within the limits of observational error. It is therefore concluded that the subdivision of a round wire into a round cable of uninsulated strands does not alter the skin effect.

The skin-effect resistance ratio of simple spiraling of strands in the same direction increased with the frequency and the resistance ratio.

The skin-effect resistance ratio of a subdivided wire, with parallel insulated strands, was found to be greater than that of the equisectional solid wire, and diminished rapidly with the increase in the degree of strand separation.

The skin-effect resistance ratio of braiding of strands, so as to effect their transposition in the cross-section at frequent intervals, was found to diminish the skin effect.

The skin effect in copper strips was found to be usually, but not invariably, greater than that of equisectional round wires.

Increasing the width of a copper strip within the limits reported was found to increase the skin-effect resistance ratio; owing to what may be called "edge effect."

The skin-effect resistance ratio of parallel going and returning flat strips, separated by a thin insulating material, was found to have a skin effect depending only on the strip thickness, without perceptible edge effect.

Changing a flat strip into the form of a slit tube destroyed the edge effect, and reduced the resistance ratio to a minimum dependent only on the strip thickness.

Cutting longitudinal slits with a sharp knife in a thin flat copper strip, was found not appreciably to affect its skin effect resistance ratio.

In order to employ a stranded wire of minimum skin effect at radio-frequencies, it seems desirable to employ thick insulation on the strands, such as gutta-percha, to transpose the strands by braiding, and to avoid spirality in the same direction.

In order to employ a flat strip conductor most effectively, it is necessary to reduce the skin effect by rolling it out laterally when the increasing edge effect more than offsets the increase in skin effect.

The hollow tubular form seems to be the most efficient type of radio-frequency metallic conductor, since, with proper mechanical internal support, the skin effect can be indefinitely diminished by diminishing the wall thickness, and the edge effect is absent.

**SKIN EFFECT IN IRON AND STEEL COILS** (also *Trolley Systems, Overhead*). Kennelly, Achard and others. The results of tests reported in the *Journal of the Franklin Institute* lead to the following conclusions:

1. The maximum observed skin-effect resistance ratio at 25 cycles per second, varied between 5.35 and 10.1, and at 60 cycles per second between 10.92 and 13.4.
2. The maximum observed skin-effect resistance ratio varied substantially as the square root of the impressed frequency, at 15 and 60 cycles per second.
3. The effective skin depth of alternating-current per second, among all the twelve rails tested, varied between 1.8 mm.
4. The values of the mean superficial r.m.s. magnetic field and the maximum skin effect developed, were between the 10 and 15 gilberts per centimeter. These were but little influenced by the permeability  $\mu$ . They were in good agreement with the values of  $H$  for maximum direct-current permeability.
5. The best workshop method of measuring the skin effect in this case, found to be based on the use of a particular form of coil.
6. The effective alternating-current conductance of a rail, for a given frequency, varied inversely as the square root of the frequency, and was directly proportional to the perimeter, and to the square root of the permeability  $\mu$ .
7. It is therefore, in general, useless to increase the conductivity of a rail if the permeability  $\mu$  is thereby increased in the same proportion.
8. From the results here reported, it would seem that the skin-effect resistance ratio of a rail, to a given alternating-current frequency, can be approximately predetermined from measurements of the perimeter and permeability  $\mu$  of the steel, by applying an experimental factor to cover edge effect and other discrepancies. This factor, called the "edge-effect coefficient," appeared to be not far from unity at the maximum skin-effect ratio.
9. The best form of rail for current-carrying capacity for a given effective perimeter is a maximum while allowing sufficient weight. Among the worst forms are probably a thick solid prism and a hollow cylinder may be greatly improved by slitting it to its interior surface.

**Skin Effect in Copper-clad Steel Wires.** — The results of tests from tests made in the Electrical Engineering Research Laboratory, Massachusetts Institute of Technology, on samples furnished by the Metals Co. For a comprehensive treatment of effective permeability of bimetallic and also of iron wires, see Miller, *Bureau of Standards*, 12, p. 207, 1915.

† Calling  $L$  the inductance of a solid round, non-magnetic wire of the same cross section and on the given spacing, taken from the tables in the article on *Inductance and Inductive Reactance*, the alternating-current inductance of the copper-clad wire on this spacing, is

$$L' = L + \Delta L \quad \text{millihenries per 1000 ft.}$$

**BIBLIOGRAPHY.** — See references in text. Complete bibliography will be found in the papers by Kennelly, et alia.

**SMOKE PREVENTION.** — The direct cause of smoke from boiler furnaces is that the gases distilled from the coal are not completely burned in the furnace before coming in contact with the surface of the boiler, which chills them below the temperature of ignition.

Smoke may be prevented from forming if each particle of gas, as it is made by distillation from coal, is immediately mixed thoroughly with hot air. Even if smoke is formed by the absence of conditions for preventing it, it may afterwards be burned if it is thoroughly mixed with air at a sufficiently-high temperature. It is easy to burn smoke when it is made in small quantities, but when made in great volumes it is difficult to get the hot air mixed with it unless special apparatus is used. In boiler firing the formation of smoke must be prevented, as the conditions do not usually permit of its being burned.

**Essential Conditions.** — The essential conditions for preventing smoke in boiler fires may be enumerated as follows:

1. The gases must be distilled from the coal at a uniform rate.
2. The gases, when distilled, must be brought into intimate mixture with sufficient hot air to burn them completely.
3. The mixing should be done in a fire-brick chamber.
4. The gases should not be allowed to touch the comparatively-cold surfaces of the boiler until they are completely burned. This means that the gases shall have sufficient space and time in which to burn before they are allowed to come in contact with the boiler surface.

Every one of these four conditions is violated in the ordinary method of burning coal under a steam boiler. (1) The coal is fired intermittently and often in large quantities at a time, and the distillation proceeds at so rapid a rate that enough air cannot be introduced into the furnace to burn the gas. (2) The piling of fresh coal on the grate in itself chokes the air supply. (3) The roof of the furnace, or tubes of the boiler, is a cold shell instead of a fire-brick arch, as it should be, and the furnace is not of a sufficient size to allow the gases time and space in which to be thoroughly mixed with the air supply.

**Methods of Prevention.** — In order to obtain the conditions for preventing smoke it is necessary: (1) That the coal be delivered into the furnace in small quantities at a time. (2) That the draft be sufficient to carry enough air into the furnace to burn the gases as fast as they are distilled. (3) That the air itself be thoroughly heated either by passing through a bed of white-hot coke or by passing through channels in hot brickwork, or by contact with hot fire-brick surfaces. (4) That the gas and the air be brought into the most complete and intimate mixture, so that each particle of carbon in the gas meets before it escapes from the furnace its necessary supply of air. (5) That the flame produced by the burning shall be completely extinguished by the burning of every particle of the carbon into invisible carbon dioxide.

If a white flame touches the surface of a boiler, it is apt to deposit soot and to produce smoke. A white flame itself is the visible evidence of incomplete combustion.

**Anthracite Coal.** — The first remedy for smoke is to obtain anthracite coal. If this is not commercially practicable, then obtain, if possible, coal with the smallest amount of volatile matter. Coal of from 15 to 25 per cent of volatile matter makes much less smoke than coals containing higher percentages. Provide a proper furnace for burning coal. Any furnace is a proper furnace which secures the conditions named in the preceding paragraphs. Next, compel the firemen to follow instructions concerning the method of firing.

**Bituminous Coal.** — It is impossible with coal containing over 30 per cent of volatile matter and with a water-tube boiler, with tubes set close to the grate

gas passages, as in an anthracite setting, to prevent smoke even by skillful firing. This style of setting for a water-tube boiler should be condemned. A Dutch oven setting, or a longitudinal setting with thick walls, is highly recommended as a smoke-preventing furnace. In such a furnace it is necessary to use considerable skill in firing.

**Jets and Mechanical Stokers.** — Mechanical mixing of the gases by steam jets is sometimes successful in preventing smoke, but it is a general preventive, especially when the coal is very high in volatile matter. When the firing is done unskillfully, or when the boiler is being driven beyond normal capacity. It is essential to have sufficient draft to burn properly and this draft may be obtained either from a chimney or a fan. There is no especial merit in forced draft, except that it enables a greater quantity of coal to be burned and the boiler to be driven harder in case of emergency, and usually the harder the boiler is driven, the more difficult it is to prevent smoke.

For draft furnaces and mechanical stokers (q.v.) of many different kinds are fully used for smoke prevention, and when properly designed and properly handled skillfully, and usually at a rate not beyond that for which they are designed, prevent all smoke. If these appliances are found to be defective, it is always due either to overdriving or to unskillful handling. It is necessary, however, that the design of these stokers be suited to the quality of the coal and the quantity to be burned, and great care should be taken to provide a sufficient size of furnace with a fire-brick roof and means of introduction of air to make them completely successful.

**SPARK GAP FOR MEASURING HIGH VOLTAGES.** — One of the simplest methods of obtaining a measure of the value (maximum value in case of an alternating voltage) of a high voltage is to determine the length of an air gap between two electrodes across which the given voltage will just cause a spark to pass. The voltage (maximum value) required to break down a gap depends upon: 1. the shape and size of the electrodes; 2. the presence of other conductors in the vicinity of the gap; 3. the time of application of the voltage; and 4. upon the temperature and pressure of the air. The dependence of the break-down voltage upon the shape and size of the electrode is due not only to the effect of these factors upon the potential gradient in the gap but also to the fact that the maximum potential gradient at which it breaks down is dependent upon the distribution of the electrostatic field in the gap (see article on Corona) and is greater for very short gaps (0.5 cm. or less) than for long gaps.

For the same maximum value of the voltage it has been found that the sparking distance is independent of the wave shape and frequency, and is the same for direct as for alternating voltages.

**Time of Application of Voltage.** — Air (and other gases) will stand for a short period of time (i.e., a few seconds) a much larger potential than it will stand for an indefinitely long period of time; this phenomenon is known as dilatation. After a voltage has been applied to a gap for about one microsecond, the apparent dielectric strength becomes sensibly constant. When measurements must be made with great rapidity, dilatation may be prevented by illuminating the gap by an arc-lamp. This procedure reduces the value of the sparking voltage, but only to a slight extent. (The theory of the action is that the ultra-violet light from the arc-lamp ionizes the air in the gap, thereby enabling the spark to pass at once.)

**NEEDLE SPARK GAP.** — Steinmetz in 1898 (*Trans. A.I.E.E.*, Vol. 15, p. 281) made a careful determination of the voltages required to produce a spark between spherical, cylindrical and pointed (needles) electrodes. Steinmetz concluded that the sparking voltage between needle points (a sine wave of potential being used) was especially constant for any given set of conditions and that after the curve connecting spark potential and distance between needle points had been carefully ascertained, the needle spark gap offered a very valuable means for measuring high voltages. Although the needle spark gap is less trustworthy than the sphere gap, the Standardization Rules of the A.I.E.E. state that the needle gap may be used for voltages between 10 and 50 kilovolts. At higher voltages it has been found difficult to duplicate conditions nearly enough for different observers to obtain results which are in agreement.

**Needle Spark-gap and Spark-over Voltages.** — The needle spark-gap shall be between new sewing needles, supported axially at the ends of their conductors, which are at least twice the length of the gap. There must be a clear space around the gap for a radius at least twice the gap length.

The sparking distances in air between No. 00 double long sewing-needle points for various root-mean-square sinusoidal voltages shall be assumed to be as shown in Table I.

**SPHERE SPARK-GAP.** — In 1913, Farnsworth and Fortescue (*Proc. A.I.E.E.*, Feb., 1913) showed that a spark-gap between two spheres is a much more reliable measure of high voltage than the gap between needle points. The sphere spark-gap is now (1922) generally recognized as standard.

Besides giving more consistent results the sphere spark-gap occupies much less space for high voltages than the needle-gap. In addition to this advantage the sphere spark-gap breaks down with a sharply-defined spark discharge

TABLE I.—NEEDLE-GAP SPARK-OVER VOLTAGES

(At 25° C. and 760 mm. barometer)

R. M. S. Kilovolts	Millimeters	R. M. S. Kilovolts	Millimeters
10	11.9	35	51
15	18.4	40	62
20	25.4	45	75
25	33	50	90
30	41		

The values in this table refer to a relative humidity of 80 per cent. Variations from this humidity may involve appreciable variations in the sparking distance.

Without previous formation of corona, provided the distance of separation is less than the diameter of either sphere. For greater distances of separation the corona forms first and the sparking voltage for a given length of gap becomes more or less variable. Another advantage of the sphere spark-gap is that the terminals do not have to be renewed after each discharge, as is the case with the needle-gap.

**Construction of Sphere Spark-gap.**— Fig. 1 shows the arrangement recommended by Farnsworth and Fortescue. The top sphere is stationary

and is slightly adjustable in height as just to make contact with the lower sphere when it is set for zero separation. The lower sphere is mounted on a piece of brass bushing which carries a threaded bushing on its lower end. This bushing works on a carefully-reamed rod having a pitch of 40 per centimeter. The bushing has a ring graduated to fiftieths of its circumference, separation may be measured to the nearest  $\frac{1}{100}$  cm. correctly, thus providing a micrometer adjustment. This arrangement is mechanically strong and the spheres are kept in constant alignment. The frame work may be conveniently mounted on wheels, to render it easily moved.

Fig. 1. Sphere Spark Gap.

**A.I.E.E. Sphere Spark-gap and Spark-over Voltages.**— The standard sphere spark gap shall be between two suitably mounted spheres. No extraneous body, or external part of the circuit, shall be nearer the spheres than twice their diameter. The shanks shall be not greater in diameter than  $\frac{1}{8}$  the sphere diameter. Metal collars, etc., through which the shanks extend, shall be as small as practicable and shall not, during any measurement, come closer to the sphere than the maximum gap length used in the measurement. The sphere diameter should not vary more than 0.1 per cent, and the curvature, measured by a spherometer, should not vary more than 1 per cent from that

a true sphere of the required diameter. When used as specified, the error obtainable should be approximately 2 per cent.

The sparking distance between spheres for various r.m.s. sinusoidal voltages will be assumed to be as shown in Table II, when the air density is that corresponding to a barometric pressure of 760 mm. mercury and a temperature

25° C. For any other air density the voltage at which the gap breaks down, at any given spacing, is equal to the break-down voltage for this spacing at standard pressure and temperature multiplied by the correction factor given in Table III. The relative air density is found from the formula:

$$\text{Relative air density} = \frac{0.392b}{273+t}$$

where  $b$  = barometric pressure in mm. and  $t$  = temperature in degrees C.

It is important that the surface of the spheres be kept perfectly clean, i.e., free from dust and moisture (*Marvin, R. H., Elec. W., 67, p. 640, 1916*).

The sphere-gap is more sensitive than the needle-gap to momentary rises of voltage and the voltage required to spark over the gap should be obtained by slowly closing the gap under constant voltage, or by slowly raising the voltage with a fixed setting of the gap. Open arcs should not be permitted in proximity to the gap during its operation, as they may affect its calibration.

TABLE III.—AIR DENSITY CORRECTION FACTORS FOR SPHERE-GAPS

**CORONA VOLTMETER.** — The corona voltmeter, described in detail in Vol. 39 of the *Trans. A.I.E.E.*, may often be used to advantage for measuring high voltages, in preference to a sphere-gap. See the article on *Corona*.

**BIBLIOGRAPHY.** — In addition to the references in the text see the following: Peek, F. W., *Sphere Gap for Measuring High Voltages*, *Proc. A.I.E.E.*, 33, p. 889, 1914; Clark and Ryan, *Sphere-gap Discharge Voltages at High Frequencies*, *Proc. A.I.E.E.*, 33, p. 937, 1914; Work, W. R., *Measurement of High Voltages*, *Proc. A.I.E.E.*, 35, p. 203, 1916.

**SPECIFICATIONS AND CONTRACTS.** — (See also *Standardization Rules and Standard Specifications*; also under name of apparatus.) Webster defines a specification as a written statement containing a minute description and enumeration of particulars, and a contract as a formal writing which contains the agreement of parties, with the terms and conditions, and which serves as a proof of the obligation. A "preliminary" specification is a descriptive enumeration of a purchaser's requirements when calling for bids. A "contract" specification is a description or enumeration of labor and material to be supplied under a contract of which the specification is an integral part. A "manufacturer's" specification is a description or enumeration of secondary details peculiar to the work of the individual manufacturer. This also is often made an integral part of a contract.

**POLICY TO BE FOLLOWED.** — When writing a specification the engineer should bear the following points in mind:

1. A preliminary specification is a commercial instrument designed to describe labor, material or results desired by a purchaser, with the object of enabling competitive bidders to estimate with equal facility upon the amount of a contract.
2. As a rule, contractors are as honest as the struggle for commercial existence permits them to be, and every unnecessary or unfair clause in a specification has its part in limiting competition and lowering the standard of honesty among contractors. A similar remark applies to requirements of which the purchaser cannot ascertain or enforce the fulfillment.
3. The standards of the national engineering societies should be followed unless local conditions prohibit them, and manufacturer's standards should be followed if low bids are to be expected.
4. No specification should contain a blanket clause covering the furnishing of unnamed contingencies unless all bidders are to have an equal opportunity to ascertain what such contingencies are likely to be. If such a clause is made very broad, it is unlikely that the courts would hold it valid.
5. Before drawing the specifications, determine to what extent the contractor is to be made responsible for the final results.
6. Avoid specifying proprietary articles or material as far as possible in order not to restrict competition.
7. Quality is an important factor in cost, hence unless the very best materials and workmanship are required, in spite of the higher cost, it is necessary to adopt some fair commercial standard.
8. There are many minor items in specifications which cannot be minutely described without making the specifications unduly long. In such cases it is good practice to specify that these items shall be made "to the reasonable satisfaction of the inspector," the word "reasonable" saving the contractor from arbitrary and unjustifiable actions of the inspector by enabling him to refer the reasonableness of such actions to the arbitrament of the courts.

**FORM OF SPECIFICATIONS.** — All specifications should be written in clear, concise language, free from ambiguity, and should be in convenient form for reference purposes.

It is desirable to number the paragraphs or clauses of all specifications to facilitate reference, and every item of the work should be allotted a separate clause.

There are two general classes of specifications. In one class results only are specified and all requirements should be rigorously exact. In the other class details of construction are specified and requirements can be stated in approximate terms only. Wherever practicable the former class of specification should be used. A combination of the two classes is also commonly adopted, but a

agreement as to results does not bind the contractor if the methods of these results are also specified. (See *J. C. West, Eng. News*;  
1. In either case considerable study should be given to securing a form between brevity and elaboration of details. The degree of detail concerned very largely by the magnitude and importance of the work. A plan is suggested as a suitable plan to follow in drawing up specifications. It is the result of a study of this subject by a special committee of the American Society for Testing Materials.  
The form adopted should be closely adhered to in writing all the specifications for a given job.

A specification shall be divided into eight "Parts."  
The titles of these Parts shall be in large upper-case type centered over the heading preceded by a Roman numeral.  
The titles of these Parts shall be as follows unless conditions necessitate a change. In case a Part is omitted, the Roman numerals shall be continuous in unbroken sequence.

1. Manufacture.  
2. Chemical Properties and Tests.  
3. Physical Properties and Tests: Mechanical, Electrical, Magnetic, Thermal, etc.  
4. Standard Sizes, Dimensions, Weights, Gauges, etc.  
5. Workmanship and Finish.  
6. Packing, Marking and Shipping.

7. Inspection and Rejection.  
8. Definition of Terms. (If a specification contains numerous terms that admit of ambiguity, they shall be defined under this sub-title.)

A "Part" of a specification shall be divided into "Clauses" or "Sections" shall be numbered continuously throughout the specification in Arabic numerals. Every Section or Clause of printed specifications shall have a heading in bold-face type, briefly indicative of its content. If printed on one side of the paper, the clause titles shall be in the left margin; if printed on both sides, as in a book, the clause titles shall be in the outer margins.

A Section or Clause may be subdivided into paragraphs distinguished by italics in parenthesis.

Immediately after the title of the specification insert sections of an introductory or general character. No sub-title shall precede this section which shall precede Part I.

Nominal values, rather than permissible limits, shall be given, followed by the permissible variations with respect to permissible variations.

Whenever as practicable, specified values shall be expressed in tabular form. The style sheets of the A.I.E.E., A.S.T.M., etc., should be followed in all matters pertaining to typography, standard terms, abbreviations, spelling, etc.

"shall" and "will" are used in the following sense by the American Society for Testing Materials. Use "shall" wherever the specifications are made binding on parties of the first or second part. Use "will" wherever the specifications are intended to express a declaration of purpose binding upon the parties of the first or second part. Many engineers use "shall" to express a command binding on the Contractor and "will" to express a declaration of purpose binding the Purchaser.

Specifications for machinery, apparatus or construction work may be written in different forms using different Part headings. In the case of apparatus and machinery the following sequence of Parts has been found very practical by the American Society for Testing Materials in this article.

The object of the specification and general conditions stated, the following parts follow:

- I. Summarized Description of principal Character Service.
- II. Style and Description of Apparatus; Details.
- III. Dimensions, Weights, Drawings and Schedules.
- IV. Work to be done by other Contractors.
- V. Performance and Tests.
  - (a) Performance which may be checked before erection.
  - (b) Factory Tests.
  - (c) Performance and Tests after Erection.
- VI. Workmanship and Finish.
- VII. Packing, Marking, Shipping and Delivery.
- VIII. Inspection and Rejection.
- IX. Guarantees.
- X. Conditional Payments. (The details of conditions upon results of inspection and tests.
- XI. Definition of Terms. (If a specification contains terms which admit of ambiguity, they shall be defined.)

It will be observed that the sequence of topics in this specification naturally follows the order of the life history of the machine, extended upon this principle to cover any kind of work.

**POINTS TO BE COVERED IN SPECIFICATION** should often cover the following points.

Items 1 to 3 refer to preliminary specifications often frequently included in the contract proper.

1. These specifications are intended to furnish such information as will enable them to prepare detail plans upon which any Bidder consider the requirements of these specifications, free exercise of his skill, any suggestions made by him.
2. Before a contract is awarded, final specifications shall be prepared by the Company.
3. In comparing proposals due consideration will be given to availability, reliability, simplicity, cost of maintenance and delivery.
4. The Engineer agrees to consider all drawings confidential, and that he will not show any such drawings to anyone, whether they are tendering under this specification or not.
5. Definition of words describing the parties to the contract, "Purchaser," "Company," "Engineer."
6. Person or persons concerned and their respective duties.
7. Where work is to be done or material delivered.
8. The point where the work of two contracts meet, as designated in both contracts, not merely in a general way, but in the minutest detail.
9. The Contractor shall be responsible for the cost of the work even after they are approved by the Engineer.
10. Materials ordered or work commenced prior to the approval of drawings will be at the Contractor's risk.
11. No approved drawing may be changed without the approval of the Engineer.
12. The Contractor shall inspect the work of other contractors which affects his and shall notify the Engineer of anything

The Contractor shall give these other contractors the privilege of doing his work in so far as it affects the acceptance of their work. Contractor shall not drill or in any way impair the strength of buildings or structures except with the written consent of the Engineer. All work shall conform to the requirements of the "National Board of Fire Underwriters," and to all Government regulations. Contractor shall obtain all necessary permits from the City or County. All like parts shall be interchangeable as far as practicable. Contractor shall install and maintain in his offices and at the site of work such telephones as may be required by the Engineer, and shall place them at the disposal of the Engineer or his representative for any purpose relating to the execution of the contract. Contractor shall follow the Standardization Rules of the A.I.E.E. and other similar documents wherever possible. All provisions of the preliminary specification and those subsequently agreed upon between Company and Bidder should be incorporated as part of the contract specification.

**POINTS TO BE COVERED IN CONTRACT.** — In addition to items listed above, the Engineer should make sure that the following points are included in the contract. The actual preparation of the contract, at least where a large amount of money involved is large, should be left to a competent lawyer.

Description and value of bond and indemnity to be delivered by Contractor to Company.

Statement of fire insurance to be secured by Contractor for Company.

Protection of Company by Contractor against losses resulting from letters

of work to be performed in such a way as not to interfere with safety and efficiency of service.

Responsibility for damage to work from fire, floods, storm, earthquake, or other cause whatsoever.

Interruption of work by other contractors shall not be delayed.

Settlement of liquidated damages to be paid in the event of work not being completed on the date agreed.

The Contractor shall not transfer the contract without permission.

Time of commencement of work, rate of progress and date of completion.

The character of the methods and appliances to be used and grade of work to be employed.

Method of payment, time of settlement and basis thereof.

Arbitration and settlement of disputes.

Drawings and claims therefor.

The subject of Engineering contracts is more fully covered in the books by Johnson and J. I. Tucker, cited in the Bibliography.)

**BIBLIOGRAPHY.** — American Electric Railway Engineering Association, *Rules Governing the Style of Specifications*, Engineering Manual, 1919; American Society for Testing Materials, *Rules Governing the Form but not the Content of Specifications*, Report of Committee E-5, 1912; Butler, H. **STANDARDIZATION RULES AND STANDARDS.** — (*The A. I. E. E. Standards are given in book.*) Numerous national and international societies have issued rules and standard specifications dealing with testing of machinery, apparatus and materials. Brief outlines of the standards of these engineering bodies, with direction for their use, are given in this article. Additional information can be obtained from the American Engineering Standards Committee. Brief summaries of the publications of the American Engineering Standards Bureau, the Bureau of Standards, and the International Electrotechnical Commission are included.

**AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS.** — (*Secretary, F. L. Hutchinson, 29 West 39th St., New York City.*) This is a pamphlet (172 pages) entitled "Standards of the American Institute of Electrical Engineers" (price \$2.00). These standards define the conditions which characterize the rating and behavior of electrical apparatus in special reference to the conditions of acceptance tests. The standards are generally accepted by the manufacturers and users of electrical apparatus in the United States. Standards for dimensions and construction are not given.

The standards of the A.I.E.E. comprise sixteen chapters:

1. **General Principles.** — Heating, Mechanical and Electrical Stresses, Wave Shape, Dielectric Strength and Insulation Rating.
2. **General Rules.** — Operation, Rating, Tests, Construction.
3. **General Definitions.**
4. **Standards for Rotating Machinery (General).** — Definitions, Operation, Rating, Tests.
5. **Standards for Electric Railways and for Auxiliary Machinery.** — Definitions, Operation, Rating, Tests, Construction, Railway Motors, Selection of Railway Motor for Specified Service.
6. **Standards for Transformers and Other Static Apparatus.** — Definitions, Rating, Tests, Construction.
7. **Standards for Switching Control and Protective Devices.** — Definitions, Operation, Rating, Tests.
8. **Standards for Meters, Instruments and Instruments.** — Definitions, Operation, Rating, Tests, Characteristics.
9. **Standards for Wires and Cables.** — Definitions, Operation, Standard, Operation, Designation, Tests, Construction.
10. **Standards for Storage Batteries.**
11. **Standards for Illumination.** — General, Surfaces, Luminous Flux, Illumination, Illuminants, Lamp Accessories.
12. **Standards for Telephony and Telegraphy.** — Definitions, Operation, Tests.
13. **Standards for Radio Communication.**
14. **Standards for Prime Movers and Generator Units.**
15. **Standards for Transmission and Distribution.**
16. **Miscellaneous Devices.** — Heating Devices.

**AMERICAN ENGINEERING STANDARDS**  
(*Secretary, P. G. Agnew, 29 West 39th St., New York City.*)

serves as a national clearing house for engineering and industrial standardization. The Committee is made up at present (1922) of representatives of, and is maintained by, nine national engineering societies, five government departments, and fourteen national industrial associations. Its functions are: to unify methods of arriving at standards; to secure nationally recognized standards, through cooperation between various interested organizations, thus preventing duplication of work and promulgation of conflicting standards; and to act as a general bureau of information regarding standardization.

Standards covering eighteen different subjects have already (1922) been adopted and active work is now in progress on about sixty projects, including a number of industrial safety codes. Information on the organization and the work will be sent free upon request.

**AMERICAN ELECTRIC RAILWAY ENGINEERING ASSOCIATION.** — (Secretary, E. B. Burrill, 8 West 40th St., New York City.) This Association issues an *Engineering Manual*, which contains all standards set by the Association, all practices recommended by it, and those practices which, while they have not been formally adopted either as standards or recommended practice, have been discussed and put forward by the Association's various committees. The *Manual* is in loose-leaf form, and is revised each year by the Committee on Standards. The contents are grouped under the headings: Buildings and Structures; Power Distribution; Equipment; Power Generation; Block Signals; Way Matters. The price of the *Manual*, including all sections in a binder, is \$5.00 to non-members.

**AMERICAN RAILWAY ASSOCIATION.** — (General Secretary, J. E. Fairbanks, 75 Church St., New York City.) This is a general association representing the steam railroads of the country. There are now incorporated in it several technical associations which were formerly distinct.

**Mechanical Division (Master Car Builders; Master Mechanics).** — (Secretary, V. R. Hawthorne, 431 South Dearborn St., Chicago, Ill.) The Division, with its predecessor organizations, has numerous specifications covering parts and details of cars and locomotives, practices, etc., which are now (1922) being unified for publication in a loose-leaf manual.

**Signal Section.** — (Secretary, H. S. Balliet, 75 Church St., New York City.) The Section publishes a loose-leaf *Manual* containing specifications for primary batteries, storage batteries, bells, insulated wires and cables for various kinds of signal use, conduit, interlocking devices, lightning protection devices, relays, and various other signal apparatus and supplies; and standard designs for a large number of devices, and parts used in railway signal work.

**Telegraph and Telephone Division.** — (Secretary, W. A. Fairbanks, 75 Church St., New York City.) The present specifications of the division, which include specifications for various kinds of conduits and conduit fittings, telephone and telegraph equipment, protection against electrolysis and against lightning, transpositions of circuits are published in a *Manual* (1922).

**AMERICAN RAILWAY ENGINEERING ASSOCIATION.** — (Secretary, E. H. Frick, 471 So. Dearborn St., Chicago, Ill.) This Association, which is closely allied to the American Railway Association, issues a *Manual* containing the various committee reports which have been formally adopted by the Association. The following items are covered: Roadway; Ballast; Ties; Rail; Track; Buildings; Wooden Bridges and Trestles; Masonry; Signs, Fences and Crossings; Signals and Interlockings; Records and Accounts; Rules and Organization; Water Service; Yards and Terminals; Iron and Steel Structures; Economics of Railway Location; Wood Preservation; Electricity.

The last edition of the *Manual* (1915) is now out of print, but a new edition is in preparation (1922).

**THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.**— (*Secretary, Calvin W. Rice, 29 West 39th St., New York City.*) The Boiler Code of this Society contains standard specifications for the construction, equipment and use of steam boilers (\$1 to non-members). Official interpretations of its Code by the Boiler Code Committee are published separately. The First Test Codes (\$2 to non-members), are rules for the testing of boilers, engines, turbines, compressors, fans, power plants, locomotives, water-wheels, etc. The Standard Pipe Thread has been approved by the American Engineering Standards Committee as an "American Standard," the Society acting with the American Gas Association as joint sponsors. The work of committees of the Society on Shafting and on Pipe Flanges and Pipe Fittings is now being extended under the auspices of the American Engineering Standards Committee. All of the publications of the Society will be sent free upon request to the Society.

**AMERICAN SOCIETY FOR TESTING MATERIALS.**— (*Secretary, C. L. Worwick, 1315 Spruce St., Philadelphia, Pa.*) This Society issues a triennial volume of "A.S.T.M. Standards," and annual supplements in intervening years. The last triennial volume was issued in September, 1921. The specifications and methods of tests cover a wide range, including Steel Rails, Structural Steel, Various Steel Objects, Steel Castings, Wrought Iron, Pig Iron, Iron Castings, Locomotive Material, Magnetic Tests of Iron and Steel (see *Magnetic Testing*), Various Kinds of Copper Wire and Wire Bars (see *Wires and Cables, Bare*), Spelter, Manganese Bronze Ingots, Cement, Lime, Clay Products, Preservative Coatings, Road Materials, Timber, Brass Paints, Oils, and various other materials. The price of the 1921 Book of Standards is \$11.00 to non-members. Single standards may be purchased for 25 cents.

**BUREAU OF STANDARDS.**— The Bureau of Standards at Washington is a branch of the U. S. Department of Commerce. It is the official custodian of the fundamental standards of measurement. In addition to making tests and comparisons of measuring apparatus, the Bureau carries on numerous researches related to the establishment and maintenance of the various standards and units of measurement, the development of measuring instruments and methods of measurement, the determination of physical constants and the properties of matter. The results of these investigations are published in pamphlet form issued in two separate series: (1) *Scientific Papers* and (2) *Technological Papers*. In addition, the Bureau issues a third series, *Circulars*, giving useful technical data, standard specifications for apparatus, description of the nature of the standard tests carried out at the Bureau, etc.

A complete list of the publications of the Bureau will be furnished by the Bureau upon request and free of charge; this list is contained in *Circular No. 22* which contains an index and a brief summary of each of the *Scientific* and *Technological Papers*, and *Circulars* most of which can be furnished by the Bureau upon request and free of charge. Others may be purchased from the Superintendent of Documents, Washington, D. C.

The *Bulletin of the Bureau of Standards* is a serial publication in which all *Scientific Papers* are published collectively. Each number of the *Bulletin* contains about 150 pages, the separate numbers being issued as material accumulates, at intervals of about three months. Four numbers constitute a volume. The bound volume is now (1921) issued under the title "Scientific Papers." Sixteen volumes had been issued at the beginning of 1921. The complete *Bulletin* is furnished free to educational and scientific institutions. Individuals may obtain separate numbers in paper covers (current or back num-

## Standardization Rules and Standard Specifications 1449

5 cents per copy, complete volumes bound in cloth at \$1.50 per volume, subscribe in advance at the rate of \$1.00 per volume to receive the four numbers as issued. Orders and payments for the *Bulletin* should be to the Superintendent of Documents, Washington, D. C., and not to Bureau of Standards.

Principal publications of the Bureau dealing primarily with specifications of interest to the electrical engineer are: Electrical Units and Standards (Circular 60); Specifications for Incandescent Lamps (Circular 13); Fire Tables (Circular 31); Wire and Cable Terminology (Circular 37); "National Electrical Safety Code" (Circular 54), which is a general code dealing with safety, covering electrical supply stations, electrical line work, electrical utilization equipment, and electrical operation.

**ELECTRIC POWER CLUB.** — (*Secretary, C. H. Roth, 1410 West Adams St., Ill.*) This Club is an association of companies engaged in the manufacture of electric power apparatus. Its standardization rules, which are published in the Handbook of the Club, deal with the industrial standardization of motors, generators, transformers, and electric power control apparatus. A pamphlet referred to may be obtained from the Secretary of the Club (5 cents).

**ILLUMINATING ENGINEERING SOCIETY.** — (*General Secretary, J. L. Law, 20 West 30th St., New York City.*) The Committee on Nomenclature and Standards of this Society published a report in 1918. The definitions in this report are substantially the same as those incorporated in the *Standardization Rules of the A.I.E.E.* (1921 edition). The Society has also published *Automobile Headlighting Specifications*, and a *Code of Lighting for Mills and other Work Places*.

**INSTITUTE OF RADIO ENGINEERS.** — (*Secretary, Alfred N. Gold, College of the City of New York, New York City.*) See the reports of the Executive Committee of this Institute. The standard nomenclature adopted by the Institute is included in the *Standardization Rules of the A.I.E.E.* bearing on radio matter.

**NATIONAL ELECTRIC LIGHT ASSOCIATION.** — (*Executive Manager, Aylesworth, 20 West 30th St., New York City.*) The Apparatus Committee of this Association has published *Transformer Standards*; *Methods of Insulating Oils*; and *Rules for the Installation and use of Motors on Station Distribution Systems*. The Underground Systems Committee has published *Specifications for Lead Covered Paper Cables*. Other committees deal with *Railway Rates, Transportation, Accounting, Prime Movers, Line Construction, Lamps, Electrical Apparatus, Meters, Terminating Secondaries, Underground Construction, Electrical Measurements, Values and Street Lighting*.

The I.E.L.A. issues the *Electrical Meterman's Handbook*, prepared by the Bureau on Meters. This book is intended primarily for practical metermen. The *Meterman's Handbook* deals with the subject of metering in great detail, containing over 1000 pages. It may be had from the Secretary of the Bureau for \$5.00.

**NATIONAL FIRE PROTECTION ASSOCIATION.** — This Association publishes the *National Electric Code* which contains the rules and requirements of the National Board of Fire Underwriters for electric wiring and apparatus. The *Code* is revised every two years, the next revision being in 1922. *Electrical Fittings* is also issued by the National Board of Fire Underwriters. This is a list of fittings which have been examined and are suitable

for the use intended; this list is revised semi-annually. Forth suggestions, rules and regulations of the National special installations of various kinds which involve fire to apparatus and equipment for fire protection. Single and *List of Electrical Fittings* may be obtained free of charge from the Board of Fire Underwriters, 135 William St., New York City.

**The Underwriters' Laboratories.** — (*President, W. L. Rouse, St. Chicago, Ill.*) This organization issues detailed covering inspection and approval of electrical fittings and devices.

**The Associated Mutual Fire Insurance Companies.** (*Lacount, 31 Milk St., Boston, Mass.*) This organization issues general rules of the National Fire Protection Association covering fittings and of fire-protection devices approved by these general rules of the National Fire Protection Association.

#### SOCIETY OF AUTOMOTIVE ENGINEERS.

(*C. F. Clarkson, 29 West 39th St., New York City.*) This organization issues standards, recommended practices, and data sheets in the form of a Handbook. These include the automobile, aeronautic, marine, and are classified as follows: Miscellaneous Fittings, Materials, Bearings, Engine Fittings, Lighting, Aeronautic Standards, Electrical Installations, Springs, Electrical Tractor, and Military Motorcycle. The price of the Handbook of individual sheets, 6 cents each.

**OTHER ENGINEERING BODIES.** — The Bodies mentioned in this committee reports or otherwise, have published specifications or matter relating thereto. The Bureau of Standards is a publication on bodies interested in engineering and industry.

American Electrochemical Society, *Secretary, J. W. Moore, University, South Bethlehem, Pa.*

American Gas Association, *Secretary, Oscar H. Fogel, New York City.*

American Society of Heating and Ventilating Engineers, *Secretary, J. B. Ober, 29 West 39th St., New York City.*

American Society for Municipal Improvements, *Secretary, J. B. Ober, 803 Lincoln Ave., Valparaiso, Indiana.*

Associated Manufacturers of Electrical Supplies, *Secretary, J. B. Ober, 30 East 42nd St., New York City.*

Association of Railway Electrical Engineers, *Secretary, J. B. Ober, C. & N. W. Terminal Bldg., Chicago, Ill.*

Association of Iron and Steel Electrical Engineers, *Secretary, J. B. Ober, Empire Building, Pittsburgh, Pa.*

Bureau of Mines, *Acting Director, E. A. Holbrook, Washington, D. C.*

National Association of Electrical Contractors and Dealers, *Secretary, W. H. Morton, 110 West 40th St., New York City.*

National Screw Thread Commission, *Secretary, H. V. Morton, Standards, Washington, D. C.* This is a government body and its standards (1921) has been issued.

#### INTERNATIONAL ELECTROTECHNICAL

(*General Secretary's Office, 28 Victoria St., Westminster, London, England.*) This Commission, which was organized in London in 1906.

Committees in about 25 countries. The United States is represented by *Secretary, Dr. A. E. Kennelly, Harvard University,*

ed by the President of the American Institute of Electrical Engineers, eps in close touch with the A.I.E.E. Standards Committee. There present Special Committees on Prime Movers, Rating, Nomenclature, s, Units, and Standard Pressures.

Commission meets in full session about every two years. The last was in 1921. These meetings are for the purpose of discussing and upon the reports and recommendations of the Special Committees.

Central Office has, from time to time, published bulletins giving reports meetings of the different committees of the Commission. The list of *ional Symbols* (see *Symbols and Abbreviations*), and the *Rules for the Rat-lectrical Machinery*, published by the Commission, are printed as appen- the *Standardization Rules of the American Institute of Electrical Engineers*,

**EIGN STANDARDIZING BODIES.** — There are now national izing bodies in Austria, Belgium, Canada, Czecho-Slovakia, France. y, Holland, Hungary, Italy, Japan, Sweden and Switzerland. These tions serve as clearing houses and bureaus of information on engineer- industrial standardization in their respective countries. Information he work of these organizations can be obtained from the American ring Standards Committee, 29 West 39th St., New York City, where of all specifications and standards approved by the various national re on file.

**STARTERS, MOTOR.**—(See also *Controllers; Motors, Alternating-Current; Motors, Direct-Current; Rheostats.*) An auxiliary resistance which is used with a motor, either d-c. or a-c., during acceleration is called a starter or a starting rheostat. A compensator, or induction starter, consists of an auto-transformer and a switch, by the operation of which a reduced voltage is supplied to the terminals of an induction motor for starting.

**STARTERS FOR DIRECT-CURRENT MOTORS.**—The starters used with constant speed d-c. motors consist usually of a resistance to be inserted in the armature circuit, this resistance being gradually cut out by the movement of a contact arm over a face plate as the motor comes up to speed. Such rheostats connect the motor field in circuit at the first step and are provided with various safeguards such as low-voltage release, overload release, etc.

**Resistance Steps for D-C. Starters.**—The resistance is designed to limit the starting current to about  $1\frac{1}{2}$  times full load current with enough steps to limit the voltage between contacts. Motors of 10 horsepower or less usually are brought up to speed in about 15 seconds and larger motors in about 30 seconds. Resistors should carry full load current for two minutes starting cold with an average temperature rise not exceeding  $350^{\circ}$  C. Resistors will withstand  $500^{\circ}$  C. without deterioration.

Fig. 1 shows the connections of a typical d-c. starter with low-voltage release. If the rheostat arm is moved from the off position shown in the cut to the contact R-1, current will flow from L+ to the arm; from this to contact R-1, through the regulating resistance to R-11, thence through the armature and series field of the motor to L-. The shunt field is connected from R-1 to L-. As the rheostat arm is being moved from R-1 to R-11 there is a small drop in voltage across the shunt-field circuit due to the field current flowing through the starting resistor, but this is so small that it may be neglected and the field can be considered as having full voltage impressed upon it. The rheostat arm is provided with a spring which returns it to the off position when the handle is released during the starting of the motor. After the motor has been brought up to speed and the rheostat arm rests upon contact R-11 the low-voltage release magnet holds the arm in this position. Brush B bridges between the terminals M and N so that in the running position the current passes from L+ to terminal M, through the brush B to the terminal N, thence to the armature of the motor and through the series field to L-.

Fig. 1.

**Overload Release.**—An overload release is often furnished, especially with motors of large capacity. This device consists essentially of a solenoid which is connected in series with the motor armature and which, in case of a predeter-

and the armature of the motor. When the starting current reaches a certain value the current in the series relay is no longer sufficient to hold the contacts so that connection is automatically made by the closing of contactor No. 2 closing that contactor and shorting the series resistors. With large motors several contactors with series resistors are used.

**A Contactor with Counter E.M.F. Control** is shown in Fig. 4. In this method of starting, the operating coils of the three contactors are on the same side connected to the motor brush farthest away from the starting resistor. The other sides of the operating coils are connected to the taps on the starting resistor, the coil on contactor 1, being connected to  $R_2$  on the resistor. The voltage on this coil is equal to the line voltage less the drop in voltage through the first section of the resistor. As the speed of the motor increases the counter e.m.f., causes a decrease in armature current. This reduces the drop to the first section of the resistor. The voltage on the operating coil of contactor 1, is greater and this closes. Contactor 2 has its operating coil connected to the second resistor. The voltage on this coil is increased by the drop in the first section. The increase in current causes a considerable drop in the voltage on the starting resistor. As this current gradually decreases the speed of the motor, contactor 2 closes. Contactor 3 has its coil connected to the motor armature and closes when the counter e.m.f. of the motor is equal to the line voltage. The main contactors for closing the motor circuits are not shown in the diagram.

**Series Lockout Contactor Method.**—Another method frequently used is the series lockout method. With this method a magnetic contactor is provided with a series coil and a damping relay for controlling it. The closing of the magnetic contactor is prevented upon the saturation of the iron in one portion of the magnetic circuit. This can be understood from the diagram of a contactor shown in Fig. 5. The flux or magnetism in the iron is caused by the current flowing through the operating coil. This flux passes through the tail piece of the contactors. Part of this flux passes through the tail piece of the armature brackets to the magnetic yoke and thence to the other part of the flux passes from the armature through the tail piece of the yoke. The flux through this last circuit exerts a pull which prevents the contactor from closing. The magnetic path through the tail piece has a small cross-section so that when the current flowing through the operating coil exceeds a certain value it becomes saturated and forces the flux through the tail piece holding the contactor open. As the current through the operating coil decreases the flux in the saturated armature bracket remains constant and the flux through the tail piece decreases until it is not sufficient to hold the contactor open. The switch can be adjusted to close at a predetermined current by turning the screw adjusting the air gaps between the tail piece and the magnetic yoke.

The success of starters with acceleration control such as the series lockout method depends largely on the contactors or contactor switches. These contactors or circuit breakers which are held in the closed position by a spring force such as a solenoid or compressed air. A typical contactor is shown in the lockout contactor shown in Fig. 5, using a shunt coil and omitting the damping coil and similar features. When the shunt coil is energized the contactor is closed against the

contactors are built both for d-c. and a-c. operation and are made single pole and multiple, single throw and double throw, in various capacities. The main arcing contacts are usually protected by means of a magnetic blowout.

These contactors are ordinarily used in connection with a master switch or controller and protective relays of various kinds to insure the performance of various functions, such as the automatic cutting in and out of resistance in the secondary of an induction motor to maintain constant input to a flywheel set or any similar feature that may be desired such as overload, low voltage and field protection relays, limit and sequence switches, etc.

#### STARTERS FOR INDUCTION MOTORS

may be divided into two classes: (1) those used with motors having a squirrel-cage or short-circuited secondary, and (2) those for motors having a wound secondary. In the former case the starting is done by impressing on the primary a voltage sufficient to induce in the short-circuited secondary the current required to develop the proper starting torque, and then transferring the primary connections to full voltage. With induction motors having phase-wound secondaries the method of starting is to connect the primary circuit directly to the line, with the secondary winding short-circuited through a resistance which is cut out in one or more steps.

With squirrel-cage motors up to about  $7\frac{1}{2}$  horsepower it is usually feasible to connect the primary immediately to the full line voltage without drawing an abnormal current from the line. The limiting feature is the power disturbance and its effect on other loads, particularly lighting. With larger squirrel-cage motors this is not feasible and consequently there have been developed various means of reducing the voltage impressed on the motor. Motors with special windings and all leads brought out, can be arranged for series-parallel grouping of coils, delta-star connections for three phase, and other similar schemes but these are not used to any appreciable extent in America.

**Starting Compensators.** — Under normal conditions the most satisfactory means of obtaining the reduced voltage for starting induction motors with squirrel-cage secondaries is by the use of auto-transformers or compensators (q.v.). The auto-transformers supplied for starting induction motors are provided with taps permitting the choice of any one of several voltages. The auto-transformers are designed for starting service only and are not intended to be left permanently in circuit.

**Connections of Starting Compensator (Fig. 6).** — The connections of the starting compensator for a two-phase motor are shown diagrammatically in Fig. 6, the switching mechanism being omitted for the sake of simplicity. Two auto-transformers are used with a two-phase motor; with a three-phase motor there would be used either three Y-connected or two V-connected auto-transformers. In the starting position the voltage at the motor primary which is connected to the auto-transformer is cut down by the auto-transformers from 200 to 130 in this particular case.

Fig. 5.

is cut out in one or more

The auto-transformers are provided with taps giving 50% of line voltage for starting, though it is usually found that 200 V gives the proper conditions for average service. With the

Fig. 6. Connections of Starting Compensator

position the auto-transformers are disconnected from the circuit and the motor is connected to the full line voltage.

**Switch Mechanism.**—The auto-starter switches or compensator switches are made of various types, with contacts suitable for the current to be carried. The equivalent of a double throw switch is usually furnished, the first throw connecting the motor to low-voltage auto-transformers and the second throw connecting the motor directly to full line voltage. The second throw always disconnects enough circuits so that the motor does not pass through any part of the winding of the transformer and so that the auto-transformers are disconnected from the circuit. The switch has three positions and locks automatically in the off position but has to be held in the starting position. In starting a motor the handle is first moved very quickly to the starting position and held there until the motor gets up to speed; the handle is then moved quickly past the starting position to the running position where it becomes locked. A mechanical device is used to hold the handle to the switch from the off position to the running position, moving first to the starting position.

Automatic protection with auto-starters is usually secured by means of overload trip coils, either connected directly in the circuit or through auto-transformers. Usually the overload protection is only in the starting position. With certain types of auto-starter switches the overload protection is provided by means of two solenoids with plungers in two different phases and a mechanical linkage on each solenoid plunger gives an inverse time element for the trip. The contacts usually trip independently of the handle so that the handle can be held closed on an overload.

**Resistance Starters for Induction Motors.**—With motors having a large secondary it is customary to connect the primary to full line voltage and to short-circuit the secondary through a resistor. As the motor starts this secondary resistance is cut out in one or more steps until the secondary is short-circuited. By properly designing the secondary resistance for continuous service instead of for intermittent service, this type of starter can be used for speed regulation as well as for starting purposes (see Co-

With constant-speed induction motors up to 200 h.p. output it is sometimes possible to mount the starting resistor upon the rotor spider, and to control it by butt-contact switches operated by a rod which passes through the hollow rotor shaft. By moving this rod out or in by means of a knob at its outer end the resistance may be connected into the secondary circuit for starting or be disconnected therefrom after the motor has come up to speed. With large motors the terminals of the secondary windings are connected by means of slip rings and a drum controller to the resistor, which in this case consists of three resistors mounted separately from the motor. Each resistor has one terminal connected with one of the three phases of the motor secondary.

The other terminals of the resistors are usually connected in star but sometimes in delta, depending on the current in the motor secondary, the capacity of the resistors, etc. When in star, the neutral is usually grounded to the frame of the controller. The drum of the controller short-circuits the various sections of the resistor by steps.

**Resistance Steps for Induction Motor Starters.** — Wound secondary motors at standstill act as transformers and the resistance in the secondary circuit has to absorb practically the entire input to the motor; as the motor speeds up, the secondary voltage drops off and resistance is cut out of circuit at such a rate that the motor draws from the line about 50 per cent more than full load primary current. Grid resistors for starting service will rise about 250° F. in two minutes. Grid resistors for speed regulation are designed for the same rise on continuous service.

**Starters for "Self-starting" Synchronous Motors.** — Where self-starting synchronous motors are used they are provided with a squirrel-cage winding on the rotor in addition to the usual field poles and field coils. Owing to this squirrel-cage winding they are started up as induction motors and controlled by the same type of starting devices. Suitable auxiliary apparatus, such as field rheostats and field switches, must be provided.

**CALCULATION OF STEPS FOR RESISTANCE STARTERS.\*** — (See also *Rheostats*.) Resistance starters usually have from four steps for small motors to seven or ten for large sizes. The number of steps used is commonly somewhat larger than the computed values as a safeguard against excessive starting currents due to improper handling by inexperienced operators. Starters for motors starting under heavy loads are frequently designed with two or three extra steps by which it is permitted to switch the loaded machine on the line with a low current and to raise the current step-by-step. On the other hand, in stations where experienced operators are available, large motors and synchronous converters are often started on three or four steps.

**Calculation for Shunt-motor Starters.** — The design is usually based on a fixed maximum current on each step of the starter, as well as on a fixed minimum current for each step. The minimum current must not be taken as less than the load current required for the maximum load with which the motor is to be started.

Let

$I_m$  = the maximum current on each step of the starting rheostat,

$I_0$  = the lowest current for which the steps are to be designed,

$E$  = the fixed line voltage,

$C = I_m + I_0$ .

Let  $K - 1$  be the number of steps required in the rheostat, and let  $R_1, R_2, \dots, R_k$  be the total resistances in the circuit, including the resistance of the motor, for the successive positions of the contact arm.  $K$  is the number of working

\* By O. R. Schurig.

contacts over which the contact arm moves, the first of which the resistance of the rheostat is in the circuit and the  $K$ th of which the resistance of the rheostat is cut out; whence  $R_2 = R_1 + r$  and  $R_1 = E \div I_m$ . This equation does not take into account the resistance of the motor resistor.

It can be shown that the successive resistances form a geometric progression with the ratio  $C$ , whence

$$K = 1 + \frac{\log \left( \frac{E}{r I_m} \right)}{\log C}, \quad \text{and} \quad R_1 = \frac{E}{I_m}, \quad R_2 = \frac{R_1}{C}$$

The value of  $C$  must be so chosen that  $K$  is a whole number. For motors which are likely to start under load, the value of  $C$  should be small. For machines which are started with no load, a larger value of  $C$  is permissible, the limiting value being determined by the ratio of maximum starting current at no load. The maximum allowable starting current is limited to 1.5 times full-load current. Occasionally twice the full-load current is taken, but the lower value is preferable, particularly if both lighting and power services are connected to the same feeders.

**Design of Series Motor Starters.**—An algebraic method of determining the various steps for series-motor starters is rather complicated, since the field flux varies with the line current. A graphic method is more convenient, the fluctuations of current on each step of the starting rheostat being determined by the magnetization curve of the machine.

Let  $E$  = the fixed line voltage,  $I_m$  the maximum allowable current during starting, and  $I_0$  = the minimum allowable current during starting.

Construct the rectangle  $AI_mOB$  as in Fig. 7, in which  $OB$  = the maximum allowable current during starting, and  $(OR_1) = E \div I_m$  = the resistance of the circuit when the contact arm of the starter is on the first contact.

Lay off  $(AI_0)$  equal to the minimum current during starting on the horizontal axis. Lay off  $(OB_0)$  equal to the armature voltage  $E_0$  for the current  $I_0$ , and the armature voltage  $E_m$  for the current  $I_m$  at this same speed (see *Motors, Direct-current*).

Lay off  $(OB_0)$  equal to  $(OB) \times \frac{E_0}{E_m}$ , and draw the two straight lines  $(I_m B_0)$  and  $(I_0 B)$ . Lay off  $(Or)$  equal to the resistance of the motor between terminals, and draw  $(rs)$  parallel to  $(OB)$ , and find the point  $D$  where  $(rs)$  intersects  $(I_m B_0)$ .

Then draw the zig-zag line  $I_0 r_1 C r_2 F r_3 \dots$ . If this line does not meet the point  $D$ , then the ratio  $I_0 \div I_m$  and the corresponding ratio  $E_0 \div E_m$  must be altered until the zig-zag line meets the new point  $D$ .

Then extend the horizontal line  $(AI_0)$  until they cut the vertical axis, at  $R_2, R_3, \dots$ . The resistances (resistances between successive contacts) are then equal to  $(R_2 R_3), \dots$

For machines working on a straight line magnetization curve the resistances of the starter would be equal, as the line  $(I_0 B)$  would be parallel to  $(I_m B_0)$ .

**Graphic Method for Shunt-motor Starters.**—This method is also applied to the determination of the steps of a shunt-motor starter, in which case the point  $B_0$  coincides with  $B$ .

**COST OF MOTOR STARTERS.**—The following figures are approximate only and are intended merely to give a rough idea of the cost of the common types of starters in 1921.

D., *Industrial Controllers, with Particular Reference to the Control of Direct-Current Shunt Motors*, trans., A. I. E. E., 1917, v. 36, p. 253; Knight, C. D., *The Principles and Systems of Electric Motor Control*, trans., A. I. E. E., 1915, v. 34-2, p. 2781.

**STARTING AND LIGHTING SYSTEMS FOR A**

— (See also *Batteries, Storage; Generators, Direct-current; Ignition, Incandescent; Motors, Direct-current.*) The items comprising the starting and lighting equipment of a gasoline automobile are (1) storage battery, (2) starting motor, (3) lamps, (4) cut-outs, and fuses. In the so-called "single unit" system the starting motor and battery are combined in a single unit. The battery supplies energy for starting and lighting but also for ignition.

**GENERATOR.** — The generator employed is almost always a series-wound, and is driven directly by the engine through suitable gears. The purpose of the generator is to charge the storage battery and to supply current connected across its terminals. In order to keep the terminal voltage of the generator substantially constant, which condition is required for the proper charging of the battery, some auxiliary controlling device is employed. Otherwise the terminal voltage of the generator would vary directly with the speed of the engine.

**Battery Cut-out.** — The generator must of course be disconnected from the battery until its voltage is equal to that of the battery. This is taken care of by means of an automatic switch which closes when the generator reaches a speed corresponding to a car speed of about 10 miles per hour and opens when the speed falls below this value.

**Common Types of Voltage Control.** — Numerous devices have been proposed and tried out for keeping the generator voltage substantially constant after the battery cut-out closes, but at the present time only three types of control are in common use, viz., (1) outside regulation, (2) vibrator control, (3) reverse series-field regulation.

**Outside Regulation.** — A simple form of outside regulation is shown in Fig. 1, which embodies the principle of the Bijur regulator. A variable resistance is included in the field circuit, which resistance is short-circuited when the vibrator is in contact with the contact C. When the vibrator is pulled away from the contact C by the electromagnet the resistance is inserted in the field circuit and the field current is thereby reduced. As long as the vibrator is operating, the field current will vary between maximum and minimum values, and its average value will depend upon the rate of vibration. The terminal voltage will depend upon the voltage across the winding, and a very small increase in this voltage will cause a relative increase in the rate of vibration, and therefore make a substantial decrease in the value of the field current. Consequently, as the speed of the engine thereby tending to produce a varying voltage at the generator terminals, the tendency is counteracted by the reduction in the field current, so that the terminal voltage of the generator remains substantially constant at all times of the speed.

A modification of this type of control is used by the Westinghouse regulator. In the Westinghouse regulator, the position of the contact C is controlled by an electromagnet connected across the terminals of the generator. This electromagnet is actuated by an eccentric coupled to the armature shaft.

Fig.

releases, the contact *C* is drawn away from the vibrator, with the resistance is inserted in the field circuit for a greater length of time. form of outside regulation which is coming into favor on vehicles is that of the train lighting systems (see *Lighting of Trains*). The machine is used and regulation is accomplished by passing the armature through a solenoid which in turn controls a plunger linked to a small rheostat.

**Brush Regulation.** — In this system use is made of the distort-armature reaction (see *Generators, Direct-current*). When current the armature, the resultant flux is skewed around in the direction (see Fig. 2), with the result that the number of lines of force entering

from the leading pole and a corresponding the number of lines of place at the trailing pole. Consequently, referring to evident that the electro-generated between the and the third brush *C*, shown, will decrease as through the armature of the shunt field is between the brushes *A* and ent through the shunt therefore decrease as the e main circuit increases,

Fig. 2

arm will reduce the electromotive force between *A* and *C* still consequently, if the battery is connected across the main brushes *A* tendency for the current to the battery to increase when the generator increases is counteracted by the decrease in the field which a generator when connected to a storage battery will tend to constant current machine, irrespective of the speed. As a matter of the effect of the short-circuit current in the coil passing under the brush which current is practically proportional to the speed and which demagnetizing action, the current to the battery actually reaches a definite value at a definite speed and then falls off.

Form of regulation has come into extensive use, due to its simplicity. The current supplied to the generator is readily controlled merely by the position of the intermediate brush. For a full treatment of brush regulation, see Langsdorf's *Principles of Direct-current*

**Series-field Regulation.** — In this system of regulation a compound generator is employed, with the series field connected so as to shunt field, i.e., differentially compounded. Up to the present has found but little favor, on account of the inability to control. It gives neither a constant voltage nor a constant current characteristic current output rising rather rapidly to a maximum and then dropping off, due chiefly to the cross magnetization of the armature

**Batteries.** — The lead-acid type of storage battery is almost invariably (see *Batteries, Storage*). Batteries of from 6 to 24 volts are employed, the 6-volt (3 cell) battery is rapidly becoming the standard. To meet starting requirements, an ampere-hour capacity of from 60 to 120 depending upon the size of car. A 60-ampere-hour, 6-volt bat-

tery weighs about 45 pounds, and a 120-ampere-hour, 70 pounds.

**STARTING MOTOR.**—The conditions under which it operates are widely different from those encountered in a normal motor. An extremely high initial torque is required to overcome the resistance of the engine. There is also a constant variation in load, due to the compression and suction of the engine. As the service periods are short, the motor is designed to give its maximum output for only a very short time, and therefore relatively small compared with a motor designed to give maximum torque continuously.

The motor is compact and rugged to withstand vibration, and is of a relatively large size and fitted with large bearings, to withstand sudden engagement. Starting motors are usually designed for a 12-volt voltage, although there are a few 12- and 24-volt systems. For an average size engine an initial current of about 200 amperes is required. At cranking speed this current drops to about 80 amperes.

The torque required to start an engine is dependent upon the compression, the clearances, and the lubricant used. Changes above zero have little effect on the starting torque, but below zero there is a decided increase in the torque required. Fig. 3

Fig. 3

engine at normal temperature, the variation with speed of the torque required to spin the engine.

The torque required to start an engine, under normal conditions, is about 1 pound-foot for each 5 cubic inches of piston displacement. The starting motor is usually designed so that under normal conditions it will start the engine at about 100 r.p.m., at which speed the torque required is about 10 pound-feet, or 1 pound-foot for each 10 cubic inches of displacement. The speed at which the motor will keep the engine turning over is called the "cranking" speed, and the corresponding torque is called the "cranking torque," as distinguished from the "starting torque," which is the torque required to start the engine turning over.

of the starting motor when developing its cranking torque ranges to 3000 r.p.m., depending upon the design. The gear reduction engages from 8 to 1 to upwards of 25 to 1.

5. — There are two common types of lamps, namely, focusing and non-focusing. In the focusing type, used for head and spot lights, the filament is wound into a compact spiral, which brings the source of light as near a point as possible. The non-focusing lamps are usually constructed with a looped filament. Lamps of this type are used for tail lights, cowl lights, and side lights.

Incandescent filament lamps are now used almost exclusively. Both the vacuum and the nitrogen filled type are employed, the former consuming about 1 watt per candle-power and the latter about ¾ watt per candle-power. The average life of these lamps ranges from 100 to 300 hours under ordinary service conditions.

The following table, taken from a paper by H. Schroeder (*Trans. Soc. Aut. Eng.*), shows the variation of the characteristics of tungsten lamps with variation of the battery.

Condition	Per cent, normal volts	Per cent, normal amps.	Per cent, normal watts	Per cent, normal C. P.	Per cent, normal W. P. C.
Fully charged (1.5 volts per cell) . .	68	79	54	23	233
Fully charged (1.2 volts per cell) . .	120	111	133	190	70

**STARTING SWITCH AND FUSES.**— Switches used on starting systems are of two types, viz., (1) those completing the circuit directly and (2) those operating a solenoid to complete the circuit.

First, the so-called harpoon type is most generally used, consisting of a sliding contact or connections to laminated copper sections at either side of the switch. The movable member extends through the cover and is held extended by a spring. Depressing this plunger completes the circuit. The solenoid is operated by a plunger closing the main circuit to the motor after the coil has been excited.

Automobile fuses are now made of standard capacity for maximum currents of 10 amperes. Two sizes of fuses are used, namely,

- 1 ¼ in. length overall with ferrules ¼ in. in diameter,
- 1 ½ in. length overall with ferrules 13/32 in. in diameter.

Automobile fuses are usually of the sight type.

6. — There are two common systems of wiring in use, i.e., the single-wire and the double-wire systems. The single-wire system is the more prevalent, having the advantage of cheapness and simplicity. In this system, the terminals of the chassis are used to complete the circuit.

The double-wire system is used when leads are not located adjacent to the terminals of the chassis. It has the disadvantages of being more expensive, and the danger from open circuits is twice as great as in the single wire.

In wiring circuits and connections between battery and switch, wires of No. 14 to No. 10 B and S. Gauge are generally used. It is well to use the larger size as it costs but little more, and there is a decided saving in electrical resistance. No. 14 stranded copper wire, rubber covered and cotton wrapped

is generally used from switches to side lights, tail light 10 stranded copper wire, rubber covered and cotton wrapped for the lines where heavier currents are carried, e.g., from switch to head lights, horn, etc.

The size of starting motor cable in general use ranges from No. 10 to No. 4 S. Gauge. The length should always be kept as short as possible to avoid excessive losses in voltage. A good rule is to use the length required the voltage drop in the cable will not exceed 0.3 volt.

**SPECIFICATIONS FOR INSTALLING ELECTRICAL SYSTEM.** — The following specification for electrical installation is from the S.A.E. specification.

**Insulation Requirements.** — Electrical apparatus shall be capable after installation of withstanding 500 volts between conducting circuit and ground. Tests of the entire circuit.

*Exception.* — Batteries will not be subjected to any insulation working potential.

**Use of Conduit.** — Insulated conductors must be protected by non-metallic conduit outside of insulation, except where they pass through from the elements or where out of contact with metal surfaces.

Metallic conduit ends must be provided with ferrules or caps and having a fit sufficiently tight to exclude free entrance of dirt.

Where wires are not protected by conduit, they are to be covered with not exceeding 10 inches. Cleats may be of metal with insulation interposed between cleats and wire.

**Clearance.** — Where no conduit is used, as on work on the engine, shall be at least two inches from exhaust pipe.

**Connectors.** — All connectors shall be so made that the section which is alive will have all live parts recessed into the end of shell of connector.

Springs used in connectors shall not be relied upon to hold the parts together.

**Protection against Accidental Short-Circuits.** — All electrical fuse and junction block or on instruments, generators and other apparatus which must have live parts exposed, shall be so constructed that an accidental short-circuit cannot be effected by means of minor repairs or adjustments.

**Bulb Sockets.** — Bulb sockets must be so made that the return path is not impaired when lamp is subjected to vibration.

In lamps, hinges shall not be relied upon to carry current. Connections must be either permanent or so spring held that they will be tight under vibration.

**Protective Devices.** — The current to all lighting apparatus shall be passed through protective devices.

Protective devices shall be on battery side of switches.

**Temperature Test.** — All insulating material used in sockets, and similar devices for electrical apparatus for use on automobiles shall be capable of withstanding for 30 minutes a temperature of 150° C.

**BIBLIOGRAPHY.** — Moyer, J. A., *Gasoline Automobile and Gasoline Engine Encyclopedia*; Heldt, *Gasoline Automobile*, Vol. 3; Hobbs and Elliot, *Gasoline Automobile*.

— (See also *Boilers; Calorimeters, Steam; Pipes and Piping; Steam Turbines; etc.*) Steam at a given pressure and at a temperature which may decrease in temperature, the pressure being kept constant, will condense into water, is said to be "saturated." When the temperature is such that a decrease of temperature, the pressure being kept constant, will result without the formation of water, the steam is said to be "superheated." The number of degrees that the temperature can be lowered before condensation of water takes place is called the "degrees of superheat." Saturated steam may contain fine particles of water in the form of spray or mist, in which case the steam is said to be "wet," while if there is no such moisture present it is said to be "dry." (When the steam produced by a boiler is wet it is also said to be "primed," and the amount of moisture is called the "priming.") Superheated steam is always dry. The weight of the steam in a pound of wet steam (steam and moisture) is called the "dryness of the steam." The temperature of saturated steam at a given pressure is the same whether the steam be dry or wet, and is the same as the boiling point of water at that pressure. The temperature of saturated steam, and its boiling point, depends solely upon the pressure of the steam.

**HEAT OF STEAM.** — The amount of heat required to change one pound of water at 32° F. into steam at any pressure,  $p$ , is called the "total heat of saturated steam at this pressure." The number of B.t.u. required to raise the temperature of one pound of water from 32° to the temperature of saturated steam at the given pressure is called the "heat of the liquid." The difference between the total heat and the heat of the liquid is called the "heat of evaporation."

In the case of superheated steam, heat is also required to raise the temperature of the steam from the temperature corresponding to saturation to the temperature of the superheated steam. The total number of B.t.u. required to raise one pound of water at 32° F. into superheated steam is given in the tables below.

**ENTROPY OF STEAM.** — (See also *Thermodynamics, Principles of.*) The change in entropy with steam the change in entropy resulting from adding to one pound of water at 32° F. an amount of heat necessary to raise its temperature to the boiling point is called the "entropy of the water," the change in entropy during evaporation, i.e., the heat of evaporation divided by the absolute temperature of the boiling point, is called the "entropy of evaporation," and the sum of the entropy of the water plus the entropy of evaporation is called the "entropy of the steam." The entropy of the water is approximately the heat added to 1 lb. from 32° to the boiling point divided by the average of these two temperatures above absolute zero.

**TABLES.** — Tables giving the values of the various properties of steam over the range of temperatures and pressures met with in practice have been recomputed by Marks and Davis, using the latest experimental data as a basis for their calculations. The following tables are condensed from those given in their *Steam Tables and Diagrams* (N.Y., 1909).

**Steam.** — Using the symbols at top of the table:

Gage pressure in lb. per square in.	= $p - 14.7$
Vacuum, inches of mercury,	= $29.92 - 2.036 p$
Entropy of evaporation	= $N - n$
Pounds per cubic foot	= $\frac{1}{v}$

**FLOW OF STEAM THROUGH A NOZZLE.**—The rate of flow of steam through a nozzle increases as the difference in the pressures on the two sides of the nozzle increases, until the absolute pressure  $p_0$  of the atmosphere behind the nozzle discharges reaches 58 per cent of the initial absolute

pressure  $p$  of the steam. For greater differences in pressure, i.e., for  $\frac{p_0}{p} < 0.58$ ,

the rate of flow through a given nozzle depends only upon the initial absolute

pressure of the steam. For  $\frac{p_0}{p} < 0.58$  the percentage change in the volume of the

steam as it passes through the nozzle also remains constant, the ratio of initial to expanded volume being 1.624. The following formulas have been given by the authorities stated for the flow of steam through a nozzle when

1. The notation is  $P$  = initial absolute pressure in pounds per square

inch;  $d$  = smallest cross section of nozzle in square inches;  $W$  = flow in pounds

per hour;  $x$  = quality of steam =  $\frac{100 - y}{100}$  where  $y$  is the per cent of moisture;

$t$  = temperature in degrees F.

	Dry saturated	Moist	Superheated
.....	$W = 0.857AP$		
.....	$W = AP^{0.845}$	$\frac{AP^{0.845}}{x}$	$AP^{0.845} (1 + 0.00065 D)$

**FLOW OF STEAM THROUGH PIPES, VALVES, AND BENDS.**— (See *Tables and Piping*.)

**GRAPHY.**—Marks and Davis, *Steam Tables and Diagrams*; Keenan, *Steam Tables*; Bausch, W. D., *Applied Thermodynamics*. See also *Tables* in the articles on *Boilers, Steam*, and *Steam Engines*.

**STEAM ENGINES.** — (See also *Condensers; Power Turbines.*) A steam engine is a machine in which the converted into mechanical energy by means of the pressure of the steam on the more parts of the machine. This article treats of the reciprocating steam engines; steam turbines (q.v.) are treated in a separate article.

**CLASSIFICATION.** — The principal classifications of steam engines are the following:

**Single- and Double-acting Engines.** — If the steam acts on one side of the piston it is a single-acting engine; if on both sides it is a double-acting engine.

**Throttling and Automatic Engines.** — A throttling engine is one in which the speed of the engine is governed by a throttle valve which varies the pressure of the steam admitted to the engine cylinder. An automatic engine is one in which steam is always admitted at full pressure by a valve or valves at different points in the stroke according to the position of a point at which the cut-off takes place being automatically regulated by a governor.

Throttling as a means of governing is seldom employed in modern steam engines. It affords a simple and reliable means of speed regulation, etc. Automatic regulation of cut-off is capable of close control and permits higher ratios of expansion.

**Condensing and Noncondensing Engines.** — A condensing engine is one in which the steam is exhausted into a condenser, by means of which the pressure is reduced usually to within 1 to 3 pounds per square inch below atmospheric pressure. A non-condensing engine is one whose exhaust steam is exhausted to atmospheric pressure. Any engine can be operated condensing, but certain minor modifications are usually made in the design when it is to be operated normally condensing.

**Binary-vapor Engine.** — This is a very special type of steam engine. Sulphur dioxide, instead of water, is used as the working fluid. The surface condenser. The sulphur dioxide in condensing is itself vaporized and this vapor, under a pressure of about 100 lb. per sq. in., is used expansively in a secondary reciprocating engine. The sulphur dioxide is discharged into a surface condenser in which it is cooled by cooling water, much the same as in refrigerating practice. The sulphur dioxide is then re-liquefied and recirculated over again. This type of engine has never come into practical use.

**High- and Low-speed Engines.** — This classification is based on (fly wheel) speed only; engines having a rotative speed of 150 revolutions per minute or less are usually classified as low-speed engines; those whose speed is greater than 150 revolutions per minute are classified as high-speed engines. A high-speed engine may have a low ratio of expansion; the relation between piston speed and engine speed depends solely on the length of stroke.

**Compound and Multiple-expansion Engines.** — A compound engine is one in which the steam is partially expanded in a small cylinder and then carried to one or more larger cylinders in which it is further expanded. If the cylinders are in line with each other, using a common crank, it is called a tandem compound; if the smaller and larger, or high-pressure and low-pressure cylinders are side by side it is called a cross-compound. Compound engines are simpler, lighter, cheaper and more compact, and serving a larger amount of work. Constant speed and uniform crank effort are not essential. Vertical or horizontal. Vertical engines take up less floor space and are less costly than horizontal engines.

line in which the total expansion of the steam is divided into three stages, intermediate- and low-pressure, is a triple-expansion engine; if four stages, a quadruple-expansion engine. Multiple-expansion engines (in compound) are seldom used for driving electric generators.

**Classification According to Valve Gear.** — Engines are also classified according to their valve gear (see *Valve Gear*, below), as Corliss engines, slide-valve engines, piston-valve engines and poppet-valve engines.

**Classification According to Construction.** — For a more complete treatment of the design and construction of steam engines see Kent's *Mechanical Engineers' Handbook*. A brief discussion of valves and governors is given below.

**Slide Valves and Valve Gear.** — Three types of valves are used to control the admission and exhaust of the steam to and from the cylinder, namely the slide-valve, the piston-valve and the poppet-valve.

**Slide Valves.** — Fig. 1 shows a cylinder with a plain slide valve of the Corliss type. The valve rests in a V-shaped groove in the bottom of the steam chest, and is held up against its seat by pressure of steam from the steam chest. The valve passes through a port in the back of the steam chest, as shown by the horizontal section of the valve and steam chest, which shows the valve to be shifted to its seat with-  
 out disturbing the valve

Fig. 1. Plain Slide Valve

drawing, the valve is shown moved over to the left so as to allow steam from the steam chest to pass into the head end of the cylinder and force the piston toward the left. Steam from the crank end of the cylinder can flow through a cavity in the valve to the exhaust space *Q*. Steam enters by the

Fig. 2. Piston Valve

Fig. 3. Riding Cut-off Slide Valve

(transverse section) and escapes through the exhaust space *Q*. As the piston moves toward the end of the forward stroke, the valve is moved by the piston to the right, and it first shuts off the supply of steam from the head end of the cylinder, and then opens the exhaust from the crank end of the cylinder, and then opens the steam for the crank end and the exhaust for the head end just before the reverse stroke is begun.

Two types of slide valves are the piston valve and the riding cut-off valve. The piston valve, shown in Fig. 2, is used a piston filling an auxiliary cylinder which takes

the place of the steam chest used with the common type. The riding cut-off slide valve, Fig. 3, is essentially a double slide valve. The riding cut-off controls the point of cut-off only, the points of admission, release and compression being controlled by the main valve. (See Fig. 3 below.)

Any adjustment of the simple slide valve changes all four events of the stroke, namely admission, cut-off, release and compression. With the riding cut-off slide valve the cut-off can be varied independent of the other events.

**Corliss Valve.** — To make all four events of the stroke independently adjustable, four separately controlled valves are necessary. One of the first successful four-valve engines was invented by George Corliss in 1848. Various modifications of the original Corliss valve gear have since been made, but the same general principle of operation is embodied in practically all modern four-valve engines.

Fig. 4 shows the general external appearance of a simple Corliss valve gear and Fig. 5 is a simplified diagram showing the principle of operation.

Fig. 4. Corliss Valve Gear

"The steam valves work in the chambers *SS*, and the exhaust valves in the chambers *EE*. The double-armed levers *DD* work loosely on the hubs of the steam bonnets; they are

connected to the wrist plate *B* by the rods *KK*; the levers *MM* are keyed to the valve stems *JJ*, and are also connected by the rods *OO* to the dashpots *PP*. The double-armed levers *D* carry at their outer ends steam hooks *PP*, these being provided with hardened-steel catch plates which engage with arms *MM*, making the arm *M* and the hook *P* work in unison until steam is to be cut off. At this point another set of levers or

Fig. 5. Diagram of Corliss Valve Gear

cams *GG*, connected by the cam rods *HH* to the governor, come into play, cutting the catch plates on the hooks *P* to release the arms *MM*, the outer ends of which are then pulled downwards by the dashpot plunger, causing the steam valves to rotate on their axis and thus cut off steam. The exhaust valve arms *N* are connected to the wrist plate by the rods *LL*, and it is seen that all the valves receive their motion from the wrist plate *B*; the latter receives its motion from the hook rod *A*. This rod is attached to a rocker arm; to this arm the eccentric rod is also attached.

"In order to obtain a greater range of cut-off in Corliss engines, a separate steam and exhaust eccentric is used. With two eccentrics the admission and

valves can be adjusted independently, and steam may be cut off anywhere to the end of the stroke." (*From Types of Modern Engines and the Setting, by M. C. Myers, Boston, 1910.*)

**Poppet Valves.**— This type of valve for engine cylinders is largely in Europe, but only to a limited extent in this country. Fig. 6 illustrates the construction of poppet valve and valve gear, known as the Sulzer valve gear.

**Comparison of Different Types of Valves.**— Multi-valve engines are more expensive than single-valve types, but give better results due to the independent control of cut-off and other factors during the stroke, and to the requirements of clearance space. Rotary valves are difficult to make and keep tight when used with superheated steam than the poppet valves. The erosive action of superheat adds much to the difficulty of maintaining a good seal, but the difficulties are overcome in the best designs.

**Governors.**— Two types of governors are used, viz., the pendulum governor and the flywheel types.

**Pendulum Governor.**— The operation of the pendulum governor is too well known to need description. The operation of this governor can be made to control the quantity of steam admitted under either by opening or closing a throttle valve, or by varying the point of cut-off. In the latter case a suitable link motion (*see below*) must be used.

**Flywheel or Shaft Governor.**— This type of governor is now largely used especially for high-speed automatic engines. The most common form of flywheel governor is the single-weight or inertia type. The center of gravity of the weight is located approximately at the center of the flywheel. The governor is shown in position for cut-off; the rotation is in the direction of the arrow. As the speed increases the gravity of the weight seeks a position further from the center of the shaft and causes the flywheel to swing on its pivot in a direction opposite to the rotation of the flywheel; the eccentric is attached to the flywheel and this movement brings the center of the eccentric nearer the center of the shaft, and increases the advance, thus effecting an earlier cut-off.

Other types of shaft governors are described in detail in a small book, *Shaft Governors* (Hill Pub. Co., 1908).

**Link Motions.**— Link motions, of which the Stephenson link is the most commonly used, are designed for two purposes: first, for reversing the motion of the valve, and second, for varying the point of cut-off by varying the travel

Fig. 6. Sulzer Valve Gear

Fig. 7. Flywheel Governor

of the valve. The Stephenson link motion is a combination called forward and back eccentrics, with a link connecting the eccentric rods, so that by varying the position of the link may be put in direct connection with either eccentric. The movement is controlled in part by one and in part by the other. The link is moved by the reversing lever into a position such that the valve rod is attached is at either end of the link, the minimum travel, and when the link is in mid-gear the travel takes place early in the stroke.

#### DEFINITIONS PERTAINING TO RATING AND CLASSIFICATION OF STEAM ENGINES. — The following terms are used:

**Indicated Horse-power.** — The indicated horse-power is found by the formula

$$P = \frac{pLAN}{33,000}$$

in which  $p$  is the mean effective pressure, in pounds per square inch on an indicator (*see below*),  $L$  the length of the stroke in feet,  $A$  the area in square inches (corrected for area of the piston rod),  $N$  the number of strokes per minute, equal to the number of revolutions of the crank twice the number of revolutions of a double-acting engine.

**Brake Horse-power.** — The brake horse-power of an engine is that delivered by its shaft as determined by a dynamometer. It is equal to the indicated horse-power minus the power absorbed in the engine. In well-designed engines working under normal conditions it is usually from 8 to 12 per cent of the indicated power; the loss due to friction is nearly a constant at all loads, so that its percentage is 100 as the load decreases to zero, when the whole of the indicated power is absorbed in overcoming friction.

**Rated Horse-power.** — When an engine is commended to a certain horse-power it is understood that it will deliver that power under those conditions for which it is designed, such as speed, steam pressure, etc., and cutting off at that fraction of the stroke which gives the best economy. Its rated overload capacity is the percentage increase in power at the same speed, steam pressure and back pressure, and under other conditions which the design of the valve motion will permit.

**Indicator Diagram.** — An indicator diagram is a graph showing the steam pressure in the engine cylinder at every point of the stroke. Such a diagram may be actually obtained by means of a steam-engine indicator, which is an instrument which causes a pencil to record on paper the pressure in the cylinder at every point of the stroke. The diagram drawn by the pencil shows whether the valves are properly adjusted, and it is also used in figuring the power developed in the cylinder, and approximately the steam consumption. A diagram of a noncondensing engine in which the steam is cut off at about one-quarter of the stroke is shown in Fig. 8.

Fig. 8

The lines and points have the following significance:

**Point of Admission, C,** is the point at which the

**Admission Line, *CD*,** shows the rise of pressure due to the admission of steam into the cylinder by opening the steam valve.

**Expansion Line, *DE*,** is drawn when the steam valve is open and steam is admitted to the cylinder.

**Point of Cut-off, *E*,** is the point where the admission of steam is stopped by the closing of the valve. It is often difficult to determine the point at which the cut-off takes place. It is usually located where the expansion curve changes its curvature from convex to concave.

**Expansion Curve, *EF*,** shows the fall in pressure as the steam in the cylinder expands while doing work.

**Point of Release, *F*,** shows when the exhaust valve opens.

**Exhaust Line, *FG*,** represents the change in pressure that takes place when the exhaust valve opens.

**Compression Line, *GH*,** shows the pressure against which the piston works during its return stroke.

**Point of Exhaust Closure, *H*,** is the point where the exhaust valve is closed. It cannot be located definitely, as the change in pressure is at first gradual during the closing of the valve.

**Compression Curve, *HC*,** shows the rise in pressure due to the compression of the steam remaining in the cylinder after the exhaust valve has closed.

**Initial Pressure** is the pressure acting on the piston at the beginning of the stroke.

**Final Pressure** is the pressure above the line of perfect vacuum which would exist at the end of the stroke if the steam had not been released. It is usually found by continuing the expansion curve to the end of the stroke.

**Definitions.** — In addition to the terms defined above, the following are commonly employed:

**Inlet Pressure** is the pressure in the steam pipe at the entrance to the cylinder valve.

**Effective Pressure** is that equivalent constant pressure which would produce the same amount of work on the piston per stroke as is done by the variable pressure shown by the indicator card. This may be calculated by multiplying the area of the card by the length and multiplying by the scale of the indicator.

**Clearance.** — The portion of the cylinder volume, including the steam trapped behind the piston by the piston but which is nevertheless filled with steam when admission occurs is called the clearance volume. It ranges from 1 per cent of the piston displacement in very large engines to 10 per cent or more in low-speed engines.

**Ratio of Expansion** is the ratio of the piston displacement (in low-speed engines in case of a multiple-expansion engine) to the volume of steam admitted through the throttle valve at each stroke (or half stroke in the case of a double-acting engine), the volume being that corresponding to the pressure on the engine side of the throttle valve.

**Flow**, as applied to steam, is the reducing of its pressure, resulting from flowing through restricted pipes and passages.

**EFFICIENCY OF A STEAM ENGINE.** — By the thermal efficiency of a steam engine is meant the quotient of the B.t.u. per hour equivalent to the work done by the engine divided by the B.t.u. per hour equivalent to the heat supplied to the engine.

indicated horse-power divided by the total number of B. per hour; or, putting

$W$  = pounds of steam supplied per hour per indicated horse-power  
 $x$  = quality of the steam supplied (= lb. of dry steam per lb. of wet steam)  
 see article on *Steam*,

$L$  = heat of evaporation per pound of steam at throttle pressure,

$h$  = heat of the liquid at throttle pressure, B.t.u. per pound,

$h_0$  = heat of the liquid of feed water, B.t.u. per pound at temperature corresponding to the pressure in the exhaust pipe.

(See *A.S.M.E. code*, 1913.)

Then the thermal efficiency for saturated steam is

$$E_t = \frac{2546.5}{W(xL + h - h_0)}$$

If the steam is superheated, let

$H$  = total heat of superheated steam at throttle pressure, B.t.u. per pound.

Then the thermal efficiency is

$$E_t = \frac{2546.5}{W(H - h_0)}$$

The above formulas are also applicable to the calculation of efficiency, including friction losses, if  $W$  is taken as the pounds of steam per brake horse-power.

**Efficiency of Rankine Cycle.** — The maximum efficiency is that of an engine performing the ideal Carnot's cycle (see *Principles of Thermodynamics*), but this cycle is not very closely simulated even when the losses are neglected. Instead the "Rankine cycle" is employed as a standard of reference. This cycle assumes that the work done by the engine is equal to that of a Carnot cycle (see *Thermodynamics*) corresponding to an adiabatic expansion from the throttle pressure to exhaust pressure and an isothermal condensation of the steam and a compression of the condensed water to the throttle pressure.

**Rankine Efficiency for Dry Saturated Steam.**

$H_1$  = total heat, B.t.u. per pound, of dry saturated steam at throttle pressure,

$H_2$  = total heat, B.t.u. per pound, of dry saturated steam at exhaust pressure,

$h_2$  = heat of the liquid, B.t.u. per pound, at exhaust pressure,

$T_2$  = temperature of exhaust steam, in °F.,

$N_1$  = total entropy of 1 pound of dry saturated steam at throttle pressure,

$N_2$  = total entropy of 1 pound of dry saturated steam at exhaust pressure.

Then the efficiency is

$$E_r = \frac{H_1 - H_2 + T_2(N_2 - N_1)}{H_1 - h_2}$$

**Rankine Efficiency for Wet Steam.** — In adiabatic expansion

let

$H_w$  = total heat, B.t.u. per pound, of wet steam at throttle pressure,

$N_w$  = total entropy of 1 pound of wet steam at throttle pressure,

$T_1$  = temperature of steam at throttle pressure, in °F.

Then the efficiency is

$$E_r = \frac{H_w - H_2 + T_2(N_2 - N_w)}{H_w - h_2}$$

**Rankine Efficiency for Superheated Steam.**—In addition to the symbols let

$H_1$  total heat, B.t.u. per pound, of superheated steam at throttle pressure,  
 $H_2$  total entropy of 1 pound of superheated steam at the given degree of superheat at throttle.  
 efficiency is

$$E_r = \frac{H_1 - H_2 - T_2 (N_1 - N_2)}{H_1 - h_2}$$

**Efficiency Ratio Referred to the Rankine Cycle.**—This is the ratio of efficiency of the actual engine (referred to indicated or brake horse-power, as the case may be) to the efficiency of the Rankine cycle between the same conditions of temperature and pressure as those observed in the actual engine. In the case of steam turbines the thermal efficiency is referred to the brake horsepower. In the case of reciprocating engines it is usually referred to the indicated horse-power.

**STEAM ENGINE EFFICIENCIES—SATURATED STEAM.**

(From Gebhardt's Steam Power Plant Engineering.)

Noncondensing				Condensing — 1 lb. absolute pressure			
Rankine cycle	Rankine cycle	Best actual (1907)	Eff. ratio %	Carnot cycle	Rankine cycle	Best actual	Eff. ratio %
7.5	7.3	5.5	76	22.6	21.0	11.6	55

23.6	21.4	....	..	36.0	31.5	....	..

all thermal efficiencies of multiple expansion engines using superheated steam range from about 19 to 23 per cent.

**Losses.** — The actual efficiencies of steam engines are necessarily less than the efficiency of the Rankine cycle due to the thermal and mechanical losses. These losses consist chiefly of (1) cylinder condensation, (2) leakage, (3) incomplete expansion and compression on return stroke, (4) clearance loss, (5) radiation and (6) the admission of wet steam.

**Cylinder Condensation** is due to the chilling of steam by the cooler walls during admission and early expansion, thus reducing the active mass of steam available for expansion. Condensation increases with the range of expansion and with the duration of the cycle. The condensation loss is

augmented by the formation of a water film on the cylinder walls. It is successfully reduced by expanding the steam in several stages, thus reducing the range of temperature in each cylinder and rendering the heat carried to the exhaust in that cylinder available in succeeding cylinders. Other remedies for condensation are: increasing the rotative speed; steam jackets about the cylinders; and reheaters to dry the steam between cylinders. The most positive and effective remedy is superheat, sufficient to keep the steam dry at least during admission.

**Steam Leakage** past valves, pistons and packing increases with the pressure difference. It is an important element of loss in all piston engines and tends to increase with the wear of moving parts. Leakage is especially serious in cylinders employing a wide range of pressures. Flow of steam through orifices, in pounds, increases directly as the pressure (Napier's rule), and through pipes as  $\sqrt{\text{density}}$ . (*p. 845 Kent's Mechanical Engineers' Pocket-Book.*)

**Incomplete Expansion and Compression.**—As a rule the release occurs before the piston reaches the end of the stroke and the point of closure comes before the piston reaches the end of the back stroke. There is a consequent loss of expansion on the forward stroke. The piston also has to do work in compressing the steam remaining in the cylinder on the reverse stroke. These two features are, as a rule, necessary; the first to reduce cylinder condensation, and the second for its cushioning effect. The first always, and the second usually, results in a net loss.

**Friction** varies with the type and condition of the engine, is greater in compound engines than in simple engines, and is nearly independent of the load, increasing but slightly as the load increases. It ranges from 4 to 20 per cent of the rated output.

**Losses Due to Radiation, Clearance and Moisture.**—With well-lagged cylinders radiation losses are small. Some clearance is necessary in every engine, but the amount is much greater for high speeds than for low speeds. The loss due to it is trifling in slow-speed engines of long stroke. Moisture dilutes the steam admitted but has little effect on the consumption of dry steam; the consumption of the fluid (steam and moisture) is of course increased in proportion to the percentage of moisture present.

**ECONOMY OF STEAM ENGINES.\***—The performance of a steam engine is frequently expressed in terms of the number of pounds of steam per hour required per indicated horse-power, per brake horse-power or per kilowatt (if used to drive an electric generator). The number of pounds of steam per unit of output is called the "economy" of the engine or of the combined engine and generator unit.

Such data may be very misleading unless comparisons are based on identical conditions of steam pressure, superheat, vacuum, etc. A true measure of economy applicable to all conditions may be expressed in net heat units consumed per unit of output, as B.t.u. per kilowatt-hour. In such determinations of economy all heat returned from the exhaust to the boiler should be credited to the engine or turbine.

The commonest means of gaining good engine economy are: raising the initial pressure, compounding, condensing and superheating.

**Effect of Steam Pressure on Economy and Capacity.**—There can be no universal rule connecting initial pressure and working economy. Compound

\* Adapted from lecture notes of Prof. W. E. Wickenden.

engines are better adapted to high pressures than simple engines. Experience indicates that the following gauge pressures are desirable:

Simple, condensing engine without steam jackets . . . . .	60 lb.
Simple, condensing engine with steam jackets . . . . .	80 lb.
Simple, non-condensing engine without steam jackets . . . . .	100 lb.
Compound, non-condensing engines . . . . .	175 lb.
Compound, condensing engines . . . . .	150 lb.
Triple-expansion, condensing engines . . . . .	175 to 200 lb.
Quadruple-expansion condensing engines . . . . .	200 lb.

An important advantage from the use of high pressures is the greater capacity which can be developed from a given engine. The ratio of pressure and capacity is nearly a direct one. High pressures tend to improve economy but not to the extent theoretically available, due to the counteracting effects of condensation and steam leakage with increasing pressure ranges. High steam pressures, however, usually add to the expense of piping and its maintenance. From an examination of a large number of engine performances Stevens and Hobart give the general relation of pressure and economy as shown in Fig. 9.

Fig. 9. Effect of Steam Pressure on Economy of Compound Piston Engines

**Effect of Multiple Expansion on Economy.** — The loss due to cylinder condensation increases with an increase of the difference of temperature of the steam during admission and exhaust, and therefore tends to become greater as the initial pressure is higher. By dividing the total range of expansion into two or more stages, the range of temperature in any one cylinder is decreased, and this lessens the total loss due to cylinder condensation.

Triple and quadruple expansion afford substantial economies with constant load as in pumping and marine service, but have little advantage with the variable loads of electric service to compensate for their great weight, complexity, bulk and cost. Compound engines with high cylinder ratios permit more complete expansion, but have less overload capacity than engines of smaller ratios. For electric service more than 18 expansions is seldom profitable. A cylinder ratio of 1 : 2.5 is well adapted to a pressure of 100 pounds; 1 : 3 to 125 pounds; 1 : 3.5 to 150 pounds and 1 : 4 to 175 pounds or above. Compound engines are relatively uneconomical at light loads, but have a greater economical range of overloads than simple engines. Compound engines, with a moderate cylinder ratio, usually give their best economy at  $\frac{1}{4}$  cut-off in the high-pressure cylinder and will safely carry an overload of 50 per cent.

**Effect of Condensing on Economy.** — Condensing serves to increase both the capacity and economy of engines. The theoretical gain from condensing to various back pressures is indicated in Fig. 10. Actual engines can avail themselves of but a part of this gain, the proportion falling as the vacuum is increased due to the added condensation and leakage. Expansion to very

low pressures requires cylinders of excessive volume. Condensing equipment, especially that for high vacuum, adds much to the first cost of a plant and hence

Fig. 10. Effect of Vacuum on Theoretical Efficiency

to its burden of fixed charges. (See article on Condensers.) Condensers require from one to three pumps and the thermal gain is reduced by the amount of their heat consumption. The temperature of the exhaust steam is lowered as the vacuum increases and so reduces the heat which can be reclaimed in the feed water. It is of great importance that the net gain rather than the apparent gain be considered in determining the economics of various vacua. Reduced steam consumption lessens the necessary investment in steam-generating equipment and piping, and this tends to somewhat counterbalance the investment in condensing apparatus. (See article on Power Stations.)

**Effect of Superheating on Economy.** — Superheating the steam is more effective than using steam jackets and reheaters as a preventive of cylinder condensation under the usual central-station conditions. With proper valve structures there is a decided net saving in heat consumption as the superheat is increased within reasonable limits, but this procedure usually adds to the

Fig. 11. Effect of Superheat on Piston-engine Economy

cost of piping, fittings and their upkeep. Stevens and Hohart report the mean relationship between superheat and economy in compound and multiple expansion engines, as shown in Fig. 11. It is especially important that economic comparison be based on the heat unit consumption as in Curve B. Additional advantages from superheating are the reduction of condensation radiation losses and pressure drop in steam pipes.

Fig. 16. Engine Performance, in B.T.U. per Indicated I.H.P.-Hr.

**Variation of Economy with Load.** — Other factors affecting the economy of engines are the size of the unit, the speed, the mode of governing and the uniformity of load. Stevens and Hobart give the relations between engine sizes, loads and economy shown in Fig. 12 as averages for compound piston engines. Simple engines as a rule show smaller variation in economy with partial loads than compound engines. Typical economy curves for simple and compound engines with saturated steam and compound engines with superheated steam are shown in Figs. 13 to 16. The curves in Fig. 16 correspond to like lettered curves in the other figures.

**Economy of the Binary-vapor Engine.** — With this type of engine there has been obtained an economy of only 8.36 pounds of steam per indicated horse-power-hour, corresponding to a heat consumption of 158.5 B.t.u. per minute. This was the best recorded performance in steam-engine practice at the time of the report (1907) and has not been noticeably exceeded since (1913).

**DIMENSIONS AND WEIGHT OF ENGINES** depend so largely upon the type, speed, etc., that it is impossible to give representative figures in the space available. The following table from the *Elec. World*, (Sept., 1902), gives the dimensions of some very large engines in New York City.

DIMENSIONS OF SOME LARGE RECIPROCATING ENGINES

Name of station.....	Metropo- litan	Manhat- tan	Kings- bridge	Rapid Transit	Edison
Type of engine.....	Vert. cross- comp.	Double 2 hor. 2 vert. cyls.	Vert. cross- comp.	Double, 2 hor. 2 vert. cyls.	3-cyl. vert.
Rated horse-power.....	4500	6000	4500	8900	5200
Cylinders, all 60-in. stroke, in.....	46, 86	44, 88	46, 86	42, 86	43½, 2-75½
Piston rods, diam., in.....	9, 10	8	9, 10	8, 10	9
Crank pins, in.....	14×14	18×18	14×14	20×18	22 & 16×14
Wrist pins, in.....	14×14	12×12	14×14	12×12	14×14
Shaft length.....	27 ft. 4 in.	25 ft. 3 in.	27 ft.	25 ft. 3 in.	35 ft.
max. diam.....	37 in.	37 in.	39 in.	37 in.	29½ in.
bearings, in.....	34×60	34×60	34×60	34×60	26×60

The shafts are hollow, with a 16-inch bore, except the Edison which have a 10-inch bore. The speed of all the engines is 75 revolutions per minute, or 750 feet per minute. The crank pins of the Manhattan and Rapid Transit engines are each attached to two connecting rods, side by side, horizontal and vertical, each rod having a bearing 9 inches long on the pin. The crank pins of the Edison engine are 16 inches in diameter for the side cranks, and 22 inches for the center crank.

**TESTING OF STEAM ENGINES.** — The actual work done by an engine may be tested by a brake or friction dynamometer, or in the case of engines driving electric generators by measuring the electric energy delivered, correction being made for the efficiency of the generator. The work done in the cylinder is obtained by taking numerous indicator diagrams and calculating

from them the mean effective pressure and the horse-power. The steam consumption is tested by condensing all the steam discharged by the engine and weighing the water of condensation. When a condenser is not available the feed water delivered to the boilers may be weighed instead, precautions being taken to insure that all of the steam made by the boiler is used by the engine. For directions for making steam-engine tests see A.S.M.E. Codes.

**Plant Tests.** — In the introduction to the report above referred to the Committee says:

The heat consumption of a steam-engine plant is ascertained by measuring the quantity of steam consumed by the plant, calculating the total heat of the entire quantity, and crediting this total with that portion of the heat rejected by the plant which is utilized and returned to the boiler. The term "engine plant" as here used should include the entire equipment of the steam plant which is concerned in the production of the power, embracing the main cylinders or cylinders; the jackets and reheaters; the air, circulating, and boiler-feed pumps, if steam driven; and any other steam-driven mechanism or auxiliaries necessary to the working of the engine. It is obligatory to thus charge the engine with the steam used by necessary auxiliaries in determining the plant economy, for the reason that it is itself finally benefited, or should be so benefited, by the heat which they return, it being generally agreed that exhaust steam from such auxiliaries should be passed through a feed-water heater, and the heat thereby carried back to the boiler and saved.

**SPECIFICATIONS.** — (See also article on Specifications.) In obtaining bids for steam engines the prospective purchaser or his engineer usually furnishes only general specifications, stating the kind of work to be done by the engine, such as driving a cotton mill, or an electric power plant, and the following requirements: (1) Indicated horse-power required, (a) Maximum, (b) Average; (2) Steam pressure available at engine; (3) Maximum absolute back pressure; (4) Number of revolutions; (5) Required steam consumption.

The bidders then furnish with their bids complete detailed specifications with guarantees of the engines they propose to supply, with drawings, when these are required. The bidders are usually prepared to contract for the installation, erection and starting of the engine, especially if it is of a large size.

**FOUNDATIONS FOR STEAM ENGINES.** — Engine foundations may be built of brick or concrete; the latter is more commonly employed in modern practice. The concrete is made with proportions of one barrel of Portland cement, three of sand, and five of crushed stone.

If the foundation is to be of concrete a wooden box is built in the ground, the inside of the box being the shape of the foundation. Over the top of this box are a number of pieces of joist, from which the anchor bolts or holding-down bolts are hung. Most engine builders furnish drawings giving location of foundation bolts and size of foundation required. The nuts at the top of these bolts are blocked up to the height they are to be when the engine is in place.

The heads of the bolts are at the bottom. A cast-iron plate eight inches by eight inches by one inch, with a square recess for the bolt head, is at the bottom of each rod. Around each bolt a piece of four-inch galvanized-iron gutter pipe is placed, and the top end of the pipe stuffed with waste to keep the mason from dropping cement into the space between the pipe and the bolt. The concrete is now dumped in and tamped down. After it has set, the wooden joists holding the bolts may be taken away.

The engine is next put over the foundation and supported on iron bars one-half inch square or perhaps larger, these bars being placed near the bolts. By means of wedges, etc., the engine is leveled; the main shaft is placed parallel

shafting which it is to drive. The bolts are next tightened fairly and it is impossible to core the holes in the engine bed exactly as called for in the drawing, the leeway given by the space between the bolts and the surrounding it takes care of variations of from an inch to an inch and

of putty, sand, or cement about one inch high is built about one inch above the engine bed. A thin, neat Portland cement, mixed to the consistency of cream, is poured under the engine bed and serves to fill the space between the bolts and to give the bottom of the bed a perfect bearing over the foundation. Before the cement becomes hard, the edge may be trimmed off by means of a trowel; the bolts are then tightened again. A special type metal instead of cement is poured under the engine bed.

**ADJUSTMENT.**— Full directions for setting the valves of a steam engine are given in a little book by M. C. Myers, entitled *Types of Modern Engines and Valve Setting* (Boston, 1910). Other useful data on the operation and performance of steam engines will be found in a book published by the Steam Gauge and Valve Co., entitled *Steam Engine Indicator*. See also the more elaborate treatises listed in the bibliography below.

**Control.**— The speed of an engine can always be controlled by the opening of the throttle valve, but this method is usually wasteful. A more efficient method is to change the point of cut-off. This can be done while the engine is running by using a suitable link motion (see *above*), or by the setting of the governor spring if the governor is of the "automatic" type. In engines driving alternators in parallel this is usually accomplished by an electric motor arranged to act directly on the governor spring so that the tension of the spring may be controlled from the switch-board.

**Equalizing Variable Load by Storing Heat in Hot Water.**— There is a very satisfactory method for equalizing the load on the engines and boilers in power stations. Storage batteries have been used, but they are expensive to install, and require repairs and attention. Mr. Halpin, of London, proposes to store the heat of the day in specially constructed reservoirs. As the water in the reservoirs is raised to 250 pounds pressure, it is conducted to cylindrical reservoirs made of English horizontal boilers, and stored there for use when wanted. A comparatively small boiler-plant can be used for heating the water to the required pressure all through the twenty-four hours of the day, and the steam may be drawn on at any time, according to the magnitude of the load. The steam engines are to be worked by the steam generated by the boiler at the pressure from this water, and the valves are to be arranged in such a way that the steam shall work at 130 pounds pressure. A reservoir 8 feet in diameter and 30 feet long, containing 84,000 pounds of heated water at 250 pounds pressure, would supply 5150 pounds of steam at 130 pounds pressure. At a consumption of 18 pounds-per-horse-power-hour, such a reservoir would supply 286 effective horse-power-hours.

**PRICES OF STEAM ENGINES (Pre-war figures).**— The price of steam engines varies not only with their size and weight, but also with their style, quality of workmanship. When builders are asked to submit bids for the purchase of a certain power of engine, with the same steam pressure and number of revolutions per minute of the same general type, such as cross-compound condensing, it is not unusual to receive prices of which the highest is double that of the lowest. The price may be as low as, for example, \$10 to \$20 per horse-power for an engine of 500 horse-power. For specially designed engines requiring new patterns to be made the price is considerably above \$20. The price also varies with the condition of the market, discounts from regular prices of as much as 20 per cent being

sometimes quoted in periods of dull business. The usually give the weights of standard sizes of engines and to the probable price may be made by taking it at from 5. the lower price being for engines with heavy bed-plates and forms.

From a number of tables and sets of curves kindly furnished by Whitham, Consulting Engineer, Philadelphia, containing data which has received for different sizes and styles of engines, the following expressions have been deduced, where  $P$  is the rated horse

Type of Engine	Co
Corliss engines:	
Single cylinder, noncondensing.....	
Single cylinder, condensing.....	
Compound, noncondensing.....	
Compound, condensing.....	
Compound slide-valve engine:	
Portable (locomotive) boiler, noncondensing engine and stack.....	

The cost of condensing engines is exclusive of condenser.

Professor Wickenden gives the following values for electric generators, these values being based on the actual number of installations.

Type of Engine	C
Simple high-speed engines and settings.....	
Compound high-speed engines and settings.....	
Simple low-speed engines and settings.....	
Compound low-speed engines and settings.....

**STEAM TURBINES.** — (See also *Condensers, Steam; Power Stations; Steam; Steam Engines.*) Steam turbines may be classified as impulse, reaction, and composite; single-stage and multi-stage; nozzle expansion and blade expansion; vertical and horizontal. A set of nozzles or stationary guide blades and the rotating vanes through which the steam passes immediately upon leaving the nozzles or stationary blades constitute a single "stage." If there are several sets of stationary nozzles or guide blades and rotating vanes through which the steam passes successively, the turbine is called a "multi-stage" turbine.

**APPLICATIONS OF STEAM TURBINES.** — The steam turbine, when designed to use steam economically, is characterized by extremely high speed of rotation. The special field of application of the steam turbine is therefore the driving of electric generators, centrifugal blowers and pumps, and other machinery in which a high speed of the motor shaft is desirable. When lower speeds are desired in the motor shaft a reduction gear of some kind is placed between it and the turbine shaft. See also articles on *Generators; Power Stations; Pumps.*

**RATING OF STEAM TURBINES.** — Turbine ratings are usually based on maximum sustained load. Momentary overload capacity is very large and moderate overloads of considerable duration can be carried but may require the admission of high-pressure steam to low-pressure stages by means of a secondary valve. Small turbines for driving pumps, blowers, etc., are rated in horse-power. Turbines used to drive electric generators are usually rated in connection with the generator, the combined unit or turbo-generator being rated in kilowatts. Turbo-alternators of 20,000 kilowatts capacity each are in use (1913), and still larger units are considered practicable.

**DESIGN AND CONSTRUCTION OF STEAM TURBINES.** — Below are noted briefly some of the chief features in the design and construction of steam turbines. For further details see the treatises by Stevens and Hobart, Moyer, Stodola, Foster, Thomas, etc.

**Impulse Turbines.** — An impulse steam turbine of the simplest form is a wheel similar to a water wheel, which is moved by a jet of steam impinging at high velocity on its blades. By expansion of the steam its pressure energy is converted into kinetic energy, and the wheel is propelled by the impact of the steam moving at high velocity.

**De Laval Turbine.** — The distinguishing features of this turbine are the diverging nozzles, in which the steam expands down to the atmospheric pressure in non-condensing, and to the vacuum pressure in condensing wheels; a single forged-steel disk carrying the blades on its periphery; a slender, flexible shaft on which the wheel is mounted and which rotates about its center of gravity; and a set of reducing gears, usually 10 to 1 reduction, to change the very high speed of the turbine to a moderate speed for driving machinery.

The number and size of nozzles vary with the size of the turbine. The nozzles are provided with valves, so that for light loads some of them may be closed, and a relatively high efficiency is obtained at light loads. The taper of the nozzles differs for condensing and noncondensing turbines. Some turbines are provided with two sets of nozzles, one for condensing and the other for non-condensing operation.

**Zolley or Rateau Turbine.** — The Zolley or Rateau turbines are developments of the De Laval and consist of a number of De Laval elements in series, each succeeding element utilizing the exhaust steam from the preceding. The steam is partly expanded in the first row of nozzles, strikes the first row of

buckets and leaves them with practically zero velocity, expanded through the second row of nozzles, strikes a second set of buckets and again leaves them with zero velocity. This process repeats until the steam is completely expanded.

**Curtis Turbine,** made by the General Electric Co. It consists of a wheel of several stages. Steam is expanded in nozzles into three or more blades, at least one of which is stationary and non-expanding, and the pressure is practically the same on both sets of blades. In smaller sizes of turbines, only one set of stationary blades is used, but in large sizes there are from two to five pressure stages, separated by diaphragms containing additional nozzles. The smaller sizes and the more recent (1914) larger sizes have horizontal shafts. Earlier large sizes have vertical shafts supported by bearings supplied with oil or water under a pressure sufficient to support the weight of the shaft and its attached rotating disks.

**Reaction and Composite Turbines.**— In a simple reaction turbine, steam expanding through a set of blades or nozzles capable of doing work on a rotating axis, produces a reacting force and drives the rotating wheel in the opposite direction to the motion of the steam. Hero's engine is the earliest form of reaction turbine. The term "reaction" turbine, however, as applied to a turbine in which the reaction principle is combined with the impulse principle, i. e., to turbines in which jets of steam striking blades in the rim of a wheel give it a forward impulse, and escaping in the opposite direction react upon it.

**Parsons Turbine.**— This is a reaction turbine in which a large number of rows of blades, mounted on a rotor or stator, and between each pair of rows there is a row of stationary blades. The stationary blades act as nozzles. A set of stationary blades and a corresponding set of moving blades constitute what is known as a stage. The steam expands and loses pressure in both sets. The speed of rotation is the same as the speed of the blades and the velocity of the steam through the nozzles is much lower than in the De Laval turbine. The rotor, or the set of moving blades are carried, is usually made in three sections, the smallest at the high-pressure end, where steam pressure is the largest at the exhaust end. In each section the radial length of the blades also their width increase from one end to the other, to accommodate the increased volume of steam. The Parsons turbine is built by the Westinghouse Machine Co. and by the Allis-Chalmers Co.

**The Westinghouse Double-flow Turbine.**— In this type of turbine is built in which the impulse and reaction principles are combined. It has a set of non-expanding nozzles, an impulse wheel, and two reaction stages (that is, two wheels with a set of stationary non-expanding blades between them), one intermediate section and two low-pressure sections. After steam has passed through the impulse wheel, it is divided into two parts, one going to the right-hand reaction section and the other to the left-hand low-pressure section. There is an exhaust at the right end. In this turbine, the end thrust, which has to be balanced in the usual type, is almost entirely avoided. Other advantages are: reduction in size and weight, due to higher permissible speed; not exposed to high temperatures; reduction of size of bearings; length of shaft; avoidance of large balance pistons.

**Comparison of Impulse and Reaction Turbines.**— The following comparison of impulse and reaction turbines:

**Impulse**

stages.  
 expansion in nozzles.  
 drop in pressure in a stage.  
 steam velocities 1000 to  
 2000 feet per second.  
 velocities 400 to 1200 feet  
 per second.  
 efficiency when the blade ve-  
 locity is nearly half the initial  
 velocity of steam.

**Reaction**

1. Many stages.
2. No nozzles.
3. Small drop in pressure in a stage.
4. All steam velocities low, 300 to 600 feet per second.
5. Blade velocities 150 to 400 feet per second.
6. Best efficiency when the blade velocity is nearly equal to the highest velocity of the steam.

Comparison has not made manifest any marked and consistent difference in efficiency and reliability between the impulse and reaction types.

**Vertical Versus Horizontal Turbines.** — There is also no marked difference in efficiency and reliability of the vertical and horizontal types. The former is more economical of floor space, especially when the base type of condenser is employed, but requires more head room, as sufficient overhead space must be provided to permit the lifting clear, and removal of, the shaft from the casing.

**Reduction Gear for Steam Turbines.** — Double spiral reduction gears, with a ratio of 1 to 10, are used with the De Laval turbine to obtain a speed of rotation suitable for dynamos, centrifugal pumps, etc. G. W. McAlpine and J. H. McAlpine have designed a similar gear, with the pinion carried on a floating frame supported at a single point between the bearings to reduce the strain on the gear teeth, for reducing the speed of large horizontal turbines to suitable speeds for marine propellers. A 6000-horse-power gear reduction from 1500 to 300 revolutions per minute has been tested, giving an efficiency of 98.5 per cent (*Eng'g, Sept. 17; Eng. News, Oct. 21 and Dec. 30,*

**TURBINES VERSUS RECIPROCATING ENGINES.** — The inherent advantages of the turbine are: (1) The perfect continuity and uniformity of motion.

This permits the working parts to be made light and gives the high angular velocity which is desired for the parallel running of alternators. (2) The high velocity of rotation and of steam flow. This tends to great compactness, permits light weights, provides for the full expansion to high vacuum, and enormous volume of expansive space, cheapens the cost of turbine and condenser, and is favorable to the efficiency of the latter. The effect of items (1) and (2) on weights, sizes and costs may be best appreciated by comparing turbine and gas-engine sets of equal maximum capacity. (3) The reduction of condensation, radiation and leakage. (4) The absence of friction from the steam space. Difficulties of lubrication with high speeds are thus obviated and the condensed steam is free from oil. (5) The absence of good economy over a wide range of fractional loads. (6) The great momentary overload capacity obtained from the high inertia of the rapidly rotating parts. To match this advantage in slow-speed reciprocating engines requires very heavy working parts and the addition of a massive flywheel. The reciprocating engine can be built to equal the turbine in economy over a wide range of loads but the refinements required to this end are costly. For equal heat consumption the costs of turbine-alternator units are from 35 to 50 per cent greater than those of reciprocating sets.

**Turbines versus Engines in Units of Small Capacity.** — Under this title, Mr. Starbuck presented the following summary before the A.S.M.E. in 1915, for units of less than 500 horse-power capacity.

**Applicability of Turbines.** — 1. Direct-connected units, operating condensing. 60-cycle generators in all sizes, also 25-cycle generators above 1000 kw. capacity. (This paper is, however, not intended to deal with units of this size.) Direct-current generators in sizes up to 1000 kw. capacity, including exciter units of all sizes.

Centrifugal pumping machinery operating under substantially constant head and quantity conditions, and at moderately high head, say from 100 ft up, depending upon the size of the unit.

Fans and blowers for delivering air at pressures from 1½ inch water column to 30 pounds per square inch.

2. Direct-connected units, operating non-condensing for all the above purposes, in those cases wherein steam economy is not the prime factor or where the exhaust steam can be completely utilized, and, in the latter case, particularly where oil-free exhaust steam is desirable or essential.

3. Geared units, operating either condensing or non-condensing for all the above-mentioned applications, and in addition, many others which would otherwise fall in the category of the steam engine, on account of the relatively low speed of the apparatus to be driven.

**Applicability of Engines.** — 1. Non-condensing units, direct-connected or belted and used for driving: Electric generators of all classes excepting exciter sets of small capacity, unless belted from the main engine.

Centrifugal pumping machinery, operating under variable head and quantity conditions and at relatively low heads, say up to 100 feet, depending on the capacity of the unit. Pumps and compressors for delivering water or gas in relatively small quantities and at relatively high pressures in the case of pumps at pressures above 100 pounds per square inch, and in the case of compressors at pressures from 1 pound per square inch and above.

Fans and blowers (including induced draft fans) for handling air in variable quantities and at relatively low pressures, say not over 5 inches water column. Line shaft of mills, where the driven apparatus is closely grouped and the L.V. factor is good.

All apparatus requiring reversal in direction of rotation, as in hoisting engines and engines for traction purposes.

2. Condensing units direct-connected or belted, for all the above purposes particularly where the condensing water supply is limited, and where the water must be re-cooled and recirculated.

**Low-pressure Turbines** compounded with high-pressure reciprocating engines are coming into extensive use where it is necessary to increase the capacity or improve the efficiency of existing engine plants. By combining the superior efficiency of the engine in the pressure range above the atmosphere with that of the turbine below the atmospheric range a resultant superior to the efficiency of either single type may be secured. Standard piston engines are able to sustain full-rated load when run non-condensing and often will carry from 25 to 50 per cent above rated load without danger or excessive wear. Under such conditions the water rate per kilowatt-hour is high but all the heat rejected in the exhaust is available to a low-pressure turbine; hence the net economy of the combined engine and turbine may be considerably superior to that of the engine when run condensing. By proportioning the turbine to efficiently utilize the exhaust steam and by connecting to it a high-vacuum condenser, the initial capacity of the unit may be doubled or even trebled, and if the engine is in good condition, the resultant efficiency may be superior to that obtainable from a new complete-expansion turbine of equal capacity.

Structurally, the low-pressure turbine is similar to the full-pressure type with the high-pressure stages omitted. It is, therefore, somewhat shorter but

spaces are necessarily greater than in a full-pressure type of equal diameter. It is highly desirable that an efficient separator be installed between the boiler and the turbine as the presence of moisture in the steam adds greatly to the friction against the turbine blades. When the exhaust is to be returned to the boiler it is also necessary to extract the oil from the steam as it leaves the turbine.

**EFFICIENCY AND LOSSES.** — The maximum theoretical efficiency of a steam turbine is the efficiency of the Rankine ideal engine between the temperature of admission and exhaust (*see Steam Engines*).

Several losses which tend to reduce the efficiency of turbines below the theoretical maximum are: (1) residual velocity, or the kinetic energy due to the velocity of the steam escaping from the turbine; (2) friction and imperfect expansion in the nozzles; (3) windage, or friction due to rotation of the wheel; (4) friction of the steam traveling through the blades; (5) shocks, eddies, etc., due to imperfect shape or roughness of blades; (6) leakage at the ends of the blades or through clearance spaces; (7) shaft friction and radiation. The sum of all these losses amounts to about 25 per cent of the available energy in the largest and best designs and to 50 per cent or more in smaller sizes or poor designs.

Leakage, windage and radiation are of small magnitude. Windage and radiation are especially marked in the high-pressure stages and the turbine is most efficient in its low-pressure stages, in direct contrast to the piston engine. Mechanical friction is relatively small, due to the small loads on wearing surfaces and the effectiveness with which they may be lubricated. Steam friction, leakage and condensation are much increased by moisture in the steam. Superheated steam is particularly advantageous in turbines because of its low specific volume, dryness and high fluidity.

**ECONOMY OF TURBINES.** — Like all heat engines the efficiency of the turbine depends on the range of expansion and the reduction of pressure.

Increasing the range of expansion by raising the initial pressure affords a small gain in efficiency.

The chief advantage of the turbine is in the decreased steam consumption per unit of output.

The relation of turbine efficiency to the steam pressure and vacuum is shown in Fig. 1. The relation of turbine efficiency to the steam pressure and vacuum is shown in Fig. 1.

The advantage gained by increasing the range of expansion at the lower end of the cycle exceeds that gained by increasing the initial pressure at the upper end of the cycle. The turbine efficiency for typical units.

Fig. 1. Relations of Turbine Efficiency to Steam Conditions and Vacuum

In the utilization of high vacua the turbine efficiency for typical units. Fig. 1 shows the relation of vacuum to turbine efficiency. This relation depends to a marked degree

on the design of the particular turbine and is therefore not identical in all units of a given general type.

**Effect of Vacuum on Economy.**—The economical limit of vacuum in turbines is much higher than in engines. The attainment of very high vacuum involves a very heavy investment in condensers and auxiliaries and a considerable consumption of heat for their operation. The ultimate effect on plant economy is therefore decidedly less than the percentage gain indicated in Fig. 1. Factors unfavorable to high vacuum are a poor load factor for the unit; costly, warm or corrosive cooling water; the necessity of artificial cooling condensing water when the supply is limited; and very cheap fuel.

The question of the most economical vacuum must be determined by con-

Fig. 2. Average Full-load Net Heat Consumption of Turbines

- A. American types, mean values from guarantees and tests  
 B. Results of 50 European Tests

fully weighing against each other the annual charges on the condenser system interest, depreciation, attendance, repairs, and the net cost of water for its operation included, and, on the other hand, the annual saving in total fuel consumed plus the saving on boiler-plant fixed charges and operation. Such an analysis takes due account of the heat consumed in driving the auxiliaries. Where an abundant supply of cold condensing water is available, experience indicates that the highest vacuum attainable is a good investment in connection with large units operated at load factors of 60 per cent, or above. Under ordinary central-station conditions vacua of from 27 to 28 inches are not advantageous.

**Effect of Superheat on Economy.**—Superheat of almost any practicable degree improves turbine efficiency, though the net saving is much less than that indicated by the water rate, due to the extra heat content of superheated steam of high temperature. On account of the influence of superheat on the first cost and maintenance expense of piping, valves and fittings, also because of the difficulties in providing for expansion of turbine parts at very high temperatures the tendency of American practice is to exceed a steam temperature of 500° F only in very large units, though the tendency in Europe is toward a higher limit. Fig. 1 shows the effect of superheat on steam consumption and net heat consumption of steam turbines, the relation being practically uniform for all types.

of Size and Type on — The efficiency of the like that of the engine, as the size of the unit see Fig. 2. Large units are cheaper than small, and better economy in piping equipment, space, and maintenance. A generator is rated as a unit. The momentary and overload capacity of the proper is very large, but is much restricted by its ability to dissipate the heat in its parts. The usual basis is either upon maximum capacity ( $M$  in Fig. 2) or normal sustained capacity ( $N$  in Fig. 2) with an allowable overload of 10% for a two-hour period ( $N$

Fig. 3. Net Heat Consumption of Modern Turbines

M. Maximum Rating. N. "Normal" Rating

has not made manifest any marked or consistent differences in efficiency and reliability between the several commercial types. The vertical type is well suited to the highest speeds, but is especially economical of space in connection with the base type of condenser. It requires greater foundation than the horizontal type. Fig. 4 shows the steam consumption of small non-condensing turbines (see paper by G. A. Orrok, *Trans. A.S.M.E.*, 1909). All curves are test results.

Fig. 4. Steam Consumption of Small Non-condensing Steam Turbines

EFFICIENCY OF COMBINED TURBINE AND ENGINE UNIT. — This subject is reported by H. G. Stott and R. I. S. Pigott in *Jour. A.S.M.E.*

Mar., 1910. The steam-engine is one of the 7500-kilowatt Manhattan type engines at the 59th St. Station of the Rapid Transit Co., New York, with 14 42-inch horizontal high-pressure and two 86-inch vertical low-pressure cylinders and the turbine, also 7500 kilowatt, is of the vertical three-stage impulse type. The principal results are summarized as follows: An increase of 100 per cent in the maximum capacity and 146 per cent in the economical capacity of the plant; a saving of about 85 per cent of the condensed steam for return to the boilers [it was previously wasted]; an average improvement in economy of 13 per cent over the best high-pressure turbine results and of 2.5 per cent (between 7500 and 15,000 kilowatts) over the results obtained by the engine alone. An average thermal efficiency between 6500 and 15,500 kilowatts of 20.6 per cent. [This efficiency is not quite equal to that reached by triple-expansion pump engines.]

**TESTING OF STEAM TURBINES.** — Turbines are tested in the same way as reciprocating steam engines, measuring the power by a Prony brake or by an electric generator whose efficiency at different loads is known and the steam consumption by weighing the water discharged from the condenser.

**SPECIFICATIONS.** — See *Specifications* in article on *Steam Engines*.

**OPERATION.** — Several important features are noted below. For additional information see article on *Power Stations*.

**Oil-pressure System for Step Bearing of Vertical Turbine.** — When running the end of the shaft is lifted slightly from its seat and supported by a forced circulation of water or oil under a pressure of from 500 to 1200 pounds per square inch. This pressure is produced by a special step bearing pump which may be of the steam-driven, direct-acting type or of the motor-driven, triplex type, and is reinforced by a heavily weighted plunger accumulator. When a double pump equipment is installed the second may serve as a reserve and, if of the motor-driven type, may readily be arranged to automatically take up the load if the accumulator falls to a certain point, due to the failure or inadequacy of the primary pump. The horizontal-shaft type is subject to an end thrust, which must be neutralized by dividing the turbine into two sections through which the steam flows in opposite directions or by the use of pressure rings opposed to the thrust on the turbine.

**Speed Control.** — Turbines having nozzle expansion are most efficiently governed by varying the number of active nozzles. Reaction turbines are governed by the intermittent throttling of steam at the admission valve. The governor is usually of the shaft or flywheel type (see *Steam Engines*). In both types, when used for driving alternators in parallel, a small motor is attached to the governor spring so that the tension may be controlled at the switchboard. This affords a convenient control of speed for synchronizing and adjusting the loads taken by the several machines.

**Speed Control of Combined Turbine and Reciprocating Engine Unit.** — In central-station service the two elements are so adjusted that the turbine takes all the steam from the engine, the load on the two is varied simultaneously and the two are electrically coupled by being connected to the same bus bars. This arrangement simplifies the problem of governing and the division of load. It has not been found advantageous to place a governor on the turbine under such conditions. The turbine operates under variable admission pressure, depending on the load. The turbine should be equipped with a speed-limiting relay, which opens the atmospheric exhaust from the engine should the speed of the turbine become unsafe.

**COST OF STEAM TURBINES (Pre-war figures).** — Small turbines for pumps, blowers, etc., cost from \$20 to \$40 per horsepower. The curves are kindly supplied by Prof. W. E. Wickenden and represent the average of the actual costs of a number of units of various

Fig. 5. Approximate Cost of Turbo-generator Sets

Impulse and reaction turbines cost approximately the same. Turbines are subject to considerable variation, the tendency being a decided increase in the cost per kilowatt from year to year. The costs given in the preceding table should therefore be checked against actual quotations, even when used as preliminary estimates.

**STEEL.** — (See also *Iron, Pig and Cast; Castings, Iron and Steel; Rails, Iron and Third.*) Carbon steel (the ordinary commercial steel) may be defined as an alloy of iron and carbon produced by any one of the methods described in the following article. It differs from wrought iron in not being slag-bearing and from cast iron in being malleable at certain temperatures.

**Slag** is the substance which collects on the surface of molten iron or steel in the blast furnace, converter or open-hearth furnace. Its constitution varies with the process but it includes oxides of the various impurities found in the iron such as silicon, aluminum, phosphorus, calcium and magnesium. It may also include some oxide of iron. The slag from blast furnaces is often very rich in calcium owing to the amount of limestone added to the charge as a flux. The manufacture of Portland cement from blast-furnace slag is an important industry. The process of puddling used in making wrought iron involves the mixing of some of the slag with the iron, thus making it an integral part of the finished product as explained in the article on *Iron, Wrought*.

**METALLURGY.** — The various processes by which steel is at present manufactured are described in the following paragraphs:

**Bessemer Process.** — This process consists of the burning out of most of the impurities and carbon contained in molten iron by the aid of a blast of unheated air, and subsequent recarbonization of the mass by the addition of spiegel-iron or ferro-manganese. The molten material is placed in a pear-shaped vessel called a converter and the blast is introduced through openings in the bottom. After the process has continued long enough to convert the iron into steel, the molten material is either poured into iron molds forming ingots which are later rolled or hammered into commercial shapes, or else cast into *steel castings*.

Two processes are in use, the acid and the basic; in the former the converter lining is of refractory acid materials composed principally of silica, so that the phosphorus and sulphur in the charge are unremoved; in the latter, the converter is lined with burnt dolomite, and lime is added to the charge to reduce the phosphorus and sulphur. The heat necessary for the process is obtained from the combustion of silicon in the acid process and of phosphorus in the basic process. The acid process alone is in use in the United States owing to the prevalence of low phosphorus and sulphur ores. Steel of fair quality is produced by this process at low cost and with great rapidity, but Bessemer steel is gradually being replaced for important structures by the more reliable open-hearth steel.

**Open-hearth Process.** — This process consists of the reduction of the carbon and other impurities contained in a mixture of pig iron, scrap iron or scrap steel and iron ore by exposure for seven or eight hours to an intense heat obtained from a mixture of producer gas and air, the process being stopped when the bath is found to have the right proportions as determined by physical and chemical analyses. The steel is then withdrawn from the furnace and either poured into ingots or cast into usable forms. Steel of excellent quality for structural purposes is thus produced in large quantities, a single furnace often having a capacity of 50 tons.

**Duplex Process.** — This process consists of a combination of the Bessemer and open hearth; pig iron is first blown into the converter to remove the silicon and a portion of the carbon; it is then transferred to the open hearth, where it is dephosphorized and the carbon reduced to the proper percentage. The process permits the use of a poorer grade of material than the Bessemer, and gives a higher grade of finished product, while the speed of production is superior to that of the open hearth.

**Crucible Process.** — This process consists of melting down, in covered clay or graphite crucibles, wrought iron (sometimes diluted with steel scraps) with charcoal, ferro-manganese and various so-called physics, such as salt, oxide of manganese, etc. The crucibles hold from 50 to 100 lb. each. Crucible steel is high in carbon and low in sulphur and phosphorus. It is superior to Bessemer and open-hearth steel and is used for tool making.

**Cementation Process.** — This process consists of converting wrought iron into steel by piling iron bars and charcoal together, bringing to a yellow heat and keeping in this condition for a period extending from ten days to two weeks. The steel thus obtained is known as blister steel. If the blister steel is cut, piled, heated and forged, *shear* steel is produced; if the operation is repeated on shear steel, *double shear* steel is obtained. Blister steel is frequently melted in the crucible to free from slag; the resulting product is of the highest quality and is used in making the finest grades of cutting tools, such as razors. Case hardening is a special form of cementation by which the outer surfaces of articles forged from wrought iron or steel are hardened. Harveyizing of armor plate is also a cementation process.

**MECHANICAL TREATMENT.** — (See also *Steel Mills, Electric Drive of*.) Steel made by any of the preceding processes may be put into usable form either by casting, or by forging while hot under the hammer, or usually by rolling while hot between heavy grooved rollers, the latter process being used for rods, plates, rails, and structural shapes such as angles, channels and I-beams. The rolling process is usually divided into two parts: (a) the reduction of the ingot into *blooms* or *billets* by the *blooming mill*; and (b) the reduction of the blooms or billets into commercial shapes by the *shaping mill*.

The blooming mill consists of a pair of horizontal grooved rollers, one above the other, between which the ingot is passed back and forth, the rolls being gradually forced closer together. These rolls are actuated by a reversing engine. This process reduces the ingot from a block of steel perhaps 16 inches square by 6 feet in length to a bar of small cross-section, usually rectangular and of considerable length. This is then cut into sections several feet in length which are called blooms if the cross-section contains more than 36 square inches and billets if less. In England this mill is called a cogging mill.

The shaping mill is similar to the blooming mill, but there are usually three non-reversing rolls in a vertical plane, the bloom passing forward between the lower and middle rolls, and returning between the middle and upper roll.

**HEAT TREATMENT; CRITICAL TEMPERATURE.** — When iron or steel cools from a high temperature, say 1000° C., the rate of cooling is not uniform, but is marked by certain periods of retardation accompanied by spontaneous evolution of heat, the opposite phenomena occurring when the temperature is increased. There are in general three of these critical points which are designated by metallurgists by the letters  $A_1$ ,  $A_2$  and  $A_3$ ,  $A_1$  being at the lowest temperature. Owing to lag the changes occur at slightly lower temperatures on cooling than on heating, and to distinguish between them, the cooling points are designated  $A_{r1}$ ,  $A_{r2}$  and  $A_{r3}$ , and the heating points  $A_{c1}$ ,  $A_{c2}$  and  $A_{c3}$ . These points vary with the percentage of carbon, and for certain grades of steel the three cooling points may be merged into one and also the three heating points. With favorable conditions when the temperature  $A_{r1}$  is reached an increase in temperature of the metal may be detected by its change of color. This point is called the point of recalescence. At this temperature also a softening of the metal occurs. An interesting feature of the point  $A_1$  is that at a higher temperature steel is *non-magnetic*, but in passing through  $A_{r2}$  it becomes suddenly *magnetic*. See *Magnetic Properties of Iron and Other Metals*.

The approximate values of these critical points in degrees Fahrenheit by Sauveur are shown in the following table:

CRITICAL TEMPERATURES IN DEGREES

Grade of steel	Low carbon	Medium-high carbon
Carbon content, per cent	0.1	0.45
$A_{r1}$	675	650 to 700
$A_{r2}$	750	725
$A_{r3}$	850	725
$A_{c1}$	700	...
$A_{c2}$	750	...
$A_{c3}$	875	...

**ANNEALING.** — Steel with a coarse structure due to cold working is improved in grain by heating to a temperature varying from 775° to 1600° F. and cooling slowly. The accompanying table gives the annealing temperatures which are commonly specified for this purpose.

Range of carbon content, per cent	Range of annealing temperature, °C.	
	Low carbon	Medium-high carbon
Less than 0.12	875 to 925	1607
0.12 to 0.29	840 to 870	1544
0.30 to 0.49	815 to 840	1499
0.50 to 1.00	790 to 815	1454

The object should be kept at the annealing temperature for a sufficient time to ensure a uniform temperature throughout and then cooled slowly. For low carbon, or the greater the ductility and softness required, the cooling should be slower. It is usually sufficient to remove the object from the furnace to allow it to cool in air protected from rain, snow and draft. For steel containing more than 0.50 per cent carbon should cool more slowly before removing from the furnace; it may then be removed and cooled in air. To remove the effects of cold working the object should be heated to 775° C. and cooled with a slowness depending upon the type of steel. For detailed specifications see *Amer. Soc. for Test. Mat.*

**CARBON STEEL.** — The alloy of carbon and iron of which ordinary carbon steel is composed is divided into the five following groups by Sauveur:

Grade of steel	Hardness	Carbon content, per cent
Very low carbon	Very soft	Not over 0.10
Low carbon	Soft	Not over 0.25
Medium-high carbon	Half hard	0.26 to 0.60
High carbon	Hard	Over 0.60
Very high carbon	Hard, extra hard	Over 1.25

The properties of these different groups when made under normal conditions depend upon the relative amounts of the following constituents:

**Ferrite**, or iron free from carbon, this being the same as the ferrite in wrought iron (q.v.).

**Pearlite**, consisting of a mixture of iron carbide and ferrite.

**Cementite**, or iron carbide, with the formula  $Fe_3C$ , combined with a varying amount of carbide of manganese.

**Austenite and Martensite.** — Steel that is suddenly cooled from a high temperature contains also certain other compounds of iron and carbon, the two of most importance being known as *austenite* and *martensite*. The former is generally considered as a solid solution of carbon, or of the carbide  $Fe_3C$ , in iron in the allotropic condition in which the latter exists at a high temperature (above  $875^{\circ}C$ ). It is not a constituent of constant composition, and is seldom found in ordinary steels since it is rapidly transformed in cooling into an aggregate of ferrite and cementite. To obtain it highly carburized steel may be suddenly cooled from a temperature of  $1000^{\circ}C$ . or more by a bath such as ice cold water. It may also be obtained by slow cooling if the steel contains a considerable portion of manganese or nickel. Martensite is generally believed to be an early stage in the transformation of austenite.

**Phosphorus and Sulphur.** — The common injurious impurities in carbon steel are phosphorus and sulphur, both of which cause brittleness and should be allowed only in small quantities. Specifications (*see section below on this topic*) frequently forbid more than 0.05 per cent of sulphur and 0.04 per cent of phosphorus. Other impurities commonly occurring in small quantities in steel are silicon and manganese, which in small quantities help to reduce blow holes by their deoxidizing action. These elements while often present in higher percentages than the carbon have comparatively little influence upon the strength of ordinary carbon steel.

**Composition of Low-carbon Steel.** — Low-carbon steel consists chiefly of a mass of ferrite with pearlite occurring at the junction of the grains of ferrite, the percentage of the former decreasing in medium and hard steels until in steel having 0.8 per cent to 0.9 per cent carbon, it disappears entirely, the steel then consisting exclusively of pearlite. In still higher carbon steels some of the pearlite is replaced by free cementite, the substance which gives steel its hardening property.

**Strength and Weight of Carbon Steel.** — The tensile strength of steel varies with its composition. For ordinary carbon structural steel the working values given in the following table may be adopted with safety:

Nature of stress	Working strength, pounds per square inch
Tension on net section, and extreme fiber stress in bending.....	16,000
Compression in columns*.....	$16,000 - \frac{70 l}{r}$ , with a maximum of 14,000
Shear on net section of plate-girder webs and on machine-driven shop rivets.....	12,000
Bending on extreme fiber of pins.....	24,000
Bearing on pins and shop-driven rivets.....	24,000
Bearing on hand-driven rivets.....	18,000
Shear on hand-driven rivets.....	9,000
Modulus of elasticity.....	28,000,000 lb. per sq. in.

\* In the expression for compression in columns,  $\frac{l}{r}$  = maximum value of ratio of unsupported length of column to radius of gyration, both values being expressed in inches. This ratio should be restricted by the form of the column so that it will not exceed 100 for main members and 120 for lateral and other secondary members.

Steel weighs approximately 490 lb. per cu. ft., or 2 per cent more than wrought iron.

## CHEMICAL COMPOSITION

**Specifications for Structural Steel and Steel Castings.**—The American Society for Testing Materials has adopted standard specifications for steel to be used in various classes of structures. (See *A.S.T.M. Standards*.) Among the items covered are the chemical and physical properties of the material, the methods and methods of tensile and bend tests and the permissible variation in weight and gauge. The preceding tables give the requirements as to chemical composition and tensile properties as given in the Society's specifications for structural steel for bridges and ordinary steel castings (*A.S.T.M. Standards*).

**SPECIAL OR ALLOY STEELS.**—The more usual forms of special steels and their uses, composition and general characteristics are as follows:

**Nickel Steel.**—Steel containing a considerable percentage of nickel, but not more than 3½ per cent, is called nickel steel. This steel has a higher strength and a higher elastic limit than carbon steel, and practically the same modulus of elasticity; it is more ductile in proportion to its strength and is harder than carbon steel of like properties, it is more expensive because of the cost of the nickel, and the additional cost of working. Nickel steel has been used considerably in recent years for bridges of large size, for steamer and automobile parts, etc.

**Low Expansion Steel.**—This is a nickel steel containing about 36 per cent of nickel. Its coefficient of expansion is practically zero. It is used in making steel tapes for line measurements in geodetic surveying.

**Manganese Steel.**—The steel commonly known as manganese steel contains from 12 per cent to 13 per cent of manganese and generally from 1.25 per cent to 2.00 per cent of carbon for castings; for forgings or rolled steel, less is used. It is austenitic in composition and is very hard without brittle fracture, making it well fitted for railroad frogs, railroad rails on curves and burglar-proof safes. It is adapted principally to parts that can be cast, since working with tools is practically impossible and forging is difficult. It is not used for structural work as its elastic limit is so low as to offset the advantage of its high strength. Like nickel, the manganese interferes with the transformation of austenite to pearlite during cooling. It is often called "Hadfield" steel from the name of its inventor.

**Chrome Steels.**—Steels containing from 1 per cent to 2 per cent of chromium are very hard and have a high elastic limit. They are well adapted for armor-plate, projectiles, steel balls, files and automobile gears. Krupp armor plate contains 3.25 per cent nickel, 1.5 per cent chromium and 0.25 per cent carbon.

**Vanadium Steels.**—The addition to steel of a small amount of vanadium, less than 0.3 per cent, adds greatly to the elastic limit, ductility and strength. Vanadium is especially advantageous in increasing strength, toughness and temper of nickel and chromium steels. This steel is particularly useful for springs, axles and automobile parts.

**Alloy Steels.**—The only silicon steels in use contain less than 5 per cent silicon. The alloy recommended by Hadfield, its patentee, contains 2.75 per cent silicon with the smallest possible amounts of carbon, manganese and other elements. Such steel has a greater magnetic permeability than the purest iron and also a high electrical resistance. Its magnetic hysteresis is low. It is a valuable material for use in electromagnetic and in electrical generating machinery. See *Magnetic Properties of Iron*.

**Quenched Steels.**—These steels have the property of becoming martensitic on cooling to a high temperature and air cooling and are said to be "self-

hardening." Such steels are used for springs, magnets and with manganese added for self-hardening tools. See also *High-speed Steels and Magnetic Steels*, below.

**Self-hardening Steels.** — Steel which is hard without tempering and cannot be annealed by known processes is called self-hardening steel. All such steels are non-magnetic. Any steel which is in an austenitic condition at atmospheric temperature is self-hardening. (See *Mushet Steel*, below.)

**Ternary and Quaternary Steels.** — These are steels consisting of three or four essential components, viz., iron, carbon and one or two alloys. Some of the more important ternary steels are nickel steel, manganese steel, chrome steel, tungsten steel and silicon steel. Among quaternary steels are nickel-chromium, nickel-manganese, nickel-vanadium, tungsten-chromium, etc. The effect of these various alloys upon carbon steels is very striking and the possibilities are very great.

**Chrome-nickel Steel.** — The chrome-nickel steels in use are pearlitic and contain moderate amounts of carbon, nickel and chromium. Such steel has a high elastic limit combined with high ductility and has greater hardness, resilience and wearing power than carbon steels. It is used in automobile construction and for the manufacture of armor plate.

**Chrome-tungsten Steel.** — Tungsten and chromium have the property of producing a finely martensitic structure in steel when heated to a high temperature and cooled in air. The martensite in this case is so stable that the steel may be heated to a red heat without losing hardness. Such steels are known as "high speed steels" (q.v.).

**High-speed Steels.** — These steels have a finely martensitic structure which is stable up to red heat. They may contain from 0.25 per cent to 1.00 per cent of carbon, from 5 per cent to 25 per cent tungsten, 2 per cent to 10 per cent of chromium and seldom over 0.40 per cent of manganese. Tungsten may be replaced wholly or in part by molybdenum. Steels of this character are of great importance in machine work as tools made from them can be driven without injury until the cutting edge is red hot.

**Mushet Steel.** — This steel contains both tungsten and manganese. It is a self-hardening steel and has been used for many years for tools which make very heavy or deep cuts such as is required for armor plates. The speed allowable is a little greater than for carbon steel, but it lasts a long time without grinding.

**Magnetic Steels.** — Steels containing 4 per cent to 5 per cent of tungsten and from 0.5 per cent to 0.7 per cent of carbon if heated to red heat and quenched in water will retain their magnetism better than carbon steel. The addition of chromium increases the permanency but decreases the magnetic force.

**STEEL MILLS, ELECTRIC DRIVE OF.**—(See also *Flywheels for Load Equalisation; Motors, Industrial Applications of.*) The application of electric motors to steel mill service may be divided in two general classes; 1. that dealing with the application of motor drive to the main rolls, that is to those rolls in which the ingot or billet is reduced in section, and 2. that dealing with the problems of electrifying the numerous other auxiliary machines and devices, such as tables, screw-downs, charging machines, etc.

**MAIN-ROLL APPLICATION.**—The term "mill" is sometimes used to designate a single stand or group of stands, and sometimes to include the main rolls and all auxiliaries involved in the production of a given class of materials. The stands are generally classified according to the arrangement of rolls and method of operation, that is two-high or three-high, the two-high being either reversing or non-reversing, see Fig. 1.

**Reversing and Non-reversing Mills.**—The great majority of rolling mills in this country are of the non-reversing type where the rolls run continuously in one direction. Flywheels are used to equalize the input to the motor. The ideal combination would be to use a motor of sufficient capacity to carry the average load and a flywheel which would take care of all the peaks. Such a wheel would be too large and a compromise between the motor and flywheel must generally be made.

As opposed to the heavy flywheel effect required by the two-high or three-high non-reversing mill, the minimum flywheel effect consistent with the necessary speed and torque is desirable for reversing mills. In order to avoid the reflection of peak loads of these motors back upon the system, it is customary to interpose a flywheel motor-generator set with one or more generators between the power station and the mill. In order to minimize the flywheel effect of the reversing motor, two or more direct-current motors are often mounted on the same shaft and their armatures connected in series. This arrangement renders possible the use of smaller armature diameters with consequent reduction of acceleration losses and also permits the use of a high-voltage generator on the flywheel set. The mill motor is separately excited and perfect speed control is obtained by varying the excitation of the generator on the flywheel set. Direct-current generators can be designed for 2400 volts to give excellent results when operating two 1200-volt motors in series.

**Power Required.**—Rolling mill loads are irregular in the extreme due to the intermittent character of the process. For any particular ingot the motor load consists of periods of heavy duty increasing in length with the length of the metal in the pass, interspersed with periods of friction load only. With a given mill the load varies widely with the difference in the section rolled, differences in temperatures of metal, personal equation of the operator, etc. The practical determination of the power required to roll steel is a matter of elaborate and extensive tests under widely varying conditions. For methods and results see papers in *Bibliography*. The information for predetermining the sizes of motor and flywheel for an installation must cover the following points:

Type of mill; rail, plate, etc.

Diameter and speed of rolls.

Weight of ingot.

Initial and final section.

Number of passes.

Time between passes.

Elongation in each pass and total.

Initial length.

Average and maximum rate of rolling.

Temperature of metal.

Fig. 1. Diagram of Two-high and Three-high Rolls

**Load Curves.**—From these data and a thorough understanding of the many variable factors encountered in steel-mill practice, it is possible to lay out load curves similar to the ones shown in Figs. 2, 3 and 4. From such curves it is then possible to determine the proper size of the motor and the flywheel.

The typical curve shown in Fig. 2 represents a load curve calculated for a two-high single-stand reversing blooming mill in which a 3000-pound ingot is reduced from initial to final section in eleven consecutive passes occurring at 5-second intervals. This curve is characteristic of blooming mills, roughing mills, etc., which in general give the lowest load factor. The work done in horse-power seconds is indicated by the area under the curve. Fig. 3 is representative of a large and mixed class with medium load factor, such as small merchant mills, bar mills, sheet mills, etc. Fig. 4 shows a load factor so high as to be scarcely approximated except in merchant mills with a large number of stands working at full capacity.

In determining the most suitable size of motor for the work indicated by the load curve full consideration must be given to the fact that excessive loads may be encountered at times due to the low temperatures of the metal in the pass, too heavy draft or other causes, and ample margin allowed. Assuming for the moment that by properly combining simultaneous passes on the several stands and the application of a suitable flywheel the load curve has been flattened out as much as appears possible, the question of continuity of service and duration of peaks must be considered to determine whether the limiting feature will be maximum torque or heating. With rolling-mill motors the limiting feature of design is usually torque rather than heating. The motor rating is determined by a consideration of the root-mean-square value of the current for a single cycle, and the frequency and duration of successive cycles.

Fig. 3.

Fig. 4.

**Induction Motors.** — The choice of alternating- or direct-current main rolls must be determined by a careful consideration of several of which are the capacity of individual units, constant, variable or speeds, reversing or non-reversing, transmission distance, existing equipment, etc.

It is generally conceded that for large units and constant speed, constant-load induction motors with phase-wound rotors possess many advantages over direct-current motors. This is due to the ruggedness of construction and ease of operation of the induction motor, and to the facility with which the current may be stepped up to any desired voltage, thus rendering the method of economic power distribution relatively simple.

In those main-roll drives where it is essential that close regulation be maintained over a large number of speeds, each constant under varying loads, a direct-current motor with shunt characteristics has until recently been practically

the only method of obtaining these characteristics by using standard induction motors with phase-wound rotors and speed regulating sets.

The method of obtaining speed control consists in replacing the non-inductive resistance by a compensated commutator machine which may be connected either on the shaft of the main motor, or more commonly as one part of a two-unit motor-generator set, in which latter case, the second unit is a squirrel-cage induction motor. The speed of the motor driving the generator may be varied both above and below synchronism. When operating below synchronism, the commutator machine acts as a motor and drives the generator slightly above synchronism, thus returning to the line energy equal to the slip of the main motor minus the losses in the regulating set. When the main motor is operated above synchronism, the induction motor acts as a motor and drives the commutator machine as a generator which returns power to the slip-ring circuit of the mill motor.

**Equipment for Induction Motors.** — The control for large steel mills is important because of the size of the apparatus involved and the importance of continuous operation. Most motors for main-roll drives are started up at the beginning of a shift, immediately brought up to full speed, and running until the end of the shift. Provision must be made for running the motor at reduced speed when desired, for making adjustments to the mill, and for reversing, in order to back out ingots which have stuck in the mill. If a motor is used, there should also be provision for quick stopping, so that if a motor is broken, the motor can be brought to rest quickly and a new spindle can be changed without delay. Current-limiting relays are desirable in order to prevent fluctuations in input during starting and to maintain an approximately constant torque without depending upon the intelligence of the operator. For service magnetically-operated contactors are necessary. It is always well to have some device by which the motor can be shut down from a mill in case of accident.

**Resistors for Starting Rheostats.** — The resistance should be liberal, and the control may often be held on the first point for some time when starts are being made and the starting torque may sometimes be heavy, especially when an ingot has stuck in the rolls. Also, where a flywheel is used, acceleration is necessarily slow, and some mills, particularly cold rolls, require a very heavy torque during starting and until they have warmed up. Rheostats should always be furnished having at least enough capacity to provide full-load torque for two minutes. In special cases more will be required.

**Contactors and Oil Switches.** — Where 440- or 550-volt alternating current is used, contactors can be employed for both primary and secondary, and the control is an easy matter. 2200- or 6600-volt motors require oil

switches in the primary, which cannot be operated readily under load. They can be operated with direct current from the system and makes the operation of the alternating-current motor upon the direct-current supply. As remote control is not used in the majority of cases, hand-operated oil switches can be used.

**Control Systems.** — Figs. 5 and 6 show two examples of double-range speed-regulating equipments. Fig. 5 shows the main mill motor when used with a speed regulating set. This set consists of an induction machine and a polyphase, commutator regulating machine with shunt-field excitation. The slip rings of the main induction motor are connected to the shunt winding of this regulating machine so that its counter electromotive force opposes the voltage of the main motor. The slip-ring voltage of the induction motor follows the variation in counter electromotive force of the regulating machine produced by changes in its shunt excitation. The shunt characteristics of the regulating machine are reflected in the speed-torque characteristics of the induction motor which is similar to that of the well-known shunt direct-current motor. The slip energy of the induction motor is conserved by converting it through the induction generator (shown in the diagram) into power and returning it to the power lines. Another arrangement (shown in the diagram) consists of mounting the polyphase regulating machine on the main-roll shaft and thus convert this slip energy into mechanical power.

In addition to the regulating set there is required a synchronous ohmic-drop exciter. Its armature is mounted on the main-roll shaft and its speed is always the same as that of the main motor. This synchronous ohmic-drop exciter to supply the ohmic-drop component of the regulating machine when operating at or near synchronism. This field of the regulating machine also received excitation from the synchronous exciter. This transformer supplies the necessary reactive power of which is greatest at speeds remote from synchronism. The use of synchronous excitation has made possible the development of a speed-regulating set for the main motor that retains all the desirable characteristics of a synchronous motor operated with short-circuited slip rings, not only at speeds well below synchronism but equally well at speeds near synchronism and above synchronism.

Fig. 6 shows the arrangement in the synchronous speed-regulating set where the slip energy is converted into direct current through a synchronous converter and in turn, into mechanical power by a direct-current motor mounted on the main-roll shaft. The arrangement shown in Fig. 5 is superior over the rotary converter method, such as greater stability of speed, when the motor is operating near synchronism, higher efficiency,

Fig. 5. Double-range Speed-Regulating Equipment

cases) and ability to operate non-regulating at an intermediate speed, typically at synchronism.

Fig. 6. Rotary Converter Speed Regulating Equipment.

Direct-current Motors are used only on low-voltage circuits, usually 250 volts, and can be handled by contactors. Quick stops can be accomplished with direct-current motors by dynamic braking, by which the armature is disconnected from the line and connected across a resistance so that the motor becomes a generator. Where flywheels are used, compound motors are necessary in order to provide automatic reduction in speed as the load increases.

**Characteristics of Gary Equipment.**—The characteristics of the main drive equipment for the rail, billet, and sheet-bar mills of the Indiana Steel Company, Gary, Indiana, are given in the table on page 1508.

**AUXILIARY MOTOR APPLICATIONS.**—The application of electric drive to auxiliary steel-mill machinery has been used for a long time. The nature of this service is unusually severe and has led to the development of a special type of motor for both d-c. and a-c. service. These motors are designed to withstand heavy overloads and abnormally rapid acceleration, and their construction is such that various parts are interchangeable, which greatly facilitates repairs and minimizes the delays incident to the same.

**A-c. versus Mixed System.**—Whether a-c. or d-c. motors should be used for driving the auxiliary machinery in a steel mill is a problem which has been seriously discussed, and has led to the use of two recognized systems. One is known as the all a-c. system, where no direct current is used, and the other is the mixed system, where both a-c. and d-c. motors are used.

In making a choice, many factors must be considered in comparing the two systems. In general, it is to be assumed that power will primarily be alternating current. Where transmission distances ordinarily preclude the use of direct-current

generators. It would therefore seem to be simplest and down to a suitable voltage through static transformer current motors. On the other hand, with certain of the screw-downs, live-roll tables, etc., the advantages in favor of the motor-generator sets are so great that they are almost universally adopted. The additional expense for motor-generator sets and entailed loss due to the low efficiency of conversion. On the other hand, the maintenance of motor-generator sets is lower in first cost than induction motors and is maintained on the entire system where they are used. The increase in power factor is effected by eliminating the induction motors, and, in addition, the motor-generator with synchronous motors which will take a leading current offset part of the lagging current on the rest of the system. The power factor enables a reduction to be made in the size and number of generators, and also increases their efficiency due to the fact that they are required to handle and to the decreased excitation of the generators.

**ERS, MECHANICAL.** — (*See also Boilers.*) Mechanical stokers have a twofold purpose: they make possible a more uniform and a more complete combustion of the fuel and thereby prevent the formation of smoke, and to reduce the amount of labor required in handling and firing the fuel. For the prevention of smoke a fire-brick arch should also be used over a part of the furnace.

**CLASSIFICATION OF STOKERS.** — There are three general types of mechanical stokers although there are several which cannot be conveniently placed in any one of these classes.

**Chain-grate Stoker.** — The first is the chain-grate stoker consisting of a chain of grate bars placed in the furnace of the boiler with its top side revolving from the front of the furnace toward the back. The coal is fed onto this grate in front and is burned as it passes toward the bridge wall, where, as the grate is moving at its proper speed, the coal will have been completely burned to ash which will drop down into the ashpit below.

The great advantage of the chain-grate stoker over most of the others is that it is suitable for burning with natural draft bituminous coals of very high volatile content. In plants where the load is reasonably steady and where accidents are not thrown upon the boilers this stoker makes a first-class boiler.

**Overfeed Type.** — The second type of stoker is the inclined grate type. These stokers consist of movable bars forming an inclined grate with a mechanism for moving these bars in such a manner as to cause the coal to be fed in at the top to be pushed gradually down the grate until it reaches the dumping grate at the bottom, at which point it should be completely burned.

**Underfeed Type.** — The third type is the underfeed. In these stokers the coal is fed onto the grate or up under the grate in such a manner that the fresh coal is always close to the grate while the coal which is being burned is at the top. The air is also introduced at the bottom and while passing up through the bed of coal is heated and thoroughly mixed with the volatile gases distilled from the coal and when passing through the incandescent layer at the top reaches the temperature of combustion, so that generally no arches are necessary.

**Other Types.** — There are several other stokers which are used to a greater extent and work on somewhat different principles, perhaps the most common being the so-called "finger" stoker, which has several oscillating paddles which pick up the coal and throw it into the furnace. There is another stoker of this order in which the coal is mechanically shovelled into the furnace. These stokers, however, have not reached any extensive application and in general are only applicable to particular conditions.

**SAVING BY USE OF MECHANICAL STOKERS.** — The difference between good and bad firing may easily amount to from 5 to 20 per cent of the fuel fired; hence, there is no investment around a steam plant which will pay better than the extra amount paid to secure good boiler practice.

Mechanical stokers are now developed to a remarkable degree of perfection, and, when suited to the fuel, have an advantage over hand-firing in that under ordinary conditions they are reliable, can be adjusted to the minimum of the air and fuel, and can be depended upon to operate continuously with a minimum amount of skilled labor. The economic saving will depend on a comparison of the method of operation. Compared with an ordinary fireman, they should show a large saving. Whether a stoker will

save labor in the fire room depends upon the size of mechanical stokers are not labor-saving devices in plants six to eight boilers (1500 to 4800 h.p.).

One man can handle the coal and ashes, fire the boiler, and maintain the water level of 700 h.p. of boilers equipped with the common chain-grate. With shaking or dumping grates 300 h.p. may be controlled by one man. Large boilers equipped with dumping grates one man will control 1000 h.p., when using the steam sizes of anthracite coal, but the stoker is in front of the boiler and a water tender is usually provided. With soft coal about 700 boiler h.p. may be fired by one man in some circumstances. In a large plant containing twelve 650 B. & O. boilers with stokers, a water tender, one fireman and one helper are usually provided for their efficient operation. In stations of this size the stoker is in the basement, and the change from hand to stoker firing will be made in their number.

One authority states that stokers save 30 to 40 per cent in plants using over 200 tons of coal per week; 20 to 30 per cent in plants using from 50 to 200 tons of coal per week, and no saving in plants using less than 50 tons per week.

It should be remembered that unless the type of stoker is adapted to the type of fuel obtainable, the maintenance of the stoker plant will be high, running in some cases twice or three times as high as under hand-fired conditions.

**COST OF MECHANICAL STOKERS** (Pre-war prices) — Mechanical stokers cost from \$3.50 to \$6.50 per boiler h.p. The cost depends more on the width of the stoker than on the h.p. Chain-grate stokers cost in the neighborhood of from \$100 to \$150 per foot of width. Inclined-grate stokers from \$140 to \$225 per foot of width. Dumping-grate stokers from \$200 to \$300 per foot of width. The cost of the stoker is usually standard and depends on the type of coal to be burned. The cost of the stoker differs considerably with the amount of auxiliary material required for the stoker, such as fronts, air boxes, coking arches, stoker rollers, etc. The cost of the stoker is based on labor and material cost prior to the European war.

R. J. S. Pigott (*Proceedings Am. Elec. Ry Assoc.*, 1914) gives the following data for mechanical stokers:

## AVERAGE DATA FOR STOKERS

Type of stoker	Step and slope overfeed	V overfeed	Chain overfeed	Gravity underfeed	Horizontal retort underfeed
Average price per rated b.h.p. . . .	\$3.60	\$3.60	\$3.50-\$6.55	\$5.65	\$4.44
Normal forcing ability in per cent of rating. . .	190	175	260	300-350	300

**BIBLIOGRAPHY.**—Carpenter and Diederichs, *Experimental Engineering, Report of Committee on Power Tests*, A.S.M.E.

**STRENGTH AND ELASTICITY.**—(See also *Buildings, Allowable Unit Stresses in; Mechanics, Principles of; Structures, Simple.*) When opposing external forces are applied to a body the latter is in general deformed more or less, and, in the case of solids, when the applied forces are increased sufficiently the body ruptures.

**STRESSES.**—A stress is the internal resisting force set up within a body opposing the external forces which tend to deform it. When the external forces cause a stretching of the body the stress is called a tension; when the external forces compress the body the stress is called a compression; when the external forces cause a relative slipping of the particles in two contiguous parallel planes in the body the stress is called a shear.

**Unit Stress.**—By unit stress is meant the stress per unit area; in the case of tension or compression the area is taken perpendicular to the line of action of the forces producing the stress; in the case of shear the area is taken parallel to the forces producing the stress. Unless otherwise stated the stress is assumed uniformly distributed over the area upon which it acts.

**Ultimate Stress or Ultimate Strength.**—The ultimate stress which a body will stand, or the ultimate strength of the body, is the greatest stress which can be produced in the body without rupturing it. Ultimate strength for tension and compression are usually quite different; the former is usually called tensile strength and the latter compressional strength. The ultimate strength of materials is usually specified in terms of the stress per unit area; see *Units and Conversion Factors*.

**DEFORMATIONS OR STRAINS.**—The deformation accompanying any stress is usually called a strain. The strain corresponding to a tension is called an elongation, the strain corresponding to a compression is a shortening, the strain corresponding to a shear is called a detrusion. An elongation is usually specified as the ratio (or percentage) of the increase in length to the original length of the specimen. For example, if a rod 10 feet long is stretched by an applied force to a length of 10.2 feet, the elongation is  $(10.2-10)/10 = 0.02$  or 2 per cent. The term elongation is frequently used to designate specifically the *maximum* elongation just before rupture.

**Hooke's Law.**—Experiment shows that when the unit stress in a body does not exceed a certain value it bears a constant ratio to the resulting unit strain (ratio of change in size to original size). This fact is known as Hooke's Law. In the case of a tension the change in size is usually taken as the change in length, no attention being paid to the decrease in cross-section, which is usually negligible, except just before rupture.

**ELASTICITY.**—A body deformed under stress will return to its original shape when the stress is removed, provided it has not been strained beyond the point at which the proportionality between stress and strain ceases. This ability to return to its original form after deformation is called elasticity.

**Elastic Limit.**—The stress per unit area corresponding to the point at which the proportionality between stress and strain ceases is called the elastic limit of the material.

**Permanent Set.**—When a body is stressed beyond its elastic limit, the deformation per unit increase in stress becomes greater than it was before this point was reached, and the material takes a permanent "set," i.e., when the stress is removed the body does not return to exactly its original form. As a measure of the "set" is taken the ratio of the permanent change in size (after the stress is removed) to the original size.

**Modulus of Elasticity.**— Let  $\Delta F$  denote the change in the total tension producing a change  $\Delta l$  in a rod of length  $l$  and cross section  $A$ ; then the quotient of the increase in the unit stress by the increase in the elongation per unit length, is called the modulus of elasticity (Young's modulus) of the material, and may be designated by the symbol  $M$ , i. e.,

$$M = \frac{\Delta F}{\Delta l} \cdot \frac{l}{A}.$$

This modulus has the dimensions of pounds per square inch.

**VALUES OF TENSILE STRENGTH AND MODULUS OF ELASTICITY.**— Values of these properties given by different authorities are extremely variable, since the measured values depend largely upon the chemical composition, heat treatment, age, size and shape of the test specimen.

**Alloys, Miscellaneous.**— See articles on *Alloys and Wires, Resistance*.

**Aluminum.**— See article on *Aluminum*.

**Baiting.**— Tensile strength, in pounds per square inch: Cotton, 4500 to 8900; Single leather, 3200 to 5900; Double leather, 2200 to 5400. See also article on *Belts and Belling*.

**Brass Wire.**— Tensile strength ranges from about 50,000 to 150,000 pounds per square inch; modulus of elasticity is about  $14 \times 10^6$  pounds per square inch.

**Brick.**— See article on *Bricks and Brick Masonry*.

**Bronze Wire.**— The tensile strength of phosphor-bronze wire ranges from about 44,000 to 140,000 pounds per square inch; of silicon-bronze wire, from 95,000 to 115,000 pounds per square inch.

**Copper.**— See articles on *Copper and Wires and Cables, Bare*.

**Earth.**— See *Soils*, below.

**Glass.**— Tensile strength of common green or of flint glass ranges from about 2500 to 5000 pounds per square inch. Modulus of elasticity ranges from about  $8.5 \times 10^6$  to  $11.5 \times 10^6$ .

The crushing or compressive strength of glass ranges from about 13,000 to 40,000 pounds per square inch.

**Granite.**— Crushing or compressive strength ranges from about 9700 to 34,000 pounds per square inch.

**Iron.**— See articles on *Iron, Pig and Cast, and Iron, Wrought*.

**Lead.**— Tensile strength ranges from about 2600 to 3300 pounds per square inch.

**Limestone.**— Crushing or compressive strength ranges from about 6000 to 25,000 pounds per square inch.

**Marble.**— Crushing or compressive strength ranges from about 7500 to 21,000 pounds per square inch.

**Nickel.**— Tensile strength of cast nickel ranges from about 40,000 to 85,000 pounds per square inch, and tensile strength of annealed nickel ranges from about 70,000 to 95,000 pounds per square inch. Modulus of elasticity ranges from about  $24 \times 10^6$  to  $27 \times 10^6$  pounds per square inch.

**Rope.**— See *Ropes and Rope Drive*.

**Soils.**— See articles on *Power Stations, Hydroelectric, and Buildings, Allowable Unit Stresses in*.

**Steel.** — Tensile strength in pounds per square inch:

Bessemer:	56,000 to 74,000,	Open-hearth:	50,000 to 70,000,
Cast:	67,000 to 106,000,	Wire:	50,000 to 100,000.

Modulus of elasticity of various kinds of steels usually  $29 \times 10^6$  and  $35 \times 10^6$  pounds per square inch. See also articles *Cables, Bars*.

**Timber.** — See articles on *Timber* and *Poles for Overhead Lines*.

**Tin.** — Tensile strength ranges from about 4000 to 10,000 pounds per square inch; modulus of elasticity from about  $2.5 \times 10^6$  to  $6 \times 10^6$  pounds per square inch.

**Zinc.** — Tensile strength ranges from about 7000 to 10,000 pounds per square inch; modulus of elasticity is about  $12 \times 10^6$  pounds per square inch.

**Wood.** — See *Timber*, above.

**STRUCTURES, SIMPLE.** — (See also *Building Laws; Cement; Concrete; Mechanics, Principles of; Steel; Timber; Towers for Transmission Lines.*) The term in the sense used by engineers is a member or combination of members constructed to hold forces in equilibrium. The common structures are beams, columns and trusses.

The outline of the contents of this article is as follows:

Definitions and Fundamental Relations.....	p. 1515
Properties of Plane Sections.....	1518

Beams, Formulas and Costs.....	1539
Design of.....	1550
Continuous Girders, Beams, Slabs and Trusses.....	1555

**DEFINITIONS AND FUNDAMENTAL RELATIONS.** — The more important terms used in the treatment of structures are defined below.

**Center of Gravity; Moment of Inertia; Radius of Gyration; Stress and Strain.** See *Mechanics, Principles of.*

**Neutral Axis.** — The neutral axis of the cross-section of a stressed bar is that line of those points in the plane of the cross-section at which the direct stress equals zero. If the bar is of homogeneous material and subjected to a single load (see *Bending Moment, below*) only, the neutral axis passes through the center of gravity of the cross-section, and if the loads causing flexure are applied in the plane of one of the principal axes, the neutral axis coincides with one of the principal axes. This is the condition commonly occurring in wooden beams. Table I which follows gives the location of the neutral axis for various cross-sections. If the cross-section is subjected to combined flexure and direct stress, the neutral axis will not pass through its center of gravity, but will deviate from it an amount depending upon the ratio of bending moment to direct stress, becoming infinite when the stress is direct tension or compression only, as in the case of a tie rod or column centrally loaded.

In the case of an unhomogeneous material the position of the neutral axis is determined by calculation. The reinforced concrete beam is the only example of such a case. For formulas for this case, see *Concrete,*

**Section Modulus.** — If  $c$  is the normal distance from the neutral axis of a beam to the most remote portion of its perimeter, and  $I$  the moment of inertia of the surface about its neutral axis the expression  $I/c$  is called the section modulus. For symmetrical beams exposed to pure flexure only,  $c$  = one-half the depth of the beam. Tabular values of this quantity for plane surfaces of various shapes are given in Table I and for the ordinary structural steel beams in Tables II to VI, which follow.

**Moment of Resistance.** — If  $s$  is the allowable unit stress per square inch at the extreme fiber of a beam or girder, the expression  $\frac{sI}{c}$  is called the moment of resistance since its value equals the maximum bending moment which the member can carry without causing a stress greater than the allowable unit stress.

**Statical Moment.** — The statical moment of a plane surface about a given point in the plane is the summation of the products of each elementary area,

$dA$ , of which the surface is composed, times the distance from the given axis, distances above the axis being considered positive and below negative. It may be expressed mathematically as follows: (See Fig. 1.)

Let  $Q$  = statical moment of a given area about an axis  $Y-Y$  lying in the plane of the area,

$dA$  = an elementary area,

$y$  = distance of center of gravity of the area from the axis,

$$\text{then } Q = \int ydA.$$

The statical moment of an area about an axis of symmetry is zero since the positive lever arm of any elementary area is counterbalanced by the corresponding negative lever arm.

**Equations of Equilibrium.** — (See also *Mechanics*.) The following laws apply to a structure lying in a plane and supported in the same plane:

- 1st. The algebraic sum of the components of all the forces acting on the structure to any axis in the plane of the forces must equal zero.
- 2nd. The algebraic sum of the moments of all the forces about any axis perpendicular to the plane of the forces must equal zero.

If we resolve the applied forces into components parallel to the axes  $OX$  and  $OY$ , and let  $\Sigma X$  and  $\Sigma Y$  equal the algebraic sum of the components parallel respectively to  $OX$  and  $OY$ , and  $\Sigma M$  the algebraic sum of the moments about any axis normal to the plane of the forces, these conditions may be comprehended by the three equations:

$$\Sigma X = 0, \Sigma Y = 0, \Sigma M = 0.$$

If  $OX$  and  $OY$  are respectively horizontal and vertical axes, the above equations take the generally used form:

$$\Sigma H = 0, \Sigma V = 0, \Sigma M = 0.$$

Unless a structure satisfies all these conditions it cannot be in equilibrium.

**Reactions.** — The forces which the abutments or piercings exert on a structure, such as beams, girders or trusses, are called the reactions. In general, there are three unknown factors, viz., direction, magnitude and point of application. In order to simplify computations it is customary to assume that the reactions on trusses to eliminate three of these unknowns by the method of joints. In the case of beams and long girders, the ends are supported by pins of comparatively small diameter thereby fixing the point of application of the reactions. Moreover, the pin at one end is in turn supported by a roller thereby making that reaction normal, or nearly so, to its surface, thus fixing the direction of one of the reactions. These refinements are not applied to short girders the ends of which are supported by piercings. Even in such cases, however, the point of application of the reactions is assumed to be at comparatively small limits, and the base plate at one end is assumed to be of such a size as to thus making the reaction at that end approximately normal to its surface. For ordinary beams no special provision is made for the reactions but each reaction is assumed to be normal to the surface and to act at its center.

When the unknown reaction factors are thus reduced to three, the reactions may be determined by the three equations of equilibrium. This is the usual procedure in the case of beams on two supports. For beams supported at more than two points, the reactions may be determined by the same method (see below) may be applied.

**Moment Equation.** — This is an equation connecting the moments adjoining points of support of a continuous structure. It is strictly true only to structures having a constant moment of inertia and on level ground but is applied approximately to structures the moment of inertia of which is not constant.

The formula for concentrated loads is as follows:

$M_c$  = moment at any support,

$M_a$  = moment at adjoining support on left,

$M_b$  = moment at adjoining support on right,

$L_1$  = length of span to left of support at which  $M_c$  acts,

$L_2$  = length of span to right of support at which  $M_c$  acts,

$P_1$  = any load in span  $L_1$  and  $k_1 L_1$  its distance from left support,

$P_2$  = any load in span  $L_2$  and  $k_2 L_2$  its distance from support at left of that span.

$$-2 M_c(L_1 + L_2) + M_b L_2 = \Sigma P_1 L_1^2 (k_1^2 - k_1) + \Sigma P_2 L_2^2 (3 k_2^2 - k_2^2 - 2 k_2).$$

If a uniform load of  $w_1$  lb. per ft. over span  $L_1$  and  $w_2$  lb. per ft. over span  $L_2$  is applied, the following formula becomes

$$M_a L_1 + 2 M_c(L_1 + L_2) + M_b L_2 = -\frac{1}{4} w_1 L_1^3 - \frac{1}{4} w_2 L_2^3.$$

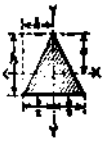

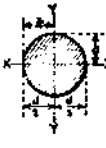

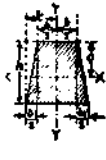

The application of these formulas to successive series of spans enables the moments at all supports to be computed and from these the reactions and shears can be determined, and the structure completely solved; see section below on *Design of*.

**Shearing Force or Shear.** — The shearing force or shear at any section of a body is the force which tends to produce slipping along the given section. Shearing failure may be due either to transverse fracture or to slipping of the fibers on each other. In ordinary structural materials wood is the only one of fibrous character in which shearing failure in this material frequently occurs on planes parallel to the grain.

**Bending Moment; Flexure.** — The bending moment at any section of a body due to a set of coplanar forces is the resultant moment about an axis passing through the center of gravity of the section of all the forces on either side of the section, it being understood that the section and the axis are perpendicular to the plane of the forces. Fractures due to excessive bending moment are usually longitudinal failure of the fibers either by tension or crushing. The bending which results from the application of a bending moment is termed *flexure*.

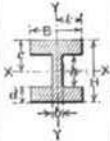

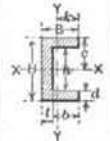

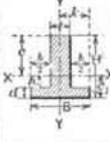

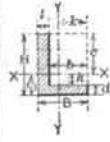

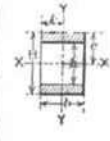

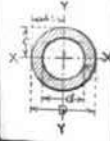

**Dead and Live Loads.** — The loads acting upon a given structure may be divided into two distinct types: viz., quiescent loads which are known as *dead loads* and moving or intermittent loads which are known as *live loads*. The first class includes all loads which are fixed in magnitude and position such as the weight of the structure itself and such superimposed loads as the floor of a building or bridge; the second class includes such loads as crowds of people, ice, snow, wind and vehicles of all sorts. The live load through its magnitude and irregularity of application is more injurious in its effect than the dead load, hence in a structure subjected to live loads, either the value of the allowable unit stress in the material should be increased as explained below under *Allowances for Impact*, or the allowable unit stress in the material should be reduced. The former method seems to be more logical and is commonly adopted at the present time by structural engineers.

TABLE I.—PROPERTIES

**Impact** is the name given to the dynamic force which is added to the forces due to live and dead loads to obtain the true forces acting upon structures; see section below on *Allowances for Impact*.

**Beam or Girder.**—A beam is a bar of wood, metal, concrete or other stress-resisting substance supported at certain definite points along its length and loaded transversely to its longitudinal axis, which is usually but not always placed in a horizontal position. The name girder is commonly applied to large beams built up of structural members; for example, a plate girder is a steel or iron structure made up of plates and angles, or other structural shapes, riveted together.

**Floor Beam; Panel.**—Frequently girders and trusses receive all their live load and much of their dead load through other members called floor beams. Fig. 2 illustrates such construction. The distance between adjacent floor beams is the panel length.

**Column.**—A column is a member intended primarily to resist direct compression, although it may also be subjected to bending stresses due either to transverse loads or to eccentric application of the direct loads.

**Truss.**—A truss is a structure consisting of separate bars constructed to carry either direct tension or direct compression. These bars are connected at their ends and occasionally

at intermediate points, the points of connection being called joints. The connections are sometimes made by riveting the bars directly together and sometimes by riveting them to a common steel plate, the truss in either case being called a *riveted truss*. The connections may also be made by fastening together with a large steel pin all the members meeting at a joint; such a truss is called a *pin truss*. The outer forces should be applied at the joints only, since the members are not intended to carry bending. This is accomplished by the use of floor beams in a bridge and purlins in a roof.

**PROPERTIES OF PLANE SECTIONS.**—In Table I are given the location of the center of gravity, and values of the moment of inertia, section modulus and radii of gyration of the more common plane sections.

Fig. 2.

**ES OF STRUCTURAL SHAPES.**—Tables II to VI give the dimensions and properties of the commonly used shapes of structural steel; sheared plates, angles with either equal or unequal legs, I-beams, and

For information upon other metallic structural material see the dimensions of the various steel manufacturing companies,

From Cambria Steel, George E. Shackray, Engineer, 1919.

\* Divide by span in feet to determine total allowable dead load in pounds, including weight of beam, uniformly distributed over length of beam. Table is based upon a fiber stress of 16,000 lb. per sq. in. For allowable live and dead load reduce load as determined from table by amount of impact. Compression flange should be supported laterally at intervals not greater than 20 times its width. If this cannot be done reduce coefficients to one-half of above value where unsupported length divided by width = 70, and proportionally for intermediate values between 20 and 70.

(s) Weights revised Sept. 1, 1920.

man in feet to determine total allowable dead load in pounds, including uniformly distributed over length of beam. Table is based upon a 1000 lb. per sq. in. For allowable live and dead load reduce load as applicable by amount of impact. Compression flange should be supported unless not greater than 20 times its width. If this cannot be done refer to one-half of above value where unsupported length divided by proportionally for intermediate values between 20 and 70.  
Revised Sept. 1, 1920.

**RES FOR IMPACT.** — The force applied to a structure by a train as a locomotive or electric car is a function of its weight and acceleration. The value of the former can usually be determined with a degree of accuracy; the effect of the latter cannot in general

From Cambria Steel, George B. Thackray, E.  
(a) Weights revised Sept. 1, 1920.

mined since it depends upon such uncertain factors as rapidity of irregularity of track, improper counterbalancing of locomotive driving action of crowds of people and similar causes. The allowance (so-called) ranges from 0 to 100 per cent of the live load and is fixed by empirical rules as indicated in the formulas below. An exception is made in the case of timber structures where the effect of impact is commonly allowed for by using a low unit stress. (See *Timber*.)

**on Buildings.** — No allowance is generally made for impact on buildings except with special loadings such as moving machinery, swinging cranes, for which the designer should use his judgment. The building laws of most cities fix arbitrary loads and unit stresses by which the designer is governed; see article on *Buildings, Allowable Unit Stresses in*.

**on Highway Bridges Carrying Electric Railways.** — The following is extracted from the *Specifications for Bridges Carrying Electric Railways* of the Massachusetts Public Service Commission (revised March, 1915), which is commonly used for such cases:

The total maximum stress in any piece shall be computed by adding together the dead and live stresses, the live loads being placed in the most unfavorable position together with a percentage of the live stress to allow for impact and vibration. This added percentage shall be as follows:

for trucks.	
for stringers, floor beams hangers and truss members receiving their whole load from one panel point only . . . . .	50 per cent
for other live loads:	
for wood flooring and wood stringers . . . . .	no impact
for floor beams and stringers . . . . .	25 per cent
for floor beam hangers . . . . .	40 per cent
for floor counters . . . . .	40 per cent

For members in trusses, and for main girders, the percentage shall be one-twelfth the loaded length in feet with a maximum of 25 and a minimum of 10 per cent."

**on Steam Railroad Bridges.** — The following rule of the American Railway Engineering and Maintenance of Way Association is commonly used in the United States:

A dynamic increment of the live load shall be added to the maximum computed strains\* and shall be determined by the formula  $I = S \frac{300}{L + 300}$

where  $I$  = impact or dynamic increment to be added to live-load strains,

$S$  = computed maximum live-load strain,

$L$  = loaded length of track in feet producing the maximum strain in the member.

For bridges carrying more than one track, the aggregate length of all tracks shall be used. Impact shall not be added to strains produced by longitudinal, centrifugal and lateral or wind forces."

**ANALYSIS OF REACTIONS.** — The reactions upon a truss, girder or beam acting in a plane and acted upon by forces lying in the same plane may be determined by the application of the equations of equilibrium (see preceding article) provided there are but two reactions which together have three unknowns; such a structure is said to be statically determined. If more than two reaction components exist the reactions cannot be computed by the method of equilibrium; the structure, although stable, is statically undetermined; if less than two reaction components exist the structure is statically undetermined; if less than

\*As here used means stresses in the more modern meaning of the word.

three exist the structure is unstable. If the structure is supported at more than two points it cannot be made statically determined except by the insertion in the structure of special devices, such as hinged joints. The tower shown in Fig. 3 is statically determined with respect to the outer forces since the points of application of the reactions at *a* and *b* are fixed in position, and the reaction at *b* is also fixed in direction. If neither of the reactions were fixed in direction the structure would be indeterminate; if both of the reactions were fixed in direction the tower would be unstable, e.g., if both ends were on rollers and neither end bolted to the masonry.

Such towers when used for transmission lines are seldom built with rollers or even planed plates, and frequently the bottoms of the columns are imbedded in a concrete base, the latter condition making it impossible to accurately compute the reactions. Similar towers for railroad and highway bridges are usually made determinate.

Fig. 3.

**Method of Computation.** — The following example illustrates the analytical method of computing reactions on statically determinate structures. The method may be applied equally well to uniformly distributed loads provided the resultants of such loads are used in place of concentrated loads.

*To Compute the Reactions on Truss Shown in Fig. 4.* — Let  $V_L$  = left reaction, and  $V_R$  and  $H_R$  = the components of the right reaction, the direction of which is unknown.  $V_L$  will be vertical since it is supported on rollers bearing on a horizontal surface.  $V_R$  and  $H_R$  may be assumed to act in either direction. A negative sign in the final result indicates that the force acts in the opposite direction to that assumed. The determination of the reactions by the application of the equations of equilibrium (see above) may be carried out as follows:

1st. Apply  $\Sigma M = 0$  about right end. This gives  $100 V_L + 12,000 \times 15 - 20,000 \times 75 = 0$ . Hence  $V_L = 13,200$  lb.

2nd. Apply  $\Sigma H = 0$ . This gives  $H_R - 12,000 = 0$ . Hence  $H_R = + 12,000$  lb.

3rd. Apply  $\Sigma V = 0$ . This gives  $V_R + 13,200 - 20,000 = 0$ . Hence  $V_R = - 6800$  lb.

In these results a positive sign shows that the reaction acts as indicated in Fig. 4.

**Reactions on Continuous Girders.** — See sections which follow on *Continuous Girders, Beams, Slabs and Trusses*.

**CALCULATION OF SHEAR.** — The nomenclature used in the discussion of shear is as follows:

- $V$  = the total external shear on any section in pounds,  
 $P$  = magnitude of a single concentrated load in pounds,

Fig. 4.

- = a uniform load in pounds per foot,
- = span of beam in feet (distance center to center of supports),
- = length of a panel in feet,
- = distance in feet from a given section to one of the points of support,
- = total number of equal panels into which a girder is divided,
- = number of panels between a given panel and the more remote abutment.

**of Computation.** — The magnitude of the shear at any section of a set of coplanar forces may be readily computed in the following

Resolve each force into components, parallel and perpendicular, respectively to the beam; the algebraic sum of the components parallel to the beam on either side of the section equals the shear. The shear is generally positive when the resultant force is upward on the left side of the section.

**of Shear.** — A curve whose ordinate at any point equals the shear at the given body at the point where the ordinate is drawn.

Fig. 5 shows typical curves of this sort.

**Curves of Shear with Single Concentrated Load and Uniform Load.** — In a simply supported beam, a concentrated load causes a maximum shear at a given section and an infinitesimal distance from the section on the side nearer the more distant point of support. The magnitude of this maximum shear is that of the nearer point of support. A concentrated load placed on one side of either point of support causes this shear to equal the weight of the load itself. A distributed live load causes a maximum shear at a given section placed over the entire span of the section; its magnitude is that of the nearer point of support given by the equation

$V = wL/2$ . Its maximum value equals  $wL/2$  at either end of the beam when fully loaded.

**Simply supported Girders or Trusses with Loads Applied by Floor-Beams.** A concentrated load causes maximum shear in any panel when

Fig. 5. Curves of Shear. Positive results are shown above the axis. Curve shown by full line.

placed at the end of the panel nearer the more remote reaction. The value for equal panels is given by the equation  $V = P_2/n$ . The maximum shear occurs in the end panel and its value for equal panels is  $V = P(n-1)/n$ .

Maximum positive shear in any panel due to uniform load occurs when all panel points to the right are assumed to be loaded with full panel loads, and all panel points to the left are unloaded; its value equals the left reaction. This method is approximate but is on the safe side and is commonly used.

The maximum positive shear occurs in the left panel and for girders with equal panels is given by the formula:

$$V = \frac{wp}{2}(n-1).$$

The same rules are applicable for the maximum negative shear by interchanging left and right in the discussion.

**Computation of Maximum Shear for System of Concentrated Loads.**—The shear at any section of a beam, girder or truss, due to a system of concentrated loads such as wheel loads of a moving crane, electric cars or electric locomotive, equals the algebraic sum of either reaction and the load lying between that reaction and the given section. In case the girder is divided into panels and the shear in a given panel is to be computed, only that portion of the load acting in the panel under consideration which is carried by the floor-beam at the end of the panel nearer the selected reaction should be deducted from its reaction. To determine the position in which a system of concentrated loads should lie to give maximum shear it is often necessary to proceed by trial. The use of the following simple rules may be helpful.

(a) The maximum shear at a given section of a simple beam always occurs with one of the loads at an infinitesimal distance to one side of the section. This load should usually, but not always, be one of the heavier loads of the system; e.g. one of the driving wheels of a locomotive. The proper load may be determined by starting with the first load just to the left of the section and moving the loads to the left until  $\sum \frac{Pa}{L} = P'$ . In this expression  $P =$  any load which may be on the span during the process of moving the loads, and  $a$  is the distance which it is moved.  $P' =$  the load which passes to the left of the section as the loads are moved from one position to another.

(b) The maximum shear in a given panel of a girder always occurs with one of the loads directly over one of the adjoining floor-beams. This load should usually, but not always, be one of the heavier loads.

(c) The position of the loads for maximum positive shear in an intermediate panel may be determined as follows. Place the first load of the system at the right end of the panel and move the system to the left until  $\sum \frac{Pa}{L} = \sum \frac{P_1c_1}{l}$ .

Apply the same criterion to the second load and following loads until the position giving maximum shear is reached. In the above expression,  $P$  and  $a$  are as before,  $P_1 =$  any load which may be at any time in the panel under consideration during the process of moving the loads, and  $c_1 =$  the distance which  $P_1$  may move in the panel.

If no load comes on or goes off the span and if no load passes out of the panel  $a = c_1$  and we may write

$$\sum \frac{P}{L} = \sum \frac{P_1}{l}.$$

It follows that for this case the first load should lie at the panel point unless the average load per foot on the entire span is greater than the first load divided by a panel length, in which case the second load should be tried at the panel point and so on until the position for maximum shear is determined.

the maximum shear in the end panel of a girder equals the maximum at the first panel point divided by the length of the panel. (See section on Moment, below.)

**DEFINITION OF BENDING MOMENT.** — The nomenclature used in the discussion of bending moment is as follows:

- $M$  = external bending moment at any section in foot pounds,
- $P$  = magnitude of a single concentrated load in pounds,
- $w$  = a uniform load in pounds per foot,
- $L$  = span of beam in feet (distance center to center of support),
- $l$  = length of a panel in feet,
- $x$  = distance in feet from a given section to one of the supports,
- $n$  = total number of equal panels into which a given girder is divided.

To determine the magnitude of the bending moment at a section it is necessary to obtain the algebraic sum of the products of every force by its distance from the section. A sign convention commonly made is the consideration of all the forces, except horizontal forces, as positive if they are considered positive when they are clockwise on the left side of the section; it follows that they are also positive if they are counter-clockwise on the right side of the section.

**Diagram of Moments.** — A diagram of moments is a line graph in which the ordinate at any point represents the bending moment on the beam at the section whose abscissa or ordinate is measured. Fig. 6 shows a typical diagram of moment curves.

**Diagram of Moment with Concentrated Load or Uniform Load on Simple End-Supports, Girders and Beams with Single Concentrated Load.** — The maximum bending moment occurs at the section where the load is placed. The following diagram shows its value:

$$\frac{P(L-x)}{L} x.$$

The maximum possible moment occurs when  $x = L/2$  and has the value

For end-supported structures a uniform load causes maximum moment at the section where it covers the entire beam. Its value at any section is

$$M = \frac{wx}{2} (L-x).$$

Fig. 6. Curves of Moments

The maximum possible moment occurs at the center of the span and equals  $wL^2/8$ .

**End-supported Girders or Trusses with Loads Applied by Floor Beams.** — Moments at panel points are exactly the same as moments at corresponding points on simple girders. It is seldom necessary to consider moments between panel points for concentrated loads. For a uniform load the moment between floor-beams varies uniformly; i.e., the moment due to that portion of the load applied through the floor-beams.

The maximum moment due to a concentrated load occurs at the panel point nearest the center with the load at that point. Its value is given by the following equations:

$$\text{For even number of equal panels, } M = \frac{Ppw}{4}$$

$$\text{For odd number of equal panels, } M = \frac{Pp}{4n} (n^2 - 1)$$

The maximum moment due to a uniform load occurs at the panel point nearest the center with load over entire span. Its value is:

$$\text{For even number of equal panels, } M = wL^2/8$$

$$\text{For odd number of equal panels, } M = \frac{1}{8} \left[ wL^2 \left( 1 - \frac{1}{n^2} \right) \right]$$

**Computation of Moment for System of Concentrated Loads.** — The moment at any section due to a system of concentrated loads, such as wheel loads of a moving crane, electric car or electric locomotive equals the algebraic sum of the moments of either reaction and the loads lying between it and the given section, the lever arm for each load being its distance from the section. In case the girder is divided into panels and the section under consideration is at some intermediate point in a panel only that portion of the load applied in this panel which is transmitted to the girder by the floor-beams between it and the reaction used should be considered.

**Determination of Maximum Moment at a Given Section.** — The maximum moment at any section of a simple beam or at any panel point of a girder loaded through floor-beams always occurs with some load at the section (usually one of the heavier loads). This load should be one which when located just to the right of the section makes the average load per foot of all the loads on the span to the right of the section greater than the corresponding average load per foot on the left of the section, and which reverses this condition when placed just to the left of the section. Such loads may be selected by trial; if more than one satisfies this criterion the largest moment must be determined by actual computation.

**Determination of Position of Maximum Moment on a Beam.** — Previous articles deal with maximum moment at a given section. The maximum moment on a beam caused by a system of concentrated loads usually occurs near the center but not at it. The following method may be used to determine the location of the section at which the maximum moment occurs.

(a) Select, by inspection, one of the heavier loads which would probably be located at the center to give the maximum moment at the center.

(b) Determine by inspection the loads which would be on the span when the load is near the center and compute the position of their resultant.

(c) Place the loads on the beam in a position such that the center of the span lies half way between this resultant and the assumed load. If the loads on the span in this position correspond to those assumed under b, the moment at the load should be computed; otherwise, another trial may be made. If more

an one set of loads corresponds to this condition the moment at the load could be computed for both sets of loads.

(d) Apply the same method to any other load which would possibly give maximum moment at the center.

Since the maximum moment at any section always occurs with some load at the section this method if applied to enough loads will give the absolute maximum moment. It is often unnecessary to try more than one load, and seldom more than two. It should be noted that with two equal loads such a distance apart as with one at the center the other will not be on the span, but that with the center of the span midway between the resultant and one of the loads both will be on the span, the maximum moment may possibly occur with either condition, both of which should be investigated.

**BEAMS; FORMULAS AND COSTS.** — The effect of the external forces on any cross-section of a simple beam is to cause bending moment and shear, the former usually being the predominant factor in determining the size of the beam. If the beam is subjected to axial forces as well as transverse forces, it becomes a combination of beam and column, or beam and tie, and can no longer be considered as a simple beam. If a beam has an end which

Fig. 7.

objects beyond its adjoining point of support, it is called a *cantilever beam*, the over-hanging end forming the cantilever portion. A beam supported at more than two points of support is a *continuous beam*. A beam having one or both ends rigidly fixed either by being built into a wall, or by being fastened to another member is called a *fixed ended beam*. Fig. 7 represents all of these types.

**Beam Formulas for Ordinary Cases.** — As a preliminary step in the design of beams, it is necessary to determine the maximum value of the external bending moments, shears and reactions on the beam by the methods given in the sections above which deal with these subjects inclusive. With these items determined, the following formulas of mechanics (see *Mechanics of Materials*, *erriman*, 10th Edition, Arts. 11 and 108) may be employed for the design of beams of *symmetrical section and homogeneous material* loaded with *transverse loads* applied in the *plane* of one of the *principal axes*. For the treatment of beams of *unhomogeneous material* (reinforced concrete) see article on *Concrete*.

Let  $M$  = maximum external bending moment on beam in inch-pounds,  
 $I$  = moment of inertia in (inches)<sup>4</sup> about the neutral axis lying perpendicular to the plane of the external loads. (This axis in a symmetrical beam lies at mid-height.)  
 $c$  = distance in inches from neutral axis to extreme fiber, equals one-half the depth for symmetrical beams,  
 $s$  = allowable value of fiber stress (working value),  
 $Q$  = statical moment about the neutral axis of that portion of the cross-section lying above the neutral axis,  
 $v$  = allowable intensity of longitudinal shear in lb. per sq. inch,  
 $V$  = maximum external shear on beam in pounds,  
 $b$  = thickness of beam at neutral axis.

Then,

$$M = \frac{sI}{c} \quad \frac{I}{c} = \frac{M}{s}$$

and

$$v = \frac{VQ}{bI} \quad \frac{Q}{bI} = \frac{v}{V}$$

**Steel Beams.** — Such beams are made in the shape of the letter I in order to obtain maximum strength for a given amount of material. They are rolled to desired shape and size while hot. For dimensions, allowable loads and properties of the standard sizes made in the United States see Table V above. In addition to the I-beams listed in the table of standard I-beams which are manufactured by all the leading structural steel makers, the Bethlehem Steel Co. manufacture certain special beams of the same general shape but either of greater depth or with wider flange, and the Carnegie Steel Co. also manufacture certain special types of beams. These beams may often be used to great advantage.

**Cost of Steel Beams (Pre-war prices).** — The cost of steel beams in place depends upon the cost of transportation, punching, riveting and other necessary shop work and the cost of erection and painting. The base price at the mills is quoted each week in the *Iron Age*; the figures which follow are from the issue of June 19, 1913, and are representative of average prices prior to the European war.

I-beams under 15 in., 1.45¢ to 1.50¢ per lb.

I-beams over 15 in., 1.55¢ to 1.60¢ per lb.

H-beams over 18 in., 1.55¢ to 1.60¢ per lb.

For cutting to length, under 3 ft. to 2 ft. inclusive, 0.25¢ per lb.

For cutting to length, under 2 ft. to 1 ft. inclusive, 0.50¢ per lb.

For cutting to length, under 1 ft., 1.55¢ per lb.

No charge for cutting to lengths 3 ft. and over.

For total cost in place an estimate of 3 cents per pound is ordinarily safe.

**PLATE GIRDERS; FORMULAS AND COSTS.** — A typical plate girder with the various parts is shown in Fig. 8. Plate girders are used for openings

Fig. 8. Typical Plate Girder

where either the load to be carried is too heavy or the clear span too great to be spanned with safety by rolled beams. The maximum length and depth are limited by the possibility of transportation. Probably the largest girder yet made was designed for the Boston & Albany Railroad for use at Worcester, Mass. It is 122 feet 6 inches long, 10 feet 11½ inches deep, and weighs 112 tons. The ordinary and economical depth of plate girders is from ¼ to ½ the span; ¼ the span is a common value. The maximum depth is usually restricted to 10 feet 6 inches or less.

al Points in Plate-Girder Design are as follows:

determination of area of web required to carry the maximum external

determination of area of flange required to resist the maximum external moment.

determination of the flange rivet spacing necessary to transmit the stress from web to flange.

determination of spacing and size of stiffeners required to prevent the web from buckling sidewise, and of size of stiffeners at all points of application of concentrated loads together with number of rivets required therein.

determination of length of flange cover plates.

design of splices for web, angles and cover plates.

design of bearing plates to transmit end reactions into masonry.

It is impossible to give in the limited space available here the necessary design data for the design of plate girders. For further information see *Theory of Structures*, N. Y., 1915.

**Design of Box Girders.** — Box girders resemble plate girders, but have two webs as indicated in Fig. 9. They are used where conditions require a girder of great strength. The rules

for plate girders apply in general to box girders, but owing to their shallow depth it is usually advisable to determine the depth against bending by the general

formula  $M = \frac{sf}{c}$ , the moment of inertia

is computed with due allowance for

(see *Spofford's Theory of Structures*, N. Y., 1915, Arts. 62 and 63).

In a two-web girder may be considered as equally divided between the two webs and in a three-web girder as carried half by the center web and half by the two side webs combined. The flange rivets, stiffeners, etc., should be designed on the same basis.

**Girders (Pre-war prices).** — The cost of girders is usually computed on a cent-per-pound basis. Price of girders erected in place and painted in the Eastern states from 2½ to 4 cents per pound, depending on the state of the market, location, amount and complexity of the work. For specifications and inspection, cost of maintaining traffic (in railroad girders) and other details, see *Price of Structural Material*.

The price of 3½ cents per pound may be considered a fair average for approximate estimates. In the West this figure should be increased to cover the additional freight rate from Pittsburgh or Chicago. For prices of material see below under *Price of Structural Material*. For rates to various points from Pittsburgh, see below under *Freight Rates*.

**DESIGN; FORMULAS AND COSTS.** — Steel columns may be made of rolled sections such as I-beams or channels, or of compound sections consisting of single sections riveted together. A typical steel column is shown in Fig. 10. Single sections of steel columns should be limited in length for convenience in erection and economy in shipment to 60 feet over all. Lengths up to 120 feet may, however, be shipped in one piece if

columns are made by pouring liquid iron into molds. They may be of various shapes, but are always of comparatively short lengths seldom over 20 feet. Common shapes are shown in Fig. 11. To obtain free of residual stresses due to unequal rates of cooling and from stresses due to

Fig. 9.

eccentricity with centrally applied loads, the shells of hollow cast-iron columns should be of uniform thickness throughout. This result may best be secured by pouring the column in an upright position; if cast in a horizontal position the core must be carefully restrained against flotation.

Timber columns should consist of single sticks and may be either circular or rectangular in cross-section. Two lengths are sometimes connected by means of cast-iron caps which also furnish seats for beams.

Concrete columns are made by pouring concrete into wooden or metal molds; they may be made of any desired shape or length. Such columns are generally reinforced by longitudinal steel rods extending from end to end of the column and held in place at intervals by transverse steel rings. The transverse reinforcement may be made to add materially to the strength of the column by placing the rings at frequent intervals or by making it in the form of a spiral extending from end to end of the column, the column then being called a hooped column. The strengthening effect of the transverse reinforcement is due to its influence in preventing the bursting tendency of the concrete when subjected to compression.

**Splices.** — Steel columns are commonly spliced by bringing the abutting ends into close contact after first planing them at right angles to the axis. Splice plates are used on webs and flanges to hold the sections in line. If the column carries no bending moment the size of splice plates and number of rivets may be determined by the designer's judgment; if the column carries flexure as well as direct stress the splice must be sufficient to transmit the flexure.

Changes of cross-sections in steel columns may be accomplished by changing the thickness of the material or by adding additional material. An advantageous location of a splice is at a section where the cross-section area is to be changed. If the column carries only direct compression and is loaded at intervals throughout its length such a section should be near the point of application of one of the loads and on that side of it in which the smaller stress occurs, e.g., in a high building column the section should be changed just *above* one of the floors. For columns carrying flexure as well as direct stress the splices should be located where the bending moment is small, as for example at a point of contraflexure. Cast-iron columns should

Fig. 10

Fig. 11. Cross Sections of Typical Cast-iron Columns

not be used for positions where a considerable amount of flexure may occur or where they may be subjected to severe shock or vibration. Their use in construction is practically confined to buildings of moderate height. They may be spliced by bolting the flanges. In interior building columns the load is sometimes transferred from one section to another by means of a pin extending between the beams which are supported on the cap of the lower column. Such a joint depends for its lateral rigidity upon the friction between the beams and column cap and can evidently transmit no bending moment.

**Ratio of Unsupported Length of Column to Radius of Gyration.** — The controlling factor in column formulas is the value of the ratio between the unsupported length of the column and the radius of gyration of its cross-section. If the column is of constant cross-section and restrained against lateral deflection at

only, then  $l$  equals the total length of the column and  $r$  its least radius of gyration. If the column is held against lateral deflection in every direction at several intermediate points, the value of  $\frac{l}{r}$  equals the largest value between any two adjoining lateral supports. If the column is held at an intermediate point in one direction only, the value of  $\frac{l}{r}$  equals the maximum length by using for  $l$  the length of either section, or the total length of the column and for  $r$  in each case the corresponding least radius of gyration relative to the axis about which the column is free to bend. If the column is of an irregular cross-section the designer must use his judgment in determining the radius of gyration to be used, but generally the value should be that at the middle of the longest length of the particular portion of the column that is under consideration.

**Design of Ends.**—It was formerly assumed that the strength of columns in ordinary practice depended very largely upon the condition of the ends. At the present time, however, no difference is made between round-ended, pin-ended, and square-ended columns as used in ordinary practice. For columns of such shape that Euler's formula should be applied, a distinction should be made between round-ended and square-ended columns (see following section). Columns with one free end should receive special consideration.

#### Design Formulas for Steel Columns.—

##### Columns of Ordinary Length:

$$\frac{P}{A} = 16,000 - 70 \frac{l}{r}, \quad (1)$$

- $l/r$  not to exceed 120 for principal members,  
 $l/r$  not to exceed 150 for secondary members,  
 $P/A$  not to exceed 14,000 lbs.

For a list of symbols, see list following equation (4).

**Long Columns** having values of  $l/r$  greater than allowed in formula (1) may fail by collapsing rather than crushing; in this case the following formulas should be used:

$$\text{Fixed Ends} \quad \frac{P}{A} = \frac{4\pi^2 E}{c} \left( \frac{r}{l} \right)^2, \quad (2)$$

$$\text{Round Ends} \quad \frac{P}{A} = \frac{\pi^2 E}{c} \left( \frac{r}{l} \right)^2, \quad (3)$$

$$\text{One Free End} \quad \frac{P}{A} = \frac{\pi^2 E}{4c} \left( \frac{r}{l} \right)^2, \quad (4)$$

$P$  = total allowable centrally applied load on column in pounds including proper allowance for impact,

$A$  = minimum area of cross-section in square inches,

$l$  = maximum ratio of length to radius of gyration for any laterally

unsupported section of column,

$c$  = suitable factor of safety, usually 5 to 6,

$E$  = modulus of elasticity in pounds per square inch.

**Recommended Formulas for Cast-iron Columns**

$$\frac{P}{A} = 6100 - 32 \frac{l}{d}, \quad \frac{l}{d} \text{ not to exceed } 40,$$

where  $P$  = total allowable centrally applied load including proper allowance for impact,  
 $A$  = minimum area of cross-section in square inches,  
 $d$  = diameter of circular column or shorter in inches.

**Recommended Formulas for Timber Columns**

$$\text{For longleaf yellow pine, } \frac{P}{A} = 1000 - 10 \frac{l}{d},$$

$$\text{For shortleaf pine and spruce, } \frac{P}{A} = 1000 - 10 \frac{l}{d},$$

where  $P$  = total allowable centrally applied load (regarding impact),  
 $A$  = area of cross-section in square inches,  
 $\frac{l}{d}$  = unsupported length divided by least radius of gyration.

The values in (6) and (6a) are for railroad bridges. For buildings and structures subject to impact, increase these values by 25 per cent. For buildings and structures reasonably free from impact, increase these values by 10 per cent. For other timbers, multiply value for longleaf yellow pine by the ratio of the compressive stress of timber in question and of longleaf yellow pine. (See *Table on Unit Stresses in article on Timber.*)

**Steel Column Details.** — Columns composed of two channels should be constructed that the various parts will resist buckling. The strength of the column will be no greater than that of the parts when combined. As an illustration of this, the column shown in Fig. 9 should be considered. If the two channels are not connected, the strength of the column will be only double that of the two separate channels. If the channels are connected together, the column will have the low value corresponding to a single channel. A column composed of thin planks bolted loosely together will have less strength than the same number of separate planks bolted together. The ribs of a steel column, plates or diaphragms should be spaced out its length, the plates forming a part of the main or stress bearing cross-section, or plates and lattice bars may be used as shown in Fig. 10. The width of the lattice bars is usually taken as the minimum value allowable for the rivets used. For columns consisting of two channels, the minimum sizes of lattice bars given in the accompanying table may be used. In no case should single lattice bars have a thickness less than  $\frac{1}{40}$  the distance between rivets connecting them to the channels; but for double channels, at the intersection the thickness may be  $\frac{1}{60}$  of the distance between rivets.

For columns of unusual size, the lattice bars should be designed in accordance with *Spofford's Theory of Structures, N. Y., 1915, Art. 100.*

**Rivet Pitch in Built Steel Columns.** — For columns under stress only, the rivets should not be farther apart than the thickness of the thinnest plate connected and at each end or at each end under concentrated loads they should not be farther apart than the thickness of the thinnest plate connected.

also sections below on *Design of Tension Members* and *Design of*

**Eccentrically Loaded Columns.** — If the resultant force acting at any cross-section is not applied at its center of gravity the column is said to be eccentrically loaded. The effect of an eccentric load is to subject the column to a combination of direct stress and flexure, and thereby to increase the maximum fiber stress over what it would otherwise be. A similar condition arises if a force on the cross-section is the resultant of an axial force acting through the center of gravity of the section and a couple causing flexure at the section. The maximum fiber stress at such a section may be determined by the following approximate formula for the usual case where the resultant force acts through one of the principal axes and the neutral axis for flexure coincides with the other principal axis.

$$s = \frac{P}{A} + \frac{My}{I - \frac{P\ell^2}{10E}} \quad (7)$$

$s$  = maximum fiber stress at any section in pounds per square inch,  
 $P$  = resultant axial force on section in pounds,  
 $\ell$  = unsupported length of column in inches,  
 $A$  = area of cross-section in square inches,  
 $M$  = bending moment on section in inch-pounds,  
 $I$  = moment of inertia of cross-section about neutral axis in (inches)<sup>4</sup>,  
 $E$  = modulus of elasticity in pounds = 29,000,000 for steel,  
 $y$  = distance in inches from neutral axis to most remote fiber. (Neutral axis as used in this formula is the neutral axis for flexure.)

**Design of a Building Column Carrying an Eccentric Load.** — The design of a column supporting a track for a traveling crane is a common case. The bending moment diagram for such a case is shown by Fig. 12 in which  $P$  is the applied load at the track at a distance  $x$  from the center of the column. The maximum bending moment always occurs at the top and depends upon the height of application of the load. Its maximum value is  $Px$  and occurs when the load is applied at the top of the column.

**Specifications for Columns.** — The following specifications should be strictly followed:

1. In tension members the metal shall be concentrated where possible in webs and flanges. The thickness of the metal shall be not less than one-thirtieth of the diameter of the bolts at its connections to the flanges. Cover plates shall have a thickness of not less than one-fortieth of the distance between rivet lines.

2. The ends of compression members shall be provided with lattice bars and tie plates as near each end as practicable. Tie plates shall be provided at intermediate points where the lattice is interrupted. In main members tie plates shall have a length not less than the distance between the centers of rivets connecting them to the flanges, and intermediate ones shall have a length one-half this distance. Their thickness shall not be less than one-eighth of the diameter of the rivets.

3. The ends of compression members when faced for bearing shall be provided with tie plates on both sides sufficiently to hold the connecting members accurately in place. Tie plates in riveted work, whether in tension or compression, shall

4. Tie plates are not in direct contact with the parts which they con-

Fig. 12.

nect, rivets shall be used on each side of the joint in exactly the extent of one-third of the number

**Column Caps, Bases and Brackets.** — The proper loads to the column, and the distribution of the loading, is a matter of great importance. The three following are the principles to be observed in designing column caps:

- a. Provide sufficient bearing area so that the crushing of the loading beam, girder or column will not be
- b. Arrange connections to eliminate eccentric application of load; if this is impossible to reduce the eccentricity to the
- c. Arrange connections so that the stress-bearing portion shall be directly under the stress-transmitting portion; e.g., if a column receives load from a girder, the outriggers or stiffeners on the girder should be located directly over

Typical column bases are shown in Fig. 13. The principles to be observed in the design of column bases as in the design of column caps. The advantage of a separate base is that it can be set up on the foundation and leveled to receive the column with less difficulty than would be the case with the finished column. Such bases should always be planed on top and the base of the column should also be planed. Steel columns to which cap and base plates are shop riveted should be planed at each end before these plates are riveted on, and the cap and base plates are also generally planed on top and bottom respectively.

Fig. 13. T

It is important that brackets for connections of girders to columns should always be designed so as to throw the resultant beam reaction as near the center of the column as possible in order to reduce the eccentricity of loading. This is particularly important for cast-iron columns; if the brackets should be slightly beveled downward so that the girder cannot be supported at or near the edge of the column.

**I-Beam Column Footings.** — On poor soils it is often necessary to spread heavy column loads over an area so large as to require a footing that may be economically constructed of steel beams. The beams should not be closer together than 3 inches to permit concrete to be poured between and around them. The method of design is, in the ordinary case, that of a column carrying direct load. (1) Determine the number of square feet required in the footing; (2) determine the number of tiers of I-beams; (3) assume the entire load on the top layer of beams (weight of over-lying footing courses distributed equally over all the beams in that layer and the load is uniformly loaded); (4) determine the maximum moment which will occur at the center and equal approximately

$$M = \frac{W}{8n} (l - h)$$

load on layer of beams under consideration,  $n$  = number of beams,  $w$  = weight of beam loaded from above, in feet, and  $l$  = length of beam loaded from below, in feet; (5) determine in the usual manner the size of beam which will carry this bending moment; (6) test the web thicknesses of the beams to see if they are sufficient to transmit the applied load without crippling formula (1).

**Foundations.** — If the ground is soft, piles may be necessary to provide bearing area. For the allowable bearing value for these see Baker's *Foundations*, N. Y., 1909.

**Columns and Footings.** — Steel columns cost about the same as cast-iron columns for which values for which are given in the section on *Cost of Girders*, above. In determining the weight of columns it should be remembered that the details of the columns are materially to the weight of the stress-bearing section, especially in the case of cast-iron columns, where the excess may amount to as much as 50 per cent. For the cost of footings, the I-beams may be computed on a pound price basis. For weekly quotations given in *The Iron Age* with a reasonable allowance for transportation and delivery, or more accurate figures can be obtained from a reliable dealer. For cost of cast-iron columns see section on *Cost of Columns* in article on *Cast*. For the cost of concrete and excavation, see articles on *Concrete* and *Excavation* subjects.

**Simple Steel Columns.** — The allowable load for a number of simple columns and the important properties of the columns are given in Tables I and II. To determine the allowable load for built-up columns not given in Tables I and II the radius of gyration may be interpolated for columns having the same dimensions and the unit stress computed by substitution in the formula. The areas and other properties of the simple structural columns, such as beams, angle irons, and channels, are given in Tables II to VI.

These values are all based on the formula

$$\frac{P}{A} = 16,000 - 70 \frac{l}{\rho}$$

The maximum value of 14,000 and are calculated for Cambria Steel Co.'s columns. The load is assumed to be applied at the center of gravity of the column and to act parallel to its axis.

$\rho_x$  = radius of gyration about axis X-X'.  
 $\rho_y$  = " " " " " " Y-Y'

TABLE VII. — STEEL I-BEAM COLUMNS

Max. allowable load  $P$  in thousands of pounds for various values of  $l \div \rho$ .

**TRUSSES, DESIGN OF.**—All trusses may be divided into two classes based upon the methods necessary to determine their stresses. Statically determinate trusses can be determined by the application of the principles of static equilibrium (see paragraph on Equations of Equilibrium, above); otherwise they are statically indeterminate. A truss may be statically indeterminate with respect to its reactions; that is, its reactions cannot be determined by statics; or it may be statically indeterminate with respect to the inner forces, i.e., the bar stresses, which can be determined by statics.

Trusses that are statically indeterminate through their reactions are frequently constructed because of their economy, but it is doubtful if such trusses are desirable.

Statically determinate trusses may be distinguished from statically indeterminate trusses by comparing the number of unknown reactions with the number of joints.

Fig. 14. Bridge Trusses

the number of bars with the number of joints. In general, that any planar truss supported at two points will be statically determinate provided the number of bars equals  $(2n-3)$ , where  $n$  is the number of joints. If the number of unknown bars and reaction components combined exceed twice the number of joints the truss is statically indeterminate but may usually be computed by methods based upon its elasticity. If the number of unknowns is less than twice the number of joints the truss is unstable and may collapse; such structures should never be constructed.

The preceding test should not be used alone to determine whether a truss is or is not stable. The framework should also be so put together as to make it consist of a series of triangles.

**Common Types.**—All the trusses shown in Figs. 14 and 15, except the double-system Warren truss and the roof truss with monitor, are statically determinate; the former may be made statically determinate by omitting one of the bars, say a diagonal; the latter by omitting one of the bars, say a diagonal; the latter by omitting one of the bars, say a diagonal.

**Theory of Trusses.**—The common theory of trusses is based upon the following assumption:

The members are connected at the intersections of their center of gravity by frictionless pins, and that in consequence the stresses in the members are all direct stresses. The assumption of frictionless pins is quite particularly in the case of riveted trusses; however, the results obtained by this method are sufficiently accurate for trusses of ordinary sizes and are in common use. Great care should be used in design that center of gravity lines meet at the joints, otherwise the connection is eccentric and the truss exposed to bending as well as direct

methods of computing stresses in ordinary trusses involve only the application of the three equations of statics (see section on Equations of Statics, above). Three methods are in common use: viz., method of joints, method of moments, and method of shear. All of these are methods of sections applied by passing a section through the bar under consideration, cutting the truss apart and applying the equations of equilibrium to the outer forces on these sections and the stress in the bar under consideration. The first two methods are described below.

**Method of Joints.** — The method of joints is the most general of the three methods of computing the stresses in trusses; it may be applied either analytically or graphically.

**Analytical Method.** — The mode of procedure for this method is as follows: (1) Computation of reactions. (2) Selection of a joint at which only two bars meet. (3) Application of the two equations of equilibrium,  $\Sigma H = 0$  and  $\Sigma V = 0$ , to the outer forces and unknown bar stresses acting at this point. (4) Selection of another joint at which only two unknown bars meet and determination of the stresses in these bars in the same manner, treating known bars as outer forces.

**Graphical Method.** — This method consists of drawing polygons of stress for each joint in succession. It can be employed readily by draftsmen and others who are not familiar with stress theories. It is also self-checking and reasonably rapid. It is more accurate than the analytical method, and the diagrams are carefully constructed so that it is accurate enough for ordinary engineering work.

The mode of procedure is: (1) A diagram of the structure is drawn to any convenient scale and on it are shown all the forces including reactions. (2) The forces and bars are designated so that each force and bar will lie between two letters and the diagram is as illustrated by Fig. 16. (3) A polygon of outer forces is drawn. This polygon should close if the reactions have been determined

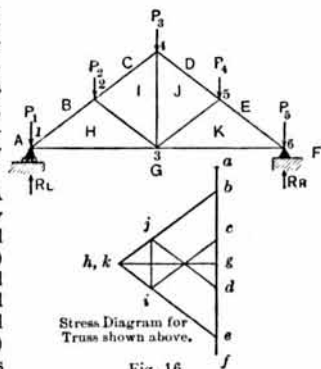

Fig. 16.

correctly. (4) A triangle of forces for each joint is drawn, beginning at a joint where an outer force and two bars only meet, and proceeding then joint by joint, selecting the joints in such an order that at no joint will there be more than two undetermined forces to consider. The sides of these triangles representing the outer forces are the sides of the force polygon. The sides representing bar stresses should be lettered at the ends by the letters obtained by going around the joints in a clockwise direction. The diagram thus drawn should form a closed figure. (5) The magnitude and character of the bar stresses are determined from the diagram. The magnitude of the stress in a member equals the length of the line of the diagram parallel to the bar in question measured to the scale of the force polygon; its character is determined by the order in which the letters are reached in going about any joint in a clockwise direction. For example, to determine the character of the stress in bar  $CI$  of Fig. 16, note that  $ci$  in the stress diagram acts downward to the left, as determined by the order in which the letters are reached in going around joint 2; hence the stress in  $CI$  also acts downward to the left, or toward the joint, since the bar is above the joint, and is therefore compression. A similar result is obtained by considering joint 4. For this joint clockwise reading gives the designation of the bar as  $IC$ , and  $ic$  in the stress diagram acts upward to the right, that is toward joint 4, since the bar is below this joint.

**Solutions by Graphical Method.** — Fig. 16 shows a small truss drawn to scale and with all the outer forces represented in direction and point of application. The force polygon is  $abcdefga$ ; this is a straight line, since all the forces are vertical. In it  $ab = P_1$ ,  $bc = P_2$ , etc. The reactions  $R_L$  and  $R_R$  are represented by  $ga$  and  $fg$ . The triangle of forces for joint 1 is  $gabkg$  ( $gb$  is the resultant of  $R_L$  and  $P_1$ ). Reading around joint 1 in a clockwise direction shows that the magnitude and direction of the stress in bar  $BH$  is determined by the length and direction of  $bk$  in the force polygon; as this acts downward to the left, it acts toward joint 1 and hence is compression. In the same manner the stress in  $HG$  is found to be tension. The stresses in the other bars may be determined similarly.

Fig. 17 shows a simple tower with wind forces acting on one side only. Ordinarily the wind forces on a tower would be equally divided between the two sides but they are all taken on one side here in order to more clearly illustrate the method. The only difference in the result would occur in the stresses in the horizontal members. In this case the diagonals in all panels are assumed to be tension members, only one of which in any one panel is in action under the forces shown. Inspection shows that in each case the bar shown dotted should be considered as out of action. The stress diagram and the scaled values of stress in the bars are also shown in the figure.

**Method of Moments.** — This method of finding truss stresses is based upon the application of the equation  $\Sigma M = 0$ . It is very useful for determining stresses in individual bars of many trusses, but is not so general as the method of joints and is frequently inapplicable to some bars even in the simplest trusses. Like the method of joints, it is also a method of sections, the truss being considered as divided into two portions and the equilibrium of one of these portions under the influence of the outer forces and the stress in the cut bar being considered. The method can be used to determine the stress in a given bar when all the other bars cut by the section, or their prolongations, meet at a point not on the line of action of the given bar. This point should be selected as the origin of moments.

**Design of Tension Members.** — The design of tension members involves little more than the selection of bars with sufficient net area to carry the total stress without exceeding the allowable unit stress. Steel or iron tension

Fig. 17.

Members may be divided into two general types: viz., solid bars rectangular or circular in cross-section, and built-up members composed of structural shapes welded together. Solid bars are used generally in pin trusses for diagonals, bottom chord members, and in Howe trusses for verticals. Built-up members are generally employed for tension members in riveted trusses and for the hangers in pin-trusses.

**Solid Tension Pieces.** — The eye bar shown in Fig. 18 is commonly used for the solid bar type of tension members. Such bars are made by most of the large steel manufacturers and are fully described in their handbooks.

Heads of these bars are designed so that the bar if tested to destruction fails in the body rather than in the head, and the engineer should specify full-sized tests should give this result and not attempt to proportion the bars. A good rule to observe in selecting bars is to keep the thickness between

Fig. 18.

Fig. 19.

one-sixth and one-third the width. Eye-bars are generally used in pairs, since an odd number of bars would give a poor arrangement on the pin. For countersunk eye-bars, such as those shown in Fig. 19, may be used, the two parts being connected by a turnbuckle or sleeve nut; iron rods with loops formed by bending may be used if the stresses are small. In proportioning adjustable members allowance must be made for the decrease in section due to the screw threads. It is usually advisable to upset the screw end, so as to give sufficient strength at the root of the thread to make the bar as strong there as elsewhere. For short rods, however, the labor cost involved in this process may be greater than the saving of material would warrant.

**Riveted Tension Bars** may be made of various shapes, such as plates, angles, etc. Although these members are riveted together to keep the separate parts from buckling, as in the case of plates, the connection between them should be used to make the joint as strong as the members. The design of these details must be left to the judgment of the designer.

**Design of Riveted Joints.**—A riveted connection may be designed in the following ways: (a) by the shearing of the rivets, (b) by the bearing of the rivets on the plates, or of one of the pieces upon which they bear, (c) by the tearing of the plates through one of the connected pieces.

**Shearing Strength of Rivet.**—Under (a) the allowable shearing value of the rivet may be found by multiplying the allowable shearing stress per square inch by the area of the rivet. For a  $\frac{3}{8}$ -inch rivet is 0.60 square inch, and of a  $\frac{1}{2}$ -inch rivet is 0.75 square inch. The allowable shearing stress for rivets to resist shear the plane upon which they are sheared must always be determined. If the maximum shear is on two planes the rivet is said to be in *double shear*.

**Bearing Strength of Rivet.**—The bearing strength of a rivet against a given plate is determined by multiplying the allowable bearing strength per square inch by the diameter of the rivet and the thickness of the plate in question.

**Distance of Rivet from Edge of Member.**—As noted under (c) the following empirical rule may be used. Rivets should be spaced closer than three times the diameter, and the distance from the edge or end of a piece may not be less than  $1\frac{1}{4}$  times the diameter. If the edge in question be rolled or planed, or  $1\frac{1}{2}$  inches from the edge where possible this distance should be at least twice the diameter. For other sizes of rivets proportional allowances should be used. The distance should be measured from the center of the rivet in each case.

**Riveted Joints Carrying Torsion.**—For cases where as direct stress has to be transferred by rivets, as in the case of brackets carrying cranes are riveted to the sides of columns or where girders are riveted to columns, the conditions shown by Figs. 20 and 21 may occur. For the case shown in Fig. 20 the rivets carry torsion only, and each rivet may be assumed to offer a resistance to torsion proportional to its distance from the center of gravity of the group of rivets. The resistance of such a group is

$$R = \frac{rI}{d},$$

where  $r$  = the allowable working value of the most stressed rivet;  
 $I$  = summation of the squares of the distance of gravity of the group of rivets to each rivet;  
 $d$  = distance in inches from center of gravity of the group to the most stressed rivet;  
 $R$  = resistance to torsion of the group of rivets.

In applying the formula to the case shown in Fig. 20 the distance from the center of gravity of the group of rivets to the rivet at  $a$  is  $r$ . For the case shown in Fig. 21 this distance should be increased to allow for the effect of the vertical load. To make the joint safe it is necessary to determine the allowable resistance to torsion of the rivet also carrying its share of the vertical load.

Fig.

## Structures, Simple

### CONTINUOUS GIRDERS, BEAMS, SLABS AND TRUSSES

These are structures which are continuous over several points of support and are statically indeterminate (see section on Trusses, above) with respect to the outer forces and hence the moments and shears should be determined by the "three-moment equation" (see above). Continuous girders are commonly used in reinforced-concrete construction, in which case the conditions are allowed for by the following simple rules recommended by the Joint Committee on Concrete and Reinforced Concrete. (See article on Concrete.)

(a) For floor-slabs, the bending moments at center and at support

shall be taken at  $\frac{wl^2}{12}$  for both dead and live loads, where  $w$  represents the load per unit area and  $l$  the span length.

(b) For beams, the bending moment at center and at support for interior spans should be taken at  $\frac{wl^2}{12}$  and for end spans it should be taken at  $\frac{wl^2}{10}$ .

(c) In the case of beams and slabs continuous for two spans only, with both ends restrained, the bending moment both at the central support and at the middle of the span should be taken as  $\frac{wl^2}{10}$ .

(d) At the ends of continuous beams, the amount of negative moment which will be developed in the beam will depend on the condition of restraint or support, and this will depend on the form of construction used. In the case of beams a moment of  $\frac{wl^2}{16}$  may be taken; for small beams running into columns this should be increased, but not to exceed  $\frac{wl^2}{12}$ .

For spans of unusual length, or for spans of materially unequal length, special calculations should be made. Special consideration is also required in the case of concentrated loads.

**SUBSTATIONS, LIGHTING.** — (See also *Batteries of; Bus-bars and Bus-bar Structures; Circuit Breakers; Distribution Lines; Distribution Systems; Lighting Regulators; Relays; Substations, Railway; Switchboards for Power Stations; Transformers.*) Three types of substation lighting systems viz.:

**Substations for Voltage Conversion and Regulation.**

These substations receive power from high-tension transmission feeders designed for economical cross section of conductors to avoid voltage drop. The standard equipment of such substations includes oil circuit breakers for high-tension lines, step-down transformers, bus-bars, oil switches and voltage regulators for delivery of power, and constant-current transformers serving local series street lighting. The construction of bus-bar and switch structures is similar to that for the control of circuits of equal power. Transformers are of the blast type, and are usually grouped in banks of three. Street lighting is supplied by constant-current transformers supplying d-c. arc circuit breakers, mercury-arc rectifiers. The equipment is usually arranged in a path through the substation as short and direct as possible. Each line has its individual equipment of voltage regulator.

**Substations for the Conversion of Frequency.**

These substations usually combined with the conversion of voltage. They receive power from 3-phase, 25-cycle primary feeders, convert it to 60-cycle power and form its voltage for the supply of local 60-cycle lighting. The frequency-changer most used is a pair of synchronous motors with a frequency ratio running on a common shaft. When a motor-generator type is generally used. By proper regulation of the motor element it is possible to control the power factor of the primary feeders to the most advantageous value.

**Substations for the Conversion of Alternating Current.**

— The alternating current is received from high-tension feeders, and is converted to low-voltage direct current for use in d-c. lighting circuits. Substations of this type are usually connected with the 3-wire lighting networks in large cities. The standard equipment comprises bus-bars and oil switches for incoming lines, converters associated with lowering transformers and voltage regulators, or (2) motor-generators, and direct-current switchboards. In many cases the above equipment is supplemented by a storage battery to insure the continuity of service in case of emergency. The motor-generator must be associated with step-down transformers while the motor-generator may be wound for voltages up to 20,000 volts. The motor-generator is somewhat more efficient and in most cases still more economical. Motor-generator equipment affords the greater range of voltage regulation.

For methods of voltage control see *Converters, Synchronous.*

In converter substations the step-down transformers are usually composed of three single-phase units. Transformer banks supplied by high-tension and are not connected in parallel on the low-tension side. The high and higher are usually wound 6-phase. The neutral of the 3-wire system may be derived from the neutral of the transformer bank. For storage battery arrangements see *Batteries, Storage.*

**BIBLIOGRAPHY.** — See articles on *Power Stations.*

**ATIONS, RAILWAY.** — (See also *Converters, Synchronous; Railway Requirements for; Switchboards; Switchgear Equipment; Trans-*

Substations are used for electric railways when the length of the road is such that the whole road cannot be supplied with one power station at the distance required by the motors without either an excessive drop in voltage or an excessive amount of copper or both. Practically all electric railways are developed to such an extent that substations are required for successful

**ECONOMIC CONSIDERATIONS.** — The location, capacity and number of substations is a matter for careful study and calculation, involving not only the cost of the copper required for distribution and the cost of the substation, but also the distribution of traffic and special local conditions. The total economics of the subject are expressed by the general theorem that the cost of operating the substations plus the cost of interest and fixed charges on investment in substations and line copper shall be a minimum. This is explained by the fact that if to any given arrangement an additional substation is added with the proper rearrangement of the spacing, the amount of copper used in the distributing system may be considerably decreased on account of the lesser distance between substations. If the saving in interest and value of the copper is greater than the cost of operation of this new substation plus the interest and fixed charges on the first cost of the substation, the investment is warranted.

**Allowable Voltage Drop.** — The distance between substations depends upon the allowable loss in voltage, the amount of copper in the trolley system and varies directly as the load. The allowable loss of voltage is a matter of the conditions of each road. Roads may be logically divided into two classes: City and Interurban. In City roads a drop in voltage of 8 per cent with average load and 15 per cent with maximum load is frequently allowed. In Interurban roads a drop of 12 per cent with average load and 18 per cent with maximum load is customary.

The conditions which determine the allowable drop in voltage are the voltage drop across the lights and the effect on the control circuit of the car, each of which requires a lesser drop in voltage than the actual operating characteristics of the motors.

**Distance between Substations.** — For the service usually found in practice the following tabulation shows the average or customary distance between substations.

If the length of track receives its power from only one direction the distance between a given drop in voltage is one-quarter the distance allowed between substations.

**Power Required.** — The capacity of the substation depends upon the number and the size of the cars, since if there are many cars operating it is probably only a few will be starting simultaneously and it is during starting that the cars demand the maximum amount of power. It is, therefore, necessary to determine the number of cars which will be located on the section of track supplied by one substation and the frequency of starting. In interurban service the number of cars on a given section is given by the formula:

$$X = \frac{2 \times (\text{length of section}) \times (\text{number of cars per hour})}{\text{schedule speed in miles per hour}}$$

The average load on the substation is equal to the average power demand of the cars times the number of cars on the section divided by the efficiency of the distributing system. In a complex system the local conditions must be

Volts	Type	Miles between substations	
		Single-track road	Double-track road
600	Direct-current, Trolley	10	15
600	Direct-current, 3d Rail	13	19
3,300	Single-phase, Trolley	17	23
1,200	Direct-current, Trolley	19	25
1,200	Direct-current, 3d Rail	38	43
6,600	Single-phase, Trolley	45	50
11,000	Single-phase, Trolley	..	70

studied to determine how many of these cars are liable to be starting at one time. In other than city roads a load factor of from 0.3 to 0.5 may be used to determine the maximum load on a substation, and in single-track interurban roads it is customary to assume one car starting and one car running. See article on *Railways, Energy Requirements for*.

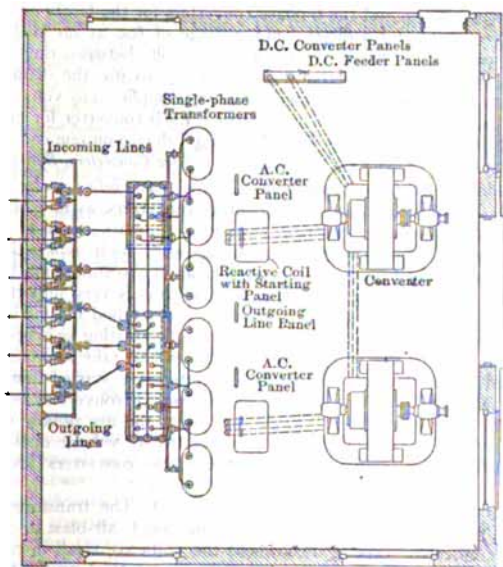

**TYPES OF SUBSTATIONS.** — In practice there are two types of substations: 1. for transforming from alternating to direct current, and 2. for transforming from high-voltage alternating current to low-voltage alternating current.

In standard direct-current railways it is customary to generate power at the power stations at about 2200-volt three-phase alternating current, step up by means of transformers to 33,000 volts 3-phase, transmit over any distance to the substations at this voltage, transform from 33,000 volts to approximately 400 volts 3 phase and then to convert to direct current at 600 volts in which form the power is used by the motors of the cars. This is the standard a-c-d-c. substation. In certain single-phase a-c. railways it is found necessary to transmit the power over long distances at a higher voltage than can be collected from the trolley, in which case the a-c-a-c. transformer substations are installed to convert the alternating current at the high transmission voltage to alternating current at a voltage convenient for the trolley and collector devices.

**SUBSTATIONS FOR TRANSFORMING FROM ALTERNATING TO DIRECT CURRENT.** — In these stations it is almost universally the custom to employ synchronous converters to convert from a-c to d-c., rather than motor-generator sets, as the converters have a higher efficiency and may be compounded to give the desired regulation. Thus the converter makes possible a saving in first cost, space and energy as compared to the motor-generator set. A standard a-c-d-c. railway substation usually contains the following pieces of apparatus: converters, transformers, reactances, blowers, cables, switching apparatus.

**Arrangement of Apparatus.** — (See also article on *Switchgear Equipment*.) It is customary to arrange the apparatus in a substation so that the current travels in as nearly as possible a straight line across the station. Thus, with the incoming line on one side there are in the order mentioned: the lightning arresters, oil switches, transformers, a-c. switchboard, reactance coils, con-

# Substations, Railway

**Fig. 1. Plan and Elevation of Typical Railway A.C.-D.C. Substa**

verters, d-c. line panel. A typical arrangement for a small station is shown in Fig. 1; see also Fig. 16 in article on *Switchgear Equipment*.

**Floor Space Required.** — For substations with all apparatus on one level the floor space required is about 0.20 square foot per kilowatt. In cities where real estate is expensive, it may be desirable to put the oil switches and lightning arresters in a gallery on the upper level and the transformers on a floor above, but this involves more expense for attendance.

**Standard Voltages and Frequencies.** — The following three-phase voltages have been standardized for railway work: 11,000 volts with transformers delta connected on the high-tension side; 33,000 volts with transformers *Y* connected; 66,000 volts with transformers *Y* connected. A frequency of 25 cycles per second is employed in almost all railway installations, as converters are more reliable at this frequency. Certain stations which are obliged to take power from previously existing power stations use a frequency of 60 cycles.

**Converters.** — (See article on *Converters, Synchronous, for data regarding converters*.) Compound-wound converters are used where the load is variable to provide automatically any desired voltage regulation. The converter means of its series winding is made to take a leading current which, in passing through the reactance of the line, the transformers or through an additional reactance introduced for the purpose, tends to neutralize the line drop. (See *Transmission Lines*.) In city service where a large number of cars are operating on one section, the load is fairly constant and shunt-wound converters are generally used.

Both 3-phase and 6-phase converters are universally used, the 3-phase for the smaller capacities and the 6-phase converters for the larger capacities. In a 3-phase converter for a direct e.m.f. voltage of 600 at no load, the transformers should supply the converter with 370 volts between rings or between lines. In the 6-phase converter it is customary to use the diametrical connection, in which each transformer secondary supplies 430 volts to the converter, giving 600 volts at the commutator. Each converter for railway work is customarily supplied with a "speed-limiting" device on one end of the shaft and an "end-play" device on the other end. (See *Converters, Synchronous*.)

**Methods of Starting Converters.** — (See also below under *Operation*.) There are several methods of starting rotary converters, as is explained under *Converters, Synchronous*. Starting from the alternating-current end as an induction motor is most desirable for railway work, as it avoids the necessity of synchronizing and requires less time. The ability to start a machine quickly and get it on the line in the shortest possible time is very important in railway work, and is an advantage inherent in this method of starting. Three-phase converters are started, by means of suitable starting switches, from one-half voltage taps on the transformer secondaries and take approximately full-load current from the line. Six-phase converters are started from  $\frac{1}{2}$  voltage taps and take  $\frac{1}{2}$  full-load line current. Since 60-cycle converters usually take a greater starting current than 25-cycle converters and are usually operated on a system supplying power for other purposes, where voltage disturbances are objectionable, special means of starting 60-cycle converters are frequently employed.

**Transformers.** — (See article on *Transformers*.) The transformers used in railway substations may be either of the oil-cooled, air-blast or water-cooled type. The oil-cooled type is used where the units are small in capacity, i.e., less than 400 kilowatts, and where the expense of the complications for air blast or water cooling are not warranted. Air-blast transformers are used in all except the smallest sizes, and for voltages up to and including 33,000; the objections to their use are the necessity of providing a pit, air ducts and blower

to supply the ventilation. Water-cooled transformers (which are oil-insulated transformers with water circulating in a special coil submerged in the oil) are built in sizes from 500 kilowatts upwards and for all voltages. Their use depends upon the availability of water for cooling purposes. The usual aggregate capacity of transformers for the various sizes of synchronous converters is about the same as the converter capacity.

**Transformer Connections.** — The transformers may be either of the single-phase or three-phase type. For small or moderate installations the single-phase type is preferable on account of the economy of maintaining only one single-phase transformer as a spare for a whole station. In railway work it is customary to connect the secondary of the transformers in delta for three-phase, because of the possibility of operating at reduced output on open delta in case of failure of one transformer. The primary windings of the transformer are usually connected *Y* with grounded neutral. It is common practice to provide transformers for railway work with four  $2\frac{1}{2}$  per cent taps on the high-potential winding, in order to use similar transformers in all substations and yet make allowances for the difference in the line drop between the power station and the various substations. Either  $\frac{1}{2}$ - or  $\frac{3}{4}$ -voltage taps are provided on the low-potential side for starting the converters.

**Blowers for Air-blast Transformers** (see *Blowers and Compressors*) are usually driven by 25-cycle 3-phase induction motors receiving power from the low-tension side of the transformers. The amount of air required per minute per kilowatt rating of each transformer ranges from 3 cubic feet in the large sizes to 5 cubic feet in the small sizes. This air is supplied at a pressure of from  $\frac{3}{8}$  to 1 ounce per square inch. The blowers must be capable of supplying this amount of air with an allowance of about 10 per cent for leakage in the air-blast chamber. It is customary to provide two blower sets each capable of supplying air for all the transformers in the station and maintaining one as a reserve unit. In a very large station 3 blower sets are sometimes provided, two of which are together capable of supplying the service and the third is a reserve. A rough idea of the size of the motor necessary to drive a blower for a given purpose may be obtained from the following formula:

$$\text{Horse-power} = \frac{(\text{cu. ft. air per minute}) \times (\text{pressure in ounces})}{1200}$$

**Air Duct for Air-blast Transformers.** — The pit or trench over which air-blast transformers are placed must be made water-tight and well drained, as any moisture accumulating is liable to be carried into the transformers where it will injure the insulation.

**Voltage Regulation. — Use of Reactances.** — The voltage at the d-c. bus-bars is regulated automatically by means of line compounding which consists in adjusting the shunt-field excitation of each converter so that the converter takes lagging current at no load, operates at unity power factor at about  $\frac{3}{4}$  load and takes leading current at all loads greater than  $\frac{3}{4}$  load. To accomplish this compounding, it is necessary that there should be a certain amount of reactance between the power-station bus-bars and the converters. (See *Converters, Synchronous*.) There is seldom enough reactance in the transmission line for this purpose, so that additional reactance is inserted either by the use of special transformers having considerable leakage reactance, or by means of reactance coils. The usual reactance coil has a capacity in kv-a. equal to 15 per cent of the kilowatt rating of the converter, i.e. with full-load current passing through the reactance the voltage measured across its terminals would be 15 per cent of the voltage to neutral on the a-c. side of the converter.

Reactance coils are either oil cooled or air blast depending upon the transformers used and are usually built with the three circuits in one unit, with the starting switches for the converters mounted upon the frame. For 6-phase converters a 3-phase reactance coil is used, but since the current per wire is one-half that of the current of a 3-phase converter of the same rating, the reactance per line must be twice as great for the 6-phase converter.

**Switchboards.** — (See also article on *Switchboards*.) The following sections of switchboards are standard for converter substations.

1. Incoming a-c. line panel.
2. Outgoing a-c. line panel.
3. High-tension a-c. converter panel.
4. D-c. converter panel.
5. D-c. feeder panel.
6. Equalizer and negative panel (on the converter).

Where a substation is tapped off a transmission line at an intermediate point it is good practice to bring the transmission line into the substation, interpose control switches, and then carry the circuit out of the substation on to the next substation. For this reason, in all but terminal substations, it is customary to provide both an incoming and an outgoing a-c. line panel. In connection with the a-c. panel of the switchboard there are a line switch, lightning arrester, choke coil, current transformers and main oil switch, by means of which potential may be removed from all transformers. Between the transformers and the converter are the starting switches, reactance coil and possible measuring devices.

**Direct-current Panels.** — Single-pole switchboard panels are used, the positive main bus-bar being the only one on the board. The negative terminals of the converters are connected with switches to the negative or ground return bus-bar, which is frequently located beneath the converter. The series field is connected on the negative side, and the equalizer, series-field-shunt and field break-up switches are frequently placed on the machine itself. The equipment of a standard d-c. converter panel comprises one of each of the following:

- Carbon break circuit breaker with overload and low-voltage release, the latter interconnected to the speed-limit device.
- Illuminated dial ammeter with shunt.
- Field rheostat.
- Two-point receptacle.
- Single-pole main switch.
- Single-pole double-throw station lighting switch.
- Watt-hour meter.

**Storage Battery.** — In certain installations, where reliability of service is of utmost importance, a storage battery is installed, operating in parallel with the converters, and preferably regulated by a series booster. Such a storage battery will not only take care of the load for a considerable period of time in case either the transmission line or converters are out of action, but it will also improve the load factor of the system and thereby the line regulation. In other cases, where the service does not warrant the outlay for such a storage-battery system, a small storage battery is sometimes installed to take care of the lighting of the substation in case the converters should shut down accidentally. See articles on *Batteries*, *Storage*.

**Ventilation.** — As the transformers, reactance coils and converters all dissipate a considerable amount of energy in the form of heat, a substation must be well ventilated in order that the temperature of the air surrounding the apparatus

is not so great as to cause an injurious temperature in the apparatus itself. This is particularly important where oil-cooled transformers are used.

**Crane.** — Where ground space is limited it is good economy to provide a crane in order that the various pieces of apparatus may be lifted over each other when they are taken apart for repairs, as otherwise considerable space must be left to move them about to and from the entrance. See article on *Cranes*.

**Operation of Converter Substations.** — The only apparatus in a converter substation that requires any great amount of attention are the synchronous converters. As noted above these are usually started from the a-c. supply.

**Instructions for Starting a Synchronous Converter from A-C. Supply.** —

1. Open all switches except main negative (on machine).
2. Close a-c. line switch feeding busses.
3. Close H.T. transformer switch.
4. Close starting switch on low-voltage taps.
5. When converter reaches synchronism as shown by low frequency of swings of d-c. voltmeter, close equalizer switch.
6. Close switch between series field and the shunt to series field.
7. Correct polarity if necessary by throwing shunt-field break-up switch to reverse position, leaving it closed only momentarily, then throw to running position.
8. Connect a-c. terminals of converter to full voltage of transformers by throwing starting switch to running position.
9. Close d-c. circuit breaker.
10. Adjust field rheostat.
11. Close main d-c. switch.
12. Adjust for correct division of load, power factor and voltage.

**Load Factor and Efficiency.** — The load factor (q.v.) of a converter substation is usually low, from 30 per cent to 50 per cent, i.e., the load on the station is relatively light except during the morning and afternoon rush-hours, 7 to 9 A.M., and 5 to 7 P.M. respectively (*see Train Dynamics*). The all-day efficiency of the station itself, or the ratio of the kilowatt-hours output to the kilowatt-hours input, is less than the efficiency at maximum or rated load; but the over-all efficiency between the a-c. generators in the power house and the cars is about constant throughout the day, since the efficiency of a transmission line increases with decrease of load, thus offsetting the low light-load efficiencies of the transformers and converters. In general practice in inter-urban 600-volt railways the maximum and all-day efficiencies of the various apparatus are approximately as given in the following table:

Apparatus	Full-load eff., per cent	All-day, eff., per cent
Step-up transformers.....	96	97
High-tension line.....	95	98
Step-down transformers.....	97	94
Converters.....	90	88
Low-tension distribution.....	85	88
Over-all, a-c. generator to motors.....	69	69

**Automatic Substations.** — To decrease the cost of maintaining the need of attendants, substations are now equipped so that control and operation are accomplished mechanically. When the voltage on the adjacent section of the trolley falls below a specified value (450 volts) a contact-making voltmeter closes a contact which operates a motor-driven controller operating a large gang of switches. These switches automatically and consecutively connect the adjacent section in the positions listed under "Operation." The converters are connected in parallel so there is no synchronizing, but the polarity of the field excitation adjusted at the proper time and the speed of the motor in parallel. Protection against overload, low-voltage, and short-circuit is provided.

When the load falls below a specified value a contact-making voltmeter closes a circuit which opens all switches and shuts the converter out of service. A number of these automatic substations have been installed on various lines. Three converters per station and in sizes up to 3000 kw.

**First Cost of Converter Substations (1921).** — The cost of a converter substation cost from \$10 to \$16 per kw. The transformers cost from \$10 to \$16 per kw. and the switch-gear from \$5 to \$20 per kw. rating of station.

All the electrical apparatus makes up about 67 per cent of the cost of the station including the building. The floor space required is from 100 to 150 square foot per kw. in large sizes to one square foot per kw. in small sizes.

In an approximate way the cost of substations including the building and installation, for 33,000-volt transmission, 25-cycle trolley is as follows:

Station capacity, kw.	No. Converters	Capacity of each converter, kw.
300	1	300
600	2	300
800	2	400
1000	2	500

#### Cost of Operation of Converter Substations.

The cost of attendants is the principal item in the cost of operation. Supplies and maintenance form a very small percentage of the total cost. Only one man per shift is necessary, as the principal duties are performed by machines in the morning and occasionally during the day. The duties are combined with that of ticket seller or express agent. The cost of attending to the substation, \$2500 to \$3000 per year for the cost of operation of a substation, allowing for the two shifts.

**PORTABLE SUBSTATIONS.** — Circumstances may arise in which the traffic on a certain branch of a railway is very heavy for a few weeks in the year, and possibly for only two or three months. Over traffic may be exceptionally heavy on one branch at one time and on another branch at another period. In such cases it is very expensive to provide on each branch substations to meet the heavy demand. To meet such conditions portable substations are used. These consist of what are practically large

installed one synchronous converter and the necessary transformers and devices. Side tracks are provided at points on the branch lines. When needed this portable substation is hauled to the place desired and its terminals are connected to the high-tension transmission line, which must be made in building the line, and its direct-current terminals connected to the trolley and the rail respectively. Such a substation has great convenience and value for interurban roads where summer races and athletic games occasionally render traffic conditions difficult. Its size is limited by the standard clearance outlines of the structure which it must pass. It usually weighs, with all its equipment, about 100 tons. Apparatus having a capacity of 500 kw. may be installed in a portable substation and the primary voltage may be as high as 33,000 volts (*see article on Equipment*).

**VOLTAGE DIRECT-CURRENT SUBSTATIONS.**— Many substations are operated at 1200, 1500, 2400 and 3000 volts d-c. between trolley and ground. For this purpose power is transformed from alternating current by means of either motor-generator sets or synchronous converters. The motor-generator set was considered more fitted to the purpose as the commutator is not as restricted in a generator as in a motor. The interpole made it possible to operate at a high potential between poles. Subsequently, synchronous converters with interpoles and operating at high voltages were developed, and are now in successful operation. At first two machines were connected in series to give 1200 volts. Later, machines were developed which would give 1200 volts on each machine and these became 2400 volts by connecting two in series. For 3000 volts three-motor-generator sets are used, one a-c. motor driving two 1500 volt interpoles in series.

**ALTERNATING-CURRENT SINGLE-PHASE SUBSTATIONS.**— For a single-phase railway operating at a high voltage on the trolley (11,000 volts) it is not necessary to place substations as near together as in the case of direct-current systems. However, even with 11,000 volts on the trolley, there comes a length of road which may be supplied from one feeding point. It becomes necessary to step up the voltage at the power station to the higher voltage and step down again to the trolley voltage at the substations. A substation for this purpose need contain only transformer and control devices. It is much simpler and less expensive than the direct-current substation. It has even been a matter of discussion as to whether a substation would require continual attendance to maintain proper operation, is, however, a matter which must be decided by local conditions. When transformers are used there is no moving apparatus in the station, and the need of an attendant is in case of accident or to reset a circuit breaker if it goes out as a result of an overload.

Y., 1910; Dawson, P., *Electric Traction on Interurban Ry.*, 1909; Harding, C. F., *Electric Ry. Engineering*, N. Y., 1911; Hobart, C. F., *Electric Trains*, N. Y., 1910; Parshal & Hobart, *Electric Ry. Engineering*, 1910; Werner, G. B., *Economic Location of Substations*, Trans. A.I.E.E., 27, p. 1201. See also files of G. E. Rev., Elec. Jour., A.E.R.A. and Power Generation.

**SWITCHBOARDS.** — (See also *Bus-Bars; C Switches; Switchgear Equipment for Power Stations*) formerly comprised all apparatus in that portion of collecting, measuring and distributing the electric energy of the switchgear is mounted on a single structure which is called a switchboard. In large modern plants the control and measuring apparatus are frequently mounted on one structure, and the switchgear on another. In such cases the term switchboard is applied to the switchgear, whether panel, pedestal, or desk type, which supports switches, handles and similar devices. The following article describes the construction of apparatus on representative switchboards selected to show the present trend of switchboard design. For a description of the various arrangements required by direct control and distant control, see *Switchgear Equipment in Power Stations*.

#### CONSTRUCTION OF PANEL SWITCHBOARDS

Older switchboards called "panel" boards were made of wooden panels on which instruments, etc., each on its own base, were attached. The wiring with the front or the rear. The trend toward the elimination of the wooden panel and framework. The switchboard was mounted on a marble slab, which was arranged in a wooden framework, and switchboards were made by combining voltmeter, switch and rheostat slabs to make the panels for circuit breakers, relays, etc. This form of construction was eventually abandoned because of disadvantages ultimately lead to its being superseded by modern panel switchboards with the apparatus grouped on comparatively large pieces of marble, or slate.

The design of modern panel switchboards has been a long process that has been applied to all electrical apparatus. It meets requirements the vast majority of plants of moderate size. Modern control switchboards that are made up by assembling

**Framework of Panel Boards.** — In general the framework of a switchboard may be divided into two types. The older type are mounted on a framework of gas pipe, and usually are 4 feet high with a space between them and the floor. The newer, more expensive boards have a total height of about 7 feet from the floor, and are provided with an angle iron or pipe

**Gas-pipe Frames.** — Although the gas-pipe construction is probably lighter than the angle-iron construction it has been used for these smaller switchboards and in fact some manufacturers still use this construction for most of their larger switchboard installations. The height of panels does not exceed four or five feet. The complete switchboard is shipped with the panels attached to the framework and the instruments, etc., undisturbed, but if the boards are large ones the instruments are shipped separately.

Fig. 1 shows the pipe framework for switchboard panels. The framework is made of 1½" wrought-iron pipe with one wrought-iron pipe running with cast-iron foot nuts and panel supports. The vertical pipes are attached to the vertical pipes by "J" bolts or "U" bolt fittings. No special fitting is required.

**Angle-iron Frames.** — Fig. 2 shows a typical angle-iron frame for switchboard panels 90 inches high. Each panel of a switchboard is provided with 2 by 3 by ¼ inch or some similar size angle iron narrow web bolted to the panel. These angle irons

to within  $\frac{1}{4}$  inch of the top. The vertical angles on adjacent slabs are bolted together through the 3-inch web. They are provided with

—Pipe Framework

Fig. 2.—Angle Framework.

for bolting at the bottom to a 6 by 2-inch channel iron forming the frame and at the top to two  $\frac{1}{2}$  by  $1\frac{1}{4}$ -in. iron strips. The side and the top irons are made continuous the entire length of the board and the length is not over 16 feet. Each panel is shipped bolted to the two angle irons in its individual frame, which obviates any necessity of disconnecting between the various slabs making up the panel. This practice of using an angle framework with the panels reduces to a large extent the breakage during handling and facilitates the erection of the board at its destination.

**Material for Panels.** — After trying various materials practically all switchboards have adopted either slate or marble, although in a few instances iron or steel has been used. The marble used in switchboards is a grade known as "Blue Vermont," although occasionally "White Pink Tennessee" is used.

**Comparison of Slate and Marble.** — Where switchboard panels are used with a black finish the choice of slate or marble is largely a question of cost. Slate is considerably cheaper and somewhat stronger than marble, but where the voltage of live metal parts mounted on the panels does not exceed 1000 volts it answers just as well.

**Finish on Panels.** — The marble is sometimes polished on the top and bevels, and occasionally on the edges and back. The present practice for marble is a dull black marine finish applied to honed panels. Slate, owing to its irregular color and marking, is usually given an oil finish and natural black slate is given an oil finish.

**Dimensions of Two-piece Panels.** — The total height of standard switchboard panels is 90 inches from the channel iron. The division resulting in a lower slab as furnished by one company is due to the fact that these dimensions were best adapted to the line of switches, circuit-breakers and fuses which were in use at the time the standard railway switchboard was first brought out. The lower 25-inch slab was used for rheostat (see

plates having the contacts and contact mechanism. In order to correspond with the old d-c. panels the design of another company provides panels with slabs high which dimensions were suited to their apparatus.

**Dimensions of Three-piece Panels.** — Where brush-type, carbon-break circuit-breaker was designed to mount this breaker at the top of the panel in order to prevent the tendency of an arc to rise. As all these standard breakers of a capacity required a vertical space of less than 20 inches, the main upper 65-inch panel into two slabs, the upper 25 inches high to contain the circuit-breaker and the other 40 inches high to contain the meters, switches, etc. For this reason the design of one maker, both for railway and for light and power, divides into three slabs, the upper 20 inches high, the middle 25 inches.

As the size of rotary converters has increased to such an extent that breakers larger than 3000 amperes are often required, the design is divided into 25 inches high to accommodate breakers up to 10,000 amperes, middle slabs 45 inches high and lower slabs 20 inches high, making a total of 90 inches. Another manufacturer uses sections 30 inches high having the same total height of 90 inches. The upper slab usually contains the instruments as well as the switches, while the all switchboard builders have adopted the three-section design for heavy capacity carbon circuit-breakers.

**TYPICAL DIRECT-CURRENT SWITCHBOARD EQUIPMENTS** described in the subsequent paragraphs illustrate standard practice.

**Small Isolated Plant Switchboards.** — Where a generator of small capacity with one or two feeders and any additional equipment being needed, a board like Fig. 3 can be used with a main slab 36 inches high, 16 inches wide, provided with a polarized ammeter and voltmeter, single-pole carbon breaker, 2-pole main switch, field rheostat in the generator circuit, and switches with fuses in the feeder circuits. This type of board uses subpanels for the feeder switches and is usually limited to 10 kw. at 125 volts or 20 kw. at 220 volts.

**2-Wire Switchboards.** — For the control of small capacity, d-c. generators operating in parallel on a 2-wire, d-c. circuit the connections are made as indicated in Fig. 4. Each generator is provided with a 3-pole, single-throw switch, a single-pole circuit-breaker, an ammeter, and rheostat and a 4-point voltmeter receptacle used for connecting the voltmeter to any machine. Each feeder is provided with a 2-pole switch with a ground detector is connected across the bus-bars.

**3-Wire Switchboards.** — Fig. 5 shows the diagram of a typical d-c., 3-wire installation and indicates the meth-

connection from the middle point of auto-transformers; the use of series fields in the positive and negative circuits; the placing of the ammeter shunts on the

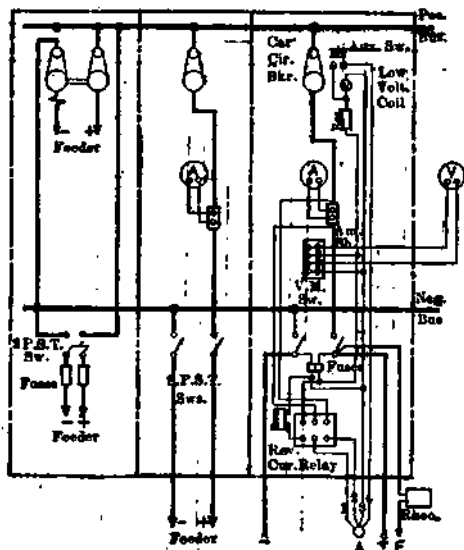

Fig. 4.

terminal boards of the machines so as to be connected inside the series fields; and the 4-pole circuit-breakers or the equivalent two single-pole breakers with equalizer contacts to open the positive, positive equalizer, negative and negative equalizer circuits.

**Double-bus Railway Switchboards.**—For direct-current railway or tramway work at about 600 volts it was for a long time the standard practice to bring both the positive and the negative leads from the generator to the switchboard and to locate both the positive and negative bus-bars on the switchboards, such boards being called "double-bus" boards. With these boards it was customary to use compound-wound d-c. generators with the series fields in the armature circuit which connected to the overhead trolley. The equalizer connection was usually made through a switch at the machine and the equalizer connection ran from one machine to the other without going to the panel board.

The double-bus scheme is still usually adopted for 250-volt, 2-wire industrial switchboards or any d-c. installation that does not use the ground return.

**Single-bus Railway Switchboards.**—Modifications in this class of switchboards came from placing the series fields in the grounded circuits instead of in the trolley circuits, and running only one polarity, usually the positive, to the switchboard. The equalizer switch and the negative switch, if the latter is used, are mounted at the machine. Fig. 6 is a typical diagram of a d-c. generator installation arranged for single-bus operation with only one polarity, namely the positive, on the board. The advantages

of this single-bus d-c. system are greater security against short circuiting of the d-c. generator or synchronous converter panel, consequent

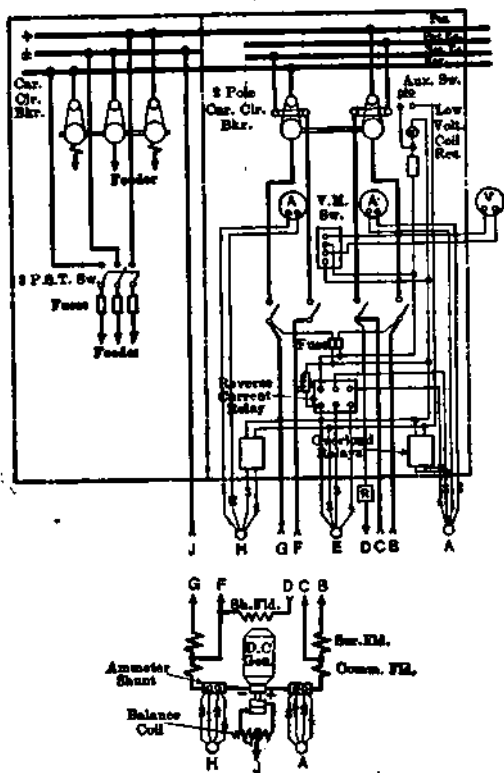

Fig. 5.

reduction in length of switchboard, reduction in amount of cable required and the use of bare copper strap or cables between machines for the negative and equalizer buses.

For converters or motor-generator sets, the panel switchboard if such is used, takes care of both the d-c. and a-c. circuits, which are usually controlled by separate panels. The d-c. panels are practically the same as those used for d-c. generators. The a-c. panels usually correspond with a-c. feeder panels and control the high-tension side of the step-down transformers used with the converter where the latter is made self-starting from the a-c. end. With such machines, in addition to the panels on the high-tension side of the transformers, it is customary to furnish a small slab mounted near the step-down transformer for connecting the converter, first to low-voltage taps for starting, then to full voltage taps for running.

It is customary to locate the 3-pole, double-throw switch used for starting the synchronous converter, on a panel with the 2-pole double-throw field reversing switch, so that if the converter should build up with its polarity reversed, it is a very simple matter to make the machine slip a pole and build up with the correct polarity. For railway service, the equalizer and negative switches are frequently mounted on the same panel as the starting switch and field-reversing switch.

It is customary practice to provide automatic protection on the alternating-current side of synchronous converters by making the breaker on the high-tension side of the step-down transformer automatic with inverse time element relays, or with inverse time element attachments to the trip coils of the breaker. A low voltage and instantaneous over-load carbon circuit-breaker is provided for the direct-current side. The low-voltage trip of the direct breaker is actuated by a speed-limit switch furnished with and mounted on the converter, the operation of which opens the breaker. It is also actuated by an auxiliary switch that is provided on the oil circuit-breaker so that when this breaker opens the direct-current breaker also opens in this manner providing

against the motoring from direct-current and eliminating the liability of reversal in polarity on compound wound machines. For 600-volt railway service where there is an independent source of direct-current power such as an adjacent substation, d-c. reverse current relays are provided, these relays being arranged to trip the alternating-current breaker upon reversal of direct-current power and this in turn opens the direct-current breaker.

**High Voltage Direct-current Railway Switchboard.**—For 1200-volt d-c. railway service the switchboard panels differ from those used for 600 volts, in the increased height of panel and in the fact that the circuit-breaker and knife switch are mounted out of reach and are mechanically operated by an insulated mechanism.

For 2400-3000 volt d-c. service special precautions have to be taken to carefully insulate the circuit-breakers and switches. Owing to the greater likelihood of flash-over occurring on the high-voltage d-c. converters or motor-generators, high-speed circuit breakers have been designed to trip on overload before the current in the machine rises to a dangerous amount. The same

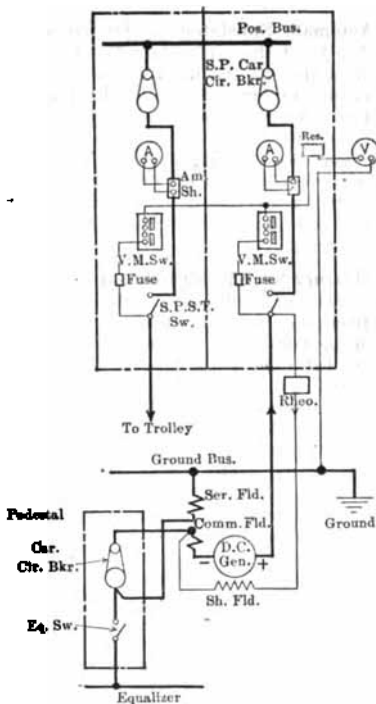

Fig. 6

result is obtained by a high-speed device that places an a-c. short circuit on the converter or generator before the direct-current has an opportunity to rise to a dangerous amount.

**Automatic Substations.** — On interurban railways operating cars or trains on hourly schedules it has been found advisable in certain cases to install automatic devices for starting a synchronous converter on the approach of a train or car and to shut it down after the train or car has passed.

This is usually accomplished by a series of contactor switches that start the converter and connect it to the lines whenever the voltage on the trolley line drops below a certain percentage of normal, this drop usually being caused by the approach of a car drawing a relatively heavy current from the line. After the car has passed and the current from the substation has dropped to a certain point, the converter will be shut down after the expiration of a definite time interval.

**Mercury Rectifier Switchboards.** — Another combination of a-c. and d-c. equipment met with in switchboard practice is that furnished for mercury rectifiers used in conjunction with constant-current d-c. arc lights fed from a constant-potential a-c. system. The apparatus supplied usually comprises a two-pole oil switch with fuses for the primary circuit of the regulator, plug switches in the secondary circuit, a mechanism for tilting the bulb of the mercury rectifier, and a high-voltage d-c. ammeter placed under a glass cover. The switchboards furnished with low-tension rectifiers are of similar arrangement, except that they are fitted with low-tension meters and switches, and have a single-pole starting switch which automatically applies a rheostat load for starting.

**Other Arc-light Switchboards.** — For use with d-c. series arc generators, switchboards are frequently supplied with a multiplicity of plug switches to permit any generator or feeder circuit to be connected in series with any other circuit to circuits. (*See Switches.*)

**Exciter Panels,** although d-c., are almost invariably combined with and form part of a-c. switchboards. The d-c. sections of the board are naturally considered with the a-c. sections and made to correspond with them in general design.

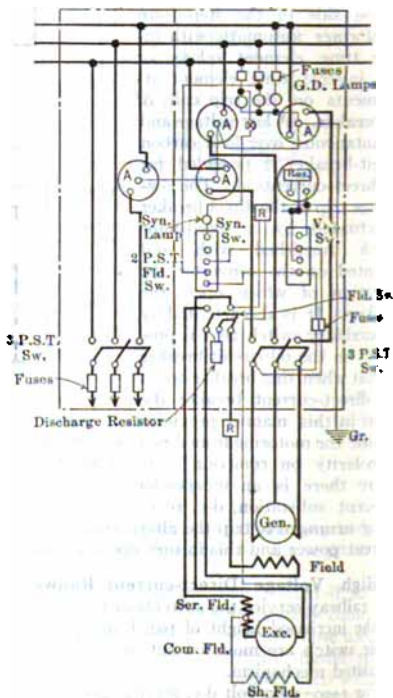

Fig. 7.

els are either single or double, depending on whether they control machines. Usually no fuse equipment or other automatic provided with exciter panels, as the sudden opening of the field to the blowing of an exciter fuse or the tripping of an exciter pt to injure the insulation of the generator and cause far greater the plant than the overloading or short circuiting of an exciter. e are several large exciters operating in parallel with each other or age battery, it is occasionally considered good practice to furnish ent circuit-breakers in the exciter circuits.

**ALTERNATING-CURRENT SWITCHBOARDS.** — Some equipments are described and illustrated in the following paragraphs.

**Low-voltage A-C. Boards (Fig. 7),** made for circuits of not over capacity at 500-volts, are usually built of panels 48 inches high on . Each a-c. generator may have its own exciter as shown in Fig. 7. ers may be operated in parallel and controlled from exciter panels. n this diagram the d-c. circuits are taken care of by an exciter rheostat, rheostat and a 2-pole field switch with discharge resistance. Each or is provided with a 3-pole single-throw knife switch, three ammeters, ltmeter switch, and a synchronizing switch. Each feeder has a h and an ammeter. A lamp ground detector and a voltmeter are n such a manner that the voltage can be read across any phase of e. In this diagram lamps are used for synchronizing.

**High-voltage A-C. Boards.** — A similar arrangement of panels may small-capacity high-voltage switchboards, using oil switches in place itches in the generator and feeder circuits, and operating the volt- amp ground detector from potential transformers.

**Low-voltage A-C. Boards.** — For low-voltage a-c. circuits of greater an can be readily handled by the 48-inch panels, larger panels made hree sections with a total height of 90 inches are usually employed. vice where the voltage does not exceed 550 volts, knife switches are used but the practice is rapidly growing, of utilizing oil circuit-break- moderate voltages, owing to the greater safety, greater convenience, dvantages. Where the voltage does not exceed 2400, or the amount es not exceed 3000 kv-a., it is customary to use oil circuit-breakers irectly on the switchboard panels. Fig. 8 shows a typical switch- panel-mounted oil breakers arranged for the control of two exciters, ators, and two feeders.

ket devices comprise two voltmeters, one connected through trans- the bus, and the other arranged to plug on any phase of any of the ators through suitable transformers, one synchronoscope with two ng lamps, and one voltage regulator. The first panel on the left o exciters and is provided with two d-c. ammeters, one d-c. volt- rheostats, two 2-pole switches, and one equalizing switch.

three panels are generator panels, each being provided with an a-c. a polyphase indicating wattmeter, field ammeter, field rheostat, , voltmeter and synchronizing receptacle, ammeter switch and a tic breaker.

two panels on the right are feeder panels and are each provided with eters, a watt-hour meter, two overload relays, and an automatic

the disconnecting switches are furnished for disconnecting the oil akers from the busses, to facilitate the inspection of the breakers.

the voltage exceeds 2400, or the amount of power to be controlled is

in excess of about 3000 kv-a., it is preferable to locate the oil breakers apart from the board and to control them either electrically or mechanically from the panel.

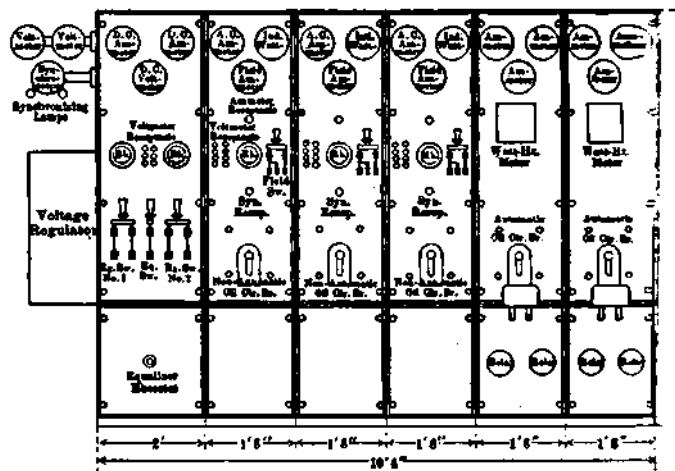

Fig. 8.

**Large Distant-control A-C. Switchboards.**—Where the amount of power to be controlled is large or the voltage is above 3300 it is customary to mount the oil circuit-breakers apart from the board and to operate them either mechanically or electrically. On these boards the usual equipment of instruments is mounted at the top of the panel, the switch-control handles are in the middle and the time-limit relays at the bottom. Targets and signal lamps to indicate the condition of the feeder are furnished with electrically operated boards.

Fig. 9 shows diagrammatically the various standard arrangements in electrically controlled equipment. *a* illustrates a typical vertical panel board with the instruments, control switches, relays, and similar devices mounted on the face of the panel.

*b* shows an arrangement of a control desk with the control switches placed on the desk and the instruments mounted on a wall in front of the operator. *c* shows an arrangement of control desk where there are comparatively few meters, these being set flush in the face of the desk. *d* shows a modification of the desk arrangement with the meters on a small slab or bracket extending up from the horizontal slab of the desk. *e* shows the control desk arrangement with vertical panels forming the back of the desk, the vertical panels containing the indicating meters. *f* is a further modification of the control desk arrangement with vertical panels containing the indicating meters and a complete switchboard at the rear to contain the recording meters, relays, and similar devices. With this arrangement a self-supporting control desk is provided. *g* shows the so-called gallery type of desk with the meters located on a framework supported above the horizontal slab of the desk at such a height that the operators standing at the control desk can look above the edge of the desk and

meter panels to observe from the switchboard gallery the machine is controlling. *h* is a modification of the gallery type of control desk is a modified arrangement of control desk using a separate instrument

Fig. 9.

supported on ornamental pillars, these pillars as a rule, being arranged as supports of a gallery railing.

The combination of a gallery type control desk for the generator panels and switchboard for the feeder.

In a combination control desk and panel board, the generator breakers are controlled from the desk, the generator instruments being on the vertical panels of the feeders being controlled from the vertical panels. The meters, graphic meters, and relays are placed on an auxiliary board with the feeder board.

The arrangement of control pedestals and instrument posts corresponding to the arrangement adopted by the Ontario Power Company at Niagara. In this control room pedestals and posts are provided for a total of 12 generators, 12,000 volts, the units averaging about 8770 kv each generator being provided with its own control pedestal and instrument post.

**DESKS** (Figs. 10 and 11).— Where it is desired to have a very compact control desk and to control the generators and feeders from the same control desk has many advantages; particularly where a group of instruments is used and it is desirable to have a miniature bus-bar to show the arrangement of connections and the arrangement of circuits in use. The control desk is supported on it the field switches, field-rheostat handles and small instruments for operating electrically the various controllers, circuit-breakers etc. Meters and rheostats may also be operated electrically.

The arrangement of the control devices and the meters is indicated in the diagrams as may be noted, various combinations can be readily secured. Where a control desk is placed in a gallery, a so-called gallery control desk is to be the most advantageous. With this type of desk the control switches and indicating lamps for the electrically operated breakers are placed on the nearly horizontal portion of the desk. The control switches for the field and excited circuits are on the vertical part of the desk. The indicating instruments are placed on vertical panels down to the horizontal part of the desk and graphic meters, meters, relays, and calibrating jacks are placed on separate panel boards with the main desk.

On the horizontal section of the desk a miniature bus is often placed showing the connections made by the main breakers.

Each generator is provided with three ammeters, one per phase, a polyphase indicating wattmeter to show the amount of power delivered to the main bus,

Fig. 10. Control Desk with Instrument Panels.

polyphase indicating wattmeter to show the amount of power going over the transfer bus, a synchronoscope, power factor indicator, field ammeter, ammeter in the circuit of the synchronizing bus, a frequency meter, and an indicating temperature meter. In addition to the indicating temperature meter a potentiometer is sometimes provided with a dial switch for other temperature readings.

**Control Desk with Separate Instrument Frame.** — Fig. 11 shows the plan view, elevation and side view of a control desk provided with 7-inch diameter round pattern meters located on an instrument frame back of and above the desk. The height of the instrument frame is 7 feet 8 inches, which corresponds to the height of standard 90-inch switchboard panels mounted on the usual 2-inch channel iron base. This control desk with a total length of 11 feet, when fully equipped, is to take care of six 10,000-kv-a., 3-phase, 6600-volt generators, six banks each of three 3333 kv-a. step-up transformers, and four 110,000-volt transmission lines.

As shown by the miniature bus system placed on the top of the control desk, each of the six sections intended for a generator and its bank of transformers is provided with a generator ammeter, transformer ammeter, generator indicating wattmeter, power-factor meter, voltmeter, and field ammeter, as well as four circuit-breaker controllers. Each generator, with the low tension side of its bank of step-up transformers, is provided with three breakers, one in the main generator circuit connecting the generator to generator bus, one for connecting this generator bus to a main bus, and the

necting the generator bus to the low-tension side of the step-up  
 . With this arrangement under normal conditions each generator  
 current to its own bank of step-up transformers, but in emergency  
 or any transformer can be connected to the low-tension bus,

Fig. 11. Control Desk with Separate Frame for Instruments.

sectionalized in the middle by means of an electrically operated  
 the high-tension side each bank of transformers connects  
 single breaker to a high-tension bus that is sectionalized in the  
 means of an electrically operated breaker. Two high-tension lines  
 each half of this sectioned bar.

**Dimensions of Panels.** — The smaller panels intended for use with  
 network are made either in single slabs and as a rule have a height of  
 a width of either 22 inches or 32 inches, although some of the  
 taller. As few of the smaller d-c. panels have to be made wider  
 as or 24 inches and as  $1\frac{1}{4}$  inches is ample thickness for a 24 by  
 the thickness of  $1\frac{1}{4}$  inches has been adopted as a standard for most  
 d-c. panels. In order to secure sufficient mechanical strength the  
 s are made  $1\frac{1}{2}$  inches thick. As these wide panels are usually  
 Alternating-current generator panels this thickness of  $1\frac{1}{4}$  inches  
 ally adopted as standard for a-c. panels. For heavier panels 2-inch  
 ate have been adopted as standards for mechanical reasons. This  
 quired for the heavy switches, circuit-breakers, etc., often furnished  
 hboards. When a board has both a-c. and d-c. panels the thick-  
 els is made the same.

**Beveled Edges.** — The edges of all panels are usually beveled to  
 appearance and to insure against chipping, as it is almost  
 handle square-edged marble or slate slabs without injury. The  
 re ordinarily beveled with a 45-degree bevel of either  $\frac{1}{4}$  inch or

**REMARKS AND TESTS.** — See article on *Switchgear Equipment*

**BIBLIOGRAPHY.**—Adams, C. C., *Switchboard Apparatus*, Chicago; Andrews, L., *Electricity Control High and Low Tension Switchgear Design*, New York; *Switches and Switchgear*, New York; See also *t G. E. Rev., Electric Journal*, etc.

(See also *Circuit Breakers; Switchboards; Switchgear Equipments; Wiring of Buildings.*) A switch is a device for making and breaking connections in an electric circuit. Various types of knife switches are used; some representative types are described

Requirements are (1) a switch must, when closed, carry the current without excessive drop, usually from 5 to 25 millivolts, or excessive temperature rise; (2) it must take care of overloads and must be designed to prevent or render harmless any arcs that may be formed when opening; (3) it must, when open, insulate all live parts from the ground potential of the circuit.

**KNIFE SWITCHES.**—The rules of the National Board of Fire Underwriters advise for pure copper blades a current density of not over 75 amperes per square inch. The recommended spacings between points of opposite polarity for various currents and voltages are given in the accompanying table.

Inches between points of opposite polarity

125 v. d-c.	150 v. d-c. 500 v. a-c.	600 v. d-c.
1¼	2¼	4½
2¼	2½	4½
2¾	2¾	4½
3	3	4½

**Types of Switches.**—A switch closing a circuit only when thrown in one position is called a single-throw switch; a switch closing a circuit in either of two positions (e.g., up or down) is called a double-throw switch; a switch closing only one side of a circuit (one blade) is called a single-pole switch; a switch closing both sides (two blades) is called a double-pole switch. Abbreviations are used, such as S.P.S.T. for single-pole single-throw or double-pole double-throw.

**Knife Switches.**—Up to 1000 amperes in capacity are usually made with single blades. For larger capacity two or three blades are supplied in order to secure sufficient contact surface between blades and jaws of abnormal width.

The smaller capacity switches are made both rear connected, while the larger switches are almost invariably made for top connection. Up to approximately 1000 amperes the standard studs for knife switches are circular and the switch studs are attached to their ends and are secured on these circular studs. Additional nuts are provided for mounting connections or terminals.

High capacity switches employed on low-voltage boards, strap connections are invariably used and to facilitate the employment of the knife switch studs are frequently made laminated. A modified design of stud employs copper studs cast under high pressure by the hot-chamber process. The conductivity of the cast studs is approximately 90 per cent of that of pure copper. With the laminated stud switches the laminations can be

**Knife Switches for A-C. Service.** — Up to 800 ampere difference in the heating of knife switches on different capacities. For larger capacities it is found that for the same capacity the rise is necessary to rate lower for alternating-current. The following are typical designs and different capacities, a typical case being: 3000 amperes (d-c.), 30 degrees; 2500 amperes (d-c.), 30 degrees; 2400 amperes (d-c.), 25 cycles, 30 degrees; 1800 amperes, 60 cycles, 30 degrees. The 30-degree rise is that covered both by the N.E.C. and A.I.E.E. Rules.

**Field Switches (Fig. 1).** — A modification of the standard knife switch (q. v.) as shown in Fig. 2 is furnished for connection with field circuits. These field switches are single-pole or double-pole, single-throw or double-throw, and are provided with an auxiliary contact and extra jaw which is used for connecting a resistor across the field terminals. When the field is disconnected from the source of supply the field discharges through this resistor without any arcing or kick such as will occur on the sudden opening of a field circuit without such a device.

**Auxiliary Breaks and Quick-break Attachments.** — Knife switches furnished with knife switches in many cases so as to prevent it is impossible to draw a dangerous arc by opening the switch slowly. Fig. 2 shows a typical quick-break knife switch. The blade here carries auxiliary blades, which are attached to a hinge and spring. When the switch is opened, the auxiliary blades are held in the jaws by friction until they are suddenly jerked out by the spring tension. A similar attachment is used on the field switch shown in Fig. 1.

**Starting Switches.** — A modification of the standard knife switch is the multi-point starting switch used occasionally for starting d-c. motors, or synchronous converters or motor-generator sets from the d-c. end. These multi-point starting switches consist usually of single-pole, single-throw switches with several break jaws connected to various steps of the starting resistor.

**Disconnecting Switches.** — In all high-tension circuits it is customary to install knife-type disconnecting switches for isolating feeders, oil circuit-breakers, etc., or for making various connections that do not have to be opened under load. The knife switches for 2500 volts or less are usually made of soapstone, marble or similar material; for higher voltages kinds are used to support the switch jaws. Up to 2500 volts disconnecting switches are made for either front or rear connection, but for higher voltages they are almost invariably made for rear connection only.

Fig. 3 shows a disconnecting switch built in capacities of 600 amperes at 7500 and 15,000 volts, and up to 600 amperes up to and including 66,000. In this switch a porcelain insulator is used with the switch part attached to the top and the bottom of the insulator attached to a metal base.

or proves defective, it can readily be replaced without the necessity of disturbing the balance of the switch. Owing to the severe mechanical stresses on the instant of short circuit on a switch of large capacity, latches are used on these disconnecting switches when they are to be blown open.

**Disconnecting Switches on Post Insulators.**—For voltages of 1000 and above, it is customary to use disconnecting switches mounted on posts of the built-up type. A sufficient number of sections are used to secure the voltage test desired, either for indoor or for outdoor service. This type of switch if an insulator is damaged or defective, the units can be readily unbolted from the built-up post and replaced by a new section.

**SWITCHES** are often used as manually-operated devices such as field switches and circuit breakers. In the type shown in Fig. 4 the operating handle and direction dial are mounted on the front of the switchboard, while the contacts are back of the board and are made part of a drum-type controller. This construction enables the operator to disconnect the d-c. operating voltage from the front of the board and readily

Fig. 3

Fig. 4. Drum Control Switch

be used for use on 550-volt control circuits. The handle is so designed that when it is turned to the trip position it can be pulled out in such a manner as to disconnect the control switch and extinguish the indicator lamps. For use on control switch lamp indicators with colored prisms are furnished.

**SWITCHES** are commonly used for interrupting small currents at various points in a circuit. They are particularly applicable for such uses as reading the voltage across various phases or circuits. By placing suitable receptacles on the control panels and using only one voltmeter plug switch, one can read the voltage across any circuit without the possibility of trouble from an attempt to connect more circuits to the voltmeter at the same time. Other types of plug switches are used in connection with current transformers for connecting instruments into any phase of any circuit. By using suitable current transformer receptacles it is feasible to connect in testing meters for calibration of board instruments without removing them from the board.

The latest designs of instrument switches are built with attached or removable handles, depending on their use. Each switch usually has an attached handle and the switch is used to connect an ammeter in any phase of the circuit. The voltage is measured by a removable handle of the key type so that by having a voltmeter and a voltmeter on a bracket the instrument can be used to measure voltage across any phase of any circuit. With the switch a removable handle is also provided. When synchronizing machines a plug must be inserted in the proper receptacle and the switch is used in synchronizing between machines the escutcheon plate. A synchronizing switch is provided with two slots, one for a key that permits turning the switch in one direction and another permitting the insertion of a key for turning in the opposite direction, for the incoming machine. Proper keys are used on the escutcheon plates and the corresponding pins on the keys.

**Synchronizer Switches** may be fitted with auxiliary handles. It is impossible to close an electrically-operated breaker in a circuit without putting the synchronizing plug in the proper receptacle. The synchronizing that particular circuit. The tripping is independent of the synchronizing receptacle so that it can be operated independently of the position of the plug.

**Plug Switches for Arc Service** are built in capacities suitable for use on circuits up to 10,000 volts. Each switch is made of fiber or similar material, with socket contacts at the top. It consists of a metallic rod or tube with an insulating handle. The handle usually mounted on the rear of the switchboard. The handle through the hole in the panel connects the contacts and the breaker.

**Pull- or Push-Button Switches** of twin type are used in the design of oil circuit-breakers. The switch operated by one button and the switch operated by the other button open or close the circuit. The wiring are mounted on the back of the panel, so that the switch is not a live circuit. By using pull buttons in place of push buttons the likelihood of the attendant operating the device unintentionally or working about the switchboard. Red and green lenses are used for signals. A little red lens is placed between the button shows the last movement that the target shows one color and the indicating lamp shows the breaker has been tripped automatically.

**Push-Button Switches with Signal Devices** are used in the design of former-type ground detectors, engine-room signal devices. These are frequently arranged as the equivalent of a switch. They are normally maintained in one position by a spring to make or break and making other connections when pushed in by hand.

**Button and Snap Switches** of various designs are used in the design of a circuit (see *Wiring of Buildings*).

**OIL SWITCH.** — (See *Circuit Breakers*.) The term is often drawn between the terms "oil switch" and "oil circuit-breaker." In some cases the term "oil switch" is applied to a switch with contacts that tend to remain closed, and the term "oil circuit-breaker" to a device with butt, brush, cone wedge or similar contacts that open and must be held closed by a toggle, latch or similar device. "Oil circuit-breaker" is the term usually employed.

## END-CELL SWITCHES. — (See Batteries, Storage.)

**COSTS.** — Switches vary so much in design that it is impossible to give a comprehensive table of costs in a limited space. The following table gives the approximate range of (1912) prices of a few typical switches:

S. P. S. T.,	100-3000 amps., 600 volts.....	\$3.50 to \$130.00
S. P. D. T.,	100-3000 amps., 600 volts.....	5.00 to 200.00
D. P. S. T.,	100-3000 amps., 600 volts.....	6.50 to 235.00
D. P. D. T.,	100-3000 amps., 600 volts.....	9.00 to 360.00
S. P. D. T. Q. B.,	100-3000 amps., 600 volts.....	9.50 to 375.00
Disconnecting Switch,	15,000 V., 400 A.....	30.00
Disconnecting Switch,	37,500 V., 400 A.....	40.00
Disconnecting Switch,	73,000 V., 600 A.....	75.00
Disconnecting Switch,	115,000 V., 400 A.....	150.00
Simple Plug Switch.....		3.00
Simple Snap Switch.....		.50

**SWITCHEGEAR EQUIPMENT FOR POWER**  
*also Bus-bars; Circuit Breakers; Fuses; Lightning Protection; Substations; Switches; Switchboards.*) This article is a practical practice in regard to the arrangement of the control equipment in generating stations, transforming stations and substations and special building arrangements to suit the switching requirements of the case.

In the earliest plants the switchgear, which then consisted of plugs, fuses and lamps, was scattered around the station in a hazardous way, or possibly assembled on one of the walls. Space was allotted to it that could possibly be used for other purposes. The next step with increasing amount of auxiliary apparatus was the placing of the switchgear on a panel switchboard near the work. This was taken up by it. As stations grew still larger, more space had to be allotted to the switchgear, until in the modern large capacity plant, one portion of the building, or in some cases a separate building is assigned to the switchgear and designed especially for this purpose.

As regards switchgear equipment power stations are classified as follows:

- Generating stations distributing at generator voltage:
  - With direct-control panel switchboard.....
  - With distant-control switchgear.....
- Generating stations distributing through step-down transformers:
  - Indoors.....
  - Outdoors.....
- Converting stations:
  - In buildings.....
  - In movable cars.....

The switching requirements of the several classes are given in the following.

#### **DIRECT-CONTROL SWITCHGEAR IN GENERATING STATIONS**

— Direct-control panel switchboards are usually installed in the generating station. For power and railway service of low voltage and medium voltage switchboards for such plants are of the panel type and may be placed on the floor, on a platform or in a gallery. All the switching is done directly on the panels of the switchboard. With such an arrangement it is simple to locate the switchboard in such a manner as to minimize the amounts of connecting cables and similar material. The relative position of the switchboards and generators is also of importance.

The amount of space required and the amount of material needed in a direct-current railway generating station is determined by arranging to have only one polarity, usually the positive, on the busboard, and to place the negative and equalizer busboards in a separate conduit near the machine, locating equalizer and machine.

#### **DISTANT-CONTROL SWITCHGEAR IN GENERATING STATIONS DISTRIBUTING AT GENERATOR VOLTAGE**

— Stations that distribute current at the generator voltage there are three types for the bus-bars, oil circuit breakers and control apparatus. They differ principally on the amount of space needed for this portion of the station. The locations are: 1. at the end of the building; 2. at the end of a gallery; 3. in a separate switch-house.

**of Switchgear.** — The end of the building is a favorite location for gear when the number of feeders is such that this location provides space for the breakers and the bus-bars, making due allowance for future additions. With this arrangement it is customary in large stations to provide a number of galleries for the switching equipment. The switchboard is usually placed on one of the upper galleries so that the attendant can readily watch the operation of the machines which he is controlling.

If the end of the building does not provide sufficient space the switchgear is frequently located along one of the side walls, usually the wall from the boiler room in a steam station, or from the incoming penstock in a hydroelectric station. The switching equipment when arranged in one series along the side of the building can easily be extended, as the length of the building provides for the switchgear proportionately with the space available for the generating equipment. With this arrangement it is customary to locate the generator breakers directly opposite the individual generators and to run the bus-bars the length of the station; the length of the leads will then be reduced to a minimum and it is sometimes possible to use smaller conductors for these leads. The switchboard itself, if electrical control is provided, may be located either on one of the side galleries or at the end of the building in such a position that the switchboard attendant can watch the operation of the machines which he is controlling.

One of the objects of this scheme of utilizing the side walls is to provide a separate room for the attendant and to control all of the apparatus electrically from a switchboard in the building or from a switchboard in the switch-house as preferred.

**Structures for Bus-bars and Circuit Breakers.** — The arrangement of the structures for bus-bars and circuit breakers is influenced chiefly by the voltage and capacity of the circuits. For circuits of moderate capacity or less, mechanical control is usually employed, though electrical control is sometimes used; for circuits of large capacity or of higher voltage electrical control is practically universal.

**Structures for Mechanical Control.** — Fig. 1 shows a typical arrangement of mechanical control applied to circuit-breakers mounted on a metal framework. The view shows a section through a 2300-volt, 500-kw. generator circuit. Each circuit is provided with a 3-pole oil circuit-breaker which can be connected to the three-phase bus-bars supported on the structure. Sprocket-operated face plates with suitable resistors are located on the structure to allow for the regulation of the voltage on the generators. Instruments and voltage transformers for the instruments are located back of the structure on a suitable framework or on the wall.

**Structures for Electrical Control of Moderate Capacity.** — Fig. 2 shows the front and rear elevations of a part of the structure for circuit-breakers and bus-bars for the control of four 500-kw., 2300-volt, 500-hp. generators, nine 3-phase feeders and six single-phase feeders. Though the voltage and capacity of these machines would have permitted the use of oil circuit-breakers, other considerations caused the adoption of mechanical control for the breakers and of inclosed bus-bars. The relative positions of the circuit-breakers, disconnecting switches, series transformers, bus-bars, etc., are indicated in the cut. The bus-bars of the upper section are supported on petticoat insulators, and porcelain insulators are used for insulating the leads where they pass through the back of the structure. The breakers here used are self-contained and all three are in the same compartment. The disconnecting switches are mounted on separate bases.

Fig. 1. Structure for Distant Control of 2300-volt

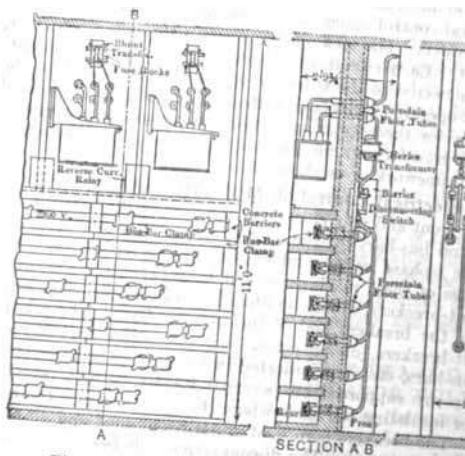

Fig. 2. Structure for Electrical Control of 2300-volt,

Fig. 3.—Structure for Top-connected 6600-volt Breakers

Fig. 4.—Structure for Bottom-connected 11,000-volt Circuit Breakers

The front, rear, and side views of a structure for solenoid operated breakers with a guaranteed rupturing capacity of 7500 amperes at 7500 volts are shown in Fig. 3. The bus-bars, connections, etc., are separated by a partition in such a manner that no two conductors of opposite polarity are in the same compartment. The bus-bars and laminated copper pillar type insulators resting on the shelves and lugs are connected from the bus-bars to the disconnecting switches. The disconnecting switches are front connected, and are attached to a steel base located on the rear wall of the structure.

With the type of breaker shown, employing solenoid operated breakers, the leads are brought out at the top of the breaker tanks, taken to the floor, and the connections can then be run either up or down.

**Structures for Electrical Control of Large Circuit-Breakers.**—A typical way of arranging bottom connected, motor operated circuit-breakers for connecting to the bus-bars placed above (A), below (B), or independent of (C), the structure containing the breaker is shown in Fig. 4. The structure containing the breaker is of this breaker used particularly when the lead connection is brought through the rear wall from the floor to the breaker pots. Where both leads are to run upwards the breaker is arranged in tandem so that the six pots of a three phase breaker are arranged in a continuous line. The breaker illustrated has a rupturing capacity of 23,000 amperes at 7500 volts. The same type with 10-inch pots and a guaranteed rupturing capacity of 32,000 amperes, and a still larger breaker with 12-inch pots and a guaranteed rupturing capacity of 52,900 amperes at 7500 volts.

**Sub Compartment Disconnecting Switches.**—In this type of breaker have the disconnecting switches located on the same floor as the breaker, and the bus-bar is placed below the breaker. The breaker is raised a sufficient height from the floor to allow disconnecting switches to be mounted below them. The blade of the disconnecting switch connects directly from the bottom terminal of the pots to a jaw on the rod running through the floor.

Fig. 5 shows a section of a heavy capacity 4000-volt installation with two sets of bus-bars and a double-throw arrangement carried out with two sets of disconnecting switches and one breaker per circuit.

Fig. 6 shows a section through the switching galleries of a 22,000-volt installation where the generator breakers with their disconnecting switches and bus-bars are located on the second floor and the feeder circuits, duplicate buses, and two sets of disconnecting switches are located on the first floor. The breakers in this installation are guaranteed capable of rupturing 5350 amperes at 25,000 volts.

**SWITCHGEAR IN GENERATING STATIONS AND TRANSFORMERS.**—Fig. 7 shows a sectional

Fig. 5

contains four 16,000 h.p. vertical shaft water wheels driving 12,000 kv-a. 6600 kv generators, and four three-phase transformers. The leads from the generators are taken through the breakers to the 6600-volt main bus, back from the bus through similar breakers to the low-tension side of the transformers. A cross connection allows the generators to feed directly to the transformers.

Fig. 6.—22,000-volt Switching Galleries

The leads from the high-tension side of the transformers are taken up through four openings where they are attached between insulators, thence through choke coils and disconnecting switches to the high-tension breakers and to the high-tension bus. From the bus the current passes through disconnecting switches and breakers to the roof bushings and so out to the lines. A grounding switch is located near these roof outlet bushings for grounding the high-tension circuit. The electrolytic arresters are located on the roof.

Fig. 7

**SWITCHGEAR IN SEPARATE BUILDING.**— In many cases it proves desirable to utilize a separate building for the transformers and switchgear. Fig. 8 shows a sectional view through a typical station of this kind with two 500-kw. 250-volt exciters, six 12,000-kv-a. 6600-volt three phase generators, six banks of transformers, and four 110,000-volt transmission lines. Advantage is taken of the natural slope of the ground as the plant is built on the side of a hill. The diagram for this station is shown in Fig. 9.

**Bus Connections.**— Each generator as shown in Fig. 9 is normally used with its own bank of step-up transformers. Three circuit-breakers, however, are provided with each transformer and generator group so that, if desired, any generator or any bank of transformers may be connected to the 6600-volt bus-bars. The low-tension neutral bus is provided with a grounding resistor and each generator is furnished with a single-pole, single-throw knife switch for connecting it to this grounding bus. In a similar manner the high-tension neutral bus is provided with a grounding resistor, and each bank of transformers is furnished with a single-pole, single-throw knife switch for connecting its neutral point to this ground bus.

**Ventilation of Generators and Field Rheostats.**— It should be noted that it is intended to locate directly opposite each machine a field-regulating panel containing electrically operated field rheostats and field switches, the

grid resistors used with these electrically operated fuses are placed just outside the building. Each generator will discharge and discharge it at the bottom of the stator to a tail race. With this arrangement of discharging generators into the tail race and locating the field generators outside the building, the question of securing the switch house is greatly simplified. The generator building is separated from the switch house by about 20 feet in order to secure ventilation for both buildings.

**Switching Gallery.** — The control desk, instrument panel, and switchboard are placed on a gallery in such a manner that the operator standing at the desk can readily observe the operation of the switchgear he is controlling. The switching gallery is on a level with the top of the transformer and switch house so that the operator can readily pass into the basement of the switch house.

**Switch House.** — The basement of the switch house contains the electrically operated oil circuit-breakers, bus-bars, disconnecting switches, and potential transformers for the 6600-volt generator. The oil and water piping for the various transformers and bus-bars are inclosed in masonry compartments. The 110,000-volt circuit-breakers and bus-bars are open, and the expense of installing masonry compartments for them is of doubtful benefit to be obtained by such a course. The transformers are arranged in one row and are mounted on rollers with wheels in such a manner that any transformer can be rolled out on a low truck and then pulled outside the building, after which the oil pipes, low-tension and high-tension connections be made.

In many cases, even for generating stations, it has been found to place the transformers and high-tension switchgear outside the building. The high-tension devices from a switchboard located in the switch house. In other cases due to local conditions it is necessary to use an indoor apparatus, particularly for moderate voltages. In 10 years, probably 80 per cent of transformers and switchgear at 110,000 volts and above have been of the outdoor type.

#### ARRANGEMENT OF SWITCHGEAR FOR TRANSFORMER STATIONS. — Fig. 10 shows

Fig. 10. 44,000-volt Step-down Transformer Station.

for the control of two 44,000-volt, 3-phase incoming lines, four of three 625-kv-a. single-phase step-down transformers, and a 66,000-volt feeder circuits. The 44,000-volt lightning arresters with disconnecting switches are placed out of doors, and the circuit transformers, disconnecting switches, and busses are located indoors. The incoming leads pass through porcelain bushings in the walls to the bus-bars and through disconnecting switches to the 44,000-volt breakers. From the breakers the current passes through other disconnecting switches to a 66,000-volt bus-bar that is hung from the ceiling by means of suspension rods. From this bus the current passes through other disconnecting switches to the circuit-breakers, and thence to the high-tension side of the transformers.

**Comparison of Top- and Bottom-connected Breakers and Closed Wiring (Fig. 11).** — (See also *Bus-bars; Circuit Breakers.*) In order to show the difference in the design of the station made necessary by the use of bottom-connected breakers and inclosed bus-bars for the high-tension

Fig. 11A, 11B, and 11C show three different designs of switching equipment for the control of 66,000-volt, single-phase step-down transformers (each transformer supplying current to the 66,000-volt bus-bars).

Fig. 11A shows the general arrangement of bottom-connected circuit breakers, bus-bars, etc., using bottom-connected bus-bars of standard design and inclosed 66,000-volt bus-bar disconnecting switches on the floor. In order to provide room for lifting the coils of a transformer case, it is necessary to slide the transformer into the building where the coils are raised under the control

in a manner as to provide the necessary headroom. With this arrangement the total height of the building from the floor line to the roof is 66 feet 6 inches.

Fig. 11A. Bottom-connected Breakers, Inclosed H.T. Bus-bars, 66,000-volt Substation

Top-connected Breakers, Inclosed H.T. Bus-bars, 66,000-volt Substation

Fig. 11C. Top-connected Breakers, Open H.T. Bus-bars, 66,000-volt Substation

Fig. 11B shows the arrangement necessary if it is desired to have the breakers and still inclose the 66,000-volt bus-bars. The 66,000-volt bus-bars, as well as the 13,200-volt bus-bars, and the control desk, are placed on the main floor near the transformers. The 13,200-volt breakers themselves with their disconnecting devices are placed on a second floor. This arrangement can have its coils or iron removed as soon as it is desired. A building arranged in this manner requires a height of 40 feet from the floor line to the roof girders and requires a second floor. Fig. 11A.

Fig. 11C shows the arrangement of this same building with the breakers and open bus-bars and wiring for the 66,000-volt bus-bars. In this arrangement there is no necessity of a second floor. The height is greatly reduced as the distance from the floor line to the roof girders is only 30 feet.

**ARRANGEMENT OF SWITCHGEAR EQUIPMENT AT TRANSFORMER STATIONS.** — The use of outdoor protective devices should be considered when designing a station where it is essential to keep the first cost of the installation low.

**11,000-volt Station.** — In Fig. 12 is shown a typical arrangement for 11,000-volt, single-phase transformers with

Fig. 12. Switchgear Arrangement for 11,000-volt Transformer Station

switches and non-arcing lightning arresters. The switches are mounted in a wooden box with a swinging door. The low-tension breakers are mounted in a similar wooden box with a glass door so that the breakers, ammeters and watt-hour meter can be taken without opening the door.

**33,000-volt Installation.** — A 33,000-volt installation consists of two single-phase radiator type transformers and one switchgear cabinet. Fig. 13. All of the apparatus furnished is suitable for outdoor use. Each transformer bank connects through its bus-bar to a switchgear cabinet sectioned between the two transformers, and each bus supplies current to two outgoing feeder circuits. The switches and their switching equipment are located immediately adjacent to the transformer station and the low-tension breakers and control equipment are located in the transformer station.

When installing outdoor equipment of this character, it is essential to

and it is advisable to obtain samples of the oil from the bottom circuit-breaker tanks at regular intervals, and if any evidence

Fig. 13.—33-kv. Outdoor Switchyard

amount of carbon appears in the oil, the oil should be immediately changed.

Fig. 14.—110-kv. Outdoor Switchyard

**Installation.** — Fig. 14 shows in plan view a typical 110-kv. switchgear and switching station with four 110-kv. lines, six banks of transformers, each of three 5,000 kv-a. capacity of the radiator type. At this station the main busbar switchgear is located in a switch-house but all of the high-voltage switchgear is outdoor. The high tension leads from the transformers pass through the busbars and breakers to either of two sets of bus-bars.

**154,000-volt Installation.**— Fig. 15 shows yard for an installation of six banks of step-up to three 7500 kv-a. units with four 154 kv. outgoing yard is close to a large hydro-electric generating station switchgear is located in that station. In the high former bank, and each line circuit is provided with sets of disconnecting switches so that it may be cut off from two sets of busses that are sectioned in the middle. with its steel work and special weatherproof equip

Fig. 15.—154-kv. Transformer and

about 13 per cent less than the corresponding building to house it.

**Advantages and Disadvantages of Outdoor** illustrations of outdoor stations indicate the tendencies. The advantages of outdoor apparatus such as cheapening of the installation due to saving in building in life and fire hazard, owing to the fact that in apparatus can be well scattered without material cost in the installation. The disadvantages are: (1) the effect of the weather when inspecting, overhauling, or making repairs; (2) the danger to trespassers and to the apparatus; (3) somewhat more expensive than the corresponding indoor installation. The difference in cost will be usually more than offset by the investment.

**SWITCHGEAR EQUIPMENT FOR CONVERTER BUILDINGS.**— The proper grouping of the apparatus in a converter station depends on the voltage of the incoming circuits, the type of transformers, and similar features. The design is provided the shape and size of the available lot is known. The design of the station.

The sectional view of a synchronous-converter substation with 6-phase converters with air-blast transformers fed from two circuits is shown in Fig. 16. The incoming leads are connected through an oil breaker and disconnecting switches located on a gallery. Provision is made for an additional set of disconnecting switches to be installed in any breaker may be connected to either of the two bus-bars.

The circuits from these bus-bars pass back through the disconnecting switches and breakers to the high-tension terminals of the air-blast transformers. The low-tension leads are connected to a starting panel provided with double-throw switches to be impressed on the converter for the purpose

The converters are provided with series fields on the negative

Arrangement of Switchgear Equipment in Rotary Converter Station

and equalizer switches are placed on a pedestal at the machine, and equalizer busses run on a bracket in the basement. The bus to the panel board near the left-hand wall and the positive bus to the back of this board. The railway feeders are run out through ducts. All of the high-tension a-c. circuits are provided with oil-circuit breakers controlled from the main switchboards. It will be seen that the entire design of this station hinges on the proper arrangement of the switchgear equipment.

**SWITCHGEAR EQUIPMENT FOR PORTABLE CONVERTING STATIONS**

Many interurban electric railways have portable substations mounted in motor cars and arranged for ready transportation to whatever point of temporary service. A typical installation of this kind consists of a synchronous converter; oil-insulated, self-cooling transformers; and the switchboard, high-tension oil circuit breaker, and lightning arresters. The apparatus may be so arranged in the car that the operator is convenient to the handle of the high-tension oil breaker, the panel board, and the commutator end of the synchronous converter.

**REQUIREMENTS FOR SWITCHGEAR EQUIPMENT.** — The great variety of conditions to be met and the numerous ways of meeting each condition on the switchboard work make it impossible to write specifications in the form of a table suitable for general use. This specification is therefore in the form of a list of memoranda to assist in writing a more specific one. (See also *General Specifications*.) The items are arranged in alphabetical order.

- A.** Purpose. Material. Method of support. Dimensions.
- B.** Control. — Number of cells. Discharge rate. Style of rack. Protection against exposed copper from acid fumes. Condition of cells when handled (whether charged or not).
- C.** (See *Switchboard*).
- D.** Material. Conductivity. Style of joints. Minimum length of bus to be supported in. Protection, if required, in case of short circuit.
- E.** H. T. bus.

**Ratio for Instruments.** — Style. Ratio. Rating and temperature rise. Maximum permissible percentage error in ratio.

**Power Circuits.** — Use. Location. Shall be clamped so that when dislodged should any joint or terminal become loose. Description of location where cables pass through floors or walls. Tagging with identification number. Conductivity. Size or carrying capacity. Conductivity of terminals. Style of insulation.

**Control and Instruments.** — Use. Location. Accordance with the regulations and rules of "National Board of Fire Underwriters." Conductors shall be tagged with numbered tags of stated material and color. Tagged with brass wire. Wires which it is inadvisable to keep in different pipes as directed by the Engineer. Size. Style

It is impossible to give reasonably accurate figures upon the cost of switchgear equipment because of the large number of independent cases, such as type of station, voltage, number of generators, number of bays and lines, single-throw or double-throw switching arrange-

**BIBLIOGRAPHY.** — See bibliography under *Switches*.

**SYNCHRONIZERS AND SYNCHRO**

*nating Currents; Converters, Synchronous; Generator Stations; Substations; Switchgear Equipment for*  
 principal functions of any synchronizing device are circuits to which it is connected are operating at when the voltages of the two circuits are in phase. The angles of the two circuits must also be equal in effect. This is determined by means of voltmeters connected to the terminals of synchronizing is simplified if the synchronizer is to be synchronized is operating at a frequency low system to which it is to be connected.

The name "synchroscope" is usually applied to a device for indicating synchronism, shows whether the machine is fast or slow (see *Standardization Rules of the A.I.E.E.*) The term is used in a broader sense for any kind of synchro

**Synchronizing Lamps.**—The simplest form of synchronizing device consists of two incandescent lamps shunted around the main circuit between the machine and the bus-bars; see Fig. 12A, p. 669. The brightness and phase between the bus-bars and the machine are indicated by continued darkness of the lamps. For a more elaborate arrangement may be used, if the lamps are connected between the phases of the two machines which are to be brought into synchronism. If the machines are not in synchronism the brightness of the lamps will be proportional to the difference in phase of the two machines. The lamps do not show whether the machine is too fast or too slow, nor is the point of exact synchronism indicated, as it requires an appreciable voltage to cause the lamps to glow. This latter difficulty may be avoided in the case of single-phase synchronizing by the connections shown in Fig. 12B, p. 669; when the lamps are dark they indicate synchronism when at maximum brightness.

It has been shown by Robbins (*Elec. World*, Vol. 10, p. 100) that synchronizing "dark" is to be preferred to synchronizing "glow" because that incandescent lamps require an appreciable fraction of full voltage to glow perceptibly. Tungsten lamps respond to a lower voltage of rated voltage than carbon lamps, and are therefore preferred for synchronizing dark, while carbon lamps are preferable for synchronizing glow.

**Use of Transformers with Synchronizing Lamps.**—Transformers are frequently used in connection with the lamp. The secondary of one transformer is connected to the primary of one of the machines, and the primary of the other connected to the bus-bars. The secondary windings are connected in series with the lamp. The primary windings may be arranged so as to have either darkness of the lamp at an instant of zero phase displacement between the bus-bars and the machine. Instead of using two separate transformers a transformer is called a "synchronizing transformer" which has two primary windings and one secondary winding. The secondary are usually connected to give full voltage across the lamp.

**Siemens and Halske Three-phase Synchronizing Lamps.**—Three lamps  $L_1$ ,  $L_2$  and  $L_3$  are connected between the terminals of the machine and the bus-bars  $B_1$ ,  $B_2$  and  $B_3$ .  $L_1$  is connected between corresponding phases, that is, between  $A_1$  and  $B_1$ ,  $L_2$  between  $A_2$  and  $B_2$  and  $L_3$  between  $A_3$  and  $B_3$ . The lamps will be reached when  $L_1$  remains dark;  $L_2$  and  $L_3$  will be bright.

falls out of step, the lamps will successively grow bright and on, no two lamps being in darkness or at maximum brightness at any one time, i. e., the light will appear to travel from one lamp to another at a definite direction. The speed of rotation of the light is proportional to the difference of frequency between the voltage of the bus-bars and the machine. The direction in which the light appears to travel depends on whether the frequency of the machine is greater or less than that of the bus-bars. For high-tension circuits, potential transformers are required.

The electrostatic synchronism indicator differs from the preceding arrangement in that it uses electrostatic "glowers" instead of lamps. These glowers are connected to the lines to be synchronized through the electrostatic capacity of potential transformers. This arrangement dispenses with the use of potential

transformers when used with a Voltmeter. — Instead of lamps, a dead-beat voltmeter is used for synchronizing. When connections are made for synchronizing such as would be made for synchronizing "dark" with lamps, the difficulty that a-c. voltmeters are very insensitive at the lower part of the scale is overcome. To overcome this, it has been suggested by Keinath (E. T. Z., Vol. 455), to replace the wire resistor of an a.c. voltmeter by a metal-plate resistor. Such a lamp when cold has only about one-tenth of the resistance and thus the sensitivity of the voltmeter for small voltages is increased. When the machines are in opposition, so that the voltmeter indicates the sum of their voltages, the greatly increased resistance of the voltmeter current to a safe value.

**Synchrosopes.** — Dial synchrosopes are similar in construction to synchronizing indicators (q.v.), but are connected between the two circuits which are to be brought into synchronism. They are designed to indicate by a movable pointer whether the machine to be synchronized is running too fast or too slow, and to indicate synchronism with the circuit to which it is to be connected.

**Types.** — A fixed coil is connected through a resistor across the two bus-circuits across one phase. The movable coil is connected between the terminals of the machine to be synchronized, and is held in a position at right angles to the fixed coil by means of a permanent magnet. There will be no torque acting on the movable coil when the machine is in synchronism. If the machine is either exactly in phase or  $180^\circ$  out of phase with respect to the bus-bars, the cause in either case the currents in the fixed and movable coils will be in phase. When the two circuits are not in synchronism, the pointer will swing back and forth over the scale. In order to indicate the point of synchronism from that of  $180^\circ$  phase displacement, a translucent glass scale is placed in front of the pointer, the scale being illuminated by a lamp connected to the low-tension side of a "synchronizing lamp" which causes the lamp to be lighted when coincidence of phase between the machine and bus occurs. Hence the pointer is visible only during the time when the lamp is lighted, i. e., it will appear to rotate in one direction; the direction of rotation indicates whether the machine is fast or slow.

The moving-coil synchroscope is applicable to single-phase as well as polyphase circuits, and is unnecessary to indicate synchronism of more than one phase.

The moving-coil synchroscope is ordinarily used with transformers to reduce the line voltage down to 110 volts.

**Vane Type.** — This instrument is similar to the moving-vane voltmeter (q.v.). The movable iron vane is magnetized by a permanent magnet connected across the machine to be synchronized. A rotating magnet is formed by passing current from the bus-bars through a split-ring magnet consisting of two fixed coils placed nearly  $90^\circ$  apart. The pointer indicates

at any instant the phase displacement between the voltages of bus-bars and machine. The speed and direction of its rotation depends on the difference in frequency of the two circuits. When exact synchronism is reached the pointer will remain at rest in a vertical position. The instrument is usually connected through potential transformers; on polyphase circuits only one phase is used.

**Lincoln Synchroscope.** — This instrument has a rotating iron core carrying two coils placed nearly  $90^\circ$  apart; one coil is connected through a resistor to the other through an inductance, both being supplied from the machine to be synchronized. A bipolar, laminated iron field is magnetized by means of a coil connected to the bus-bars. The operation of this instrument is similar to that of the moving-coil type of single-phase power-factor meter. A pointer is attached to the moving system indicates at every instant the difference in phase angle, as well as the approximate difference of frequency, between the voltage of the bus-bars and that of the machine to be synchronized. The current to be led into the armature coils through slip rings, as the armature is to revolve. These instruments are furnished for direct connection to circuits of 110 or 220 volts; other circuits require transformers.

**Weston Synchroscope.** — This consists of an electro-dynamometer with a permanent magnet having the fixed coils connected to the buses through a non-inductive resistance and the moving coil to the incoming machine through a condenser. When the voltage of the machine is either in phase with or in opposition to the bus voltage no torque is exerted on the moving coil, and the pointer is vertical. For any other phase relation the pointer will be deflected to right or to left when the incoming machine is ahead or behind. The pointer is back of a translucent screen, and only its shadow, cast by a synchronizing lamp, can be seen. Thus when the shadow is seen to be vertical, the incoming machine is in phase, and when the machine is too fast or too slow the shadow appears to rotate in the clockwise or counter-clockwise direction respectively.

**Use of Reactance in Synchronizing.** — Synchronous machines may be connected to the bus through suitable current-limiting reactors, and brought to speed by an auxiliary motor. They will synchronize after a few oscillations. With large machines, considerable current rushes will occur when the reactance is short-circuited. Osnos has described (*Elektrotechnik und Maschinenbau*, Vol. 19, p. 29, 1917), the use of reactors having an auxiliary d-c. winding which may be connected in the field circuit. The field current is very small at starting, and as it increases the d-c. flux in the reactors reduces their reactance gradually to a value permitting the machine to synchronize as it approaches normal voltage. The reactors may then cut out of circuit without disturbance.

**COSTS.** — A moving-coil synchroscope costs approximately \$80; a moving-vane synchroscope costs approximately \$70; a Lincoln synchroscope for voltages of from 110 to 220 costs from \$55 to \$65; transformers and accessories are extra in all cases. Only one synchroscope or synchronizer is required in a station, although a spare instrument is usually installed. (1922 prices.)

**PH INSTRUMENTS AND APPARATUS.** -- (See also *Telegraph Lines; Telegraph Systems.*) The more important and apparatus used in the various systems of telegraphy are as follows.

A telegraph key is essentially a switch for opening and closing a circuit. The following are the most common types of keys in use.

**Standard Morse Key (Fig. 1).** -- The knob end of the lever is normally held in the open position by an adjustable coiled spring. The auxiliary spring constitutes the "circuit closer" by which the key is kept closed, through which the current of the line is kept closed, through which the key is not in use.

**Double-Acting Key.** -- While the key of the type illustrated in Fig. 1 is still standard, the double-acting keys, having a sidewise rather than a vertical motion of the lever, have come into use.

One type of these, known as the double-acting key, has its lever arranged to swing in a horizontal arc between two stationary points. The key lever normally stands clear of both points, leaving the circuit open. A movement either to the right or left will close the circuit.

Another type of key is represented by such instruments as the automatic key, which are more properly semi-automatic transmitters. The key lever in this is similar to that of the double-acting key just described, normally standing in the middle or open position. When pushed to the left, it closes the circuit in the ordinary way to make a dash. When pushed to the right, a vibratory reed is set in motion, which opens and closes the circuit rapidly to form a succession of dots, the number of dots being determined by the length of time the key is held in this position. By this type of key the operator is relieved of the muscular effort of rapidly vibrating the key.

**Operator's Paralysis.** -- The objects of the double-acting key and of the other similar transmitters are, in the main, twofold: To relieve the operator of the muscular effort of rapidly vibrating the key; and to prevent the operator's paralysis, known as "operator's paralysis" or "loss of grip," which follows long continued use of the ordinary key; and to prevent the operator's paralysis of transmission.

**Automatic Transmitters.** -- (See also *Telegraph Systems.*) The automatic systems usually employ a paper tape, perforated in accordance with the code to be sent. This tape, so prepared, is caused, by means of rollers, to pass rapidly through the transmitter, the perforations they pass to permit electrical contacts to be made which produce the necessary impulses to the line.

(Fig. 2). -- A standard form of Morse sounder is shown in Fig. 2. The winding of the magnet is connected directly between the line and ground on the base of the instrument. The armature is attached to a lever which is pivoted in a fixed support. The contacts provided for the lever permit a downward movement of its free end, the current being caused by the pull of the magnet.

The upward movement is caused by the force of an adjustable retractile spring. The construction of the armature lever and its co-operating parts is such as to produce the necessary loudness and quality of sound.

Fig. 1. Standard Morse Key

Fig. 2. Morse Sounder

This, with the heavy retractile spring necessary for the prompt return movement of the lever, makes the instrument require more energy for its operation than can usually be delivered to it directly over the line wire. On this account the sounder magnet is usually placed in a local circuit, which is in turn controlled by the more sensitive relay, the magnet of which is placed directly in the line.

When used in local circuits sounders usually have a magnet resistance about 4 ohms, and require about  $\frac{1}{4}$  ampere for their proper operation. When the sounder magnet is placed directly in the line, it is termed a main line sounder and differs in no respect from the local sounder except that its magnet is wound to about 20 ohms.

**RELAYS.** — Two kinds of telegraph relays are employed; the ordinary Morse relay, and the polarized relay. The armature of a Morse relay always moves in the same direction irrespective of the direction of the current impulse, while the armature of a polarized relay moves in one direction for a positive impulse, and in the opposite direction for a negative impulse.

**Morse Relay (Fig. 3).** — The Morse relay has the same essential construction as the sounder, with the addition of a pair of contacts closed by the armature lever when in its attracted position. The armature lever is usually mounted vertically, and is made light in construction so as to be capable of the necessary rapid to and fro movements with a minimum expenditure of energy. The retractile spring is light and delicately adjustable. An extra pair of binding posts is added to form the terminals of the local circuit, these binding posts being wired to the armature and the magnet frame, respectively, so that the circuit between them will be closed upon attraction of the armature. The back contact of the relay is non-conducting so as to avoid closing the circuit when the armature is released. A typical form of relay, known as the "pony relay," is shown in Fig. 3.

Fig. 3. Morse Relay

**Polarized Relay.** — A polarized relay is similar to a Morse relay except that the end of the armature which plays between the soft-iron pole pieces is permanently magnetized. For example, if this end of the armature is a south magnetic pole, then, obviously, the armature will be moved in one direction or the other, according as the magnetizing force of the coil tends to set up a south pole in one or the other of the poles. The polarity of the poles, of course, changes with the direction of the current in the coil.

**RECORDERS OR REGISTERS.** — (See also *Telegraph Systems*.) Recorders or registers are used only where for some reason it is desired automatically to record a message. Simple forms of comparatively slow speed registers are used in connection with district telegraph messenger and fire alarm telegraph service. More elaborate high speed recorders are used in connection with automatic and printing systems. A special form of recorder, known as a signal recorder, is used on submarine lines.

**Slow Speed Registers.** — The paper upon which the message is to be recorded is a narrow strip of tape, carried on a reel. A clock-work mechanism is provided for moving the tape at uniform rate under the recording pen or stylus. The receiving magnet of the register is placed in a local circuit controlled by a relay in the line, and this magnet, when attracted, serves either to move the pen or stylus against the tape or the tape against the pen or stylus, in either case resulting in a mark upon the tape. Some registers record by merely embossing the tape; others by marking thereon with a pen or pencil and still others by actually punching holes in the tape.

**Speed Recorders.**—In very high speed automatic and printing devices have been developed giving a record in ink on ordinary paper or a record on a sensitized paper, or in ordinary print. For a list of the more important printing recorders see below under *Telegraphs*.

**Chemical Recorders.**—For very high speed work with non-printing recorders the chemical recorder has been generally found the most satisfactory. The tape is impregnated with a solution of some unstable chemical compound which will easily be decomposed upon the passage through it of an electric current which, either by changes within itself or by combination with the oxygen of the air, will cause a definite discoloration of the tape upon the passage of the current. A sensitizing solution is formed of 5 parts of prussiate of potash, 10 parts of ammoniac nitrate, and 100 parts of water. Under electric decomposition sets free an acid which attacks the iron of the pen, leaving a mark on the paper.

**Submarine Recorder.**—The high electrostatic capacity of long submarine cables necessitates some modification of the methods ordinarily employed for signaling. This high capacity results in the variations in the signaling current being less sharply defined than on land lines. The receiving apparatus must, therefore, be responsive to minute variations in current intensity in order to preclude the use of the responsive devices employed on land lines.

The submarine recorder is merely a special form of recording galvanometer. The proper type is of the D'Arsonval or swinging coil type. The motion is imparted to a very light glass tube bent to form a siphon and supports a receiving tape and its short end dipping into a reservoir of ink. The siphon moves across the width of the tape, the tape being agitated so as to be nearly frictionless. Displacements of the record line to the left of an imaginary zero line represent dots, and to the right, dashes. The Continental code is universally employed when the submarine code is used.

**REPEATERS.**—When, for any reason, it is desired to transmit messages from one line to another line without manual retransmission, a repeater is used. By its use lines of excessive length may be used and a consequent increase of speed may be attained. Also, the repeater is useful in automatically transmitting messages from a through line to a branch circuit.

**Automatic or "Button" Repeater (Figs. 4 and 5).**—A fundamental principle of the repeater may be gained from Fig. 4, where a relay magnet

Fig. 4.

Fig. 5.

in the line causes an armature to act as a key to make and break the circuit. This conception may be carried a step farther by considering Fig. 5, where a relay magnet in the West line receives impulses from the distant West line and controls a local circuit containing a battery and a second relay magnet. The latter causes its armature to act as a key in transmitting signals to the East line.

to the East line. From these two figures it is obvious that such a repeating scheme would transmit in one direction only, providing no facilities for transmitting from East to West.

The "button repeater" of early telegraph history consisted practically of two such sets of relays as are shown in Fig. 5, these sets being arranged for transmission in opposite directions. Only one set of relays could be kept connected to the line, for when both are connected in, the impulses sent out from the repeating station on, say, the West line react on the line relay of that line at the repeating station in such way as to act through its local circuit to send impulses back on the East line. This difficulty was overcome in the button repeater by providing a button switch, operated by an attendant at the repeater station, this switch being thrown manually in one direction or the other, according to the direction of transmission desired.

**Automatic Repeaters.** — The necessity of an attendant for the purpose of working the switch of a repeater has long since been overcome by the production of the so-called automatic repeaters, of which there are many forms. In these the arrangement is such as to automatically prevent the transmitter of the line that is being repeated into from reacting to make and break the line over which the signals are initially sent.

**The Milliken Repeater (Fig. 6).** — This is one of the most common of the automatic repeaters for the simple Morse system. Its action may be

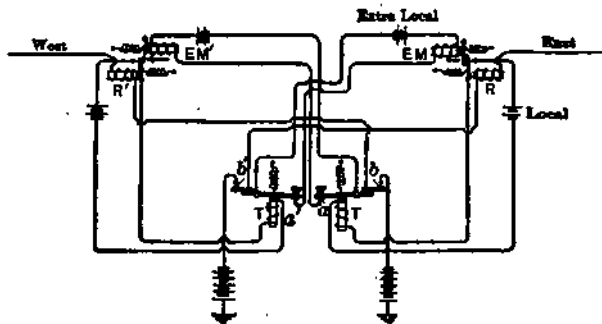

Fig. 6. Milliken Repeater

understood by reference to Fig. 6. If the line East is sending, the relay R will respond to the make and break impulses of the key at the distant station on that line, this line being closed to ground and battery at the repeater station through the contacts  $b'$  on transmitter  $T'$ , which is held closed by an action that will be described. The operation of the relay R of the line East will, by its local circuit, cause the corresponding operation of the transmitter T, and this, by the make and break at the tongue  $b$ , will open and close the line West in accordance with the originally transmitted impulses. The armature of the relay R will be free to work, because as long as the magnet of transmitter  $T'$  remains energized it will hold the circuit of the extra magnet EM closed at the point  $a'$ , and thus will hold the armature of that magnet out of the way of the armature of the relay R. The extra magnet EM', associated with the relay R' of the line West, prevents this relay from breaking the West line in response to the repeated signals, for the following reason. When the line West is closed by the transmitter T, the current through the relay R' holds its armature attracted. When

is opened, however, by the transmitter *T*, the circuit of the extra is also opened by this transmitter, and the retractile spring of the set prevents the armature of the relay *R'* from falling back. In this the relay of the West line cannot react on its own transmitter to cause breaks in the transmitting line. When the operator at the distant the West line breaks, the relay *R'* is then permitted to open and thus transmitter *T'* to open the line East.

**Duplex and Quadruplex Repeaters.** — Automatic repeaters are for duplex and quadruplex systems than those already described wire working. The reason for this is that in the duplex or quadruplex transmission from a given sending operator is always to a corresponding operator, and — as between these operators — it is never in the reverse sense, a one-way repeater only is required for any one of the several transmissions. It therefore suffices to place the transmitter at station under the control of the neutral or polar relays of the duplex or quadruplex, the repeating operation for each set being in one direction

**CURRENT SUPPLY.** — Either a battery or a dynamo may be used to the current required for telegraph transmission.

**Gravity Battery.** — The gravity battery was once almost universally used for current in telegraph systems. It is still largely used on unimproved and in small offices where it is not economical to employ machine secondary batteries.

**Storage Battery.** — The storage battery, on account of its extremely low resistance, is capable of handling any desired number of lines in parallel, and is the use of the so-called "universal battery system," in which a

single pole is used, with one pole connected to the line wires, and the other grounded. This is done by tapping off from the line wires suitable resistances in the lines of the office, if desired, to provide for the variation in the resistance of the lines. One set of these batteries, would not be used in an office, however, but various systems of storage batteries for quadruplex work are necessary to send current

of opposite polarity to line, thus making necessary the use of another set of batteries, the opposite pole grounded. Usually also a reserve is provided for these batteries, so that one can be used while another is being recharged.

Figure 7 shows an arrangement of storage battery supply that provides for the use of either voltage of either polarity in an obvious manner. By using this arrangement, one set may be used while the other is being recharged.

**Dynamo Supply.** — The dynamo has generally supplanted both the primary and secondary batteries in all offices large enough to warrant its use. In Fig. 8 an arrangement employed by the Western Union Telegraph Company is shown, in which this five machines constitute a set, their armatures being connected in series, taps being made as indicated to give the required voltages. These machines are separately excited except the fifth, which

Fig. 7. Storage Battery for Current Supply

latter is a shunt machine and furnishes current not only for line supply but also for exciting the fields of all the other machines. Each field circuit is provided with a separate rheostat *R* for varying the field strength. Another set like this is employed to furnish currents of the opposite polarity, and another set of five machines is employed as a reserve, this being so arranged that

Fig. 8. Western Union Dynamo Arrangement

Fig. 9. Postal Dynamo Arrangement

it may be made to generate either positive or negative according to which of the regular sets it is to replace. The dynamo arrangement employed by the Postal Telegraph-Cable Company is shown in Fig. 9.

**TELEGRAPH SWITCHBOARDS (Fig. 10).**—Telegraph switchboards were the precursors of the vastly more complicated telephone switchboards. The telegraph switchboards which have been most commonly used in America are of two types—the “strap and disc” and the “cross-bar.”

A simple “strap and disc switchboard” with its connections is shown in Fig. 10. The lines terminate in the vertical straps and the instrument circuits, each including key and relay, terminate in the horizontal rows of discs, the discs in each row being connected together, as indicated by the dotted line. This figure also shows a typical method of line and instrument protection.

**COSTS (Pre-war figures).**—

The following prices were current prior to the World War, standard Morse key, \$2.00; double-acting key, \$10.00; Vibroplex, \$12.00; standard Morse sounder, \$3.00; standard Morse relay, \$7.00; polarized relay, \$20.00; ink recorder, \$35.00; punching recorder, \$75.00. See also *Batteries, Generators, etc.*

Fig. 10. Strap and Disc Switchboard

**BIBLIOGRAPHY.**— See Bibliography in article on *Telegraph Systems*.

**GRAPH LINES.** — (See also *Poles and Cross-Arms; Telephone Transmission Lines; Wires and Cables.*) The conductor over which an electric current is effected is commonly referred to as the line. These conductors are open wires, or they may be disposed in aerial, underground and submarine cables.

**WIRE LINES.** — Most of the open-wire telegraph lines are of hard-drawn copper or of galvanized iron. Recently a wire known as copper-clad steel consisting of a core of steel wire with an outer shell of copper welded to the steel has appeared as a competitor. For the properties of these wires see *Wires and Cables, Bare.*

Hard-drawn copper wire is vastly superior to iron in point of conductivity and ability to withstand the action of the elements. Galvanized-iron wire is more advantageous in point of first cost, it has a somewhat greater strength, and a longer life ranging from 4 to 20 years, according to atmospheric conditions. Steel has a conductivity superior to that of iron, but inferior to that of copper. It is stronger and somewhat cheaper than hard-drawn copper, and possesses the same ability as copper to indefinitely withstand the action of the elements.

The ohm values (i.e., the weight in pounds of a wire one mile long having a resistance of one ohm) of the various grades of wire used for telegraph lines are as follows: E.B.B. iron, 4700 pounds; B.B. iron, 5500 pounds; B.B. steel, 6500 pounds; hard-drawn copper, 395 pounds; copper-clad steel (having a conductivity 40 per cent of solid copper), 2010 pounds.

It is noted that No. 10 S. gauge hard-drawn copper wire, weighing 209 pounds per mile, is stronger than any other size of hard-drawn copper wire for telegraphic purposes. No. 8 B. W. G. galvanized-iron wire, B.B. grade, weighing 378 pounds per mile, is the principal standard in iron wire.

**CABLES.** — The paper-insulated, lead-covered cable of the type used for telephony (see *Telephone Lines*) but with single wires instead of pairs, is rapidly supplanting the old form of rubber-insulated cable used in telegraphy. Sometimes the cores are saturated with insulating oil, and sometimes they are left "dry," according to whether the weight of the cable for greater safety outweighs the desirability for lower capacity. Such cables are supported from messenger wires, either by means of a wrapping of marline around both the cable and the messenger, or by means of a support being applied by means of the well-known "Spinning

**UNDERGROUND CABLES.** — (See also *Wires and Cables, Insulated.*) Under-ground telegraph cables are of the same type as those used for aerial lines, but instead of placing them in ducts extending from manhole to manhole, so as to facilitate their withdrawal, has largely replaced the older practice of burying the cable in such manner as to necessitate its being dug up for replacement.

**UNDERSEA CABLES.** — For comparatively short lengths, in crossing straits or bays where the current is not swift and the bottom is of such a nature as to permit of embedding the cable, ordinary multiple-conductor, lead-covered cables with either paper or rubber insulation, provided with a heavy braiding of galvanized iron, are often employed. Where paper insulation is used, it is customary in telegraphic work to thoroughly impregnate the core so as to minimize the absorption of moisture; but this increases the electrostatic capacity of the

Where great tensile stresses or abrasion are likely to occur, the cable, provided with its lead sheath, is served with a thick coating of jute, and then with an armor of closely wrapped galvanized steel wires, which an additional protecting layer of tarred jute is served.

**Long Submarine Cables.** — For long submarine cables across the Atlantic Ocean, a single conductor is employed in the form of stranded copper, weighing from 70 to 650 lbs. per mile. This conductor is then encased in several layers of gutta serena. The core, so formed, is protected with a thick layer of jute. An armor of galvanized-steel wires is placed. After being served with jute, the cable is sometimes covered with a thick layer of tarred jute. The length of cables, where there is greater liability to mechanical damage, is a layer of very heavy galvanized-steel wires.

**LIMITING TRANSMISSION DISTANCE.** — The distance over which a signal can be transmitted depends upon the strength of the impulses sent out, the sensitiveness of the receiving instrument, and capacity of the line and upon the number of stations.

**Open Wire Lines.** — The following table, compiled by Mr. A. S. Noyes, shows the result of his calculations as to the limiting length of working (no intermediate stations) of simplex, duplex and quadruplex transmission with standard apparatus over open wire lines having different resistances per mile, and also the maximum length of way circuits equipped with 35-ohm line relays.

Resistance per mile in ohms	Limiting length of line for Through Working, miles			Limiting length of way circuit, miles
	Duplex	Simplex	Quadruplex	
2	78.3	597	531	597
3	65.8	510	442	510
4	58.0	459	386	459
6	48.5	376	313	376
8	42.5	331	268	331
10	38.4	299	236	299

plex systems .....	1617
tr systems .....	1619
tic systems .....	1620
telegraphs .....	1622
telegraphs .....	1624

ht modification the original system of electric telegraphy devised  
still largely used, the great bulk of telegraph work still being done  
its simplest form it consists of a circuit, connecting the points  
ich intelligence is to be transmitted, a battery or other generator  
it for supplying the current, a key at each station for facilitating  
and closing of the circuit by hand, and a sounder for giving response  
ng and closing of the circuit by audible clicking.

**GRAPH CODES.**— Two different codes are used in telegraphy,  
ode and the Continental code.

ode.— The Morse code is an arbitrary system of interpreting the  
ers, numeral digits and punctuation marks employed in writing, this  
n being intelligible either audibly or visually. This code is formed  
es and spaces. The dot is made by a quick depression of the key  
its immediate release; the dash by a depression of the key with a  
ase; and the space by permitting a short interval to elapse between  
on of two dots. Thus, the letter *a* is represented by a dot and a  
is formed by depressing the key, immediately releasing it, depress-  
again and holding it a slight interval before release. Similarly,  
is represented by two dots, and it is formed by depressing and  
key twice in rapid succession. The letter *e* is an example of a so-  
letter, and is represented by dot-space-dot. It differs from the  
in that an interval of time is allowed to elapse between the two  
Morse code, as it has been employed practically without modifi-  
the time of Morse, is as follows:

B	C	D	E	F	G
I	J	K	L	M	N
P	Q	R	S	T	U
W	X	Y	Z	&	
2	3	4	5		
7	8	9	0		
Period	Comma	Interrogation			

**Continental Code.**—The so-called Continental Code differs from Morse code in that it is composed entirely of dots and dashes, employing no spaces. It is almost universally used for submarine lines, for land lines in nearly all countries except the United States, and is the world's standard for radio telegraphy. This Continental or universal code is as follows:

A	B	C	D	E	F	G		
H	I	J	K	L	M	N		
O	P	Q	R	S	T	U		
V	W	X	Y	Z				
1		2		3		4		
5		6		7		8		
9		0						
Period			Comma			Interrogation		

**SIMPLEX OR MORSE SYSTEM.**—There are two types of circuit used, the so-called "open-circuit" system and the "closed-circuit" system. In both cases but one line wire is employed, the earth forming the return circuit.

**Closed-circuit System (Fig. 1 and 2).**—This system is mainly used in the United States. In its simplest form the keys and the sounder magnets are placed in series in the line with a source of current, as shown in Fig. 1.

Fig. 1. Simple Telegraph Circuit

switch or "circuit closer" is provided with each key, the function of which is to keep the line circuit closed around the key contacts when the key is not in use. When an operator begins to send he opens this circuit closer, thus making his key effective in controlling the line circuit. When the line is idle, the circuit is closed at all stations, and all sounder levers are held down by the magnetizing effects of the current flowing in the line.

but two stations are shown, one at each end of the line. Obviously one or way stations could be added by merely placing the necessary instruments in the line circuit at the desired points.

Common practice is to employ a line relay at each station as the device responsive to the line currents, using this line relay to control a local key containing a local battery and a sounder. The reason for the choice of this more complicated system for commercial practice is that the sounder, to make the necessary amount of noise, is required to be of a rather heavy type and is not as readily responsive to the comparatively small line currents as the relay, which, having no other function than to be responsive,

Fig. 2. Closed Circuit System with Way Stations

of the required sensitiveness. A line equipped for three such stations as in Fig. 2. While the constant flow of current in the closed-circuit system results in the use of a greater amount of current than would be necessary, it has the advantage of keeping the line under test at all times, without requiring a line battery at each of the stations, as is the case in the open-circuit system.

**Open Circuit System (Fig. 3).** — This is largely used abroad. A battery is connected to each station. Each key has a front and back contact so arranged

Fig. 3. Open Circuit System with Way Stations

to connect the line to the local battery when the key is raised, and to cut the line circuit and substitute the battery for it when the key is depressed, therefore, the line circuit is normally closed from one end to the other. The line and the local batteries stand in normally open circuits, so there is no waste of current. Besides requiring a line battery, sufficient to energize the entire line, at each station, this system does not hold the instruments under automatic test conditions, which is automatically done by the constant flow of current in the closed-circuit system. A diagram of the open-circuit system is shown in Fig. 3.

**Sound Reading.**—In the first use of Morse characters were recorded on a moving tape and subsequently found in practice, however, that the operators so coming over the wire by the clicking of the instrument. This method of sound reading was condemned at first, but it has survived to such an extent that the major part of the world is to-day received in this way.

**Speed of Handling Messages by Morse System.**—The speed of handling messages by Morse was limited by the speed of writing down the message, as long as this was the case. The use of the typewriter for transcribing has, however, increased the possible speed, and the limitation where the typewriter is used is sending operator to "write" the Morse code. This is where the line conditions permit. A poorly worked line will give the possible speed far below the limitations prescribed for good operators. While speeds of over fifty words a minute are possible for experts during short periods of time, and while operators can receive thirty-five and forty words a minute in a normal way, the average under working conditions is far below twenty words a minute.

**DUPLEX SYSTEMS.**—Duplex telegraph systems for the simultaneous sending of two messages in opposite directions over the same line employ different methods for making the relays at each end responsive to the home key. These two methods are termed "bridge" methods, respectively. There are also methods for sending impulses over the line, one of which depends on current strength and the other on changes in current direction.

**Differential Method (Fig. 4).**—The differential method is understood from a consideration of Fig. 4, which shows two windings in opposite directions. Current from the battery is supplied through one of these windings to the line, and through the other of these windings to the artificial line represented by a resistance at the left. The resistance and other characteristics of the artificial line are made approximately equal to those of the real line, so that impulses of current sent by means of the key from the battery to the line will produce no effect on the relay, because an equal current passes also through the artificial line. Obviously, however, there is no such difference in the currents, and, therefore, the relay is responsive to currents from the distant station.

The differential method is ordinarily employed in land telegraphy.

**Bridge Method (Fig. 5).**—The bridge method of rendering the home relay unresponsive to the home key and responsive to the distant key is illustrated in principle in Fig. 5. In this method the resistances shown are so proportioned with respect to the line that the line relay will receive no current upon

Fig. 4.

Fig. 5.

reason that the galvanometer in a Wheatstone bridge does not respond when the bridge is balanced.

The bridge method finds its chief use in overland and in submarine telegraphy.

**Stearns Duplex for Land Lines (Fig. 6).**—The Stearns duplex for land lines operates on the increase and decrease in current strength, without changing the direction of current flow; and for the reason that it employs the differential method of making the home relay unresponsive to the home key, it is usually referred to as the Stearns differential duplex system.

A simplified diagram of the Stearns differential duplex is shown in Fig. 6.

It should be noted that the batteries at opposite ends of the line have their opposite terminals grounded, so that whether one or the other, or both, of the batteries are

Fig. 6. Stearns Differential Duplex

in circuit the current flows in the same direction. The key controls a local circuit of an electromagnetic transmitter  $T$  or  $T'$ . The tongue of each transmitter normally engages the contact on the under side of the bend in the lever; the latter is attracted by its magnet upon the closure of the key, the transmitter makes contact with the adjustable screw on the standard, and this prevents the tongue from moving farther upward, so that the making of this contact is immediately followed by the breaking of the normally closed contact of the transmitter. Because these transmitters make one contact before breaking the other, they are called "continuity-preserving transmitters." When the key is depressed, the corresponding transmitter keeps its end of the line connected to the line through the resistance  $r$ , but upon the closure of the key the transmitter causes the substitution of the battery at that end of the line for this resistance. This resistance  $r$  sometimes is called the "spark coil," since its use is to prevent sparking at the transmitter contacts, and its function is to compensate for the internal resistance of the line battery.

The artificial line shown at each station is composed of resistances and condensers arranged for ready adjustment, so as to balance not only for the resistance of the line, but for its capacity also.

**Stearns Duplex for Submarine Cables.**—Fig. 7 shows the Stearns duplex arrangement of terminal apparatus for cable working. This is a bridge circuit. The normal position of the keys grounds the cable conductor, thus charging it. Alternately depressing the two keys gives the cable alternate positive and negative charges, thus sending dots and dashes. By moving the

Fig. 7. Stearns Cable Duplex

arm of the balancing rheostat, delicate adjustments and artificial cables are secured.

**Jacobs' Duplex for Submarine Cables**  
 cables frequently have two conductors, making

Fig. 8. Jacobs' Cable Duplex

Fig. 8 available. This is similar to simplex work and telegraphy. This method is found preferable to using each conductor separately for the two transmissions, since it avoids inductive interference between the two wires.

**Polar Duplex** (Fig. 9 and 10). — The polar duplex depends for the principal feature of its operation on the fact that a polarized relay will move its armature oppositely for opposite directions of current. The key used in sending operates to close and open a local circuit which controls a pole-changing transmitter. The action of this is made clear in Fig. 9. With the key closed, as shown in that figure, the negative side of battery will be connected to line and

When the key open, the reverse will be true. The circuit of the polar duplex shown in Fig. 10.

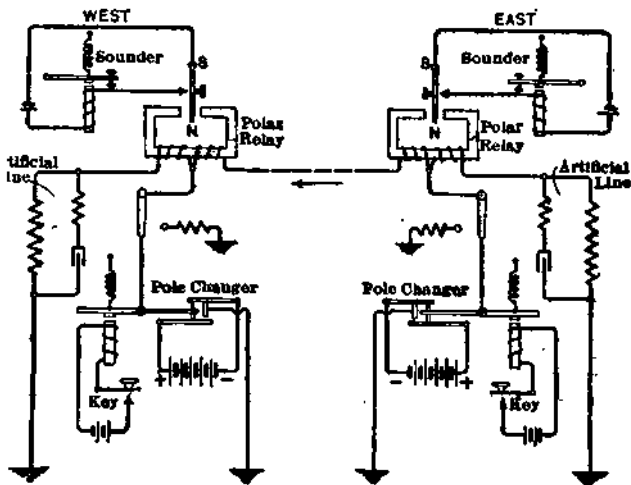

Fig. 10. Polar Duplex

**QUADRUPLIX SYSTEMS.**—In quadruplex systems four messages, in each direction, may be transmitted simultaneously over a single line.

**Edison Quadruplex (Fig. 11 and 12).**—The Edison quadruplex depends its principle of operation on a combination of the two duplex systems, Stearns and the polar just described. At each station two relays are provided, one, the neutral relay, responsive to currents in either direction, and other, the polar relay, responsive only to currents in one direction. At each

Fig. 11. Principle of Edison Quadruplex

station also two key-controlled transmitters are provided, one of which operates, as in the polar duplex, to change the direction of current in the line and the other, as in the Stearns duplex, to increase and diminish the strength of current flow.

The principle of transmitting in one direction by means of the Edison quadruplex is indicated in Fig. 11, where *N* is the neutral relay and *P* the polar relay at the East station. *K* and *K'* are transmitting keys at the West station, *P*, key

*K* operating to alternately weaken and strengthen the line current, and *N* operating as a pole changer to reverse the line current. As shown, the line will always have some current flow, the amount being determined by key *K* and the direction by key *N*. As the neutral relay will operate on currents of either direction, if strong enough, it will be responsive only to key *K*; and as the polar relay will operate on either current strength, if in the right direction, it will be responsive only to key *N*.

The circuits of the Edison quadruplex are shown in Fig. 12. The windings of the neutral relays *N* and of the polar relays *P* are in each case made different for the same reasons as pointed out in connection with the Stearns and polar

Fig. 12. Edison Quadruplex

duplex systems. At each station of the "quad" system one winding of each relay is in the line, and the other in the artificial line. As will be seen from Fig. 12, the two transmitters at each station modify the main battery current, as pointed out in connection with Fig. 11, the continuity-preserving transmitter controlling the current strength and the pole-changing transmitter controlling its direction.

**Key Systems for Quadruplex Working.**—In the quadruplex so far described, the current was supplied by batteries, and the strength-varying transmitter operated to accomplish its purpose by alternately cutting a portion of the line battery out of and into the circuit. Where dynamos furnish the current, a different scheme is employed. One system, known as the Field key system,

Fig. 13. Field Key System

is illustrated in principle in Fig. 13. Two dynamos are employed, having opposite poles grounded. The pole changer merely chooses between the two live poles for securing its reversals in polarity. The continuity-preserving transmitter varies the current strength in the line by changing the resistance relations as shown. Thus, when the key is closed, the 1200-ohm resistance is short-circuited and the 900-ohm "leak" resistance to ground is cut off. Th

these circumstances flows to line at full strength. When the key resistance of 1200-ohm is introduced in the line and the 900-ohm is effective. The resistances shown are those for an 1800-ohm line.

**MULTIPLEX SYSTEMS.**—The term "multiplex" should include duplex systems, but practice has been otherwise, and has resulted in the term "multiplex" principally to a system wherein two moving switches, one at each end of the line, serve to connect sets of telegraph instruments momentarily and successively with the line. While each set of instruments, therefore, is on the line for only a small fraction of the total time, the successive current flows so rapidly as to afford, to all intents and purposes, a practical use of the line.

**Synchronous Multiplex System (Fig. 14).**—The principle of the synchronous multiplex system is shown in diagram in Fig. 14. Six sets of instruments, each consisting of a pole-changing key and a polar relay, are connected at each end of the line. The two switch arms of the synchronous rotary

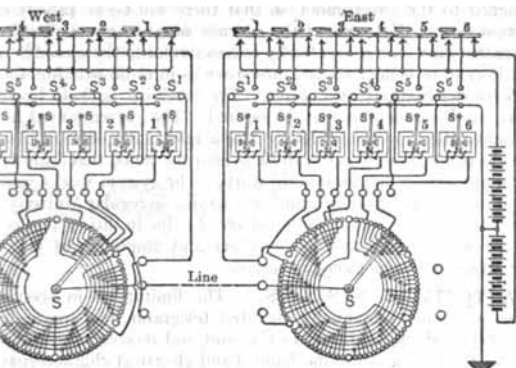

Fig. 14. Delany Synchronous Multiplex

are made to revolve in unison, so that the correspondingly numbered arms at each end will be simultaneously connected with the line. The arms make about 180 revolutions per minute, and as each set of instruments is connected with the line twelve times at each revolution, it follows that each set of instruments is connected with the line thirty-six times per minute. Therefore, any closure of a key which an operator may make will be effective a time during which at least one connection will be made with the line. In this particular embodiment of the Delany system shown polarized keys are used, the advantage of this being that the key will remain in the position to which it was last brought by a closure, in spite of the rapid interruptions caused by the synchronous switching mechanism. Each switch lever,  $S^1$ ,  $S^2$ , etc., is associated with each key and is operated by the operator to one or the other of its positions, according to whether he is sending or receiving.

The mechanism for the switch movements is ingenious and the two arms are each driven by step-by-step motors, the driving mechanism being regulated by means of tuning forks, as accurately tuned to each

other as possible. Obviously, complete synchronization means alone, and, therefore, the two driving de- association with the line by the rotary switch arms s- tion, the arrangement being such that if one switch dead or synchronizing contacts slightly in advance corrective measure to its motor device, which will t- corrective measure is in the form of an electromagn- tuning fork vibrates, and the energization of this m- fluence on the rate of vibration, and, therefore, on synchronous switch.

 per tape to make a mark, although there is no actual contact  
 el and the tape.

tems. — These systems, once employed in commercial work  
 extent, have been in large measure superseded either by the  
 stems or by ordinary Morse. They present possibilities for  
 ent, however, which give them more than an historic interest.

**Chemical Automatic System (Fig. 16).** — The salient  
 erson chemical automatic system are shown in Fig. 16. The

Fig. 16. Principle of Chemical Automatic System

the transmitting tape under the contact pen serves to short-  
 ting battery and thus cause a cessation of current in the line.  
 he receiving end, previously charged by the flow of current  
 hen discharges into the line, this being intended to cause an  
 current flow. This is an interesting example of so-called  
 working with a single battery. At the receiver the chemically  
 ses under a contact pen, so that the current is compelled to  
 per. Its flow decomposes the solution and marks the paper,  
 l. The reverse flow of current from the condenser tends to  
 nce of "tailings."

**Anderson System.** — This system, like the Wheatstone,  
 dashes, and, according to Maver, it has been found capable  
 words per minute over a 1000-mile line having a resistance

of 2500 ohms, under all sorts of weather conditions in length, having a resistance of about 700 ohms. A speed of 20 words per minute has been accomplished.

### WRITING TELEGRAPHS OR AUTOGRAPHS

Writing or autographic telegraphs are to be distinguished from ordinary telegraphs in that they write the received messages in the receiving systems actually print them as from type.

In these systems the message to be transmitted is written at the sending end as with a pen or stylus, while at the receiving end a pen or stylus executes the same movements and thus writes the message. The receiving system executes similar handwriting. Nearly all autographic systems employ the movements of the transmitting pen or stylus into two perpendicular movements at right angles to each other, electro-magnetically converted into component rectilinear motions at the receiving end, which are then recombined there into the resultant movement, which, therefore, reproduces the handwriting that originally made by the sending stylus.

**Robertson System.**— Fig. 17 is a schematic diagram of the Robertson system and clearly illustrates the principle of autographic telegraphs. The sending and receiving systems are employed, each including a battery and

Fig. 17. Principle of Robertson system.

at the transmitting station, and an electromagnet at the receiving end. The variable-resistance elements are composed of two sets of carbon discs arranged at right angles to each other, the transmitting stylus that its movements in writing are converted into two perpendicular paths through the discs. The receiving pen is actuated by the two magnets at the receiving end. At the receiving end two magnets are at right angles and vary as the stylus moves. The two components of the transmitting stylus are recombined to produce the corresponding motion at the receiving end.

**Telautograph.**— This is another autographic telegraph system, invented by Elisha Gray. It employs two wires, and like the Robertson system, it solves the complex motion of the transmitting pen into two perpendicular components at right angles, reproduces these at the receiving end by means of two bell-cranks which obtain the facsimile writing. The transmitting end consists of two bell-crank arms carrying rollers which operate on the variations in resistance and current strength. The receiving end is attached to the arms of two bell cranks which

iform magnetic fields and which, under the influence of the varying currents passing through them, cause the required movements of the bell

**g System.** — In this the message is prepared by perforating a strip of paper through which the transmitter results in currents passing through the two line wires in proper sequence, direction and strength to the receiving instrument to record the message in a style very similar to ordinary printing. Two circuits are obtained from the two wires; one circuit and the other the two wires in parallel with earth return. At each end two instruments closely resembling telephone receivers are connected to receive the currents received over the two circuits. The diaphragms of these instruments control the movements, on horizontal and vertical axes, respectively, of a small mirror. A ray of light reflected from this mirror is caused to pass over a rapidly moving strip of light-sensitized paper, and the co-ordinated movements of the two axes of the mirror under the influence of the currents received at the receiving instrument produce the message in writing. The photographic paper is automatically passed through the necessary developing and fixing baths, the time required in this process being usually about twelve seconds.

**TELEGRAPHS.** — These are systems in which the received message is automatically recorded in print. Most printing telegraph systems require a high degree of synchronism being maintained between the two wheels at the sending and receiving stations; although in some systems, such as the Morse system, no such requirement exists.

**Morse System.** — In the ticker systems, which are widely employed for recording stock-market quotations, the type wheels are moved synchronously with the message either by causing the same set of line impulses to affect each wheel at the sending station, in its revolution, to transmit the message to the distant wheel. The wheels must not only revolve at the same rate but a given letter on each must come opposite a given fixed point on the receiving wheel. By stopping the wheels when the desired letter is brought opposite the printing magnet, an impulse of different character is sent which causes the impression of the next letter. Some ticker systems operate over one line wire, and the message is transmitted by causing the rotation of the type wheel occur so rapidly as not to be perceptible to the printing magnet, but upon their cessation the printing magnet is brought into play. Many of the ticker systems operate over two line wires and employ two type wheels, one carrying letters and the other carrying figures. Means are provided for shifting either the wheels or the message on either as desired.

**Step-by-step System.** — This is largely employed in Europe, and is a step-by-step wheel system in which the type wheels revolve continuously by step-by-step movements. Electric motors furnish the power for the wheels. The wheels are adjusted to revolve at as nearly the same rates as possible, and suitable corrective means are brought into play over the line to maintain complete synchronism. The transmitting apparatus resembles a piano, a key being assigned to each character. In connection with the receiving instrument there is a rotating contact device revolving in synchronism with the wheels, and the arrangement is such that the depression of any key causes a contact to be made at the exact instant when the letter corresponding to that key is in printing position at both instruments.

**Hughes System.** — The Hughes system is capable of operating with great accuracy at a speed in the neighborhood of from thirty to fifty words per minute.

**Phelps System.** — The Phelps system is a modification of the Hughes and

ven letter are brought about by reversing certain of the half waves of line current waves. The simultaneous transmission of four in the same direction is provided for by an adaptation of the multiplex distributing switch giving each set of four transmitting and receiving successive and simultaneous control of the line. Since each letter is represented by a specific combination of positive and negative currents, it is by means of these combinations to effect the closing of the proper local receiving end to cause the paper to be pressed against the type when the letter required is opposite it.

**Rowland System.** — Each transmitter and receiver has a capacity of 200 words per minute, making a total transmission of 240 words per minute. The octoplex method of working is employed.

**Automatic System.** — This is a non-synchronous printing system. The messages are first prepared by perforating a paper tape. This tape is used by the transmitting device and permits currents to flow over the same in the same manner as to cause the receiving device, which in itself is a tape-machine, to perforate another tape there. This receiving tape is used by the transmitting tape, and when passed through an automatic printing device, the perforations are translated into Roman type letters, the message being printed on the tape.

**Murray System.** — This system is capable of transmission of 200 words per minute, but speeds of from 100 to 125 words per minute have been found to be the best for practical working.

**Delany System and Modifications.** — This system is in wide use in the United States. The Western Union Telegraph Company uses it in a form different from the original. It is capable of being quadruplexed in the same manner as the method described under *Delany Synchronous Multiplex*. The use of the line among the four sets in regular succession. The receiving tape perforated manually before transmitting begins; the transmitting is done on electrically operated typewriting machines which write in page form. The paper is fed to the machines from a roll. Only capital letters are used, and these are of the simplest and most common known to printers as Gothic. The use of the system has largely superseded the use of manual key-sending and ear-receiving between the stations, and is used very greatly.

The telephone transmits speech and other sound waves in air vibrate a diaphragm; this current in a line joining the transmitter to a diaphragm produces vibration in the diaphragm of produce sound waves in air.

Bell's original telephone utilized one device as a receiver. It survives in its original form as a receiver, but more powerful devices having supplanted it.

**RECEIVERS.** — The original telephone consisted of a wire and a diaphragm, arranged as in Fig. 1. *d* is

Fig. 1. Principle of Permanent Magnet Receiver

Fig. 2. Principle of Bipolar Receiver

Fig. 3. Section of Bipolar Receiver

and *c* is a coil. The magnet was first made of soft iron from direct currents in the line; a permanently magnetized with soft iron poles (Figs. 2 and 3) soon was substituted.

**Bipolar Receiver.** — The bipolar receiver is shown in Fig. 2, in which *d*, *m* and *c* represent, as before, diaphragm, magnet and coil. Both poles of the permanent magnet are being extended by soft iron pole pieces, each carrying a silk-covered or enameled wire. The wires of the two poles are connected in series. When used to transmit speech, such as in a receiver, it is connected to a transmitter.

winding and diaphragm of a receiver are assembled in a case of an imitation thereof, adapted at one end to fit the ear and at the other on a hook switch. Fig. 3 is a section of a typical assembled receiver. It requires permanent magnets, arranged to produce opposite poles at the ends of soft iron cores carrying the windings  $w$ ,  $w$ ;  $d$  is the diaphragm. The entire mechanical arrangement of parts is supported by the shell and not from the other end. This precaution is taken to prevent the adjustment of the pole pieces to the diaphragm due to the difference in expansion of the shell and magnet.

**Iron-core Receiver (Fig. 4).** — For use in lines carrying direct current, as in common-battery systems, the iron-core type has been revived. They are extremely simple and cost little. It has not yet been established that they are as efficient as permanent-magnet receivers, but the difference seems to be slight. They have the virtue that the flow of direct current through them is not important.

The Telephone Manufacturing Company uses a receiver which has two windings, as in Fig. 5. One pair is of larger diameter, serving to magnetize the cores, while the other, of smaller diameter, serves to actuate the diaphragm. When direct currents pass through both pairs of windings, their magnetizing effects being additive, the current through the coils farther from the diaphragm is the larger. Voice currents pass through both pairs of windings and their effects are additive. The current through the windings nearest the diaphragm are the larger.

Fig. 5. Monarch Receiver

**Band Receiver.** — A band receiver is a compact one carried by a band around the ear, leaving her hands free. The compactness is gained by using small magnets and placing them parallel with the diaphragm.

**Carbon Transmitters (Figs. 6 and 7).** — Present standard carbon transmitters are more powerful than the best magneto transmitters. Carbon transmitters in their circuits take many forms, but in all cases they produce current fluctuation as a consequence of the vibration caused by sound.

The elements of a transmitter are a diaphragm, two carbon electrodes, and a charge of polished granules.

Vibration of the diaphragm moves one electrode to press and release the granules between the two electrodes. Fig. 6 illustrates the elements;  $d$  is the diaphragm and  $f$  the fixed electrode. Fig. 7 is a schematic of a typical granular carbon transmitter.

Fig. 6. Principle of Transmitter

Carbon transmitters operate by varying the resistance of the circuit proportionally to movement of the diaphragm. Receivers, on the other hand, are caused to operate by a varying magnetic flux. The reason for the operation of carbon in varying its contact resistance under pressure is as follows:

**Inductive Bells (Fig. 8).** — The present standard telephone signal bell is actuated by alternating current. Its principle is that of an inductive relay. Its construction, as in Fig. 8, is of two coils, one on each leg,  $N$ , two gongs and an armature  $S$ .

**Generator (Fig. 9).** — The bells of telephones in all exchanges are actuated by alternating current sent out from the central office power plant. The subscriber calls the central office by operating a push-button, which is a part of his telephone, and with this generator

magneto generator, which is a part of his telephone set. The subscriber also rings other bells on the same line. The bell is a standard part of subscribers' equipment for signaling, being the best way for a subscriber to do signaling on one line. The armature has many turns of fine

Fig. 7. Granular Carbon Transmitter

Fig. 8. Alternating Current Ringer

gauge), of a resistance of from 300 to 1000 ohms. An e.m.f. of from 60 to 80 volts can be produced by hand.

**BATTERIES.** — (See articles on Batteries.) The set requires direct current and produces from it (fluctuating) voice currents, which pass over the line. The central storage battery furnishes the direct current in "central battery systems," or "central energy systems." In the direct current in systems not having a central storage battery.

**Dry Cells.** — The primary battery usually is associated directly with the telephone set. Such a set is called a local battery set. Two or three cells are used in series, each of about 1.5 volts, and can give a current on short circuit. Dry cells, designed particularly for local battery use, have a lower internal resistance than those intended for gas engine use. They are used for current intermittent work. Longer life, with a lower internal resistance, is obtained by increasing the internal resistance. They can stand on open circuit for a few minutes at a time.

**Gravity Cells.** — Other types of primary cells are used in telephone sets. Gravity cells are suitable for operators' sets and can furnish current steadily with no period of rest. They do not stand long on open circuit. They give about 1.5 volts. Cells in series are suitable for a transmitter.

**Fuller Cells** are suitable for heavy service (for example, for a day), and also can stand on open circuit without recharging. They are the storage battery in e.m.f. (about 2 volts) and are used for signaling and are costly to maintain and are used less widely than the other types.

**Storage Batteries** give good results in local battery use. They are suitable for charging by direct current from outside themselves. They are suitable for the lack of frequent charges. They are suitable for local battery use for those reasons. The most widely used is the lead-acid battery.

orage batteries is by motor-generator sets, the motor being adapted to the source energy and the generator being shunt wound. Shunt-wound generators driven by internal-combustion engines are used as emergency charging equipments.

**POLE CHANGERS.** — Ringing current in central offices is usually produced by alternating current generators or by pole changers. The latter are vibrating contact-makers having natural frequency corresponding to the frequency of the current desired. They are operated by direct current from a storage battery or other source. The Warner pole changer, Fig. 10, is widely used for ringing ordinary telephone bells at a frequency of from 16 to 20 cycles per second. Pole changers of multiple frequency are also used to ring harmonic bells on party lines.

Fig. 10. Warner Pole Changer

**IMPEDANCE COIL.** — An impedance coil is a single coil of wire wound on an iron core. In telephony the iron core usually is of wires, or occasionally sheets.

**INDUCTION COIL.** — A step-up transformer used in a telephone circuit called an induction coil in telephone parlance. Fig. 11 shows the use of such transformer in a local battery set. The battery and the carbon button are connected in series with its primary winding; the line and the receiver are connected in series with its secondary winding. The function of the induction coil is to convert the small variations of direct current of low e.m.f. into alternating currents of higher e.m.f. in order that they may pass over the line with less loss.

Fig. 11. Induction Coil in Local Battery Set

Local battery induction coils have a large ratio between the two windings. The primary winding is of low resistance and of fewer turns than the secondary winding. Single silk insulated wire is used for both windings; practice varies as to wire sizes and turns; a representative example has 350 turns of No. 20 B. & S. gage wire in the primary and 2400 turns of No. 30 B. & S. gage wire in the secondary. Other examples use from 200 to 700 turns in the primary, 700 to 1000 turns in the secondary, No. 20 to No. 28 B. & S. gage wire in the primary and No. 26 to No. 36 B. & S. gage wire in the secondary.

The induction coils in common battery sets have different functions from those in local battery sets. Figs. 12 and 13 show two forms of common battery telephones using them. In most cases one function of the induction coil is to in-

Fig. 12.

Fig. 13.

isolate the receiver from the direct current of the line, so that its permanent magnetism never shall be opposed by direct current flowing in its coil. In Fig.

12 the induction coil has the further function the denser  $c$  it assists the transmitter to convert the an alternating voice current. The condenser alte charges, responsive to the state of the varying This particular transforming function is lacking in type of Fig. 13.

**REPEATING COIL.** — A repeating coil is a phone circuit. A one-to-one ratio repeating coil such a manner that when equal currents flow through (or opposite, depending upon the point of reference) fields of the two currents neutralize each other, impedance is offered to the flow of such current has a high impedance. As the result of such an coil offers a high impedance to any current tending which is not accompanied by an equal current in other winding. The use of a repeating coil in a shown in Fig. 29, and in phantom circuit practice

**HOO-K-SWITCH.** — The time during which idle much exceeds the time in which it is in use. to receive or to make a call. When in use, its trans direct currents and its receiver to receive voice makes these changes automatically.

**PROTECTIVE DEVICES.** — Telephone apparatus from damage due to abnormal currents by means important co-operating elements. The latter are arresters"), and air-gap arresters. Heat coils operate of contacts when small currents flow for long time for short times. Air-gap arresters operate when p exist at their terminals. The operation of either arrester short circuits the line, grounds the wires i On account of the high resistance of the telephone current in the line may not be large enough to blow short circuit. The heat coil insures such a short or duration of the current exceeds a safe value.

The relation of the three elements to each other shown in Fig. 14. The fuses should be located at wires which are "exposed" and wires which are "tact with a source of dangerous current. All ac

Fig. 14. Arrangement of Protective

exposed. Underground and indoor wires are to be indoor wires are run in accordance with good rules, Electrical Code.

**ONE SETS.** — The several elements necessary at a subscriber's associated to form series magneto sets, bridging magneto sets and battery sets.

**Series Magneto Sets (Fig. 15)** are suitable for use on single party lines, and are also used in exchange practice, and, unfortunately, to some extent on lines having more than one telephone (party line). Fig. 15 is the circuit of a series set. When the line is on the hook, the bell is connected between the terminals of the set, the battery and receiver are open, and if the generator is not in use, the winding is shunted. When the line is turned in calling, the shunt is broken

so that the voice currents must pass in series through one of the ringers of a line. The impedance of the ringers, therefore, must be as low as possible, high enough to respond to ringing current of reasonable e.m.f. 80 to 100 ohms is the usual impedance of both coils of a series ringer. The cores are usually smaller than in bridging ringers.

**Bridging Magneto Sets (Fig. 16)** are better than series magneto sets for use where the ringer is bridged across the line permanently. The generator is used only when the crank is turned. The transmitter circuits are closed when the line is in use, as in Fig. 16.

**Common Battery Sets** (Figs. 17-19) have no local battery and can, therefore, be used in a central office. A storage battery is used in a central office, common to all the lines, and is connected to the instrument. Common battery sets do not send out current to ring bells, as in series sets; when used on a party line they can call each other only indirectly, through the central office operator to send the necessary current over the line. Common battery sets are always bridging sets.

Figs. 18 and 19 are typical circuits of common battery sets. Fig. 17 is that used in the circuit of the Associated Bell Telephone Company's apparatus in the central office of the world. As the condenser is "opaque" to direct current, but "translucent" to alternating current in a degree dependent on its capacity, no direct current from the central office normally will flow

Fig. 15. Series Local Battery Magneto Set

Fig. 16. Bridging Magneto Set

Fig. 17. Bell Common Battery Desk Set

through the set when the hook switch is down, but the central office can actuate the ringer. When current from the central office flows through the transmitter of the induction coil.

In the circuit of Fig. 18, used by the Kellogg Switch-hook set, the ringer, in series with a condenser  $c_1$ , normally carries the current. When the switch-hook is up, the transmitter is in series with its current. The receiver is in a path "opaque" to voice current, because of the high inductance, which is shunted by a condenser  $c_2$ . No direct currents can pass through the

Fig. 18. Kellogg Common Battery Set

Fig. 19.

The circuit of Fig. 19 is one in which all of the current is allowed to pass through the receiver. The latter is of the "direct current" type, Fig. 4 or 5, and carries current from the central office to magnetize its core.

**Wall and Desk Sets.** — Telephone instruments come in two forms, wall sets and desk sets. The latter are portable, having the receiver, transmitter and hook switch on a single case that can be carried about. Wall sets are self-contained and are usually mounted, if needed. In local battery and common battery sets, the receiver and transmitter are separately mounted, usually upon a wall. Local battery sets require housing for batteries, and magneto desk sets require hand generators.

A desk set is connected to line and ringer, and is usually used, by a flexible cord. The number of strands in the cord, the type of circuit used, and on whether the induction coil is mounted in the portable set itself or on the wall set. In Figs. 18 and 19 the parts of the circuit carried by cords between the wall and desk portions of the set are shown by dotted lines.

Desk sets are more convenient for use but are more expensive than wall sets. They fall frequently, breaking transmitter shells, and other parts. Supporting arms for desk sets are also used.

**Extension Set.** — An extension set is a set used in connection with a terminal set; the extension set usually has no bell; signals are sent to the terminal set, and if the user of the extension set desires a separate signal, such as a buzzer, operated by the terminal set. Any number of extension sets may be connected to one office nor from another station on the line unless the office is not then from other stations on the line unless the

**PARTY LINE CIRCUITS.** — Party line sets differ in the methods of signaling. The apparatus used in party line circuits depends upon whether the party lines are to be

**Non-Selective Party Lines.** — On such lines a

e line operates the ringers at all stations. Each station has a particular group periods of bell ringing, which group only it is meant to answer. Up to five stations from one to five short rings per station serve well. Beyond five, long and short rings are combined. Magneto sets, both series and bridging, are used on non-selective party lines. The generator of the magneto set at any station can ring all the bells of the line at once, and operate the central office signal also, the line leads to a central office. The bridging system is so used on many private lines, farmers' co-operative lines, rural toll lines, and, to a degree, on exchange party lines in towns.

Non-selective stations should not answer other calls than their own; this extra listening on lines is an extra drain on local batteries in sets having them; also destroys privacy. A receiver off the hook impairs signals unless circuits are specialized; for example, as follows:

If a condenser of low capacity, say one-half microfarad, be placed in series with the receiver, it will obstruct ringing current (frequency 20 per second) considerably, but voice currents (mean frequency 800 per second) very little.

Selective Party Lines are equipped with ringers arranged to respond each to its own call, the others remaining silent. There are three such methods in use in the United States, and still a fourth method, which has certain very decided advantages, is coming into use.

**Metallic Circuit Two Party Lines** (Fig. 20.)—On metallic circuits selective two party working is simple. Fig. 20 is the standard system of the

Fig. 20. Two Party System

sociated Bell Telephone Companies in the United States. Each wire of the metallic circuit is used as a private grounded ringing circuit to one station, and a pair of wires is used as a talking circuit by each station. Key A connects the ringing generator to the upper wire, ringing station No. 1; key B rings station No. 2. If a station answers while being rung, the other station is not rung falsely, the ground on the non-ringing side of the used key preventing that.

**Harmonic Selective Systems** (Fig. 21) operate on the principle that a ringer having a spring-supported armature will ring for one frequency of current but not for any other frequency. Frequencies of 16, 33, 50 and 66 per

Fig. 21. Four-party Harmonic System

second are used in the Dean four-party harmonic system. Each calling cord at the central office switchboard can be rung upon by one of four keys, as in

Fig. 21. The ringers are alike except as to the cylinders of metal, heaviest for the lowest frequency for the highest frequency.

The number of selective stations may be made twice by connecting harmonic ringers from each wire to ground across the line as in Fig. 21. This enables eight lines leading to a four-frequency central office.

**Biased Ringer Systems** (Fig. 22).—This system uses unidirectional pulsating current for the selective party lines. An improvement on that system (Fig.

Fig. 22. Four-party Biased Bell

American Telephone & Telegraph Company. A biased ringer which has its armature drawn to one side by a magnet in one direction only will operate the ringer. Connections with such ringers would interfere with the selective system necessary to prevent ringer connections from interfering with common battery lines. In common battery systems each station, as in Fig. 22, connects the ringer to the line for ringing. The same current that operates the ringer

**Step-by-Step Party Line Systems** select the operation one after another of a set of switches controlled from the central office. Step-by-step party lines come into wide use, but the development of automatic central office use is increasing knowledge, faith and interest in a step mechanism. (See article on *Dispatching of Traffic*.)

**Semi-Selective Party Lines.**—Semi-selective party lines connect more than two stations on a line, as in Fig. 20, by connecting to each wire, ringing code signals on key *A* for the ringer on the high frequency and ringing code signals on key *B* for ringers on the low

**CENTRAL OFFICE EQUIPMENT.**—There are two general ways: (1) On a line permanently connect this line not being connectible to another, and, (2) more telephones, this line being connectible at will to other lines. In the second case a switchboard and the various kinds of current required must be connected to any line to any other. Such a switchboard and its equipment are called "central office." A "telephone exchange" is an organization of central offices and the connecting lines and apparatus employed to provide service to a community. A central office is, therefore,

A "manual switchboard" is one in which a human operator connects the lines by hand, as instructed by the subscriber's speech. An "automatic switchboard" is one in which the operator disconnects the lines in response to electrical changes. The functions of manual and automatic switchboards are combined in systems named "semi-automatic systems" or "automated systems."

A switchboard designed to interconnect telepho

magneto is called a "magneto switchboard," while a board de-connect telephone sets supplied with current from a single battery office is called a "common battery switchboard." When each of a central office is permanently connected to a single "jack" or board is called a "simple switchboard." When each line is connected to a plurality of jacks, located at different parts of the board, is called a "multiple switchboard." A multiple switchboard is divided into sections accommodating three operators, and containing a jack entering the central office. The group of jacks in each section is called the "multiple." "Simple switchboards" can be used only in case the number of lines connected to the central office is small (less than about 300), and the work in the central office is resorted to. It should be noted that the number of subscribers of central office switchboard equipment increases as the number of subscribers increases when the total number of subscribers is sufficient to warrant the use of multiple switchboards.

**Plugs, Jacks and Drops.**—As principally used, manual switchboards connect lines by means of flexible conducting "cords" tipped with line-terminal-sockets called jacks. The plug contains two parts, electrically insulated from each other but connected to the ends of the cord terminating in the plug. There are two types of simple magneto switchboards, and therefore two parts in the plug and jack to two conductors of the jack. Fig. 23 shows a jack and

Fig. 23. Jack and Plug

Fig. 24. Diagram of Plug and Jack

and cord. Few switchboards require circuits calling for more than two conductors in regular switching cords. Plugs and jacks for that purpose can be made in compact and serviceable forms. Fig. 24 shows schematically a three-conductor jack and plug, in which it is intended that the plug shall engage the short spring, the ring of the plug the sleeve of the plug the tubular sleeve or thimble of the jack. Plugs are associated with keys, signals, wiring and current keys which the operator uses to do her work upon the lines made up of jacks. At *D* in Fig. 25 is shown diagrammatically the type of drop used on magneto manual switchboards. This signal, called a gravity drop, is bridged across the switchboard end in the same manner as the ringer at the subscriber's station. When the core is energized by the magneto, at the subscriber's station, the drop is attracted, lifting the catch and releasing it to fall forward by gravity. This is called gravity drops for this reason.

Fig. 25. Magneto Drop and Jack

— The power plant is an organization of a central office to furnish to the subscribers that office the several kinds of currents required. The types of power plants are storage batteries, charging generators, and rotating current for ringing. In a battery system one storage battery usually supplies current to all subscribers or operators, and actuates all principal signals. In magneto offices storage batteries need only be

large enough to supply operators' transmitters and magneto equipments usually have primary batteries

**Magneto Manual Switchboards** (Figs. 25 and 26) diagrammatically the central office end of a subscriber's line includes the essential elements of a magneto cord circuit. When one plug is connected through the cord to the tip contact of the plug sleeves. When a subscriber rings the central operator then inserts the plug  $P_1$  (Fig. 26) of an idle cord circuit in the jack of this subscriber's line; this disconnects the line drop, the shutter of which is returned to its normal position either by hand or automatically. She then connects her telephone set to this cord by closing the switch  $A$  and gets the number of the subscriber wanted, and inserts the plug  $P_2$  in the corresponding jack. By closing the switch  $B$  she connects to the central office source of ringing current, which continuously. The called subscriber's bell rings as long as the ringing key. When she releases it, direct connection results. When the called subscriber answers, on the close of it the subscribers are expected to signal. The gravity drop  $D$  (Fig. 25), in this case called a line drop, is thrown across the cord circuit, and in response to this signal the line signals of both lines thus are recognized as calling signals.

Fig. 26.

The operator's set is connectible to the cord circuit, enabling her to answer the calling subscriber to the conversation, and, by releasing one listening key, to shift her telephone set from cord circuit to cord circuit. Under a variety of conditions, an operator can utilize from one set to another, transferring her telephone set from one to another.

In Fig. 26, ringing current can be sent out only on the left-hand lines. Calls, therefore, are answered by using the left-hand lines being taken up by the right-hand plug. Some switchboards are equipped with calling keys, in which case the left-hand lines are arranged in an arrangement symmetrical with that of the right-hand lines.

The shutters of gravity drops used as line or clear drops are returned to their upright position by hand in most simple magneto switchboards. Formerly the drops were placed in one group and the jack was restored directly by the operator's fingers. Latterly the drops are associated together, so that the plug as inserted into the jack is associated with the shutter by some thrusting movement on the part of the operator. This shutter by some thrusting movement on the part of the operator forms a tongue upon the jack spring, this tongue then falls into its latch.

Large magneto switchboards have been equipped with line drops at a distance from the jacks and out of reach of the operator. These drops are stored after operation by electro-mechanical means, and are returned in the jack of a line closing circuits to restore the signal.

Jacks are adapted to be mounted in insulating strips

any jack of a group may be dismantled. When more compact desired, jacks are made up in strips of ten or twenty, an entire strip must be removed from the framework of the switchboard to enable it to be inspected or worked upon.

For light telephone traffic, as at night, it is desirable to use as few operators as possible to handle the traffic satisfactorily, and, in small exchanges, even a single operator to sleep between calls. On a long switchboard a drop may be made from the night operator and its falling be unheard. A night operator is provided by equipping each drop with a contact closed by the night operator. These contacts of all the drops of a group are wired in series with a battery, bell and switch which is closed at night. When any drop falls, the bell will ring if the switch is closed.

Plugs, when not in use, stand vertically in a plug shelf, the cords are held in position by the switchboard framework and kept reasonably taut by being supported by pulleys. Weights should be heavy enough to enable cords to fall into position after disconnection, and not so heavy as to shorten the life of the flexible conductors within the cords.

Subscriber circuits are connected to metallic circuit switchboards and in connection with metallic circuits, a ground connection must be provided for the second limb of the line, as switchboards now are built for metallic circuits. Such grounds must be connected to jacks in one or two grounded circuits may be connected so as not to be able to be connected. The usual practice is to connect the line wire to the spring of the jack and the ground to the sleeve.

**Simple Common Battery Switchboard (Fig. 27).**—The circuits of a simple common battery switchboard are shown in Fig. 27 and

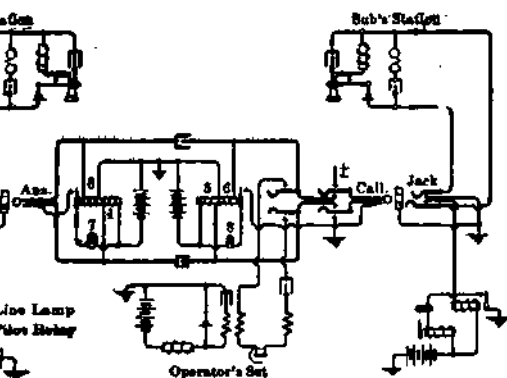

Fig. 27. Circuits of Simple Common Battery Switchboard

Logg Switchboard & Supply Company. They are a type of common battery switchboard. The subscribers' lines terminate in cut-off jacks. There is one line. The calling plugs only are equipped with ringing

operations of such a system is as follows: The subscriber removes the hook and as there is no plug in the jack of his line at the time the line relay is actuated, lighting the line lamp and operating the pilot relay, in turn, lights a pilot lamp, of which there is one

for a considerable number of line lamps, and with an alarm signal can be associated. Responsive to a plug which in practice is mounted close to the line jack, the calling plug in the jack, breaking the line relay circuit, extinguishing the line lamp. Operating her listening key with the talking set with the cord circuit, asks for the subscriber by inserting the calling plug in the jack of the line already occupied by a plug. If it is occupied, she knows that the called line is busy. If it is not occupied, she rings. At this stage, the supervisory lamp 7, adjacent to the calling plug, is dark and the supervisory lamp 8, adjacent to the calling subscriber's receiver is off. When the called subscriber's receiver is on the hook, lamp 8 is extinguished. At the close of the call, lamp 8 will re-light as the respective receivers are hung up. She can tell at all times the state of the connection and to the final lighting of both supervisory lamps, she has the positive knowledge that the conversation has been completed.

The heavy lines in Fig. 27 are those over which the conversation takes place. In the cord circuit the two conductors are continuous from tip to tip and from sleeve to sleeve. A condenser is interposed in each of the two conductors. The current to actuate subscribers' transmitters is furnished to the

Fig. 28. Impedance Coil Cord Circuit

Fig. 29.

the windings 3-4 of the answering supervisory relay through the windings 5-6 of the other. Each supervisory lamp has two purposes, one being to supply the subscriber's transmitter and the other being to co-operate with the ground at the line jack to light the supervisory lamp if no direct current flows through the line. The supervisory lamp while the direct current does so flows through the line.

There are three general ways in which direct current is supplied to subscribers' lines. In Fig. 28 current is supplied through coils without condensers. Such a plan is suitable where all the lines of a switchboard are of about equal resistance, as in a private exchange. If the lines are of varying resistance, a high resistance line will be denied proper current when connected through such a cord circuit to a low resistance line (low compared to the resistance of the impedance coil). The circuit of Fig. 29, using a repeating coil, is free from this objection and is standard with the American Telephone & Telegraph Company. The circuit of Fig. 30, using condensers, is as efficient as that of Fig. 28, though it is widely used in manual and automatic switchboards. It is widely used in manual and automatic switchboards of the American Telephone & Telegraph Company.

Comparison of Magneto and Common Battery

best in small towns and country exchanges. Magneto systems are best in exchanges under 500 lines and common battery systems best above 500. No positive rule can be laid down. For example, the magneto system is best arranged in exchanges which start with little equipment and do not exceed 500 lines while the equipment still is in good condition. Common battery systems may be warranted in exchanges as small as 200 lines if the conditions are favorable and the need of the highest grade of

**Systems or Local Trunking.**—When it is desired to use a common battery system in an office requiring more than 20 lines so that there will be lines beyond the reach of each operator, provide local trunks or transfer circuits to interconnect lines which cannot be reached directly. These are called transfer systems or local trunking systems. If an operator has a call for a line which she cannot reach directly, she inserts the calling plug in a jack of a trunk which leads to the second jack of the called line. At that section an operator connects the trunk with the called line and assists in disconnecting it at the end of the call.

These systems have service disadvantages which in most cases outweigh the savings, and the best practice is to use multiple switchboards where simple switchboards are outgrown. An important exception is in large cities where the majority of calls would have to be connected to a second central office in any event. Under such circumstances local trunks only are provided, the subscriber's line being connected to a single jack and practically all calls are trunked irrespective of the distance.

**Multiple Switchboards (Fig. 31).**—A multiple switchboard is one in which a large number of lines of the office are brought within reach of each operator by

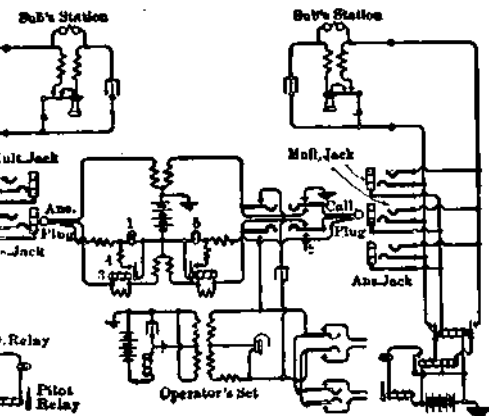

Fig. 31. Circuits of Multiple Battery Switchboard

each line with a number of jacks, distributed over the board in such a way that each operator can reach at least one of these jacks. The usual practice is to provide each line with one answering jack, at which all its calls will

be answered, and in addition with a plurality of lines a plug may be inserted when that line is called. A guard is provided for taking the line when it is in use at another place. This guard is called the "busy test" and is provided by a metal thimble of each jack of a line whenever all the thimbles of all the jacks of a line are at the line. Touching the tip of a plug to the sleeve of all idle plugs produces no electrical result. But when a plug is touched to the sleeve of a line which is busy, difference of potential and sleeve causes current to flow and a click to be heard. This click tells the calling subscriber the called line is busy.

Fig. 31 shows the complete circuits of a calling line. The connecting cords of the Western Electric Company which is the standard of the American Telephone Company. The cycle of operations is exactly as described with reference to a battery switchboard with the addition of testing current supply to the cord circuit is of the form shown in Fig. 31. It has fewer parts than in the simple switchboard system. The cut-off relay is disconnected from the line by a cut-off jack. The cut-off relay is operated by current from the line. A plug is placed in any jack of the line. This current is shunted around the supervisory lamp. This current is potential to all jacks of a line so long as a plug is in the jack which actuates the subscriber's transmitter also energizes the lamp. It results in the lamp being lighted or dark, depending upon whether the switch is up or down.

All principal common battery multiple switchboards in use have the common features of an audible busy signal and supervisory signals per cord circuit — one for each answering jack supplementing the multiple (or calling) signal. This requires more than two wires in the subscriber's line, but the system of Fig. 31 requires three wires in the switchboard. Other systems require only two wires through the line. In these systems the busy test and cut-off relay function as other functions of one of the wires of the line. The advantages over the three-wire system lie principally in the greater simplicity and the fewer wires necessary in the switchboard circuit.

Common battery multiple switchboards for use in offices and lines sometimes are provided with cut-off jacks, and cut-off relays. Some such switchboards use magnets to substitute for lamp signals. This is not the best system to have decided advantages. They are compact, can be used in small spaces, show great contrast between actuated and unactuated, and are not easily obscured by cords.

**A and B Operators.** — Manual multiple switchboards bring all the lines of the office within reach of each operator. Switchboards cannot concentrate more than 10,000 lines. If jacks are made smaller than is considered the best practice, a switchboard contains more than 10,000 lines, it is customary to use a trunk. This makes possible a saving in lines and things required. Calls to be trunked from one office to another. In a large office, for example, there would be ten switchboards of 1,000 lines each board serving a district of the exchange.

Calls originating in one district will be for lines

in the originating district can be completed in the switchboard. Calls for subscribers in all the nine other districts must be accomplished this, the operators in a multi-office exchange have to be able to complete calls directly in the multiple switchboard. To connect subscribers with trunk lines leading to the other districts each office furthermore there are operators and equipments adapted to complete calls trunked to them from the offices where they

are called *A* operators; operators who answer incoming calls from other offices are called *B* operators. The cycle of a call for a line not in the office first called is as follows: subscriber calls; receiver and his line lamp lights; operator answers and asks for the subscriber by prefix that call is for a subscriber in a distant office, operator marked with that prefix, so connecting her telephone set with a multiple jack directly to a receiver of a *B* operator in the distant office; *A* operator asks for the number desired, following with the *prefix of her own office*; *B* operator asks the distant office names back a trunk number; *A* operator inserts a multiple jack of that trunk and simultaneously distant *B* operator inserts the plug of that trunk in the called line; method of ringing is determined by apparatus; at close of conversation *A* operator disconnects lamp before *B* operator, who disconnects in answering signal.

**Distributing Frame.**—The main distributing frame is a device which is terminated, usually upon opposite sides, the lines from sub-switchboard apparatus. Between these terminals connections, called "jumpers," are soldered. The purpose of the main distributing frame is to enable a subscriber's line to be connected semi-permanently to a given switchboard line. A subscriber may move anywhere within the office of his central office and may utilize any pair of wires entering the switchboard without relinquishing his particular telephone number, as his switchboard line may be connected by jumper to whatever entering cable wires are available. Protective apparatus, consisting of sneak current arresters and grounders, is associated with all lines entering a central office. These devices customarily are mounted on the switchboard side of the distributing frame.

**Intermediate Distributing Frame.**—The intermediate distributing frame is a frame on which lines to multiple jacks and lines to answering jacks are connected, accessible for inter-connection. Its object is to enable a given subscriber to connect an answering jack at any part of the switchboard and this connection is semi-permanent. By this is meant that when a subscriber's line is connected by jumper to an answering jack on a certain operating position, all calls of that line will be answered at that position until the intermediate distributing frame has been changed. The purpose of the intermediate distributing frame is to equalize the traffic of an office originated by the subscribers of an office to be divided among the operators. This equalization is not automatically done by the main distributing frame, as is the intent in the automatic system.

**FOR MACHINE-SWITCHING SYSTEMS.**—There are two methods of switching lines in a central office by means of machines. The first, commonly known as the automatic system, connects and disconnects lines by the agency of central office machines under the control of the subscriber. The other utilizes machines similar in function to those of the automatic system, but these are controlled by skilled operators in the central office, and the subscriber gives his call orally to these operators. This is a common battery relay manual system.

The fundamental merit of machine systems is the substitution of machines over human beings in doing certain things. In the case of line switching has become so fully standardized that the change to machine methods, with diminution of error, is in the same order as resulted from the adoption of type-writing as a substitute for script and mental addition.

Such systems are in successful use in many countries and to a growing degree abroad. Their use has been encouraged by rising labor costs and by the difficulty of securing sufficient skilled women operators for the manual systems. In many system managers throughout the world recently have been turning to machine switching, principally for economic reasons. It is a fuller but perhaps belated recognition of what machines can do.

Machine switching systems so far most widely used are based on the principle. In the system of the Automatic Electric Company there are units in the digit called.

In manual multiple switchboards, all the lines of the operator. At the time of making a connection the operator seeks out of a cord circuit may be considered as a terminal line and seeking the called line in the multiple switchboard or in the trunking of a call from a central exchange having several offices with multiple switchboards. The operator must co-operate to complete certain connections.

A machine system represents a third case in which the machine co-operate to complete a connection. In a word, the machine are engaged in making a connection as there are no human operators less one.

Success in machine telephony came with the adoption of the multiple principle and the adoption of the complete automatic had been abandoned in manual telephony some time ago.

**Selector and Connector Switches.**—The type of machine trunking system is that the calling party uses a "selector switch" to seek an idle trunk from a group of trunks which lead in a direction determined by the first digit of the number called. This first switch makes as many vertical steps as there are units in the digit called, and immediately thereafter seeks out the trunk of that group. On the calling of the next digit the selector switch selected trunk takes as many vertical steps as there are units in that digit, and immediately seeks out and appropriate trunk. This process is repeated until all but two digits have been called. The connection to the last switch which will be a "connector" and has vertical and rotary motion. The selector switch, but, unlike them, both vertical and rotary motion is under automatic control. As he calls the next to the last (tens) digit the selector switch makes as many vertical steps as there are units in that digit but with automatic rotation. It rotates in response to the calling party's many steps as there are units in that digit and seeks out the trunk in contact with terminals of the called line. Ringing is caused by automatic means or by relays responsive to the calling party's subscriber's telephone. Disconnection ensues when the calling party hangs up his receiver.

**Automanual System.**—What has just been said is a system under subscriber control, in which all the digit-m

These are dictated by the subscriber's turning of a disk attached to the dial. In the second type of machine-switching apparatus, of later date and formerly called automatic, there are in the central office operators who receive by telephone the orders of subscribers as in the manual system, and they execute those orders wholly by machines. The latter are controlled by a dial, like those of an adding machine. Disconnection is instantaneous by the turning of subscribers' receivers. Very high efficiencies are attained, and operators' labor costs are low, as few operators are required to handle a large amount of business done under most favorable conditions.

Automatic systems share the advantages of the use of machines; one requires the subscriber to operate a dial, the other requires him to state his wants orally; the former is determined which shall be properly called the "natural" method. In both systems, however, a higher quality of service is attainable than in the manual system, and operating costs are somewhat reduced.

**Automatic System.**—The subscriber-controlled system first operates on the step-by-step method within the central office. The automatic system contains no such devices, but consists almost entirely of relays, much like those used for telegraphy or for relay manual systems. Current impulses resulting from the operation of the subscriber's dial operate these relays in the central office, connecting the lines of the calling station to the receiver hanging up the receiver of the calling station. Furthermore, relays of this type may be used in connection with dial-less telephony for the distribution of trunk lines leading to operators in automanual central offices. This meets the requirements of many small rural exchanges adjacent to city offices. Calls from the rural subscribers are answered by city operators, and the necessary relay equipment in the rural exchange over signal trunks. When the connections are made the trunks are released for other use. The subscriber's line follows hanging up the receiver of the calling station. In any rural exchanges thus can be operated from one city office, and for all other work, the rural offices requiring no operators or attendants.

**CHANGES.**—A private exchange is a group of telephone instruments and switching apparatus subordinate to a central office, and usually on the premises of the user, for the uses of a single business. Private exchanges are widely used in apartment houses, factories and suites of offices.

They are of three types: those using simple switchboards which require the attention of operators through whom all local and outside calls pass; those using a dial whereby each user may select the line of any trunk line to a central office, and those having a local equipment consisting of relays or switches of the step-by-step or of the relay type.

The object of the private exchange is to enable the telephones within the exchange to communicate with each other directly without using lines through the central office. A second object is to enable communication from telephones within the private exchange through the central office by the use of fewer lines. There are telephones in the private group. A serviceable ratio of telephones may be from one-tenth to one-fifth, at a cost less than the cost of providing a line to the central office from each telephone.

**CIRCUITS (Fig. 32.)**—In Fig. 32, four wires join two offices. They are designed to be efficient in transforming both direct and alternating currents. Currents from telephones connected to either office pass at any instant in opposite directions in the two wires. The phantom circuit uses one of the physical pairs as a wire of its own, by tapping the middle point of the line side of each of the

Circuits (Fig. 34) depend upon a different principle. Impedances are inserted to oppose alternating currents, and condensers to oppose direct currents. In Fig. 34 one telephone circuit forms two Morse circuits, so that two telegraph sets form one telephone circuit and (with the earth) two telegraph sets. Each Morse circuit includes in series two 50-ohm impedance coils and is shunted to ground between the Morse sets and the impedance coils. The 50-ohm impedance coils are connected differentially and so offer low impedance to the Morse impulses, whose frequency is not high. The coils, however, offer high impedance to voice currents, since they are not differentially connected with respect to the latter. Voice currents can pass through the com-

Fig. 34. Composite Telephone and Telegraph Circuit

telephone line, but direct currents cannot. Impulses due to discharges and capacities in the Morse circuit would make sounds in the telephone that they are choked off or led off by the 50-ohm impedance coils and the capacities connected to the Morse sets.

**Composite Systems.** — The principles of the respective impedances and capacities to direct and alternating currents, upon which a composite system depends, are applied to the conversion of series circuits into combined telegraph and telephone lines. It sometimes is of advantage to modify a single-wire telegraph line so that telephones may be connected without abandoning its use as a regular telegraph circuit.

Such an arrangement is known as a railway composite system. Calls between stations on such a circuit are sent by means of high-frequency alternating currents, such as are developed, for example, in an automobile spark coil. These are received at the telephone stations on "howlers," which are merely receivers with special horn-shaped mouthpieces. These calling currents are of high frequency as not to affect the telegraph relays. The paths for the low-frequency currents in general are supplied by condensers and the paths for the high-frequency currents for telegraphy in general are supplied

**THE REPEATERS.** — A telephone repeater is an apparatus that repeats the voice currents flowing in the line. Repeaters are not used within a city, but are useful in long-distance working. They amplify speech in both directions in the line, without requiring any adjustments of the apparatus, so that the conversation may proceed as if the line having no repeaters. Amplifications sufficient for around-the-world transmission are now possible, assuming a line to be available. The principle of operation of a repeater of amplification exist. That of Shreeve uses an electromagnetic induction to operate the movable electrode of a carbon-granule transmitter.

The other method uses a three-electrode vacuum tube whatever, unless electrons be called moving there are associated transformers and condensers requirements of the problem.

In the vacuum-tube method one of the tube's electrodes is as in an incandescent lamp; the other two electrodes are insulated from each other and from the filament within the tube. Variations of potential on one of the insulated surfaces are different in a circuit between the filament and the second electrode so current so varied may have many times the amplitude of the current causing the varying.

Repeaters are adaptable to other uses than repeating signals. It is possible to pick up at considerable distances stray signals on a single wire or even two-wire telephone line, and repeat them. It is possible to repeat between radio-telephone lines, and with such freedom that the conversation over the radio is equivalent to wire conversation. Speech originating in a radio can be amplified and delivered to loud-speaking receivers, thus enabling large groups of people to hear one speaker. Where the amplification desired is greater than one stage, two or more tubes can be used. The current delivered to one tube by another, and so on in "cascade." As many as ten tubes can be in cascade.

For a detailed discussion of the three-electrode vacuum tube see *Radio Communication*.

**MULTIPLEX TELEPHONY.**—Vacuum tube multiplexing converts into high-frequency alternating currents, carrying electromagnetic waves through space or along conducting surfaces. In the case of propagation a number of different frequencies are used on separate wires, each frequency being a carrier for one conversation. The capacitances properly related to the frequencies are used to separate the several conversations. The currents used in space multiplexing are believed to be carried through space adjacent to the wires rather than through the metal of the wires. This multiplexing is used for telephony over wires that at the same time are being used for Morse telegraphy. See article on *Telegraph Systems*.

**COSTS (Pre-war figures).**—The following figures are all f.o.b. factory. These costs are given as preliminary estimates. For accurate estimates quote to the manufacturers.

Magneto wall set complete:

Series (80-ohm ringer).....

Bridging (1000- to 2500-ohm ringer).....

Magneto desk set complete:

Add 75 cents to above prices.

Common battery wall set complete:

Oak or walnut, 500-ohm ringer.....

Oak or walnut, 1000-ohm ringer.....

Hotel type, 1000-ohm ringer.....

Common battery desk set complete with cord:

500-ohm ringer.....

1000-ohm ringer.....

Automatic wall or desk set.....

## Switchboards:

lines, 1-operator equipment.....	175-575
lines, 2-operator equipment.....	730-865
Common battery switchboards:	
lines.....	550-2500
ending cost per line.....	5.50-4.17

Common battery switchboards, formerly standard for offices in changes, are so largely superseded by machine-switching equipments practice that prices will fluctuate widely among different types. Switching equipment prices vary with the type; the amount of equipment on the amount of traffic and on the number of telephones in the general, however, machine-switching equipments cost more to operate than do manual equipments.

**TELEPHONE LINES.** — (See also *Distribution Lines; Wires and Cables.*) The line always consists of two wires, one of which may be the earth. The standard telephone wires are of the same size and of the same material. When the earth forms the return the line is called a "grounded line" and two wires without earth return is called a "metallic line."

**LINE CONSTANTS.** — (See also *Transmission Lines.*) The efficiency of a telephone line depends upon its resistance, capacitance, inductance, and leakage.

**Leakage.** — High insulation, i.e., small leakage to earth from a line and from each wire to earth is possible in open wire lines. Insulation is possible in open wire lines.

**Resistance.** — The resistance of the conductor of a telephone current, but does not distort it appreciably. Resistance to resistance are practically independent of the frequency.

**Electrostatic Capacity.** — The electrostatic capacity of a line distorts the current and distorts it also, because the capacity is dependent of the frequency. As the voice current is of a definite frequency, the higher frequencies are reduced.

There are two ways of expressing the important capacity in cables, i.e., in terms of the "mutual capacity" or in terms of the "grounded" or "regular capacity and Charging Current." The mutual expression of the amount of mutual capacity which determines the capacity in telephone cables is about two-thirds that of the same wires. A given cable has higher capacity than a single wire. Cable capacities should be referred to a standard test.

**Inductance.** — The inductance of telephone lines is small, since the wires are usually close together. Inductance together for use as lines in cables have very small inductance and inductive reactance.)

**Pupin Coils.** — In 1887 Oliver Heaviside proposed a method of decreasing the harmful effects of capacity and inductance. Pupin made public (*Trans. A.I.E.E., Vol. XVII, 1887*) a method of reducing attenuation and distortion by inserting additional inductance. He showed how to determine how much inductance to insert. An ideal method distributed inductance would offset the effects of capacity. In the Pupin method the inductance is inserted at predetermined intervals. The coils are ordinarily of iron. They are called "loading coils" because of physical effects. See the publication cited.

**CHARACTERISTICS OF OPEN WIRE LINES.** — Hard drawn copper is now almost universally used for important lines, where iron wire may be employed. The wire employed range from No. 16 B. & S. to No. 8 B. & S. The length and importance of the line. Where the length is unimportant, as when the wires are fastened along poles close together, smaller sizes may be employed. Aerial wires are usually strung horizontally, and from 18 to 24 inches vertically, depending upon the cross arms. For the resistance, capacity, and inductance, see *Wires and Cables, Bare.* The insulation resistance of a wire depends upon the types of insulator, pin and

condition of the weather. The following values are representative of good practice:—

Very dry,	500 megohms per mile.
Average,	25 megohms per mile.
Very wet,	2 megohms per mile.

Three different gages are employed for specifying the size of telephone wire: B. & S., the B. W. G., and the N. B. S. (See article on Gages, Wire.) The following table gives the diameter, weight and resistance of the various sizes employed in telephone practice.

TABLE I

Number	Diameter in mils	Weight per mile in pounds	Resistance per mile of wire in ohms, 60° F.	Resistance per mile of circuit in ohms, 60° F.
1 B. W. G.....	165	435	1.07	3.95
2 B. & S. G.....	162	419	2.05	4.10
3 N. B. S. G.....	160	409	2.70	4.20
4 B. W. G.....	148	393	2.45	4.91
5 B. & S. G.....	144.3	371	2.59	5.19
6 N. B. S. G.....	144	378	2.59	5.19
7 B. W. G.....	134	287	2.98	5.97
8 B. & S. G.....	128.5	262	3.26	6.56

12 B. & S. G.....	114.4	208	4.14	8.27
13 B. W. G.....	109	190	4.52	9.05
14 N. B. S. G.....	104	173	4.97	9.94
15 B. & S. G.....	101.9	166	5.17	10.31
16 B. W. G.....	95	144	5.96	11.91
17 N. B. S. G.....	92	135	6.33	12.70
18 B. & S. G.....	90.74	130	6.49	12.98
19 B. W. G.....	83	110	7.80	15.61
20 B. & S. G.....	80.81	105	8.19	16.39
21 N. B. S. G.....	80	102	8.40	16.80

**CHARACTERISTICS OF TELEPHONE CABLES.**—Telephone cables are groups of pairs of paper insulated wire twisted together and encased in a lead sheath. Soft drawn copper is invariably used for the conductors. The size wire usually employed ranges from No. 10 to No. 22 B. & S. For long distance underground lines individual wires as large as No. 10 B. & S. have been employed. For the resistance of the different sizes of conductors see *Wires and Cables*. The capacity of any pair of wires and the capacity of any wire to ground depends largely upon the way in which the cable is made up. When the wires are twisted tightly together the capacity is greater than when they are loosely assembled. The mutual capacity ranges from 0.067 to 0.090 microfarad per mile, and the regular or grounded capacity from 0.10 to 0.12

microfarad per mile for tightly twisted wires, as 0.080 to 0.10 respectively for loosely twisted wires. Capacity is usually referred to as "high" and the loss is "low."

The effective insulation resistance between the two wires is about 10 megohm per mile at 800 cycles per second in a wire of No. 14 gauge. This figure includes the effect of dielectric hysteresis. The insulation resistance measured by direct current would be about 100 megohm per mile.

The inductance of a pair of wires in a telephone cable is about 0.1 millihenry per mile of cable (2 miles of cable).

**DISTORTION AND ATTENUATION.**—(See also *Distortion*.) Corresponding to any vowel, syllable or word spoken into the transmitter, a definite wave of a definite shape is sent over the line. This wave is a number of simple sine waves of different frequencies, each placed with reference to one another, i.e., reaching the receiver a certain number of times. Each of the simple sine waves as it progresses along the line is attenuated in amplitude or is "attenuated." Moreover, the shorter waves are attenuated more than the longer ones, with the result that the wave which reaches the receiver is made up of harmonics of relatively lower frequency than the wave sent out from the transmitter, that is, the wave received at the receiver is "distorted." The sound produced by the receiver differs from the word spoken into the transmitter, since the sound depends upon the relative magnitude of the constituent harmonics, also a displacement of the harmonics with reference to time, and the placement, although it changes the shape of the wave, has no effect if any, effect upon the quality of the sound.

Attenuation of a wave without distortion merely means that the amplitude of the wave since the wave form remains unchanged, only the amplitude is reduced thereby, were it converted into a sound wave, it would be heard alone, since it produces the same relative attenuation of the harmonics as before. Attenuation is therefore the least troublesome of the line characteristics. The loss of energy of the line is the controlling characteristic, since the amount of distortion depends upon the wave length, and therefore distortion is more pronounced at higher frequencies.

In addition to the distortion produced by the line characteristics, there is also distortion in the transformation at the transmitter of the sound wave into an electrical wave, and again another distortion at the receiver when the electrical wave is reconverted into a sound wave.

**DISTURBANCES DUE TO NEIGHBORING TELEPHONE LINES.\***—(See also *Distribution Lines*.) The small voltage between the wires of the telephone line induced by the power lines produce noise in the telephone apparatus comparable to that produced by the voice currents. The noise is due to the harmonics of the power system, especially to those between 100 and 10,000 cycles per second. At these frequencies induced currents in the telephone line of the order of millionths of an ampere are sufficient to make conversation intelligible.

**Balanced versus Unbalanced Power Circuits.**—In a balanced power circuit of neighboring power circuits on telephone circuits, the induced currents in the balanced and unbalanced power circuits must be completely balanced. A completely balanced power circuit consists of two or more wires, the vector sum of the currents in all the wires being practically zero, and the vector sum of the voltages between any wire and ground is practically zero. A completely unbalanced power circuit consists of two or more wires with a ground return, the currents in

\* By H. Pender.

and the voltages between the several wires and the ground being equal and in phase. In practice power circuits are frequently not completely balanced nor completely unbalanced, but the currents and voltages may be resolved into completely balanced and completely unbalanced components. Examples of such circuits are a three-phase circuit having one wire grounded and a three-phase circuit with grounded neutral; in the latter case the neutral current may be of fundamental frequency due to an unbalance in the system, or the neutral current may be of triple frequency as a harmonic in the voltage wave (see *Generators, Alternating Current*). The effects arising from unbalanced voltages or currents are very different from the inductive effects arising from balanced voltages or currents. The magnitude, because with balanced voltages and currents the effect is largely neutralized by the near presence of other wires of opposite

**Induced Voltages between Wires and between Wires and Ground.** Power circuits affect the telephone circuits by producing: (1) a voltage between the two wires of the telephone circuit; (2) a voltage between telephone wires and ground.

The voltage induced between telephone wires and ground is usually large compared with the voltage induced between wires. Even though the telephone circuit is transposed between power lines, voltages are induced between the two wires and ground, the voltage induced between wires because of the unavoidable unbalances in the constants of the two sides of the circuit. If the induced voltage is high it endangers the users and operators of telephones and puts the circuits out of commission by operating the devices.

**Prevention of Inductive Disturbances in Telephone Lines.**—It is impossible to perfectly realize any of the following remedies, and no remedy could be sufficient even though perfectly realized. In order to avoid inductive disturbances it is therefore necessary to carry out each of the following remedies as far as possible.

**Transposition of Power and Telephone Circuits.**—The way in which the effects are affected by the transposition of the power and telephone circuits is indicated in the following table:

EFFECT OF TRANSPOSITIONS

Line	Voltages Induced in Telephone Line	Affected by Transpositions in	
		Power Circuit	Telephone Circuit
.....	{ To ground	Yes	No
.....	{ Between wires	Yes	Yes
.....	{ To ground	No	No
.....	{ Between wires	No	Yes

In order to reduce the inductive effects between a three-phase power circuit and a telephone circuit it is necessary to divide each unit of the exposure into six or a multiple of six equal sections in which the six possible phase angles are induced. The methods of transposing a telephone line are described below in the section on *Transposition*; methods of transposing power lines are described in the section on *Transmission Lines*.

2. **Balancing the Power Circuit.** — The telephone circuits and ground by small unbalanced power voltages and currents are relatively large and in various positions. In order to reduce the inductive interference it is important to construct and operate the power circuit in the most possible balanced with respect both to voltage and to current.

3. **Balancing the Telephone Circuit.** — It is necessary that the telephone circuits be carefully balanced by the voltage between the telephone wires and ground. It is necessary that the telephone circuits be carefully balanced on two sides of the circuit be of the same resistance and the same insulation resistance and the same capacitance to ground. Balancing due to unequal insulation and to unequal conductors and ground is frequently important and even necessary to minimize it. All apparatus connected to the circuit should be balanced. Impedances inserted in the two sides of the circuit, between the two sides of the circuit and ground, are necessary to equalize the impedances.

**A Joint Committee on Inductive Interference.** The Commission of the State of California made a thorough study of the interference between electric power and electric communication in 1911 and 1919, and its findings, reports and recommendations, the Commission's rules and orders, are a source of information on the subject. The matter is available in a volume issued by the State of California in bibliography.

**COMMERCIAL TRANSMISSION. — LIMITING TRANSMISSION DISTANCES.** — Transmission is said to be "commercial" when with normal ears and voices, using standard transmission apparatus, conversation can take place with reasonable ease. The length of the limiting transmission distance of a pair of No. 19 B. & S. insulated cable is about 30 miles, the resistance per mile (2 miles of wire) being 88 ohms and the mutual capacitance being 1.5 microfarad per mile. Such a line is taken as a standard and may be referred to as a standard line.

For ease in comparing various lines, the qualities described are very closely imitated by assembling a number of coils and condensers in a portable case, the number of coils and condensers in the artificial line thus made is equivalent to many miles of actual line. An artificial line is usually referred to as a standard line.

To determine the qualities of an unknown line the observer listens to a distant speaker alternately through the standard cable set. He adjusts the latter until the sound is heard equally through both. The number of miles of standard cable gives the limiting transmission distance of the line. The limiting transmission distance by the actual line is then determined by the actual limiting transmission distance of its transmitting ability.

The limiting transmission distances of various types of lines as explained above are given in Table II, being corrected for allowance for switchboard and connection losses.

**Effect of Bridging Telephone Set Across Line.** — The limiting transmission distance of a standard local telephone set across a non-loaded line is increased by the limiting transmission distance by approximately the limiting transmission distance of the bridging set. The limiting transmission distance of a set across a cable circuit is constant.

or cent. These figures also apply roughly to each of several sets bridged across the line, provided these sets are widely separated.

**WIRE CONSTRUCTION.**—In open country and small towns aerial lines with bare wires are almost invariably used. In large cities cables containing from 5 to 600 pairs of wires are usually employed. Cables may be run overhead or underground. Aerial telephone cables, on account of their low tensile strength, hung from steel messenger wires, the latter being supported from the cross

TABLE II

Gage of wire	Theoretical limiting distance, with no allowance for switchboard losses and without Pupin coils
	Miles

10 B. W. G. copper, open wire line.....	700
10 B. & S. copper, open wire line.....	400
12 N. B. S. copper, open wire line.....	400
12 B. & S. copper, open wire line.....	240
14 N. B. S. copper, open wire line.....	240
8 B. W. G. iron, open wire line.....	135
10 B. W. G. iron, open wire line.....	120
12 B. W. G., iron, open wire line.....	90
16 B. & S. cable, copper.....	40
19 B. & S. cable, copper.....	30
22 B. & S. cable, copper.....	20

Wires smaller than those given in this table should not be used on pole lines, on account of their lack of mechanical strength.

Wires are usually fastened directly to the poles. Underground cables are usually run in conduits or other type of ducts. (See *Conduits and Conduit Lines, Underground; Cables and Cables.*)

**Open Wire Lines.**—With the exception of the smaller insulators, usually used, and the larger number of wires carried on a single pole line (as many as 100), the construction of open wire telephone lines differs but slightly from that of pole lines for power transmission. (See *Cross Arms; Distribution Circuits; Poles for Overhead Lines; Transmission Lines.*)

The size of poles and their spacing usually employed for various classes of lines through level country are given in the following table:

Type of line	Ultimate number of wires	Height, feet	Diameter of top, inches	Number per mile
Short, local.....	6	22	5 to 6	30
Important routes.....	20	25	6 to 7	40
Long distance.....	30 to 40	30 to 35	7 to 8	40

Where special conditions arise the height and size of poles must be selected accordingly. The depth to which a pole is set in the ground ranges from one-

fifth to one-eighth of its total height, the larger figure (25 feet), the latter to tall poles (65 feet).

Hard-drawn copper wire is now used on all important lines; iron wire is still employed on short unimportant lines. Steel wire has been proposed for telephone lines. Special properties of wires. The particular size to be employed depends upon the length of the line; see Table II above. Wires are usually spaced 1 foot apart horizontally and the poles to 24 inches apart.

**Transpositions to Prevent Cross-Talk.**—which may thread the space between the two wires and produce a varying electrostatic field about the line, will set up a sound, and if the frequency is such as to produce in the telephone a note of the same pitch, this sound will interfere with the proper functioning of the line. Noise produced in this manner by one telephone line on another is called "cross-talk." Noise may be produced in a similar manner from other sources, such as railway or lighting (alternating current).

To prevent such cross-talk or noise the wires of a line are transposed every quarter of a mile. Fig. 1 shows a transposition scheme. The vertical lines represent the cross arms

Fig. 1. Transposition Scheme.

transpositions are made. The ordinary method of transposing is to cut each wire at each transposition point for that distance, and the ends either to separate insulators or to an insulator which will make the cross-overs with short wires. Transposition can also be made out cutting the wire by using a single insulator with two wires on each side of the other. This scheme, known as the "single pole" scheme, is cheaper than the ordinary scheme.

The transpositions for the first and second cross arms are shown in Fig. 1; when there are more than two cross arms, the wires on the even numbered arms in the same manner as the wires on the even numbered arms in the second arm. When phantom circuits are used the wires are not transposed alike.

Transposition systems become more comprehensive with the growth of phantom circuit working and the technique in neutralizing inductive disturbances. For a full description of the principle of transpositions.

**Telephone Cables** for either aerial or underground use. The following are the general rules: Soft copper wires are insulated with dry paper or such insulated wires then are twisted into a pair, the

ent colored papers; a number of pairs are laid up a core. The core then is wrapped spirally with paper and a lead sheath molded on it in a lead press. M cent of tin in the lead sheath.

The external diameter and weight of a cable co pairs depend upon how closely the wires are wrapped determines the capacity of the wires, the capacity wires are wrapped together. Table III gives the standard cables.

Telephone cables, if used in connecting subscri offices, usually are formed of 22 B. & S. gauge v when No. 19 B. & S. is generally used. For trunk exchanges, cables are usually formed of No. 19 B. coils are used in trunk lines, and successful operat would be impossible without loading coils.

Cables for long distance purposes have large wi mit the use of loaded cables between cities, the op uniform. Chicago and New York are connected to hundred miles by loaded underground cables, and The principal advantages are that the cables are n their insulation does not vary. The insulation res tion and distortion of the waves sent over the wire. coils are particularly sensitive to changes in insulat age in wet weather greatly exceeds the normal leak more harm than good.

**Installation of Cables.**—(See also *Conduits ground; Wires and Cables.*) It is of particular impo nected with telephone cables to keep the core dry. only by paper, which is useless if moist and is of v dry air. As soon as the sheath is removed from a nating, the paper absorbs moisture from the air fore expose the core as little as possible and boil hot paraffine over and through the conductors cable.

**Splicing.**—To splice a telephone cable, a le of the ends and the sheath cut off of each of the en part at which the sleeve later is to be soldered with is bound tight with dry muslin just at the end of packed under slightly. The cable ends are boiled in immersion. If white fumes arise from the paraffin then are joined by stripping the paper from the en together so as to include a little of the insulation, sleeve previously placed over one wire.

When all the pairs are spliced, the conductors paraffine. The lead sleeve is slipped into place, it wipe joint made at each end. This gives the splic the cable itself. A *V-splice* is one in which one ca

**Cable Terminals** are devices in which the p phone cable are made accessible to wires outside t requirement is that the insulation of the conducto by keeping moisture from the cable insulation and which the wires outside the cable attach.

A standard form of cable terminal consists of s iron and partly porcelain, wherein the end of the c

compound. Binding posts in the porcelain receive the cable wires inside the lead part and the outer wires on the outside.

**Potheads** are splices between rubber-insulated wires and paper-insulated wires. They are filled with bituminous sealing compound, so that moisture shall not lead to the paper insulation along the rubber-insulated wires. Potheads are less widely used than before the development of the porcelain terminal. They are necessary for places where more than 50 pairs of wires are to be terminated. At the junction between aerial and underground cables, splices require to be inserted to complete the protective system. Potheads then are placed on both cables, and the rubber-covered wires led to the fuse terminals. It is good practice to house the fuses and pothead ends in wood or metal protecting boxes.

**Drop Wires.**—The wires used to connect open wire lines or aerial cables to subscribers' premises are called drop wires and are of hard drawn copper insulated with rubber, covered with a braid, then twisted into pairs. Standard sizes are No. 16 B. & S. gage in regions where ice does not form, and No. 14 B. & S. gage in other regions. No. 17 B. & S. copper-clad steel wire is successfully used as a substitute for either.

**ELECTROLYSIS** of the sheaths of underground telephone cables takes place when the sheaths carry stray direct current from one region to another; the current leaves the sheath in the presence of moisture (see *Electrolysis of Buried Structures*).

**COSTS.**—The cost of building a telephone line depends on so many variables that no data of any value can be given in the space here available. Useful data on telephone lines will be found in J. C. Slippy's *Telephone Cables* and Clark's *Telephone Construction Methods and Costs*, Appendix A. Approximate costs of the various constituent items will be found in the articles on *Conduits and Conduit Lines, Cross Arms, Insulators, Poles for Overhead Lines, Wires and Cables, etc.*

**BIBLIOGRAPHY.**—See *Bibliography* in article on *Telephone Instruments and Circuits*.

[S. G. McMANUS.]

## TELEPHONE TRAFFIC AND RATES.—

*ments and Circuits; Telephone Lines.*) For the purpose of designing and using telephone equipment the unit of telephone traffic is the "conver- sion unit." A call does not always result in a conversion unit. Obviously, telephone traffic relative to business is subject to general variations closely linked with working days; on all days telephone traffic varies fairly uniform from day to day. It is possible to draw a load curve representative of what happens each working day in most regular exchanges. The number of calls which subscribers originate depends on the kind of service rendered, whether residence, business, etc., and on the method of charging. Subscribers will call about twice as often under flat rates as under measured rates.

A knowledge of the amount of traffic in a system, of its distribution as to time and as to divisions of the exchange, is important. By that knowledge the equipment must be designed, modified from time to time, and distributed upon it as changing circumstances shall require.

**Methods of Counting Calls.**—Amounts of traffic are observed in three general ways. A peg-counting operator actuating some counting device for each call. A second way is to determine a ratio existing, for time, between the calls in a given period and the average use in that period. Knowing these, the probable use of the cord circuit as counted. The third method is to use service meters on all lines and is to associate one meter with all the meters of that position, so that it will count the number of meters of the position is operated.

In machine switching systems, meters can be arranged to tabulate any desired part of the traffic automatically. They themselves are equipped with service meters for charging for the service.

**Operator's Speed.**—The number of calls an operator can handle in an hour depends on the percentage of total calls which are trunked. With standard manual equipment, for example, an operator can handle 165 calls in an hour if none have to be trunked, and 100 calls if 40 per cent of them have to be trunked. In machine switching systems of the controlled type, an operator completes a much larger number of calls per hour. All calls being handled alike, whatever the position within the exchange system, the work of the operator may be as many as 1200 connections per busy hour. This is an average and usual performance, as compared with 165 per hour.

Prompt disconnection is of great importance. A disconnection signal shall be given prompt attention by the operator, precedence over a call for connection. A flashing signal for recall should be given precedence over all other calls. In modern systems disconnection is automatic and instantaneous.

**NG.**—Traffic studies enable the determination of the number required for an anticipated traffic. The number of trunks required, central offices, or between a central office and a private exchange is determined by the number of calls which must be trunked per maximum or busy hour. The element of the probable coincidence in the time at which the calls must be considered, and for this reason the more trunks installed will be the number of calls which each trunk may be expected to handle. The following illustrate current manual practice:

Number of calls per busy hour	35	90	1080
Number of trunks required	5	10	60
Number of calls per trunk	7	9	18

**RATES.**—Rates for telephone service are of two kinds, "flat rates" and "measured service rates." Under flat rates, a fixed sum per month is paid and the subscriber may use his telephone as much as he pleases. Under measured service rates, the subscriber is charged a certain sum for each call he originates. Ordinarily also the subscriber guarantees to pay a certain minimum amount per month. Rates for private exchanges are determined by charging a rate per month for each local telephone, another rate for each section of local switchboard, another rate for each trunk line, and a further rate for each outward call over the trunk lines leading to the exchange, the monthly charge being the sum of all. The cost of telephone service depends on the amount of use, though there is a tendency to charge a flat-rate to the measured-rate system. The latter is in operation in large cities.

**Flat-rate Systems.**—In flat-rate systems there is no continuous effort to count the number of conversations. Counting is done from time to time for billing purposes.

**Measured-rate Systems.**—In measured-rate systems it is necessary to count the number of conversations as they occur, so that each subscriber may be charged for the service he receives. Sometimes this is done by hand on tickets, but this interferes with the operator's regular work, losing not only time in operating but wasting switchboard investment by not using it in the best way is to equip each line with a meter under electrical control which causes it to count one unit for each completed conversation. Such meters have extensive use in the larger cities. In manual systems, when a call is made, the operator presses a meter key associated with the line, and this makes the record upon the meter. In automatic systems, the answering of the called station operates the meter.

In London usual calls are charged at a penny each and certain special calls at two-pence each. In trunking calls of the latter kind, the operator charges the higher charge by the lighting of a specially colored lamp as well as the trunk order key. Being so reminded, she presses the meter key when a conversation occurs, the result being that the calling subscriber pays two-pence for each such special call, because his meter records two

**LONG-DISTANCE CALLS** are those which occur between cities, as distinguished from calls within cities, no matter how large the latter may be. Long-distance calls are handled by special operators at special switchboards connected by trunks to the switchboards which handle city service. Long-distance calls require that a particular person be found in the called city, and the record of such calls includes the name as well as the number of the called party. A ticket is recorded the duration of the conversation in minutes

and fractions so that the charge may be computed and recorded by a time-computing machine which prints

**Two-number Method.**—Where calls between numbers, it is found economical to provide for connections of the subscribers who call frequently, a "two-number" method. Such connections generally are made by going to and from special long-distance switchboard positions. Multiple-switchboard positions make and complete connections ticketed only at the originating end.

**COIN-COLLECTING DEVICES.**—Measurements for long distance, may be made over telephones by means of coin-collecting devices. These are so arranged that the operator is notified in advance of conversation that the proper amount of coin has been inserted in the machine. Machines of one type require that the central office can be signaled at all; the coin is collected after the conversation is completed. Machines of the other type require that the coin is collected after the order has been given but before the conversation is completed.

#### **DEVELOPMENT STUDIES — FACTORS**

A development study is an inquiry to determine whether the construction or reconstruction is warranted by the needs and conditions of a region. Some form of development study is necessary for all work. Economical construction and efficient operation are the objects of development-study methods and their improvement.

**Forecasting Requirements.**—In cities a first development through a period of from 15 to 20 years is made. Statistics of growth. Ratios of telephones to population for the past, and future ratios estimated. A study is taken. This means the counting of existing buildings and the estimation of the telephone-using abilities of the occupants. A forecast is made of the probable future development of the city.

**Determination of Number of Central Office.**—In cities requiring switchboards for more than 10,000 lines there is one central office. The more switchboards there are in a town, the shorter will be the average length of subscribers' lines and the shorter the mileage of trunk lines. The more offices there are, the more expensive owning and maintaining the buildings for them, and operating the equipment in them. A balance for the most economical number of offices is determined.

The economical number of districts having been determined, a district can be located so as to attain the greatest economy. Trunk runs and pole lines then are laid out for the subscribers. In general, it is good practice to provide a main office and having cross routes extending from it to alternate streets or in alleys if they exist.

In machine-switching practice, it is possible further to divide districts and to place some of the apparatus in smaller districts. Trunk lines leading to the district office, still other trunks leading to district offices. This lowers still further the cost of trunk lines. It increases still further the cost of trunk lines.

**BIBLIOGRAPHY.**—See Bibliography in articles on *Telephone Traffic and Circuits*.

**TEMPERATURE AND THERMOMETERS.** — (See also *Heat and Calorimetry; Pyrometers; Thermodynamics, Principles of; Units and Conversions.*) The temperature of a body may be defined as its relative position with respect to some standard substance under standard conditions. The change in some physical property of a standard substance must be known in order to give a number to temperature. Any device which serves to measure temperature is called a thermometer; if the device is applicable to the measurement of high temperatures it is also called a pyrometer, q.v.

**TEMPERATURE SCALES.** — The standard\* temperature-measuring instrument is a constant volume hydrogen thermometer, which consists essentially of a glass bulb containing a constant mass of hydrogen gas kept at a constant pressure, viz., the volume it would have at a pressure of 760 millimeters mercury at the temperature of melting ice, with means provided for measuring the variation that may be caused to take place in the pressure of

the gas. The temperature of melting ice at a pressure of 760 millimeters mercury is arbitrarily taken as zero degrees, and the temperature of boiling water at a pressure of 760 millimeters of mercury is taken as 100 degrees. If  $p_0$  is the pressure of a constant volume of hydrogen gas at the temperature of melting ice and  $p_{100}$  its pressure when the gas is immersed in the boiling water, and  $p_t$  its pressure when immersed in any other substance (the pressure in each case being measured after the lapse of a sufficient time for it to reach a constant value), the numerical value of the temperature of the substance is defined as

$$t = \frac{p_t - p_0}{p_{100} - p_0} \times 100.$$

The degree is abbreviated deg. cent. or °C.

**Fahrenheit Scale.** — The Fahrenheit scale of temperature is derived from the centigrade scale, except that the temperature of the melting ice is taken as 32° and the boiling point of water (at 760 millimeters mercury) as 212°. A difference of 1 degree Fahrenheit is then equal to

$$t_c = \frac{5}{9} (t_f - 32) \quad \text{degrees centigrade.}$$

The temperature of  $t_c$  degrees centigrade is equal to

$$t_f = \frac{9}{5} t_c + 32 \quad \text{degrees Fahrenheit.}$$

The degree is abbreviated deg. Fahr. or °F.

**Réaumur Scale.** — This scale, which is used to some extent in Europe and in this country, is defined in the same manner as the centigrade scale, but the boiling point of water (at 760 millimeters mercury) is taken as 80°. The temperature of  $t_r$  degrees Réaumur is then equal to

$$t_c = 1.25 t_r \quad \text{degrees centigrade.}$$

\* See article on *Pyrometers*.

**TEMPERATURE.** — Let  $p_0$  = absolute pressure of a given mass of gas at 0° C.,  $p$  = absolute pressure of this same mass of gas at any other temperature  $t$  as above defined. For all values of  $t$  between about  $-150^\circ$  and  $+150^\circ$  C., for all values of  $t$  within the experimental range, it is found

Example:  $-12^{\circ}\text{C.} = 10.4^{\circ}\text{F.}$ ;  $-33^{\circ}\text{C.} = -27.4^{\circ}\text{F.}$

that, in the case of the so-called permanent gas, which does not readily liquefy, such as air, hydrogen and nitrogen, a linear relation exists between  $p_0$ ,  $p$  and  $t$  provided there is no change of volume.

$$p = p_0 (K + t),$$

where  $K$  is a constant, approximately equal to 273 in  $^{\circ}\text{C.}$ \* Consequently, assuming this relation to hold when  $p$  becomes zero, the value of  $t$  which would correspond to zero pressure is

$$t_0 = -273^{\circ}\text{C.}$$

This temperature is called the absolute zero. The Fahrenheit scale is  $273^{\circ}\text{C.}$  above the absolute zero.\* Similar to the Fahrenheit scale is approximately  $460^{\circ}\text{F.}$  above the absolute zero.

\* For hydrogen Callender gives the

temperature measured above the absolute zero is called the absolute temperature. Let  $t_c$  = temperature in °C. above the centigrade zero,  $t_f$  = temperature above the Fahrenheit zero, then the absolute temperature in °C. is

$$T_c = 273 + t_c.$$

The temperature in °F. corresponding to  $t_f$  is

$$T_f = 460 + t_f.$$

**Thermodynamic Temperature.** — (See article on *Thermodynamics*.) The difference between the temperature scale as shown by a constant-volume hydrogen thermometer and the absolute temperature scale is less than 0.1° C. at ordinary temperatures, and is less than 1° C. at a range from -150° to 1000° C.

**STANDARDS.** — The standard constant-volume hydrogen thermometer used except for standardizing purposes, and then only for temperatures up to about 500° C. The constant-volume nitrogen thermometer used for standardizing purposes for temperatures up to about 1500°. For high-temperature measurements radiation pyrometers are used as standards (see *Pyrometers*).

**Glass Thermometers.** — For ordinary temperature measurements from about -35° C. and 350° C., the ordinary mercury-in-glass thermometer is almost universally employed. The temperature may be read from the position of the end of the mercury column as given by a graduated scale on the stem, provided the 0° and 100° points have been accurately located and the stem has a uniform bore.

For high-temperature measurements the scale on the thermometer should be checked frequently to see whether the 0° and 100° points are properly located and whether the stem is uniform. Unless the proper quality of glass is used the bulb does not contain exactly the same volume after successive heatings. Even when a constant-volume thermometer is employed, the zero should be frequently checked and a radiation thermometer is used for high-temperature measurements.

Methods of calibrating mercury thermometers are described in text books. At the present day it is more convenient to compare the thermometer with a secondary standard mercury thermometer which has been calibrated by a central standardizing bureau, such as the Bureau of Standards.

**Stem-Correction Mercury Thermometers.** — The mercury thermometer made of very hard glass and filled under pressure with the space above the mercury column containing some inert gas, like nitrogen, may be used for high-temperature measurements up to about 550° C. If a considerable length of stem is used, a very considerable error, 25° C. or so, may be introduced by stem expansion. This "stem correction" varies slightly with the kind of glass and may be represented very nearly by the formula

$$\text{Correction to be added to reading} = 0.00016 n(t_b - t),$$

where  $t_b$  = bath temperature,  $t$  = mean temperature of the mercury column,  $n$  = number of degrees centigrade.

Ordinary mercury thermometers cost from 50 cents to \$5.00 according to the accuracy of their calibration. A 100° C. mercury thermometer is sufficiently accurate (error not over ½ per cent) for ordinary work and costs about \$4.00. A 400° C. mercury thermometer costs about \$12.00. A 550° C. mercury thermometer about \$12.00.

**HY.** — See Bibliography in articles on *Heat* and *Pyrometers*.

**THERMODYNAMICS, PRINCIPLES** (*istry, Principles of; Heat and Thermal Properties, Temperature and Thermometers.*) "Thermodynamics" is employed to include all problems involving the transfer of energy from one body to another, and the transformations of energy. The word "energetics" is a better general term, but the term "thermodynamics" is the one ordinarily used. (Greek, "thermos") is developed in practical applications. The formation of energy. The transfer of energy from one body to every known instance is found to be consistent with certain principles or laws:

**FIRST PRINCIPLE OF THERMODYNAMICS.** — The experimental facts are in accord with the principle that the energy given out by a body in passing from a given state or condition 1 to any other given state or condition 2 is given out by the body is always the same, independent of the path or place.

**Intrinsic Energy.** — Any given body in any state or condition may, therefore, be considered as having associated with it an energy, which, in general, changes when the state or condition changes. This energy is called the "intrinsic energy" of the body. It depends solely upon the state or condition of the body. If the body in a given state or condition 1 is  $U_1$ , and in some other state or condition 2 is  $U_2$ , then the total energy given out by the body in passing from state 1 to the state 2 is  $U_1 - U_2$ , and this difference is independent of the initial and final states of the system and is independent of the path or place.

**Heat and Work.** — The energy given out by a body in passing from one state to another may be in the form of mechanical work, electrical, magnetic or other forces. The sum of all other forms of energy given out by the body is called the "external work" done by the body. Hence, if  $W$  is the external work done by a body when it changes from one state to another, the total energy given out by the body may be expressed as  $U_1 - U_2 + W$ . The amount of heat evolved and the external work done depend upon the path or place the change takes place, but the sum of the heat evolved and the external work done is always the same for given initial and final states, independent of the path or place.

**Mathematical Expression of First Law.** — The relations given above for the total energy transferred from a state 1 to a state 2, gives the relation

$$U_1 - U_2 = Q_e + W,$$

which is the usual mathematical expression of the first law. If, in the change from state 1 to state 2, heat is evolved,  $Q_e$  is positive, while if the heat is absorbed  $Q_e$  is negative. It is convenient to consider the heat absorbed by the body as  $Q$ . Hence, putting  $Q = -Q_e$ , the above expression may be written

$$W = U_1 - U_2 + Q,$$

in which  $U_1$  is the intrinsic energy of the body in any state or condition 1,  $U_2$  is the intrinsic energy in any other state or condition 2,  $Q$  is the heat absorbed by the body when it changes from the state 1 to the state 2.

**PATH OF CHANGE.** — Consider a body in any state or condition 1 to another state or condition 2.

state the body passes through a series of successive states, but infinitesimally from the preceding. The given series of which the body passes is called the "path" from state 1 to state 2. A body may pass from a state 1 to a state 2 by an infinite number of paths; therefore, a change can be completely specified only by the "path" of the change as well as the initial and final states.

The work done and the heat given by a body when it changes from state 1 to state 2 depends only upon these states, i.e., upon the ends of the path, and not upon the proportions of the energy given out as work and heat respectively during the process (upon the series of successive states through which the body passes, or the "shape" of the path), but also upon the relation of the given body to other bodies which may in any way affect it.

**ADIABATIC PROCESS.**—Any process by which a change can be produced under conditions such that the body neither absorbs nor gives out heat to or from any other body is called an "adiabatic" process. Adiabatic processes are not completely realized, since no known substance is a perfect insulator. Such processes can be closely approximated, e.g., the expansion of a gas in a cylinder with well-insulated walls when the expansion is so rapid that no heat is conducted through the walls.

**ISOTHERMAL PROCESS.**—Any process by which a change can be produced in a body without changing its temperature is called an "isothermal" process. For example, the melting of ice, when the ice and water are in contact, is an isothermal process.

**REVERSIBLE PROCESS.**—Whenever a change takes place in a body *A*, it also takes place in some other body or bodies *B*. If the conditions of *A* and *B* are such that the path of each can be reversed in direction without changing by an appreciable amount any property of the system, then the process by which the change takes place is called a "reversible" process.

Heat never passes only from a hot to a cold body and never in the reverse direction (i.e., from cold to hot), it follows that, if during any step of a process there is a transfer of heat between bodies whose temperatures differ by a finite amount, the process is irreversible. Hence, a reversible process can take place only when the transfer of heat must be between bodies which differ in temperature by an infinitesimal amount.

Heat, the last type of process is absolutely reversible only in the limit when the bodies between which the transfer of heat takes place are at the same temperature. This condition can be only approximated, since there is always a difference in temperature, though this difference may be made small, in order that a transfer of heat may take place.

**LAW OF THERMODYNAMICS.**—The so-called second law of thermodynamics involves three distinct principles, which may be stated as follows:

1. A body cannot change from a state 1 to a state 2 by any reversible process, and then return from 2 to 1 over the same path, but in the reverse order, then the work done by the body during the change from 1 to 2 is exactly equal to the work done on the body during the reverse change from 2 to 1.

2. A body cannot change from a state 1 to a state 2 by any irreversible process, during which the change can never be greater than the heat which is given out during the change from 1 to 2 over the same path produced under conditions which would render the process reversible. Similarly, if the body returns from 2 to 1 by an irreversible change, the heat given out can never be

less than the heat which it would give out were it produced under conditions which would render the

3. The heat ( $Q$ ) absorbed by a body during any process bears the following relation to the temperature ( $t$ ) of the body

$$Q = MK(t + T_0)$$

where  $M$  is the mass of the body,  $T_0$  is a constant on which the temperature is measured, and  $K$  solely upon the nature of the body and its initial and final temperatures.

**Absolute Thermodynamic Temperature.**—Any known means to produce a negative temperature scale, numerically greater than the constant  $T_0$  in the above expression (equation (2)). Hence the temperature of any given scale equal to this constant  $T_0$  is called the "absolute zero" of this scale, and the temperatures measured on this scale are called "absolute thermodynamic temperatures." They may be written

$$Q = MKT,$$

where  $T = (t + T_0)$  is the absolute temperature of the body at temperature  $t$ . The value of the absolute thermodynamic temperature is that temperature, as measured on the constant pressure thermometer, at which the pressure of the gas would be zero in pressure per degree ( $= 1/273$  of the pressure at all temperatures).

On the centigrade scale the absolute zero is, therefore,  $-273^\circ$  and on the Fahrenheit scale  $-460^\circ$  (approximately).

**Entropy.**—Since the factor  $K$ , in equation (2), is constant upon the nature of the body and its initial and final temperatures, it may be looked upon as representing a change in a property of the body. Calling this property  $N$ , and looking upon this property of the body for the initial state as  $N_1$ , and for the final state as  $N_2$ , then  $K$  may be put equal to  $N_2 - N_1$ , and equation (2) becomes

$$Q = M(N_2 - N_1)T.$$

This equation, which represents the relation between the heat absorbed and the change in temperature, for a reversible isothermal process or an adiabatic process, if the property of the body is assumed to remain unchanged during such a process, the heat absorbed is zero, by definition, and this, of course, is consistent with equation (2), since  $N_2 = N_1$  in such a process, and the change in  $N$  during such a process, is consistent with equation (2).

In general, the temperature of a body during any process may be considered as made up of a series of small isothermal and adiabatic steps, and the above definition of  $N$  may be applied to each step. That is, the change in  $N$  for each isothermal "tread" and an adiabatic "rise" is

$$dN = \frac{dQ}{MT},$$

where  $M$  is the mass of the body,  $dQ$  is the heat absorbed during this step, and  $T$  is the temperature of the body during this step.

This property  $N$ , whose increase during any process is equal to the heat absorbed per unit mass divided by the temperature of the body during this step, is called the "entropy" of the body. Since entropy is defined in terms of its change, it

of a body may be arbitrarily taken as zero. In steam tables, water at 32° F. and at atmospheric pressure is usually taken as zero. The entropy of a body can in many cases be calculated from the other properties of the body. (See article on Steam.)

According to the above definition of entropy the heat absorbed by a body in changing from a state 1 to a state 2 by any reversible process is then

$$Q = M \int_1^2 T dN, \quad (3)$$

where  $M$  is the mass of the body,  $T$  its absolute temperature during any step of the process, and  $dN$  the increase in its entropy per unit mass during this step.

**Entropy of the Increase of Entropy.** — It can be shown, from the above definition, that the only possible changes which can take place in a system to which no energy is added or subtracted are changes which leave the total entropy of the system. Reversible changes may take place without increasing the total entropy, but reversible changes do not take place in nature nor can they be realized *absolutely* by any natural means.

**Maximum Work.** — The maximum external work which a body can do in changing from a state 1 to a state 2 along a given path (i.e., by passing through a given series of states) is equal to the decrease in its intrinsic energy minus the maximum amount of heat it can absorb when it changes along that path. The maximum external work which a body can do in changing from state 1 to state 2 along a given path is therefore

$$W_{\max} = U_1 - U_2 + M \int_1^2 T dN. \quad (4)$$

The last term in this expression depends upon the temperature at which the heat is absorbed, and this temperature depends upon the "path" along which the change takes place. If the path is such that *all* the heat is absorbed at a constant temperature  $T$ , then

$$W_{\max} = U_1 - U_2 - TM(N_1 - N_2). \quad (4a)$$

It can be written

$$W_{\max} = U_1 - U_2 + T \frac{dW_{\max}}{dT}, \quad (5)$$

where  $T$  is the rate of increase of the maximum work done by the body in changing from state 1 to state 2 at the temperature at which the heat is absorbed.

**Free Energy.** — The maximum work which a body can do in changing from a state 1 to a state 2 is sometimes referred to as the "free energy" of the body available for doing work in connection with this change. This free energy depends not only upon the initial and final states of the body itself but also upon the temperature of the external body available as a source of heat; this is apparent from equation (5).

**Cycles.** — In the theory of the steam and other heat engines the question arises as to what is the maximum amount of external work which can be obtained from a body by alternately heating it to a high temperature, allowing it to do work (e.g., by expanding), thereby cooling to a lower temperature, and then heating it to the high temperature again, the cycle of operations being repeated over and over again. That the "working substance" changes from a state 1 to a state 2, then from state 2 to state 1, and so on for any number of cycles, the initial energy of the body at the beginning and end of any cycle is then the same. Therefore, the net work done by the body during any cycle is

the difference between the heat actually absorbed during the cycle.

**Thermal Efficiency.**—The ratio of the heat absorbed during the cycle gives the proportion converted into external work, and is called the thermal efficiency.

**Carnot's Cycle.**—From the principles stated, the heat absorbed will be a maximum when this heat is taken in a manner under conditions such that the temperature of the heat source is the same as that of the hottest body available, and the heat given out is a minimum when this heat is taken out in a manner under conditions such that the temperature of the heat sink is the same as that of the coldest body available. The path along which the body changes (see Fig. 1) is called a "Carnot's cycle." It consists of a thermal change at temperature  $T_1$ , an adiabatic change to a lower temperature  $T_2$ , an isothermal change at this temperature  $T_2$ , and then a second adiabatic change to  $T_1$ . Such a path is called a "Carnot's cycle." The figure represents such a path for a perfect gas, the ordinates being pressure and volume.

From the general expression for maximum work, equation (4), it follows that the efficiency of this cycle is

$$\frac{W}{Q_1} = \frac{T_1 - T_2}{T_1}$$

For a given amount of heat added to a working substance, the maximum possible work which can be done when the cycle is a Carnot's cycle, and the efficiency is proportional to the difference between the temperatures of the heat source and the heat sink. The working substance absorbs heat and the temperature of the heat source is  $T_1$ , and it gives out heat, and is inversely proportional to the temperature of the heat sink, and is inversely proportional to the temperature of the body from which it absorbs heat.

#### APPLICATIONS OF THE LAWS OF THERMODYNAMICS

The laws of thermodynamics serve as the basis for the performance of the steam engine, steam engines, refrigerating machines, air compressors, and other machines. In many important electrochemical relations (see Chapter 10). It is beyond the scope of this book to go into the details of these applications. The following bibliographies are listed in the following bibliography.

**BIBLIOGRAPHY.**—Ennis, Wm. D., *Applied Thermodynamics*; Hicks, R. C., *The Steam Engine and Turbine Engine Theory and Practice*; Peabody, C. H., *Thermodynamics of the Steam Engine*; Carpenter and Diederichs, *Experimental Thermodynamics*; *Practical Engineers' Handbook*.

**RAIL, OR CONTACT-RAIL, SYSTEMS.** — (See also *Bonding; Rails, Track and Third; Standardization Rules of the Trolley Systems, Overhead; Trolley Systems, Underground.*) The brief table of contents of this article:

A rail, or third rail, is a conductor supported on insulators near the track, presenting a continuous contact surface to a collector or shoe on the rolling stock. In its commonest form it is a rail of standard gauge, spaced at intervals of a few feet by substantial insulators, electrical contact between adjacent lengths being obtained by copper bonds across the insulators.

**TERMINOLOGY.** — The following terms and definitions are used in connection with third-rail systems. See also Standards of the A.I.E.E.

**SHOE.** — A third-rail contact shoe is a conductor, fastened to the track, which is designed to make electrical contact with the third rail. It is often referred to as the "shoe."

**CONTACT SURFACE.** — The contact surface of a third rail is the surface against which the shoe presses.

**TRACK GAGE.** — The minimum clearance between the inside surface of the two track rails, i.e., the distance *A* in Fig. 17. The track gage is 4 feet 8½ inches.

**CONTACT SURFACE GAGE.** — The distance measured parallel to the plane of the track between the gage line of the nearer track rail and the inside contact surface of the third rail, i.e., the distance *B* in Fig. 17 of this article.

**THIRD RAIL LOCATION.** — Third rail locations will be described in terms of the third-rail elevation or vertical distance (*C* in Fig. 17) between the normal top of the track rail and the normal top of the third rail. See also Table II below.

**TOP-CONTACT RAIL.** — A top-contact third rail is one on which the contact surface is on the upper side of the rail.

**UNDER-CONTACT RAIL.** — An under-contact third rail is one on which the contact surface is on the under side of the rail.

**THIRD-RAIL INSULATOR.** — A third-rail insulator is that portion of the track which forms the principal electrical insulation.

**INSULATOR BASE OR BRACKET.** — A third-rail insulator base or bracket is a support for the third-rail insulator.

**THIRD RAIL INCLINE.** — A third rail incline is a portion of third rail sloped to gradually bring the contact surface into contact with the normal surface of the third rail shoe.

**END INCLINE.** — An end incline is an incline at the end of a run of third rail which receives shoes moving in line with the third rail.

**Offset-end Incline.** — An offset-end incline is a third rail and is made to receive shoes moving laterally towards the rail.

**Cross Incline.** — A cross incline is a combination of two inclines from adjacent third rails which meet at a point.

**Side Incline.** — A side incline is an incline which is made to receive shoes moving laterally towards the rail.

**Offset-side Incline.** — An offset-side incline is a standard third rail in order to gain clearance between the maximum equipment line of the rolling stock.

**Maximum Equipment Line.** — The maximum equipment line is a line which encloses the cross-sectional outlines of the rolling stock under all normal operating conditions.

**Third-rail Protection.** — A third-rail protection is a device which affords some degree of protection against accidental contact with foreign bodies.

**Third-rail Anchorage.** — A third-rail anchorage is a device which prevents third-rail creeping longitudinally.

**Tie Motion.** — Unless otherwise specified, tie motion means the vertical play of the ties caused by the passage of the rolling stock.

**TYPES OF CONSTRUCTION.** — Third-rail construction is divided into the top-contact and under-contact types, with a number of important variations in design, especially with reference to the type of protection.

**Interborough Top-contact Type (Fig. 1).** — One of the most commonly used types is illustrated in Fig. 1. It is often called the "Interborough Type" on account of its use in the subways of the Interborough Rapid Transit Co., of New York. The rail is a standard T-section and rests on reconstructed granite insulators. A board protection is attached to the rail itself by means of clamps and uprights and is thereby kept in perfect alignment.

**Pennsylvania Top-contact Type (Fig. 2).** — Another type has the protection supported on separate brackets independent of the third rail itself. It is claimed that this reduces the amount of labor required for repairs when repairs are being made, but it cannot be used in the same manner as the Interborough type to keep the rail and protection in perfect alignment.

**London Tube Type (Fig. 3).** — The mounting of the third rail and the negative contact rail of the London Tube is shown in Fig. 3.

**Under-contact Types (Figs. 4, 5, 6 and 7).** — While under-contact types have given first-class service, they are considered to be unsuitable for exposed locations as they cannot be wholly protected from sleet. The lower part is only a few inches from the ground and generally reduce this clearance, increasing the danger of contact with the lower part of the rolling stock. The accumulation of wet snow and ashes and from flooding. The traffic during sleet and snowstorms and floods, on railroads, led to the idea of an under-contact type of third rail, led to the idea of an under-contact

Fig. 2. Pennsylvania Top-contact Type

Fig. 3. London Tube Type

Fig. 4. Type X Bracket, for use on Straight Work

Fig. 5. Type Y Bracket, Applied to End Incline

in insulators by hook bolts hung from brackets, with the top and sides of a rail completely sheathed in a flexible insulating material for protecting the rail from accidental contact with man and beast, and from sleet, snow and spray. With this type of rail (Figs. 4, 5, 6 and 7) the protection is of such character that there is no packing of snow between the sheathing and the contact rail.

Fig. 6. Type Z Bracket, for use with end inclines A at frogs

Fig. 7. Type W Bracket, for use with offset end inclines B at frogs

some other forms, and in sleet storms no ice forms on the contact surface. Some icicles may form at the edge of the petticoats, but hanging down clear of the edge of the rail, are easily broken off by the passing shoe. A special device using a standard T-rail, is shown in Fig. 8, and is used for 1200 volts.

Where the rail is buried in snow, the passage of the contact shoe breaks a snow away, leaving the rail surface clear, instead of ironing the snow down on the rail, as may happen with the top-contact type.

**Sheathing and Special Work.**—The sheathing between the insulator blocks, depending upon local conditions and the price of materials, as well as the potential used, is usually formed of three wooden strips, one grooved on the under side and inclosing the head of the rail, and the other two, attached to and dependent from it, reaching in toward the web of the rail. Where good wood is not available, an alternative protection costing about the same and having a higher electrical resistance, although not so good mechanically, is a semi-flexible shell of indurated fiber conformed to the rail sections.

The special work, i. e., inclines, jumpers, etc., used with the under-contact rail, is shown in Fig. 9.

**Combined Top- and Under-contact Shoes.**—The employment of collecting shoes on rolling stock so constructed as to press upwards on the under-contact rail and downwards on the top-contact type solves the question of interchange between railroads not using the same type.

Fig. 8. 1200-volt Under-contact Rail

**CONTACT RAILS VERSUS OVERHEAD TROLLEY.**—The contact rail is used as a part of the positive conductor system whenever the current to be collected by each collector exceeds the amount which can be taken safely from a trolley wire, or whenever the total current taken by a train exceeds the amount that can economically be carried by conductors of such expensive metal as copper or aluminum.

**Positive Contact Rails.**—Considered as a part of the positive conductor system, the contact rail and overhead trolley possess the relative qualifications given in Table I.

TABLE I.—RELATIVE QUALIFICATIONS OF THIRD RAIL AND OVERHEAD TROLLEY SYSTEMS.

(Adapted from Table by C. E. Eschle.)

I Protected third rail	II Overhead high-tension bridge, catenary construction	III Overhead side bracket, catenary construction
Interference with track maintenance.	Entirely clear of road bed.	Same as II.
Can be maintained by section gang.	Requires special tools, crews and work trains.	Same as II, but not as important.
Easily cleared up and insulated when derailment occurs.	In the way of boom of derrick car—liable to be knocked down and put all tracks out of service.	Same as II.
Hindrance to coupling freights, etc. With protected rail this is not very serious.	Dangerous to freight brakemen on account of parts hanging down and small bridge clearance. Very difficult to install satisfactory ticklers to warn trainmen when approaching bridges.	This point is of less importance.
Interference with clearing snow between tracks.	Not affected.	Not affected.
Ease of satisfactorily collecting current on account of location, where relative motion between track and rail is small. Collectors may be safely replaced on the road.	Difficult to collect current, as a more complicated mechanism is required on account of the grade of the wire due to low clearances at bridges and high clearances at road crossings.	Similar to II.
May be readily inspected by track walker.	Requires a man with special training.	Similar to II, but of less importance.
Ease of sectionalization. Jumpers may be disconnected at the nearest adjacent road crossings.	Difficult of sectionalization.	Sectionalization not of so much importance.

TABLE I.—RELATIVE QUALIFICATIONS OF THIRD-RAIL AND OVERHEAD TROLLEY SYSTEMS—*Continued**(Adapted from Table by C. E. Emsleb.)*

I Protected third rail	II Overhead high-tension bridge, catenary construction	III Overhead side bracket, catenary construction
May be worked on while alive to make track changes or repairs, making system very flexible.	Requires that current be shut off no matter how slight repairs are, making system infeasible.	Similar to II, but not of such importance.
No interference with visual signals.	Signals located and seen with difficulty, as they must be lower than the bridges and even then have the distant bridges as a background. Dangerous to maintain signals in this location, as it must be done from ladders.	Not affected.
Danger of wreck from burning off track rail due to arcing current. This is a possible contingency, but one not very likely to occur.	Danger from dangling overhead work when messenger cable is burned off at a defective insulator.	Same as II.
Little interference with fire-extinguishing apparatus in the car storage yard.	Difficulty in removing cars on account of high-tension wires interfering with firemen.	Will probably have low-tension wires for this type of construction.
Absolute freedom from lightning disturbances.	Very much exposed to lightning.	Same as II.
Entire freedom from telephone and telegraph disturbances, also inductive effects on signal wires.	Difficult problem in connection with these interferences, affecting not only the railroad company's wires, but those belonging to other interests.	Same as II.
No trouble at grade crossings with crossing trolley wires.	Probably trolley crossings will have to be avoided by overhead or undergrade crossings.	Troubles similar to II.
Can add sidings or more tracks with little difficulty.	Can make such additions only at considerable expense.	Difficulty not very great.

**Negative Contact Rails.** — Negative contact rail is used in a negative-feeder system when the drop of potential is so small that it is cheaper to use an equalizer than to force the track rails with feeders. Considered as a separate system, the contact rail possesses the following advantages over a return system. If used in connection with a positive rail is placed between the track rails.

(I) When properly insulated, it eliminates every

(II) It gives the block-signal system complete independence of traction system. Among the advantages which this system has are: (1) Reduction of signal circuits, saving the cost of reactance bonds and increased economy in signal circuits.

(III) It gives greater safety to passengers.

(IV) It reduces the probability of short circuits.

(V) It decreases the cost of track-rail maintenance bonds.

(VI) It halves the first cost of bonds, as one bond usually replaces two track rails.

(VII) It reduces the wear of bonds by saving the

These advantages are usually offset by the first cost of a central rail, by the complications it introduces at special track crossings, and by the difficulty of protecting a central rail from snow and ice, and the clearance for any kind of covering.

**ELECTRICAL DESIGN.** — The calculations for resistance, etc., are treated under *Trolley Systems*, Chapter 10. The weight, dimensions, resistance and reactance of rail are given in *Rails, Track and Third*.

**Selection of Suitable Rail.** — When the various rails are under consideration it is well to arrange a table with the following columns: (1) To compare the relative economy of the different rails; (2) Additional circular mils of copper equivalent to rail; (3) Additional circular mils of copper equal the rail of highest conductivity; (4) Cost of additional copper for entire railroad; (5) Additional copper for entire railroad.

**MECHANICAL DESIGN.** — The general design has already been settled, the next step is to secure a set of track plans for the special work. When an entirely new railway is being designed and the third-rail designer can work together with the general designer, the general track plans can be made sufficiently accurate for the electrical engineer. When the contact-rail engineer has to take measurements on an existing line to make drawings of the cross-overs and other complicated work.

**Location and Weight of Third Rails.** — The location of the contact rails, corresponding to the standard track conditions, arises from lack of uniformity in the clearances between the rails and in the maximum equipment lines of various gauges. Standard clearances have been recommended (1913) by the Railway Engineering Association:

The clearance lines for third-rail and permanent way equipment to be as shown in Fig. 10, thus reserving the space between *AT*, *BT*, *CT*, *DT*, *ET*, *FT* and *AT*, *JT*, *KT*, *LT*, for the rolling equipment not to encroach upon the third-rail

1 deflection beyond the line AE, BE, CE, DE, EE, FE, way structures not to encroach upon the third-rail space S, JS, KS, LS, MS; this leaves a clearance space or 10 inch both horizontally and vertically upon which il structures nor equipment shall encroach. On curves 800 feet, the third rail must be moved back and the

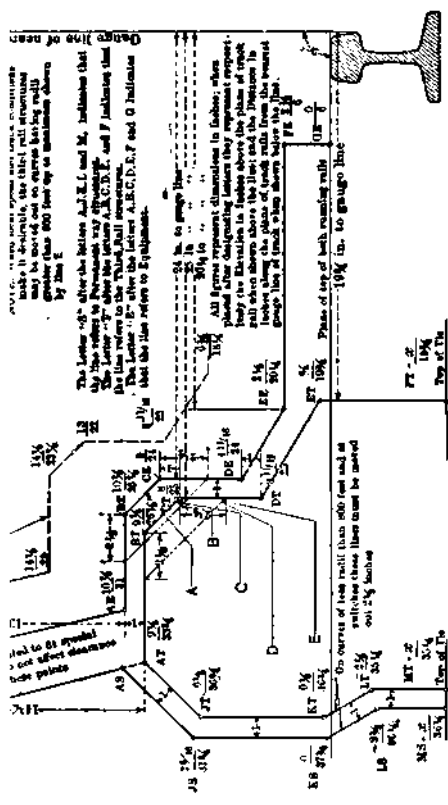

Fig. 10. Recommended Standard Design for Limiting Clearance Lines for Third-Rail and Permanent Way Structures and Rolling Equipment. A. E. R. A.

allowed to swing outward as indicated by the lines and 1. construction of new rolling stock to be used in interference must be made for such horizontal and vertical variations reasonable probability occur in combination at one time as for deflections on curves. Encroachments on normal deflection of springs and wear vary with the type of construction the practice of the respective roads as regards permissible before repairs and adjustments are made. For the general standards, in designing equipment, but not as a standard, there-

† Gage, as defined under Terminology.

a dotted line is shown on the diagram located 2 inches distant horizontally and 4 inches distant vertically from the limiting clearance line for alignment.

**Turnouts.** — (See also *Railways, Location and Permanent Way for.*) A typical turnout is shown diagrammatically in Fig. 11 which shows the lengths which

should be measured;  $F$  is the distance from the point of the switch to the point of the frog, and is called the "frog distance";  $D$  is the gth between the adjacent frogs, and  $Z$  the distance apart of the centers. In such a diagrammatic view the lines represent the

Fig. 11. Typical Turnout

parallel lines of the track rails. When, however, a contact rail is represented by a line, it is the center line that is given. Having measured the four distances specified above, the radius of the turnout curve may be calculated from the following formulas:

$R = 0.127 F^2$ , when the turnout is from a straight track.

$R = 0.271 F^2$ , when the turnout is from a track of equal radius to the turnout.

**Graphical Method of Locating Contact Rail.** — The track plans having been drawn from the field sketches, to a scale of say  $\frac{1}{4}$  inch to the foot, the contact rail may be drawn in, as outlined below. An aid in this work is an outline plan of the electric car or locomotive to the same scale as the track work swings — say  $\frac{1}{4}$  inch to the foot. Such a plan is shown in Fig. 12, in which the points  $W$  represent the wheels,  $S$  the contact shoes and  $K$  the king-pins. This

aid better be made of celluloid with a large pinhole at each point  $S$ . In order to lay out the contact rail the plan is drawn along the tracks with the points  $W$  on the rails and a pencil stuck in one of the pinholes. The line traced by the pencil represents the center line of the car path, and therefore that of the contact rail. Such a

Fig. 12.

aid should be made on each side of the car. In cases where there are sharp curves, it will not do to run the wheel points  $W$  along the tracks, as an error will arise due to the truck rotation not being represented. In such a case the king-pin points must be run along a track center line.

**Location of Incline.** — The exact location of the contact-rail inclines on each side of a track-rail intersection depends upon a number of conditions, an important one of which is the extent to which the equalizer bar and journal box project outward. If there is a train-bus line connecting all the cars, the end lines may be situated many feet back from the switch point or frog, but if there is no such bus line, the contact rail will probably have to be terminated at a cross incline extending

as near as possible to the switch point or frog.

**Sectionalizing the Contact Rail.** — Where a train-

bus line is not used, it is customary to break the third rail in front of substations and use an isolated section of third rail between the two main sections, as shown diagrammatically in Fig. 13. The length of this isolated section and the gaps which bound it should be such that both gaps are never spanned by cars at the same time.

Fig. 13.

Let  $L$  = car length, feet,

$T$  = distance between shoe centers (usually truck centers),

$S$  = shoe length.

Then,

Total space must be  $> L + T$

Rail section must be  $< 2L -$

Length of each gap must be

For example, on the Manhattan Railway, New York, was adopted, a short isolated section was used.

$L = 46.37, T = 32.27, S =$

Total space  $> 79.64$ , actually

Section of rail  $< 59.47$ , actually

Gap length  $< 31.27$ , actually

**Cross and End Inclines.**—Inclines serve to guide the contact shoes to rise (or fall) from their free position with the rail. They should, therefore, have sufficient slope to prevent any undue shock either to the rail or to the shoes. Low-speed lines and sidings may therefore have shorter inclines than high-speed lines. The usual length of straight slope (i.e., without end nose and flat surface at top) is from 60 to 70 inches for high-speed work and 30 or 40 inches for sidings. The slope ranges from 1 in 45 for high-speed work to 1 in 30 for urban railways.

The inclines are usually made of cast iron. A typical design is shown in

Fig. 8

**Third-rail Insulators.**—Third-rail insulator qualifications. Strength to withstand weight and to moisture; resistance wet shall not be less than that of a dry edge; shall allow free motion of rail laterally to allow for expansion, contraction and tie motion and quick removal without disturbing the rail.

**Spacing of Insulators.**—A spacing of 12 inches is recommended by the American Street & Interurban Railway Association and represents present day practice.

**INSTALLATION OF CONTACT RAIL.**—When a railway being electrified, the first step is to replace the ties by long ones. A man then proceeds along the line and marks on them the location of the screw holes or brackets (in the case of an under-contact rail) or the stools (in the case of a top-contact rail) are distributed along the line. A gang then screws the brackets or stools to the ties.

Where the rails rest on tie plates which have not yet been laid it is not unusual to place shims under the brackets until they have reached their normal position.

of under-contact rails the brackets must be accurately checked for dimensions before being distributed. Fish-plates, etc., are next distributed along the line on that side where they are to be installed and a gang follows which installs the fish-plates. In the case of an under-contact rail, the gang attaches the insulators and hook bolts. In the case of a top-contact rail, another gang follows, attaching the fish-plates. Whatever is used to fasten the rail to the insulators. Another gang installs the expansion joints and anchorages, if any. If expansion joints are used, an allowance for expansion and contraction must be made at all joints, depending on the temperature at which the rails are installed. This is done by inserting an "expansion shim" between the rails at each joint. The thickness of the shim varies with the temperature of the rail at the time it is laid together. The thickness of the shim for different temperatures on a 30-foot rail is shown in Fig. 15.

Fig. 15. Thickness of Expansion Shims for 30-ft. Rail

are being distributed and a gang follows them. A last coat of protection is applied and then the rails are primed and then painted. The rails must be carefully located to make sure that the shoes will ride on them.

**OPERATION AND MAINTENANCE OF CONTACT RAIL.**—The maintenance of third rails is negligible and even without painting the deterioration is very slow. The principal items of maintenance are the insulators, fish-plates, and bonds. Unless the supports are carefully designed, insulators are subject to "tie motion," i.e., by the depression and rebound of the ties when a wheel passes over them. Every time a wheel passes over a tie carrying an under-contact rail, the latter is pounded against the rail and is likely to be broken unless a special support is provided.

Effects due to large currents sometimes causes the third-rail voltage to rise 3 times its normal value. (D. D. Ewing, E. R. J., 1917, Vol. 36, No. 1, p. 10.)

**Protection of Sleet.**—The best protection against sleet is undoubtedly the use of a top-contact third rail and the next best is a top-contact third rail with a wide flange. Where these are impracticable the deposit of ice on the rail must be prevented and means for its removal have to be adopted. The two methods are scrapers and hot water. Electrical heating of the rail has been suggested but found to require too much energy. When the hot-water method is used, some salt such as calcium chloride, or some other substance which lowers the freezing point of water must be added to the water. The principal objections to the hot-water method, especially on elevated lines, are the saline solution not only rusts the metal of the structure but also causes the water, damage also occurs to the roofs of the stations, underneath.

**TESTING OF CONTACT RAILS.**—Contact rails have to be tested for (1) continuity at the joints, (2) conductivity, (3) insulation from the ground.

Methods of testing continuity at joints are described in the article on *Bonds, Rail-*

The **Conductivity Test** is best performed by passing a considerable current through a length, measuring the drop with a milli-voltmeter and calculating the resistance by Ohm's law.

The **Insulation Test** is best performed by means of a pair of voltmeters, as shown in Fig. 16. The rail *A* to be tested is connected to a live rail *B* through a voltmeter, and the voltage  $V_1$  between the two noted. At the same instant the voltage  $V_2$  between the rail *B* and ground is also read. Let  $L$  be the length in miles of the rail *A*. Then the insulation resistance of rail *A* in megohms per mile is

Fig. 16.

$$\frac{\tau L}{10^6} \left( \frac{V_2}{V_1} - 1 \right),$$

where  $\tau$  is the resistance in ohms of the voltmeter on which  $V_1$  is read.

**Testing of Gage.**—The gage line of a third rail is measured by means of a template which fits over the track rails as shown in Fig. 17.

Fig. 17.

**COST OF CONTACT-RAIL CONSTRUCTION.**—The estimates in Table III include the cost of (1) handling and distributing the material from the storehouse to the place where it is used; (2) the solder, gasoline, etc., used in bonding contact rail; (3) putting three coats of paint on the protection; (4) bending rails on curves; (5) 5 per cent for breakage; (6) foremen's and engineers' salaries. They do not include the cost of tools or of jumpers.

These estimates are approximately correct where existing traffic does not materially impede the work. Under less favorable conditions, the cost may rise 50 per cent or more over the figures given.

The estimate on the top-contact type is based upon the Interborough Rapid Transit Co.'s construction, New York (Stillwell-Slater patent), the weight of rail, however, being slightly less than on that railway. The estimate of the under-contact type is based upon construction similar to that used by the New York Central Railroad (Wilgus-Sprague patent). Little third-rail cost data having been published since the Great War, the data from the 1914 edition are reproduced.

includes only the difference in cost between the long ties which are used and the cost of the same number of standard ties. The cost of third rail on the West Jersey and Seashore R. R. is given as \$4, 235 per mile, and the average cost of maintenance, as \$1, 101 per mile.

**APPENDIX.**—(See also *Railways, Systems of Electric Traction for Grounded Structures; Endosmosis; Trolley Systems Overhead.*)  
*Journal of the American Institute of Electrical Engineers*, 1906, Vol. 27, p. 100; J. A., *Tests of Steel for Electric Conductivity*, Trans. A.I.E.E., 1908, Vol. 27, p. 1215; Duer, J. V. B., *Third Rail and Trolley on West Jersey and Seashore R.R.*, Trans. A.I.E.E., 1915, Vol. 34-2, p. 1547; Jones, C. H., *Top Contact Unprotected Rail for 600-volt Traction Systems*, Trans. A.I.E.E., 1915, Vol. 34-2, p. 1547.

**TIMBER.**—(See also *Structures, Simple; Poles for Overhead Lines.*) The standard names for structural timbers as adopted by the Am. Soc. for Test. Mat. and the Am. Ry. Eng. Assoc. are reprinted below by permission from the present (1913) board of the Am. Soc. for Test. Mat.

**Fir, Douglas.**—The term "Douglas Fir" is to cover the timber known likewise as yellow fir, red fir, western fir, Washington fir, Oregon or Puget Sound fir or pine, northwest and west coast fir.

**Hemlock,** to cover Southern or Eastern hemlock; that is, hemlock from all states east of and including Minnesota.

**Hemlock, Western,** to cover hemlock from the Pacific coast.

**Larch, Western,** to cover the species of larch or tamarack from the Rocky Mountain and Pacific coast regions.

**Pine, Norway,** to cover what is known also as "Red Pine."

**Pine, Southern Yellow.**—This term includes the species of yellow pine growing in the southern states from Virginia to Texas, that is, the pines hitherto known as longleaf pine (*Pinus palustris*), shortleaf pine (*Pinus echinata*), loblolly pine (*Pinus taeda*), Cuban pine (*Pinus heterophylla*), and pond pine (*Pinus serotina*).

Under this heading, two classes of timber are designated: (a) dense southern yellow pine and (b) sound southern yellow pine. It is understood that these two terms are descriptive of quality rather than of botanical species.

**Pine, Western,** to cover the timber sold as white pine coming from Arizona, California, New Mexico, Colorado, Oregon and Washington. This is the timber sometimes known as "Western Yellow Pine," or "Ponderosa Pine," or "California White Pine," or "Western White Pine."

**Pine, White,** to cover the timber which has hitherto been known as white pine, from Maine, Michigan, Wisconsin and Minnesota.

**Pine, Idaho White,** the variety of white pine from western Montana, northern Idaho and eastern Washington.

**Redwood,** to include the California wood usually known by that name.

**Spruce,** to cover Eastern spruce; that is, the spruce timber coming from all points east of and including Minnesota.

**Spruce, Western,** to cover the spruce timber from the Pacific coast.

**Tamarack,** to cover the timber known as "Tamarack," or "Eastern Tamarack," from states east of and including Minnesota.

A fuller description of the timbers used for transmission line poles is given in the article on *Poles for Overhead Lines.*

**DEFECTS IN TIMBER.**—The standard names for defects in structural timber as adopted by the above association are the following:

**Encased Knot.**—An encased knot is one whose growth rings are not intergrown and homogeneous with the growth rings of the piece it is in. The encasement may be partial or complete; if intergrown partially or so fixed by growth or position that it will retain its place in the piece, it shall be considered a sound knot; if completely intergrown on one face, it is a watertight knot.

**Large Knot.**—A large knot is a sound knot, more than  $1\frac{1}{2}$  inches in diameter.

**Loose Knot.**—A loose knot is one not firmly held in place by growth or position.

**Pin Knot.**—A pin knot is a sound knot not over  $\frac{1}{2}$  inch in diameter.

— A pith knot is a sound knot with a pith hole not more than 1/4 meter in the center.

ot. — A rotten knot is one not as hard as the wood it is in.

ot. — A round knot is one which is oval or circular in form.

ot. — A sound knot is one which is solid across its face and which is in the wood surrounding it; it may be either red or black, and is so placed in position that it will retain its place in the piece.

ot. — A spike knot is one sawn in a lengthwise direction; the mean diameter shall be considered in measuring these knots.

ot. — A standard knot is a sound knot not over 1 1/2 inches in diameter.

etc. — Pitch pockets are openings between the grain of the wood due to the loss of pitch or bark. These shall be classified as *small*, *standard* and *large* pitch pockets.

*Small Pitch Pocket.* A small pitch pocket is one not over 1/8 inch wide.

*Standard Pitch Pocket.* A standard pitch pocket is one not over 3/8 inch wide and 1/2 inch in length.

*Large Pitch Pocket.* A large pitch pocket is one over 3/8 inch wide, or over 1/2 inch in length.

streak. — A pitch streak is a well-defined accumulation of pitch at the surface of the piece. When not sufficient to develop a well-defined streak, or when it occurs between grains, that is, the coarse-grained fiber, usually termed *pitch*, is not saturated with pitch, it shall not be considered a defect.

Shakes are splits or checks in timbers which usually cause a separation of the wood between annual rings.

— An opening between the annual rings.

shake. — A shake which extends between two faces of a timber.

and Red Heart. — Any form of decay which may be evident in the form of a red discoloration not found in the sound wood, or the presence of rotten spots, shall be considered as a defect.

is bark, or the lack of wood from any cause on edges of

**WOOD PRESERVATION.**— Decay is due usually to a fungus which is prevented by cutting off the air by immersing the timber in water. This is known as a sure preventive. Decay is retarded by thorough seasoning, naturally or in the kiln, or by poisoning the food supply of the fungus by chemical treatment. The latter method usually consists in impregnating with creosote or zinc chloride, the former being more commonly used. The methods used for preserving timber poles are described in the *Manual for Overhead Lines*.

**STRESSES FOR STRUCTURAL TIMBER.**— The values of stresses for structural timber given in the following table are recommended by the American Association of Bridge Engineers on Wooden Bridges and Trestles of the American Railway Engineering and Building Association. See *Manual of the Association*, Chicago, 1911. For values applicable in various cities of the United States see article on *Buildings and Bridges in Various Cities*.

## UNIT STRESSES FOR STRUCTURAL TIMBER IN POUNDS PER SQUARE INCH

(See Note under table)

Kind of timber	Compression						Ratio of length of column to diameter
	Perpendicular to grain		Parallel to grain		Working strength of columns		
	Elastic limit	Working strength	Average ultimate	Working strength	Length under 15 diameters	Length over 15 diameters

\* Partially air dry.

L = unsupported length in inches.

D = least side in inches.

NOTE. — These unit stresses are for a green condition of timber and are to be used without increasing the live-load stresses for impact.

The working units given in these tables are intended for railroad bridges and trestles. For highway bridges and trestles the unit stresses may be increased twenty-five (25) per cent. For buildings and similar structures in which the timber is protected from weather and practically free from impact, the unit stresses may be increased fifty per cent. To compute the deflection of a beam under long-continued loading instead of that when the load is first applied, only fifty (50) per cent of the corresponding modulus of elasticity given in the table is to be employed.

RESSES FOR STRUCTURAL TIMBER IN POUNDS PER  
SQUARE INCH

**STANDARD SIZES.**—The commercial sizes of spruce and yellow pine in part of the United States are as follows:

Cross-sectional dimensions in inches are:

2 by 5, 2 by 6, 2 by 7, 2 by 8, 2 by 10, 2 by 12

3 by 8, 3 by 10, 3 by 12

4 by 8, 4 by 10, 4 by 12

6 by 10, 6 by 12

8 by 12.

..... ft. are ordinary lengths.

..... ft. are less common.

..... ft. are obtained with difficulty.

..... — Same cross-sectional dimensions as spruce and also the following (in inches):

..... by 16      6 by 14, 6 by 16      12 by 14, 12 by 16

..... by 16      8 by 14, 8 by 16      14 by 14, 14 by 16

..... by 16      10 by 14, 10 by 16      16 by 16

..... Sticks are commonly longer than spruce sticks, frequently exceed.....

**DESIGN OF TIMBER BEAMS.**—Timber beams may be designed by use of the ordinary beam formulas (see *Design of Beams in article on Simple*). Timber is especially weak in longitudinal shear which is a governing factor in many cases as shown by the preceding tables. It should be noted that the projection of the end of a beam over the support gives the timber a greater resistance to shear than would be obtained by strict application of theory and the designer must often use judgment in applying the shear formula.

**ALLOWABLE LOADS (POUNDS) ON BR  
YELLOW PINE**

*(See Note below table)*

Allowable uniformly distributed load in pounds per square foot in excess of weight of beam, for end-supported beams, applied laterally at intervals of 12 times their thickness or 12 times their width of beam in inches to get carrying capacity.

Span in ft. = distance c. to c. end bearings	Depth of beam in inches

NOTE.—The tables pp. 1688 and 1689 are for yellow pine timber and require no allowance for impact.

For highway structures add 25 per cent to tabular values.  
For buildings and other structures where timber is used add 50 per cent to tabular values.

Bold-faced type is used for lengths where shear is critical.  
Values below zigzag line cause a deflection under load of  $\frac{1}{800}$  of span.

For actual deflection in inches, except where otherwise noted, divide deflection coefficient by depth of beam in inches. Under permanent load will ultimately equal double this value.

## ALLOWABLE LOADS (POUNDS) ON SPRUCE BEAMS

(See Note, bottom p. 1688)

uniformly distributed load in pounds per inch width per lineal foot, height of beam, for end-supported spruce beams, supported laterally 12 times their thickness or less. Tabular values to be multiplied in inches to get carrying capacity of beams per lineal ft.

Depth of beam in inches									Coefficient of deflection

Modulus of elasticity

1,310,000

city

Values used are the same as given in the table on pp. 1686 and 1687, modulus of elasticity for Yellow Pine, which is taken as 1,500,000. For other values of stress modify tabular values in proportion to stresses.

**WEIGHT OF TIMBER.** — This is variable in the timber and whether it has been chemically treated. It is common to assume yellow pine at  $4\frac{1}{2}$  lb. per board foot in estimating the strength of beams. See *Name and Weight of Poles* in article on *Poles for Overhead Lines*.

**COST OF TIMBER** (Pre-war figures). — This varies and depends for ordinary stock upon the size and quantity. The New York market in New York in June, 1913, gave the price of spruce at \$36 per board feet. Similar quotations on longleaf yellow pine are given below.

**COST OF YELLOW PINE IN DOLLARS  
AT YARD IN NEW YORK**

Cross section	20 feet and under
	\$36
7 in. thick by 8 in. wide, and under..	42
10 in. thick by 10 in. wide, and under..	43
12 in. thick by 12 in. wide, and under..	47.50
14 in. thick by 14 in. wide, and under..	50
16 in. thick by 16 in. wide, and under..	

For regular quotations on timber see the first issue of the *Engineering-News Record*.

The cost of hauling timber and putting in place is about \$10 per 1000 board-feet for fairly heavy yellow pine, exclusive of labor.

Association; *Yellow Pine Manual*, published by the Yellow Pine Manufacturers' Association, St. Louis.

**FOR TRANSMISSION LINES.** — (See also *Distribution Towers for Transmission Lines; Poles for Distribution Lines; Structures for Transmission Lines.*) Steel towers are often used instead of wood for supporting electrical circuits. They have the advantages over wood that they can be of as large size as desired and are much more permanent. Steel towers are especially advantageous for high voltages (over 50,000) where wide wire spacing is necessary; for long spans, such as river crossings, where mechanical stresses are exceptionally heavy; and in localities where there is a danger of forest fires occur.

**FEATURES OF DESIGN.** — Towers are composed of two parts, the tower proper and the foundation. Towers are usually built of standard steel shapes. Angles are used for most members. Channels are used for larger members of some towers, usually the cross arms, or for posts on lattice towers. Flat pieces are sometimes used for the minimum-sized members on lattice towers. Round rods are used for tension members in some towers. The principal members of a tower are the corner posts or legs, which are approximately vertical, and are usually the heaviest members of the tower proper, and the horizontal and diagonal web members which connect the legs together in vertical planes which constitute the sides or faces

of a tower at the base is generally between one-fourth and one-third the height. The greatest economy in cost of tower plus foundation is obtained by a little wider base than that which gives the least cost for the tower alone.

Towers are usually designed for either one or two three-wire circuits, usually with two ground wires above and sometimes with a telephone circuit below. If two circuits are on one tower they are usually located on opposite sides to reduce the hazard of repairing the line. The three wires of a three-wire circuit are usually arranged to form an equilateral triangular prism, but in a single plane which is usually horizontal for single-circuit towers and vertical for two-circuit towers.

**Types of Towers.** — There are two general types of towers, viz., (1) the lattice tower, having only two legs and (2) the rigid, having three or more legs.

**Flexible Towers (Fig. 4).** — The flexible tower is set with face at right angles to the line so as to rigidly resist any transverse force, such as a wind blowing across the line, while bending if necessary to relieve any stress in the direction of the line. The stability of the tower in the direction of the line is maintained by the conductors which it supports acting as guys. Where conductors do not perform this function, due to being attached by suspension insulators, round wires are used as the guys. The flexible tower is especially advantageous at the smaller sizes, where the line conditions approximate those of a rigid tower. On lines of flexible towers, rigid towers are set at intervals.

**Rigid Towers.** — These are usually triangular, square (Fig. 2) or rectangular (Fig. 3). The square tower is probably the most common. Square towers have the four faces framed with the same size members (even though the stresses in the longitudinal and lateral faces rarely figure the same), and the economy of manufacture and erection which results from this feature has an advantage in design in that the torsional stresses are simply determined. Rectangular (including square) towers have the advantage that the unequal settlement of the foundations may be allowed without internal stresses not allowed for in the design. Triangular towers have the advantage of freedom from stresses from unequal foundation settlement, but present diffi-

culties in the joining of standard structural shapes, cult to calculate.

**Connections of Members.** — The members of by bolts. By using no rivets the members may handled even in rough country, erected by less sk ing can be done after all shop work is complete should be of one diameter ( $\frac{5}{8}$  inch is suitable for and of as few different lengths as possible. Bolt than the bolts ( $\frac{1}{16}$  inch is a usual amount). By so that friction between the surfaces develops the members, the play in the bolt holes with changin the members is eliminated.

**Clearance Between Conductors and Tower.** — ductor and tower should be sufficient so that the tower at a lower voltage than is required to arc usually determined approximately by making the length of the string of suspension insulators. A for change of position of conductor with swing amount of swing will not ordinarily exceed 45 d should be determined for each case with and wit *mission Lines*. The angle of swing will be greater ductors and will be more for aluminum than for Clearance to the cross arms will require special c of swing exceeds 45 degrees from the vertical an insulators are used which do not have an arc-ove to the working voltage.

**Foundations for Towers (Figs. 5 and 6).** — enforced) concrete, reinforced concrete or piles dations. Rock footings are also used in special k

**Structural Steel Foundations** are cheap a their durability has been questioned, they have b trouble on this account yet apparent.

**Concrete Foundations** have an advantag they can more easily be varied in depth, spread, selves to local conditions of soil. This is especially or irregular ledges interfere with the use of a stan

Mass-concrete foundations are advantageous in sary or desirable to have a foundation of such w uplift with little reliance on the holding power o be conveniently attached to anchor bolts imbedded tension in the concrete the bolts must extend to t for distributing the stress. The anchor bolts an system of reinforcement.

Reinforced concrete foundations are durable a mass concrete, thereby facilitating transportation.

Piles are used under or for foundations i the holding power of other foundations is unreliab

**Rock Footings** for towers standing on l bolts grouted into holes drilled in rock and ext plates grouted to the rough rock surface at the pe

**FORCES ACTING ON TOWERS.** — The st  
(1) The weight of tower, insulators, clamps, cabl

wires) and ice loads on them; (2) The wind pressure on above; \* balanced tension in cables when dead ended or broken on one side; balanced resultant due to cable tension at angles in the line; loads imposed when erecting towers, stringing wire or repairing line.

A study should be made of all the combinations of these loads which are probable. Often no single combination can be found which will give the maximum stress in all tower members, and therefore several combinations must be used to determine the design.

In the case of an anchor tower carrying six wires, three on each side, the maximum stress is expected in the corner posts when all six wires are pulling in the same direction; the maximum stress in the web members will probably be produced by three wires pulling on one side in one direction and the three on the other side in the opposite direction. In the first case the tower is subject to a bending moment and in the second to a torsional stress. In each case the stresses due to wind and wire are to be superimposed. The wind may act as a force parallel to or across the line, but generally its longitudinal effect is negligible and its transverse effect is important.

**Stresses in Tower Members.** — The stresses in the several members of a tower are usually determined graphically from the assumed loadings by means of stress diagrams; see section on *Trusses* in the article on *Structures, Simple*. The actual distribution of stress is not fully determinate.

**Basic Assumptions.** — Certain assumptions are, however, commonly made to give a determinate distribution for the purposes of design. Among these assumptions are:

1. The stress on the tower (say a broken wire pulling on one side) is resolved into an equal stress at the axis of the tower and a torsional moment.

2. A windward stress at the axis of a tower can be considered as balanced by the two faces parallel with it, each taking one-half the stress.

3. A torsional moment can be considered as balanced between all four faces of a tower.

4. If the tower is square each face takes one-fourth the torsion.

5. The above relations may be expressed as follows (Fig. 1):

1.  $P$ , balanced force in pounds applied at end of cross arm,  
 $L$ , distance, in feet, from end of cross-arm to axis of tower,  
 $R$ , distance, in feet, from side of tower body to axis of tower;

2.  $P$ , balanced force in pounds applied at each corner post equivalent to  $F$  in bending effect on body of tower,

3.  $w$ , pressure on a tower is assumed to be uniformly distributed per square foot of area which the wind blows, one-half of it consequently being on the windward face and the other half on the leeward side (inside) of the tower; for simplicity in calculation this uniformly-distributed force is replaced by concentrated forces, one at each panel point equivalent to the total load acting over a half panel above and a half panel below the panel point. A panel point is a point of intersection of principal members, for example, the intersection of members with vertical members in Fig 4; and by panel is meant the area between panel points, a panel usually being bounded by two vertical members as in Fig 4.

Fig. 1.

$f' = \frac{F_a}{8b}$  = torsional force in pounds applied at each corner post equivalent

to  $F$  in twisting effect on body of tower.

(5) In a tower framed with a double system (i.e., diagonals in duplicate suitable for compression as well as tension) each system may be considered taking one-half of the stress as far as possible.

**Approximations Made in Calculating Tower Stresses.**—The stress diagrams are usually simplified by employing certain approximations:

(a) Faces of towers are usually battered so that they deviate slightly from a true vertical plane, but the stress diagrams usually neglect this inclination and are based on the vertical projection of the face.

(b) Where the face of a tower does not lie in one plane (i.e., has a change of batter as occurs frequently at bottom cross arm where a prismatic cage has a pyramidal base) the change of inclination is neglected and the diagrams are based on a single vertical projection as before.

Subject to the limitations of the assumptions and approximations given above, the four faces of the tower can be regarded as four cantilevers, supported at the base and loaded at the top, which are independent except that the corner posts are each common to two faces and must contain the resultant stresses.

Where a face of a tower or any part of a face has any considerable inclination the above approximations may not be used without danger of serious error.

**Unstressed Members.**—A tower usually contains members not stressed in which is shown by the stress diagram, viz.:

(1) Diagonal members in a horizontal plane do not usually appear in the stress diagram when located below the lowest cross arm. These members play an important part in the distribution of torsion among the faces. In a rectangular tower the torsion will usually redistribute between the four faces at each level where there are horizontal diagonals, therefore the failure of the stress diagram to show stresses in them may be taken to indicate that the assumed distribution of torsion is not quite correct rather than a true absence of stress.

(2) Redundant members are braces which carry no determinate stress but perform the important function of supporting the compression members which do carry stress. The unit stress allowable in a compression member diminishes as the unsupported length increases. The weight of compression members is therefore diminished by dividing their unsupported length by braces applied at one or more intermediate points.

**Unit Stresses in Towers.**—The factors of safety and unit stresses used in tower design have not been standardized. In some cases it has been assumed that the combination of loading taken for tower design represents conditions which would happen so rarely that a tower which would stand these loadings in test without failure would be sufficient. This is equivalent to taking a severe combination of loads and designing for a factor of safety of but one. The result, however, may be as good a tower as one designed for the same conditions individually (but not in combination) with a factor of safety of two or four. It is probable that few towers are designed for the combination of all loadings, each taken at the most severe condition reasonably possible with an actual factor of safety exceeding two.

For a factor of safety of from  $2\frac{1}{2}$  to  $1\frac{1}{2}$  (as determined by test of complete tower, not of individual members) the following unit stresses have been used:

Tension: 12,000 to 20,000 lb. per sq. in.

Shear: 12,000 to 20,000 lb. per sq. in.

Bearing: 16,000 to 30,000 lb. per sq. in.

Compression:  $12,000 + K$  to  $20,000 + K$  lb. per sq. in.

$R_1$   
 supported length of member, in inches,  
 radius of gyration of section, in inches,

is limited that for main members  $L + R$  does not exceed 125 to  
 secondary members  $L + R$  does not exceed 150 to 220.

**Eccentricity in Stresses at Joints.**—As tower members are ordinarily  
 either the stresses in them are slightly eccentric, thereby prevent-  
 ing full strength of the members being developed. The eccentricity should  
 be kept to a minimum or reduced as much as possible by having the center of gravity  
 of members at each connection meet at one point as exactly as

**ACTING ON TOWER FOUNDATIONS.**—Foundation stresses  
 arise: first, the foundations resist the tendency of the tower to slide  
 due to the external forces on it considering the tower as a self-  
 contained structure; second, the foundations resist certain stresses which would  
 otherwise be internal stresses were the tower framed as a complete self-contained  
 structure which become external stresses because the ground is depended  
 upon for the support of certain omitted members. The weight of the tower can  
 be reduced by thus substituting the ground for certain members, but  
 the foundation is thereby increased. The amount of these latter stresses  
 depends on the outline and framing of the tower and their effect should not be  
 determining loadings on foundations.

To determine the magnitude and direction of the forces acting on the tower foundations  
 is done by taking the case of a rectangular tower, and considering  
 a line which runs north and south.

$a$  (feet) of base of tower (east and west);  
 $b$  (feet) of base of tower (north and south);  
 $w$  (pounds) weight of tower, insulators, fittings and one span of all  
 wires, including ice load, if any;  
 $u$  (pounds) of any unbalanced load, such as a wire  $c$  feet off  
 center;  
 $F$  (pounds) of the wind on the tower and a complete  
 span of all the wires (with ice coat, if any), acting at a distance of  $d$   
 feet above the foundation, wind assumed blowing across line from  
 west to east,  
 $U$  (pounds) of any unbalanced force toward the south applied at a  
 distance of  $e$  feet above the foundation and  $f$  feet to the west of axis  
 of tower, as for example, a dead-ended wire or when a wire on the  
 east side of the tower is broken.

It is assumed that the forces divide equally among the four foundations and  
 that all forces are in a circumferential direction, the relations given  
 in the preceding table hold. These assumptions are reasonably correct for a  
 tower with four legs joined at the bottom with a horizontal strut in each  
 face and with horizontal ties across the diagonals, unless the  
 foundation usually provided in the other faces is inadequate. Probably  
 they do not fully meet these requirements. Therefore, there are usually  
 stresses of large magnitude due to the foundations performing the  
 required duty or inadequate members, as pointed out in the notes ap-  
 pended.

## FORCES ON TOWER FOUNDATIONS

Magnitude of force on each of the four foundations	Direction at each corner	
	N. E. corner	S. E. corner
$\frac{W}{4}$	Down	Down
$\frac{cW'}{4}$	Down	Down
$\frac{F}{4}$ (Note 1)	East	East
$\frac{dF}{4}$	Down	Down
$\frac{P}{4}$ (Note 2)	South	South
$\frac{eP}{4}$	Up	Down
$\frac{aP}{4(a^2+b^2)}$ (Note 3)	North	North
$\frac{bP}{4(a^2+b^2)}$ (Note 3)	West	East

NOTES. — Where there are no struts between the bottom panels where the bottom panel is framed on the single system, the directions are usually:

(1) The force of the wind  $F$  will give a greater force than on the two west foundations and a correspondingly less force on the two east foundations. In addition produce four new forces tending to force the tower to the east and draw them together on the tension side.

(2) Similarly the pull of the wire  $P$  will give a greater force in the direction of the two north foundations and a correspondingly less force on the two south foundations. In addition produce a westerly force at the N. E. and N. W. corners and an easterly force at the S. E. and S. W. corners.

(3) Similarly, the torsional forces due to  $P$  will increase on the two north foundations, and the unbalanced pull  $P$  may develop new forces on the two north foundations and depress the other two.

**Resultant Forces on Foundations.** — From the above it is seen that the resultant force on each of the four foundations may be found. The resultant force will be on each foundation: (1) a downward pressure, (2) a horizontal overturning force, producing a tension on one side of the foundation and a downward pressure on the other.

**Downward Pressure.** — The downward pressure is of importance in determining the size of the foundation and the foundation for uplift and overturning is unnecessarily safe against uplift.

**Direct Uplift.** — The uplift is very important in determining the size of the foundation and the foundation is rarely sufficient to provide more than the holding-down power required. The excess uplift is usually in which the foundation is buried. Not only is the weight of the earth over the foundation effective but there is an additional force of cohesion of the earth which may be several times the weight of the earth. These forces are usually computed on the assumption that they are the weight of the earth in a frustum of an inverted cone or pyramid.

tending to the surface of the earth. The face of this cone is as making an angle of  $30^\circ$  with the vertical.

**Horizontal Overturning Force, Sliding and Indirect Uplift.** — The overturning force is also important. Its effect on the base may be in two components, one a horizontal force tending to slide the foundation and the other a moment tending to rotate the base about a horizontal axis. The resistance of the earth to these forces is an obscure subject, especially when the foundation is of irregular shape. The following discussion which neglects the lateral resistance of the earth may be considered as a conservative view of the earth

resistance to sliding may be considered as due to the friction of the foundation on the earth, and it may further be assumed that any base which is to resist uplift will also furnish sufficient friction to prevent sliding. The resistance to the overturning force is then the same as the height of the foundation (from the bottom of base to top where tower is attached), and the overturning moment is equal to the horizontal force multiplied by this arm. The lateral resistance may be considered as due entirely to the vertical reaction of the earth at the top and bottom of the foundation. These vertical pressures are assumed to vary uniformly from zero at a horizontal neutral axis through the base, to a maximum at the edges of the base most remote from the center of resistance is calculated as for a beam subject to a uniformly distributed load having a cross-section identical with the area of the base. It may be assumed that any unit pressure allowable on the uplift edge will be amply sufficient to resist the pressure on the opposite edge where the pressure is downward, so that calculations of lateral resistance are unnecessary. The maximum allowable unit stress on the uplift edge may be taken as equal to the average unit resistance to uplift of the earth, determined as described above under *Direct Uplift*.

**Designing Conditions.** — Usually the most severe condition that a tower is required to meet consists of a combination of uplift and overturning. In this condition the unit stress of uplift proper must be added to the unit stress of uplift due to overturning and the sum must be equal to the allowable average unit resistance to uplift.

**Foundations.** — (See also article on *Strength and Elasticity*.) A foundation is subject to stresses from the tower tending to move it and from the earth tending to prevent motion. The foundation should of course be designed to resist these stresses without breaking when subject to these opposing forces. As the magnitude of the resistance of the earth and the magnitude of the stresses transmitted by the earth at any point are subject to great variations, the foundation should be designed for strength for the distribution of stresses which is most severe, considering for example that while the resistance is calculated on a uniformly-distributed earth resistance, it may be overcome in practice by concentrated pressure from stones or timber located at the edges of the base.

**Points Regarding Design of Foundations.** — The following are conclusions which follow from the above discussion:

1. The inverted cone theory of resistance to uplift gives a calculated resistance which increases at a rapid rate with the depth (eventually increasing as the cube of the depth). It would however be unsafe to apply these results to foundations differing much from those of usual dimensions, especially for foundations much exceeding six feet and for foundations where the spread of the base is less than the depth to which it is buried.

2. The top of the tower (top of foundation) should be brought as close to the ground as possible to reduce the overturning moment.

## Towers for Transmission Lines

The tower diagonals of the bottom panel of the tower should intersect the posts as low as possible, because this is the actual point of application of the overturning force to the foundation and if this intersection is above the foundation this extra length must be added to the arm of the overturning force.

By inclining the axis of the foundation approximately in line with the tower leg (i.e., to bring it as near as possible into line with the resultant of the horizontal overturning force and the vertical pressure or uplift) a critical use of material may be made to resist the combined uplift and overturning.

**TESTING OF TOWERS.**— Since towers are generally indeterminate structures, few designs are usually tested. Test loads proportional to the load for the design are applied until the required factor of safety has been reached or failure occurs. Towers are usually mounted on a rigid base for testing, which gives the strength which the tower would develop on an ideal foundation. In practice the tower must be expected to develop somewhat less strength, as unequal movement of the foundations will ordinarily overstress the members. Test loads may be applied by means of weights suspended from the tower at proper points for vertical loads and applied by means of pulleys attached to a tower-testing structure ("test tower") for horizontal loads. The method of application makes the determination of the test loads easy, but inconvenient to have the weights fall any considerable distance if the tower fails.

**TESTING OF FOUNDATIONS.**— Foundations are occasionally tested, but this is usually more for determining the holding power of the soil than the strength of the foundation. For the former purpose the test result will depend on the character of the soil and its condition (dry, wet or frozen). Testing for holding power are only necessary for uplift and overturning forces. It is important that the testing machine should not press down on the surface of the soil near the foundation. The machine should rest on the ground at the base of an inverted cone of angle of  $45^\circ$  from the vertical and extend to the base of the foundation under test.

**TESTING SPECIFICATIONS, CONTRACTS AND PROPOSALS.**— Different manufacturers of towers use different details of construction so that specifications written for the purpose of obtaining proposals should contain only general requirements. These should state the loadings, factors of safety, allowable stresses, and show outline dimensions of the tower as determined by clearances required.

Specifications should state whether towers are bolted or riveted, galvanized or painted, shipped assembled or partly assembled, tested or not tested, and sides containing the usual structural steel specifications; see *Steel*. Proposals should show the arrangement and sizes of members and type of connections.

Contracts are oftentimes let on the basis of furnishing an approximate number of towers when the exact number required cannot be determined in advance and a unit price per pound is included to cover extensions, special conditions and modifications that may be required.

Galvanizing and sherardizing of towers and parts are usually specified in the American Telephone and Telegraph Co's. Specification for galvanizing of wire (see *Galvanizing for Iron or Steel*). All members of towers that are too heavy, so that there is danger of their buckling in the process, may be galvanized by the hot dip process. All bolts, nuts, threaded rods and turnbuckles may be specified to be sherardized.

**ERECTOR AND ERECTION.** — Towers are generally shipped assembled, all of the members for one tower being bundled together, usually assembled lying on its face on the ground adjacent to the foundation. When assembled it is temporarily braced when necessary (usually between the legs at the base of the tower) and up-ended onto the foundation. For the latter operation temporary hinges connecting the two legs to the ground to the two adjacent foundations are convenient. Towers to be up-ended and towers in inaccessible places are built up in place.

For connections the nuts should be prevented from working loose by washers on bolts, riveting over the end of the bolt, or by lock-nut or

each member should have a number which should be shown on the drawings and marked on the corresponding member of each tower.

Members should be cut, bent and punched to template so that the parts are interchangeable and the assembled tower will fit the foundation prepared

**FOUNDATIONS.** — Foundations should be set with their bases on a level line. The hole should not be excavated deeper than necessary, the foundation may rest on undisturbed earth. If any of the several legs of a tower rest on loose backfill, unequal settlement may be expected and may greatly weaken the tower. The hole should not be larger than necessary, as the backfill will be less effective than undisturbed earth in supporting the tower. The resistance of concrete foundations can sometimes be increased by cutting a hole smaller in diameter than the base and undercutting the foundation. When using structural steel foundations large stones can be set against the steel to increase its resistance to motion, either horizontal or vertical. The backfill should be well tamped in place and especially used if it is probable that the foundation will be subject to heavy loads. The earth has had time to settle. On sloping ground filling may be used on the low side to give the designed weight of earth against uplift. In the case of floating power of hydrostatic pressure beneath the foundation should be provided for. Where towers are raised on extensions the increased stresses due to increased moment must not be overlooked.

Foundations of a tower should be set accurately by template to give the proper spacing and elevation so that towers stand truly vertical and free from stresses due to distortion.

**MAINTENANCE OF TOWERS.** — All bolted connections on towers should be regularly watched and kept tight, and the galvanizing or paint should be regularly renewed and towers must be repainted before any deterioration occurs. Foundations are the most likely source of trouble in towers and these should be kept properly backfilled and should be watched for settlement of legs.

**WEIGHTS, COSTS.** — Data on these items for a number of towers are given in the following table. Galvanized towers cost from 2 1/2 to 3 1/2 cents per pound, f.o.b. factory. Galvanizing costs from 1/2 to 1 cent per pound. The cost of galvanizing is included in the figures just given.

**General Description.**—The electrical transformer, commonly called the electric transformer, is a piece of stationary apparatus used to transform alternating-current energy at one voltage to some other higher or lower voltage. The single-phase transformer consists of two electrical circuits, usually of a large number of turns, interlinked with a common magnetic circuit of iron. Since the power is approximately the same in both windings, the currents in the two windings are inversely proportional to the voltages in the windings. The polyphase transformer is essentially two or more single-phase transformers made into a single piece of apparatus, but so designed that at least a part of the magnetic circuit is common to all the phases. A three-phase transformer has three high-tension and three low-tension windings arranged on a single iron core; see Figs. 1 and 2. The auto-transformer is treated in a separate article, viz., *Auto-Transformers*.

**Terminology.**—The winding by which the energy enters the transformer is logically the "primary" and the one by which the energy leaves the transformer is called the "secondary." Since either winding of the transformer may be connected to the source of energy, these terms are not definite unless the manner of connection is also stated. When referring to the transformer as a separate piece of apparatus the terms "high-tension" winding and "low-tension" winding are used to distinguish the two windings, the high-tension winding being the one with the greater number of turns. When the high-tension winding is connected to the source of supply it is the primary, and the transformer is said to be used as a "step-down" transformer; when the low-tension winding is connected to the source of supply, the high-tension winding is the secondary, and the transformer is said to be used as a "step-up" transformer.

**CLASSIFICATION.**—Transformers may be classified according to their operating characteristics, to their construction, or to the method of cooling.

**Constant Potential and Constant-current Transformers.**—Transformers may be either constant potential, such as are intended to give an approximately constant potential on the secondary side, or constant current, intended to give an approximately constant current on the secondary. Both types are intended to operate on a supply circuit of a constant potential.

**Series Transformers** are connected in series with the main circuit and receive a variable voltage and current in the primary. The secondary circuit is

closed through a path of low impedance and thus the secondary current will be proportional by the ratio of turns to the load current flowing in its primary or supply circuit. They are usually used to supply low-readings ammeters and wattmeters from circuits carrying very heavy currents.

**Auto-Transformers or Compensators**, sometimes called single-circuit transformers, consist of one electric circuit interlinked with the magnetic circuit as a tap brought off from some part of the winding. The voltage between its tap and either terminal of the electric circuit will be a fraction of the total voltage and thus a fractional voltage may be secured from this piece of apparatus. It is customary to proportion the windings on each side of the tap in accordance with the current to be carried. Auto-transformers are generally used where the ratio of voltages is quite near to unity as in this case they can be constructed with much less copper than the regular transformer. See article on *Auto-transformers*.

**Potential Regulators** are a form of transformer in which the voltage of one member may be varied from zero to a fixed maximum either by changing the direction of the magnetic flux or by changing the phase of the electromotive force of the secondary with respect to the electromotive force of the primary.

**Core and Shell Types.**—Two methods of arranging the electric and magnetic circuits are in use, the corresponding construction being designated as the "core type" or the "shell type." At present a large number of lighting transformers of small and medium capacity are constructed in a manner which is a composite of the core and shell types.

Fig. 1. Core-type Transformers

**Core Type (Fig. 1).**—The single-phase core-type transformer consists of a single magnetic circuit interlinked with two electric circuits, each consisting of a group of coils as shown in Fig. 1. The three-phase core-type transformer is also shown in Fig. 1.

Single Phase

Fig. 2. Shell-type Transformers

Three Phase

Fig. 2a. Distributed Core Type

**Shell Type (Fig. 2).**—In the shell type of transformer each electric circuit is interlinked with two magnetic circuits having a common path inside the coils but branching outside of the coils as shown in Fig. 2.

**Distributed Core Type (Fig. 2a)** is a compromise between shell and core type and is much used for small lighting transformers because it economizes in iron and distributes the heat. It consists of the two electric circuits wound concentrically about one central core which divides at the top and bottom into four radiating magnetic circuits surrounding the coils on four sides. It is shown in Fig. 2a in plan view.

**Comparison of Core and Shell Type.**—The core type of construction is best adapted for high-voltage low-capacity transformers and the shell

for low-voltage high-capacity transformers. This arises from the fact that the most economical disposition of material in the core type demands a large number of turns and small cross-section of iron, while in the shell type a large cross-section of iron and small number of turns may be used to advantage. In the shell type the coils are usually wound in flat "pan-cakes," this type of construction being particularly well suited to the use of heavy copper ribbon or straps. In the core type the coils usually consist of two or more layers, long in comparison with their diameter. The use of the core type is increasing both in number and size of transformers as it is found possible to space the coils so they will better withstand the mechanical strain due to short circuits.

**Classification According to Method of Cooling.** — (See also below.) Transformers may be subdivided into classes in accordance with the method adopted for dissipating the heat due to their internal losses. As a transformer is a compact piece of apparatus the problem of carrying away the heat is an important and various ingenious means have been devised for the purpose.

**Naturally Cooled Transformers.** — As this name implies this type of transformer has no special means of cooling but relies upon the ordinary circulation of the air. It is only used in transformers of very small sizes, such as those intended to supply meters.

**Oil-cooled Transformers.** — In this type of transformer the core and windings are submerged completely in oil in a tank and the windings and core are subdivided by ducts in order that the oil may circulate and carry off the heat from the internal parts. The heat is carried to the surface of the tank which contains the transformer and from there carried off by the surrounding air. The tank is specially designed to provide large air-cooling surfaces, provided with deep corrugations, or with projecting vanes or tubes.

**Air-blast Transformers** are designed with special passages through which a current of air is forced by means of a blower, the heat being carried off to the atmosphere in this manner.

**Water-cooled Transformers** consist of a construction similar to that of the oil-cooled type and in addition a coil of pipe carrying running water is submerged in the oil.

**Forced-oil Transformers.** — Transformers artificially cooled by circulation of oil are used when the size is too great for the self-cooling oil type and no cooling water is available. The oil circulates through external coils or tubes which give a greater cooling surface.

**METHODS OF RATING.** — The *Standardisation Rules of the A.I.E.E.* specify that the continuous rating of a transformer is that load in kilovolts-amperes which when applied continuously will cause a rise in temperature of the windings, as measured by a thermometer, or  $55^{\circ}$  as measured by resistance of the windings. The iron of transformers takes a long time to reach a constant temperature, that of oil-cooled transformers in particular requiring from 10 to 12 hours. Thus a transformer will stand a considerable overload for a short time without overheating, the principal danger being excessive mechanical stresses.

**TRANSFORMER PRINCIPLES.** — (See also *Electricity and Magnetism, Principles of.*) The essential features of a transformer consist of a primary winding having a number of turns interlinked with a magnetic circuit, and a secondary winding also interlinked with the same magnetic circuit, as shown in Fig. 3.

**Simple Theory, Neglecting Leakage Reactance.** — In the following discussion the assumption will first be made that all the flux links both primary and secondary windings; the effect of the leakage flux will be discussed later.

In Fig. 3,  $S_1$  is the primary winding,  $M$  the magnetic circuit (of iron) and the secondary winding. If an alternating current is caused to flow in  $S_1$  it sets up a flux in  $M$  which at any instant is proportional to the current  $i_1$ . Thus

$$\phi = \frac{4\pi S_1 i_1}{10R}$$

where  $S_1$  is the number of turns,  $i_1$  the instantaneous value of the current and  $R$  the magnetic reluctance of the path in  $M$ .

Thus  $\phi$  alternates with  $i_1$  and since it interlinks with  $S_2$  it will induce a voltage in  $S_2$  at any instant equal to

$$e_2 = -S_2 \frac{d\phi}{dt} \times 10^{-8} \text{ volts}$$

in which  $S_2$  is the number of turns. The negative sign means that any current due to  $e_2$  will tend to diminish  $\phi$ .

**No-load Conditions.**—When there is no current in the secondary the vector relations are as shown in Fig. 4. Let  $E_1$  be the voltage impressed on  $S_1$ , then the maximum value of the alternating flux will be

$$\phi = \frac{10^8 E_1}{4.44 f S_1}$$

where  $f$  is the frequency of alternation of  $E_1$ . Strictly, the numerator is  $10^8(E_1 - r_1 I_m)$ , where  $I_m$  is the exciting current and  $r_1$  the resistance of the primary, but the term  $r_1 I_m$  is practically negligible. This flux will lag behind  $E_1$  or  $90^\circ$  ahead of the counter electromotive force  $E_c$  which it induces in  $S_1$ . The true magnetizing current  $I_m$  will be in phase with the flux and the hysteresis component of current  $I_H$  will be in phase with  $E_1$ . Hence the no-load current  $I_0$  will assume some phase a little less than  $90^\circ$  behind  $E_1$ .

The flux  $\phi$  will induce in the secondary turns  $S_2$  an e.m.f.  $90^\circ$  behind  $\phi$ , hence  $180^\circ$  behind  $E_1$  or in phase with the primary counter e.m.f. The effective value of this e.m.f. is

$$E_2 = 4.44 f S_2 \phi \times 10^{-8}$$

**Load on Secondary.**—When the secondary is closed through an inductive external circuit a current will flow. This current will tend to demagnetize the iron, that is, to reduce the flux and hence the counter e.m.f. in the primary. This action, however, allows the current in the primary to increase until the secondary m.m.f. is balanced and there is left an excess m.m.f. in the primary to give sufficient flux to induce the counter e.m.f.  $E_1'$ . The vector relations are as shown in Fig. 5, again neglecting the leakage flux.

**Leakage Reactance.**—Due to the fact that a part of the lines of induction set up by the currents in the two windings pass through the air space (Fig. 3), the m.m.f.'s set up by the secondary current and the load current

Fig. 3. Elementary Transformer

Fig. 4. No-load Relations

Fig. 5. Full Load, No Leakage

(the current  $I_2'$  in Fig. 5) cannot neutralize each other, since the e.m.f.s established by the two currents are in the same direction, and in phase as are the fluxes in the iron. The primary leakage flux is in phase with the total primary current and the secondary leakage flux is in phase with the secondary current; these leakage fluxes are therefore not in phase with the useful flux (i.e., the flux which links both primary and secondary). It is thus seen that the leakage fluxes cause a decrease in the secondary voltage and a shifting of its phase with respect to the primary voltage.

The two leakage fluxes are in phase with the total currents in the primary and secondary respectively the voltages induced by the alternation of these fluxes are in quadrature with the currents. The primary resistance drop is the primary e.m.f. divided by the primary current is called the "primary leakage reactance," and the secondary resistance drop is the voltage induced in the secondary by the alternating secondary leakage flux divided by the secondary current is called the "secondary leakage reactance." These reactances are practically constant, since the major portion of the magnetic path is in the iron.

Fig. 6. Diagram of Circuits

the alternating secondary leakage flux divided by the secondary current is called the "secondary leakage reactance." These reactances are practically constant, since the major portion of the magnetic path is in the iron.

Fig. 7. Complete Vector Diagram

### Vector Diagram

Fig. 6 shows the equivalent circuits of the transformer and Fig. 7 the vector diagram.

Primary terminal e.m.f.;

Primary resistance drop;

Primary reactance drop in volts; in phase with  $I_1$ ;

Primary induced e.m.f. in the secondary (hypothetical);

Primary resistance drop in volts due to  $I_2$  of leakage flux, at  $90^\circ$  to  $I_2$ ;

Primary induced e.m.f. in the primary (hypothetical);

Primary resistance drop in volts due to  $I_1$  of leakage flux, at  $90^\circ$  to  $I_1$ ;

Primary induced e.m.f. in the secondary (hypothetical);

Primary induced e.m.f. in the primary (hypothetical);

Primary load current; opposed and proportional to  $I_2$  by ratio  $\frac{I_1}{I_2}$ ;

Primary no-load current;

Primary resultant primary current;

Primary resistance drop; parallel to  $I_1$ ;

Primary reactance drop, at  $90^\circ$  to  $I_1$ ;

Primary induced e.m.f. in the primary, that is, the impressed e.m.f.

**Equivalent Circuit of Transformer.** — In practice it is not possible to separate the primary and secondary reactances. They must be combined and treated as one quantity, called the total reactance  $X_t$ , which may be expressed in terms of either the primary or secondary turns.

A convenient approximate method which is sufficiently accurate for all practical purposes is based on the equivalent circuits shown in Fig. 8. This method is

used in calculating the characteristics of a transformer from constants obtained from tests.

Let  $E_2$  = terminal e.m.f. of secondary;

$\cos \theta_2$  = power factor of load;

$I_2$  = secondary current;

$n$  = ratio of transformation =  $\frac{S_1}{S_2}$ ;

$$E_2' = nE_2;$$

$$I_2' = \frac{I_2}{n};$$

$R$  = total resistance in terms of primary =  $r_1 + n^2 r_2$ ;

$X$  = total reactance in terms of primary;

$I_M$  = primary magnetizing current;

$I_W = \frac{\text{core-loss}}{nE_2}$ , to a close approximation;

$E_1$  = primary impressed e.m.f.;

$I_1$  = total primary current;

$\cos \theta_1$  = power factor of transformer with load, i.e., power factor at primary terminals;

$P_1$  = watts input at primary terminals;

$\eta$  = per cent efficiency.

Then

$$E_1 = \sqrt{(E_2' \cos \theta_2 + RI_1)^2 + (E_2' \sin \theta_2 + XI_1)^2};$$

$$I_1 = \sqrt{(I_2' \cos \theta_2 + I_W)^2 + (I_2' \sin \theta_2 + I_M)^2};$$

$$P_1 = E_1 I_1 \cos \theta_1 = E_2 I_2 \cos \theta_2 + R(I_2')^2 + E_2' I_W;$$

$$\cos \theta_1 = \frac{P_1}{E_1 I_1};$$

$$\eta = \frac{100 P_2}{P_1};$$

$$P_2 = E_2 I_2 \cos \theta_2;$$

$$\text{Per cent regulation} = \frac{100 (E_1 - nE_2)}{nE_2}.$$

Fig. 2. Equivalent Circuit

**Constant-current Transformers** are used for supplying current to arc lamps connected in a series circuit which requires from 4 to 10 amperes and about 2000 volts. The principle of operation for this type of transformer is based on the existence of the leakage or useless flux which causes a repelling force between the primary and secondary windings. One winding is arranged so that it can move with respect to the other. As the current in the windings increases the repelling force increases and the windings move apart. This allows more flux to leak or pass between the windings and less to thread the secondary. Therefore the voltage induced in the secondary decreases as the current tends to increase. A counterweight is attached to the movable winding to regulate the amount of movement. The current in the primary remains fairly constant, but the power factor decreases with decreasing load on the secondary so the power in the primary is approximately proportional to the output of the secondary.

**Series Transformers** operate under conditions similar to those in a constant-potential transformer with short-circuited secondary. Under operating conditions the flux is small as the only voltage to be induced in the secondary is that required to overcome the impedance drop in that winding and the instrument which it supplies. The only counter e.m.f. in the primary is that due to impedance drop. The series transformer must be operated with the secondary

short-circuited by a low impedance. If the secondary circuit is open there is counter m.m.f. to balance the primary turns, which, being in series with the in line, carry a current irrespective of the secondary circuit. The primary per-turns would then set up a magnetic flux of considerable magnitude. The transformer is not designed for this condition, the density would become very high in the magnetic circuit of small cross-section, and the transformer is liable to burn up from the heat due to core-loss.

**TRANSFORMER CONNECTIONS.** — The various transformer connections which are commonly used in lighting and power services are described below; see also section on *Operation* below.

**Single-phase System with Three-wire Secondary (Fig. 9).** — Standard practice in residence lighting with the a-c. system involves grounding the neutral wire on the low-tension side, the primary side not being grounded. Lamps and motors operating at 110 volts are connected between the neutral and either

Fig. 9. Single-phase, Three-wire

Fig. 10. Two-phase, Four-wire

the. The maximum potential between any secondary and ground is 110 volts. If either of the outside wires becomes grounded it constitutes a short-circuit on that half of the transformer.

**Two-phase or Quarter-phase Four-wire System (Fig. 10).** — The standard two-phase or quarter-phase system is essentially two independent single-phase systems which are usually independent electrically throughout. When the two phases are not electrically connected inside the generator, either wire of one phase may be connected to either wire of the other phase, without any flow of current resulting. In certain two-phase generators, however, the windings are interconnected, in which case any interconnection of the wires coming from the generator will cause a flow of current through this connection.

**Two-phase Three-wire System (Fig. 11).** — This connection is occasionally used for the distribution of power in small systems. There is a possibility of a slight saving in copper, but the chances of unbalanced voltage and bad regulation, particularly with an inductive load, render it objectionable.

Fig. 11. Two-phase, Three-wire

**Three-phase Y and  $\Delta$  Connections (Figs. 12 and 13).** — Transformation in a three-phase system with either three independent single-phase transformers or with a three-phase transformer, having three primary coils and three secondary coils on one iron core, is accomplished by connecting the primary either in  $Y$  or in  $\Delta$  and the secondary either in  $Y$  or in  $\Delta$ . With  $Y$  or  $\Delta$  connections there are the following relations between voltage per transformer winding and voltage between lines, and between current in transformer windings and current in a line. The power in the three transformers in any case is  $3 \times 0.58 \times EI = 1.73 EI$ .

Fig. 12. Three-phase Y

Fig. 13. Three-phase Delta

Connection	Volts bet. lines	Volts per winding	Current per line	Current per winding
Y	$E$	$0.58 E$	$I$	$I$
$\Delta$	$E$	$E$	$I$	$0.58 I$

There are four combinations of these connections which may be used on any bank of transformers. These connections are given in the following table, and also the ratio of the voltage between lines for the low-tension and high-tension sides for a given ratio ( $\mu$ ) of transformation in each individual transformer connection.

Connection		Low-potential volts bet. lines	High-potential volts bet. lines
Low pot.	High pot.		
$\Delta$	$\Delta$	$E$	$\mu E$
Y	Y	$E$	$\mu E$
$\Delta$	Y	$E$	$1.73 \mu E$
Y	$\Delta$	$E$	$0.58 \mu E$

**Parallel Connection of Three-Phase Banks.**— If there are several banks of transformers in the same system connected in parallel on one side then to connect the other sides in parallel the connections must be such that the voltage between any two lines on this side will have the same phase in all the banks. From this relation result the following rules:

With  $\Delta\Delta$  on one bank, the other bank must be  $\Delta\Delta$  or  $YY$ .

With  $YY$  on one bank, the other bank must be  $\Delta\Delta$  or  $YY$ .

With  $\Delta Y$  on one bank, the other bank must be  $\Delta Y$  or  $Y\Delta$ .

With  $Y\Delta$  on one bank, the other bank must be  $Y\Delta$  or  $\Delta Y$ .

Even when these relations are satisfied a short-circuit will result unless the three phases of each bank are connected in the proper sequence. This can be

examined by the polarity test described below in the section on

**Relative Advantages of Y and  $\Delta$  Connections.**— There has been discussion as to the relative advantages of Y- and  $\Delta$ -connected transmission and as to the value of a grounded neutral. General and fundamental arguments may be summed up as follows:

**$\Delta$ -system** the advantages are that if one transformer becomes disconnected the system may be operated from the other two, operating on open delta.

If the load is unbalanced the voltages do not become unduly unbalanced. Resonance cannot occur. On the other hand, each transformer is subjected for full line voltage as there is no neutral to ground, and if one becomes grounded the voltage strain on the rest of the system becomes the normal strain, and this strain may extend to the low-tension transformer of the generator which is connected to the transformers.

**Y-connection** there is a very unstable neutral and a possible excessive strain on one phase, unless the neutral is grounded.

**Y arrangement for step-up transformers**, the neutral on the high-voltage may be grounded. The voltage strain on any transformer is then 33 per cent of the line voltage. There is a possibility of operating with two transformers, if one becomes damaged, by using the neutral conductor. However, there is the possibility of resonance under certain circumstances and the danger of causing disturbances in nearby telegraph circuits. Any accidental ground on the system makes a short-circuit on one phase.

**Grounding of Y $\Delta$  for step-up transformers** is not desirable on account of the possible neutral with unbalanced load, but is permissible with a balanced load. A good connection from neutral of transformers to neutral of generator connection, however, is frequently used for step-down transformers when connected to a balanced load.

**Grounded Neutral vs. Ungrounded Neutral.**— In any system with ungrounded neutral there are numerous possibilities of disturbances. In a high voltage strain on the various parts of the insulation of the system. In the high voltages now in use for transmission systems these disturbances may give a great deal of trouble by breaking down the insulation. It is always possible to employ a large margin of safety and lightning rods do not always protect from these disturbances. On the other hand, if the neutral is grounded, most of these disturbances will merely result in an interruption of service, and if the circuit breakers are installed in the proper places in the circuit, so that the only adverse result will be a temporary interruption of service.

The choice is then between a system with ungrounded neutral and a large margin of safety in the insulation, and a system with grounded neutral, modification and the possibility of occasional interruption of service.

**Effect of Higher Harmonics.**— Many alternators generate an e.m.f. whose wave shape contains higher harmonics (see *Wave Analysis*) and the magnetic flux of transformers operating at high magnetic densities has a wave shape which contains a prominent third harmonic. If these harmonics are present in a Y-connected machine they cause the voltage between line and the neutral to vary so that there exists an unstable neutral. The voltage strain on any one phase is indeterminate. If the neutrals of the apparatus in which these harmonics exist are grounded or connected together, a high-frequency current will flow in the neutral connection. On the other hand these pieces of apparatus are  $\Delta$ -connected a third harmonic will circulate inside the apparatus. This may be measured by con-

necting an ammeter in the  $\Delta$  between two phases. This current heats the apparatus, does no profitable work, and is therefore to be avoided. High frequency current in the line will cause high voltages to occur at certain points if a large amount of capacity is present, as is the case in any underground line even of moderate length, and also in long overhead lines. All possible means both in the design of the generators and the connection of the apparatus should be taken to prevent the occurrence of, or to diminish the effect of, these high harmonics.

**Three-phase Open  $\Delta$  or V Connection (Fig. 14).** — This system consists in omitting one transformer from the delta connection, and is used to save expense, particularly in temporary installations or in new installations where the load is not great at first but is expected to increase in time. Thus it

Fig. 14. Three-phase, Open Delta

Fig. 15. Two-phase to Three-phase

purchase and installation of the third transformer is postponed until the load requires it. This connection can only be recommended for low voltages, such as 2,300, as it is liable to produce dangerous potentials due to electrostatic unbalancing. The regulation and efficiency are also poor, as one phase of the load receives its power from two transformers in series. The aggregate capacity of the two transformers should be 15 per cent greater than the load.

**Two-phase to Three-phase Transformation (Fig. 15).** — The Scott or T connection, the standard method of transforming from two-phase to three phase, consists of two transformers which on the two-phase side may be connected in the normal two-phase manner either independently or interlinked. On the three-phase side one transformer has a tap at the middle point of the other a tap giving 87 per cent of full-transformer voltage. Fig. 15 shows the method of connecting and the currents in primary and secondary with balanced loads. Since the total power is  $3 E_2 I_2 = \sqrt{3} E_1 I_1$ , it follows that

$$I_2 = \frac{2}{\sqrt{3}} \frac{E_1}{E_2} I_1, \text{ or the three-phase current is 16 per cent greater than it would be}$$

for straight single- or two-phase transformation. Thus one of the windings of one transformer must carry 16 per cent more than its share of the volt-amperes of the load and is overloaded in that proportion.

In commercial practice it is customary for the sake of interchangeability to make the capacity of both transformers 16 per cent greater than the load, and to put both a 50 per cent and 87 per cent tap on both transformers. For this connection of transformers each half of the main transformer winding must be distributed over both legs of the core in order to prevent flux (and therefore voltage) unbalancing. If this precaution is taken both the primary and secondary voltages are balanced if the load is balanced. Any unbalancing of the secondary causes a like amount of unbalancing on the primary; thus if this connection is used to transform from 3-phase to 2-phase and all the load comes on one phase of the secondary it will also come on one phase of the primary.

## Transformers

**Transformer Connection for Synchronous Converters.**—For a transformer converter the connections are simple as shown under *Converters*. For a base converter there is a choice between  $\Delta$  or  $Y$  secondaries, which is decided in deference to the conditions in the high-tension line. The delta connection is customary in railway substations. A diagram of the connections is given in the article on *Converters, Synchronous*. When the converter is to supply a three-wire d.c. lighting system, the "distributed"  $Y$  connection for the secondary should be used as shown in Fig. 16. By this arrangement the unbalanced current from the d.c. neutral is divided, and sent through the two

Fig. 16. Distributed  $Y$  for  $T$  Converter

alves of each transformer in opposite directions. Thus it does not increase the magnetic densities in the transformers, and avoids the excessive core-loss which would occur with a  $\Delta$  connection.

For six-phase converters there is the choice between the "diametrical double delta" connections as shown in Figs. 17 and 18. The diam-

Fig. 17. Six-phase Diametrical

Fig. 18. Six-phase Delta

etrical is not needed to prevent an unstable neutral.

For regulating pole or split-pole converters certain special conditions come in mind in choosing between the diametrical and the double delta connections. With the variation of the direct voltage of the converter the shape of the alternating e.m.f. is distorted and this introduces harmonics in the counter e.m.f. or current waves, among which the third is prominent. If the delta connection is used a local harmonic current circulates in the converter armature and transformer secondaries, which increases losses and heating and lowers the efficiency. If the diametrical connection is used the higher harmonic voltage gives an unstable neutral, and in the case of a  $Y$ -connected secondary this may be obviated by grounding the neutral, but then a considerable current may flow in the neutral connection, which may interfere with the operation of the converter. The best solution is to use the diametrical connection in the secondary and ungrounded  $Y$  in primary, and use transformers having a good safety in the insulation of the high-tension side.

**THREE-PHASE TRANSFORMERS.**—Considerable space, with the lowest cost may be saved by the use of a three-phase transformer instead of three single-phase transformers. This saving is warranted in large installations but not in small installations where the convenience of having one interchangeable single-phase transformer as a spare for several banks of three transformers is an important item.

**Core of Three-Phase Transformer.**— Three-phase transformers may be of the core type as shown in Fig. 1, in which case all the magnetic paths are of the same cross-section, or of the shell type shown in Fig. 2. In the latter type the horizontal cross pieces and outside vertical pieces may have one-half the cross-section of the central vertical core, providing the coil on the central leg is connected with a definite polarity with respect to the other two coils in order to have the fluxes differ in phase by 60 degrees.

**Operation of Damaged Three-phase Transformer.**— In a shell-type three-phase transformer if the primary and secondary are delta-connected it is possible to operate with only two phases in open delta at reduced capacity in case of trouble in the third phase of the system. This is accomplished by separating the third phase entirely from the system and short-circuiting both the primary and secondary windings.

**DESIGN.**— (See also section below on *Cooling of Transformers*.) The methods of design for single-phase and polyphase transformers are similar, the chief difference being that of the magnetic circuit. In the design of polyphase transformers each leg is treated as an independent single-phase transformer. The number of turns is adjusted to the voltage per phase and the cross-section of the conductors to the current per phase. All legs are wound alike and the phases are connected up as described in the preceding section.

The alternating-current transformer is the most efficient piece of electrical apparatus. Its efficiency at full load is usually better than 95 per cent, and frequently better than 98 per cent. For this reason it is very small in volume and light in weight for a given output compared to other pieces of electrical apparatus and hence the chief difficulty in design is the necessity of providing sufficient surface and a proper means to carry off the heat developed.

The difference in mechanical construction between the core and shell types is that the winding of the core type usually consists of two or more long spaces (in which the length is considerably greater than the diameter) surrounding each leg of the transformer. The shell type consists usually of large flat "pancake" coils, laid alongside of each other on the central core with proper separating devices to permit ventilation. See Figs. 1 and 2.

The following discussion applies alike to both core and shell types except where specific mention to one or the other is made.

#### Preliminary Calculation of Main Dimensions. — Let

$E_1$  = primary voltage, effective value;

$I_1$  = primary full-load current, effective value;

$E_2$  = secondary voltage, effective value;

$I_2$  = secondary full-load current, effective value;

$f$  = frequency in cycles per second;

$S_1$  = number of primary turns;

$S_2$  = number of secondary turns;

$\phi$  = maximum value of flux;

$C = \frac{\phi}{S_1 I_1}$  = ratio of total flux to full-load primary ampere-turns;

$e$  = volts per turn, effective value;

$B$  = maximum value of magnetic flux density in lines per square inch;

$A$  = cross-section of core in square inches;

$f_1$  = space factor of winding space;

$D$  = total section of copper in square inches;

$U$  = current density in amperes per square inch;

$\sigma$  = ampere-conductors per inch length of core.

determination of Flux ( $\phi$ ) and Number of Primary Turns ( $S_1$ ).— estimate a desirable value of the flux to be used there is employed which is defined by the relation

$$C = \frac{\phi}{S_1 I_1} \quad (1)$$

value of this factor  $C$  depends upon the type, capacity and voltage transformer, and the relative weights of copper and iron.\* Usual values are given in the accompanying table.

VALUES OF  $C$ 

Type of transformer	Voltage	Core type	Shell type
		Value of $C$	Value of $C$
Dry-cooled...	0-6000	55-70	500-700
	6000 up	70-75	500-700
	0-10,000	75-100	
Water-cooled...	10,000 up	100-150	
	0-10,000	110-160	600-1000
	10,000 up	160-240	600-1000

relation between the effective value of the primary voltage and the value of the flux is

$$E_1 = 4.44 f S_1 \phi \times 10^{-8} \quad (2)$$

From equations (1) and (2) the proper values of the primary voltage, frequency  $f$ , the constant  $C$  and the primary full-load current  $I_1$ , and from equations for  $\phi$  and  $S_1$ , reasonable values for the flux  $\phi$  and primary turns  $S_1$  are obtained.

In a preliminary estimation of the full-load primary current  $I_1$  it is sufficient to ignore the efficiency and power factor and to take the current output divided by primary voltage.

Flux per Turn ( $e$ ).— The above value of  $\phi$  should be checked by its value per turn,

$$e = 4.44 f \phi \times 10^{-8}$$

Compare with values used in practice. In large transformers a greater number of turns is permissible than in smaller. The accompanying table for dry transformers is based on the use of double-cotton-covered wire insulation. With special insulation other values may be used. For the shell type transformers as great are customary.

Number of Secondary Turns ( $S_2$ ).— In a preliminary way the number of secondary turns, the number of turns in

$S_2 = \frac{E_2}{E_1} S_1$ . It will considerably

depend upon the mechanical arrangement of the coils if the primary has 4 or 5 turns. The nearest multiple of 4 is the value of  $S_2$  and then  $S_1$  and  $\phi$  correspond to this value of  $S_2$ .

Kilowatt rating of transformer	Allowable volts per turn for core type
10	2.5
20	3.5
50	5.5
100	7
200	9
500	13
1000	18

The value of this factor  $C$  will be found in Arnold's *Transformers* and in S. P. *Practical Electric Machinery*, Vol. II.

**Cross-section of Core ( $A$ ) and Magnetic Flux Density ( $B$ ).**—The cross-section is determined by the magnetic density which it is desirable to use, which in turn is determined by the core-loss. It is found that in average practice, loss of one watt per pound of iron can be dissipated without excessive rise of temperature. The corresponding flux densities in iron having a thickness of 14 mils are given in the following table. These values are approximate, since the quality of the steel used is exceedingly variable. It should also be noted for a transformer intended for supplying a load of low power factor that the iron loss should be less than 1 watt per pound for the best distribution of material.

VALUES OF FLUX DENSITY

Size of transformer	Kind of steel	Lines per sq. in.	
		25 cycles	60 cycles
Small	Ordinary transformer sheet	50,000	40,000
Small	Special; silicon-steel	70,000	60,000
Large	Ordinary transformer sheet	75,000	65,000
Large	Special; silicon-steel	90,000	75,000

The proper cross-section of core in square inches is then

$$A = \frac{\phi}{B}$$

In the core type this cross-section may be assumed as a square whose side is  $d$ . Since the core is made up of laminations whose effective length one way is  $0.9d$ , the value of  $d$  is

$$d = \sqrt{\frac{A}{0.9}}$$

In the shell type this cross-section is a rectangle whose length is from 2 to 3 times its width.

Fig. 19. Dimensions, Core Type

Fig. 20. Dimensions, Shell Type

**Dimensions of Winding Space (Figs. 19 and 20).**—The area or cross-section of the "window" or winding space depends upon the amount of copper

sulation and ventilating space. The first can be determined accurately by the chosen current density in the copper. The second and third are allowed for by a space factor ( $f_1$ ) which gives the ratio of the actual total cross-section of copper ( $D$ ) to the cross-section of the window. Usual values of  $f_1$  are given in the following table.

SPACE FACTOR IN TRANSFORMERS ( $f_1$ )

Size of transformer, Kw.	Core type		Shell type		
	Up to 10,000 volts	33,000 volts	Up to 2000 volts	2000 to 10,000 volts	33,000 volts
0-50	0.22	0.15	....	....	....
50-1000	0.33	0.25	0.40	0.33	0.18
Above 1000	0.38	0.33	0.45	0.36	0.21

In the core type there is one window and it contains  $S_1I_1 + S_2I_2$  ampere conductors; in the shell type there are two windows and each contains  $S_1I_1 + S_2I_2$  ampere conductors. The cross-section of copper in one window in either case is

$$D = \frac{S_1I_1 + S_2I_2}{U} = \frac{a S_1I_1}{U}$$

where  $U$ , the current density in amperes per square inch, has the following values:

Condition of transformer	$U$ - amperes per sq. in.
Poorly cooled .....	850-1200
Ordinary oil cooled, air blast, etc. ....	1100-1600
Large, well cooled .....	1500-1900

Then the height  $h$  and width  $a$  of the window, see Figs. 19 and 20, must be such that

$$ha = \frac{D}{f_1}$$

**Height of Core.** — In the core type this depends upon the ampere-turns of ampere-conductors per inch length of core, which in turn is related to the heating. The ampere conductors per inch length of core is

$$\sigma = \frac{S_1I_1 + S_2I_2}{2h} = \frac{S_1I_1}{h}$$

where  $h$  is the height of core.

For a maximum rise in temperature of 50° C.  $\sigma$  will have values as given in the accompanying table. A reasonable value of  $h$  can then be found.

Form of transformer	$\sigma$ = amp. conductors per inch of core
Natural cooled.....	500-750
Oil cooled or air blast.....	750-1250
Water cooled.....	1250-2000

In the shell-type transformer the practice is to make the height ( $h$ ) for 1.5 to 3 times the width of window ( $a$ ) and the width of window from 0.75 to 1.25 times the width of the central iron core, as in Fig. 20. See also paragraph above on *Cross-section of Core*.

#### Details of the Winding. —

Cross-section of primary conductor in square inches =  $\frac{I_1}{U}$ .

Cross-section of secondary conductor in square inches =  $\frac{I_2}{U}$ .

For minimum loss the copper density should be the same in both members but to save space the copper density in the high-potential winding is sometimes greater than that in the low-potential winding.

The low-potential winding is usually placed between the high-potential winding and the iron.

Each coil is now laid out in detail, placing as many turns in a layer as the height and insulation will allow. The voltage per layer must not exceed 150 to 200 volts. A space of 10 mils is to be allowed for insulation between layers when insulated wire is used and 8 mils when insulated strip is used. The space between coils is from 0.04 to 0.30 inch, depending upon the voltage per coil. Space for the air or oil ducts is also provided. Each duct is from  $\frac{1}{4}$  to  $\frac{3}{8}$  inch wide and there should be one on each side of each coil. No part of the winding should be more than  $\frac{3}{8}$  inch from the surface of a duct.

**Insulation of Windings.**— The insulation of each turn usually consists of the cotton covering if the coils are wound with wire, or mica paper if the coils are wound with strip copper. This is proportioned to withstand the potential between turns as given above. The voltage between conductors on adjacent layers may be equal to twice the voltage per layer. To prevent breaking down between layers, a layer of Fuller board is used as a separator and this should project beyond the windings at the ends to prevent creepage. The maximum voltage between layers should be kept below 400 and to accomplish this it is customary to limit the voltage per coil to about 5000 volts. Between the windings and the core a layer of pressboard and sometimes wood is placed while between primary and secondary windings a layer of pressboard or micaite may be used. For very high voltages the end turns of the high-tension winding for about 75 feet from the terminals is given a special insulation to withstand the sudden high potentials which occur when there is a sudden change in the potential applied to the transformer. These high potentials result from the distributed capacity of the transformer, between the high-tension winding and the core, frame and other winding.

**Terminal Bushings.**— At the point where the high potential leads pass through the case there is a very great dielectric stress which must be taken care of by the use of a proper kind of insulation and a proper disposition of the

to prevent a concentration of the dielectric flux at a few points. For low voltages a porcelain bushing is customarily used. For high voltages it is necessary to supply a large creepage distance and to immerse the bushing in oil to prevent corona effect. This is accomplished by the "condenser type," by surrounding the bushing with successive layers of insulation and putting sheets of tinfoil between the layers. This arrangement is equivalent to a series of condensers. By properly increasing the area of the successive layers of tinfoil the drop in potential across the insulation is kept uniform. The whole terminal is inclosed in an oil-filled type. Another form of bushing known as the "oil-filled type" consists of a cylinder of composition insulation which surrounds the lead and is divided into compartments to keep the oil from being distributed, and disks or collars project outward from the outside to increase the creepage distance.

**Coils of Shell Type.** — With the flat coils customarily used in a shell transformer the subdivision of the windings is usually such that there is one coil of the low-potential winding at each end of the winding space. This is to reduce the leakage flux. In order to further reduce the leakage flux all coils may be divided into halves with a ventilating duct between the halves. The space between a primary and secondary coil is then not necessary for the insulation.

**Choice of Core Dimensions.** — After the final details of the windings are settled the cross-section and length of core is finally settled. Sometimes the cross-section of core in the core type is made cruciform instead of square to use more effectively the area inside of circular coils.

#### TERMINATION OF THE PERFORMANCE OF A TRANSFORMER

— From the above calculations a drawing to scale of the transformer is laid out. The next step is to calculate its performance, i.e., to determine the values of the efficiency, regulation and temperature rise. Temperature rise is treated in the following section on the *Cooling of Trans-*

**Final Magnetizing Current ( $I_M$ ).** — The final flux density will probably differ a little from the value assumed earlier in the calculation. The cross-section of the core is usually proportioned to give the same magnetic density in all parts. The length of path in the iron is measured or calculated. If  $H$  (found from the magnetization curve of the iron, see article on *Magnetic Properties of Iron*) is the ampere-turns per inch for the given density the magnetizing current of the transformer will be

$$I_M = \frac{H \times (\text{length path})}{\sqrt{2} S_1}$$

It is desired to allow for the minute air gaps at the joints of the core. Arnold finds that under practical conditions each joint represents an air gap of 0.002 inch. Thus if there are  $n$  joints (usually 4) there should be an amount

$$\frac{0.313 \times 0.002 B n}{\sqrt{2} S_1}$$

— The core-loss consists of hysteresis and eddy losses in the core. These losses have been considerably reduced in recent years

by improvements in the manufacture and quality of the steel (see article *Magnetic Properties of Iron*).

$$\text{Core-loss} = k_1 f V \left( \frac{B}{1000} \right)^{1.6} 10^{-8} + k_2 V \left( f \frac{B}{1000} \right)^2 10^{-8} \text{ watts,}$$

where  $f$  = frequency in cycles per second;

$V$  = volume of iron in cubic inches;

$B$  = magnetic density in lines per square inch;

$t$  = thickness of laminations in inches;

$k_1$  = a constant, ranging from 8 in ordinary transformer steel to 4 in silicon-steel;

$k_2$  = a constant, ranging from 4 in ordinary transformer steel to 1.5 in silicon-steel.

The core-loss may be calculated more easily by the method and curves given in the article on *Magnetic Properties of Iron*.

**Copper Loss.** — The mean length of turn of both primary and secondary windings is obtained from a sketch to scale. The direct-current or ohmic resistance of each member at 60° C. is obtained by substituting the proper values in the formula

$$R = \frac{0.0093 l S}{12,000 a n},$$

where  $l$  = mean length of turn of primary or secondary respectively in inches

$S$  = number of turns in series,

$a$  = cross-section of conductor in square inches,

$n$  = number of conductors or coils in multiple.

To allow for eddy currents caused by the leakage flux, the above resistance is increased by 15 per cent to give the effective resistances  $r_1$  and  $r_2$ . The total copper loss is then  $I_1^2 r_1 + I_2^2 r_2$ .

**Transformer Reactance.** — As explained in the section above on *Transformer Principles*, the leakage of flux between the primary and secondary windings of a transformer causes a component of voltage in each member which is out of phase with the current; if the current lags very much this voltage may have a considerable component opposed to the useful voltage and cause a drop of voltage or poor regulation. It is, therefore, necessary in designing to estimate the amount of this flux and calculate the voltage it would produce. In practice empirical formulæ are usually used, but a logically deduced formula is desirable as it is more easily adapted to unusual cases.

The phase of the current in the secondary coil is nearly opposed to that in the primary and may be assumed to be exactly opposed without any great error. The result as shown in Fig. 21 is that all these ampere-conductors, both primary and secondary, tend to set up a flux in the same direction in the space between the windings and to a lesser degree in the windings themselves. A part of the flux in the intervening space interlinks with the primary turns and another part with the secondary turns. In addition the flux in the windings themselves interlinks with some of the turns. The flux in each part is proportional to the ampere turns producing it and to the permeance of the path. In this case since the path is in air, the permeance is the area divided by the length, where the length is the average length of the flux lines.

Fig. 21. Leakage Flux

the leakage flux passes between the windings and one part closes its path by the iron inside the inner coil and the other part in air outside the outer coil (the core type). The reluctance of the path between the two coils is large compared to that of the other two portions, because the inside path has a high permeability and the outside path has a large cross-section. The reluctance of the path between the coils is therefore accurately (and easily) calculated and constant used to allow for the rest of the path.

In order to calculate the inductance it is necessary to have a cross-section of the windings showing their thickness, length and arrangement, as in Figs. 19 and 20.

Two cases must be considered:

- A) Where there are as many primary coils as secondary coils, and all coils are full size (usual core type).
- B) Where there is a "half" secondary coil at each extremity of the group of windings (the usual arrangement in the shell-type transformers).

**Arnold's Method of Calculating Reactance.** — Arnold calculates the inductance of a single primary coil and its secondary mate or mates, and multiplies by the number of primary coils in series or divides by the number in parallel. This gives the total "short-circuit" inductance of the transformer in terms of the primary voltage or turns.

Referring to Figs. 19 and 20 for the core and the shell type respectively, let various quantities be represented as follows, all dimensions being in inches:

- $q$  = number of primary coils in series,
- $p$  = number of primary coils in parallel,
- $s_1$  = number of turns in one primary coil,
- $s_2$  = number of turns in one whole secondary coil,
- $l_0$  = height of coils in cylinder type,
- $l_s$  = depth of coils in flat type,
- $h_1$  = thickness of a whole primary coil,
- $h_2$  = thickness of a whole secondary coil,
- $t$  = distance between coils,

$U_1$  and  $U_2$  = mean length of primary and secondary turns respectively,

$U_m$  = average of  $U_1$  and  $U_2$ ,

$k$  = an empirical constant, varying from 0.95 with flat coils to 1.06 with cylinder coils.

**Reactance of Core Type (Fig. 19).** — In a core-type transformer with cylindrical coils and an equal number of full-sized primary and secondary coils, permeance of the path of the flux in the duct which interlinks with a primary is  $\frac{tU_1}{2l_0}$  and the permeance of the path in the winding itself is  $\frac{h_1U_1}{3l_0}$ .

Inductance of one primary coil is

$$L_1 = \frac{3.2 k s_1^2 U_1}{l_0} \left( \frac{h_1}{3} + \frac{t}{2} \right) 10^{-9}.$$

Inductance of one secondary coil is

$$L_2 = \frac{3.2 k s_2^2 U_2}{l_0} \left( \frac{h_2}{3} + \frac{t}{2} \right) 10^{-9}.$$

Reducing the latter to terms of the primary turns by multiplying by  $\frac{s_1^2}{s_2^2}$ , adding together and multiplying by  $2\pi f$ , the total reactance of the transformer in terms of the primary is

$$X = 2\pi f \frac{3.2 q k s_1^2 U_m}{p l_0} \left( \frac{h_1 + h_2}{3} + t \right) 10^{-9}.$$

**Reactance of Shell Type.** — If, as in the in Fig. 20), there is a half secondary coil at each end, then

$$X = 2\pi f \frac{3.2 q k n^2 U_m}{2 \mu l_2} \left( \frac{l_1 + l_2}{6} + l_2 \right)$$

**Efficiency and Regulation.** — The efficiency is calculated as described above under "Equivalent" Circuit or by the following method, which is sufficiently accurate for all purposes.

Let

$E_2$  = secondary terminal voltage,

$I_2$  = secondary current,

$\cos \theta_2$  = power factor of load on secondary,

$P_2 = E_2 I_2 \cos \theta_2$  = secondary output in watts,

$A$  = core-loss in watts = input for no-load on secondary,

$n$  = ratio of number of primary to number of secondary,

$R_2 = \frac{r_1}{n^2} + r_2$  = total resistance in terms of secondary  
actual resistances of primary and secondary,

$X_2 = \frac{X}{n^2}$  = total reactance in terms of secondary  
reactance in terms of primary.

Then the per cent efficiency is

$$\eta = \frac{100 P_2}{P_2 + A + R_2 I_2^2}$$

Secondary voltage at no load is

$$E_{20} = \sqrt{(E_1 \cos \theta_2 + R_2 I_2)^2 + (E_2 \sin \theta_2)^2}$$

and the regulation is then

$$\frac{100 (E_{20} - E_2)}{E_2} \text{ per cent.}$$

**All-day Efficiency.** — The all-day efficiency is calculated from the readings of a watt-hour meter connected to the secondary and a similar meter on the primary. It is of importance for transformers, particularly for lighting, operate at full load for a large part of the day, but the core-loss or iron losses are just as great when there is no load at all. Hence these transformers waste a considerable amount of energy, although their efficiency at full load is high.

To calculate the all-day efficiency multiply each reading of the watt-hour meter for efficiency by the number of hours per day that it is used.

$$\text{All-day eff.} = \frac{100 P_2 \times h}{P_2 \times h + h_1 A + h R_2 I_2^2}$$

where  $h$  = hours per day of secondary load;  $h_1$  = hours per day transformer is on line, and the other symbols as above. Since transformers for lighting are on a day and  $P_2$  only 7 or 8 hours, the importance of the transformer for this class of service is apparent.

However, there is another side to the question, since transformers for lighting are on as much during the day when there is little demand as in the evening when the demand is great.

**EXAMPLES OF DESIGN.**— In the following table are given the chief characteristics of four different transformers.

**EXAMPLES OF SINGLE-PHASE TRANSFORMER DESIGN**

American or foreign	Foreign	Foreign	American	American
Core (cooling).....	Oil	Air	Oil	Air
Core.....	Core	Shell	Distributed	Shell

**COOLING OF TRANSFORMERS.**— It is necessary to keep the temperature of the various parts of a transformer within such limits that the materials of which it is constructed do not become damaged and deteriorate rapidly. When subjected to too high a temperature the insulating materials integrate and lose their mechanical and dielectric strength, and the iron deteriorates in its magnetic qualities so that the core-loss becomes greater for a given density. This so-called ageing of the iron may cause an increase of as much as 50 per cent in the loss in the iron. The effect varies with the character of the iron and is practically negligible in silicon-steel.

**Maximum Rise in Temperature.**—The maximum rise in temperature above a room temperature of 25° C. at which the various materials of a transformer should be operated are given in the table.

To guard against this possibility of damage the Standardization Rules of the A.I.E.E. recommend that the windings shall not increase in temperature more than 50° C., as measured by resistance, above the surrounding air, and the other parts shall not increase more than 50° C. as measured by thermometer.

**Means of Dissipating Heat.**—The problem is to provide a path of low thermal resistance by which the heat energy may pass to the surroundings. To accomplish this it is necessary, first, to provide sufficient surface in a subdivided transformer to transfer the heat to the cooling agent, air or oil without too great a difference in temperature; second, to so subdivide a transformer that no part of the iron is more than one inch, and no part of the copper more than  $\frac{3}{8}$  inch, from a cooling surface; third, to provide a sufficient quantity of the cooling agent, air, oil or water to carry away the heat at the same rate as it is generated; and fourth, to provide sufficient surface in the containing case or tank to transfer the heat from the internal oil to the external air without too great a difference in temperature.

**Calculation of Exposed Surface of Transformer.**—The practical method of estimating the rise in temperature consists in calculating the drop in temperature in the successive media through which the heat must pass to be dissipated. The first step is to calculate the exposed surface of the transformer core ducts, coils and coil ducts. In accordance with design practice the surface in the ducts is only rated at half the effectiveness of the outside surface of *Generators, Alternating-current*, and therefore only half the duct surface is included in the figure for "Effective Radiating Surface,  $A_1$ ." Having found a value for  $A_1$  in square inches, the following criteria apply to the respective types.

**Naturally-cooled Transformers** should have from 4.75 to 5.3 square inches of surface ( $A_1$ ) for each watt loss for 50° C. rise in temperature.

**Oil-cooled Transformers.**—(See also *Oil Transformer*.) The transformer is submerged in oil in a tank so that the level of the oil is from 2 to 3 inches above the top of the transformer. The quantity of oil is from 6 to 10 pounds per kv-a. rating, or in small sizes 500 pounds per kilowatt loss. There should be from 1.5 to 2.3 square inches of transformer surface ( $A_1$ ) per watt loss. The oil ducts should be  $\frac{1}{4}$  inch wide and run vertically. If the tank is small there should be from 4 to 8 square inches of tank surface (not including top or bottom) for each watt loss. For sizes greater than 25 kilowatts it is customary to use fluted or corrugated sides to the tank. In this case there should be from 6 to 10 square inches of radiating surface per watt loss, but the air does not circulate as rapidly in the grooves as over a smooth surface and consequently radiation is poor.

For a rise of 50° C. of the transformer there is an average rise of 30° of oil. The maximum rise of the oil is 1.3 to 1.5 times the average.

The rise in temperature of the windings by resistance or of the iron by the thermometer is

$$T = \frac{2W}{A_1} + \frac{1W}{S} + t_0$$

Material	°C
Iron.....	70-75
Cotton.....	60
Paper.....	55
Mica, asbestos.....	50

total watts lost;  
 radiating surface of transformer in square inches;  
 radiating surface of tank in square inches;  
 from 160 to 200 with smooth tanks.  
 20 to 270 with corrugated tanks;  
 maximum difference of temperature in oil, usually 40 to 45° C., depending upon circulation.

**Transformers.** — This type of transformer is usually set over a tank on the floor which is supplied by a blower with air at a pressure of 1/4 to 1 1/4 inches of water). The air enters the transformer at the bottom and is divided into two streams, one passing vertically through the iron and the other transversely through the iron. There is a damper or baffle in the air stream so that the proper amount of air is provided to each part of the transformer. Ducts 1/2 inch wide are provided every 3 to 4 inches. For 50° C. rise the surface of the transformer ( $A_t$ ) should be from 1.5 to 2.3 square inches per watt loss. A liberal amount of air for 50° C. rise is 150 cubic feet per watt loss. The air is expected to rise from 15° to 20° C. in its passage through the transformer. The theoretical quantity of air in cubic feet

$$Q = \frac{1.65W}{T_a}$$

is the rise in temperature of the air, which is usually about half as much as the rise of the transformer.

**Water-cooled Transformers.** — The cooling coils are suspended in the tank near the top, usually above the transformer, and carry a circulating stream of water. It is customary to provide 1/2 gallon of water per minute for each kilowatt of loss and to allow the outgoing water to be 10° above the incoming. Other requirements are from 1 to 1.5 square inches of surface ( $A_t$ ) per watt loss for 50° C. rise and 1 square inch of surface per watt loss. This assumes a temperature drop of 20 to 25° in the cooling water and oil, 2 to 3° between oil and water and 20 to 25° in the transformer.

**SINGLE-PHASE TRANSFORMERS.** — The customary sequence of tests on transformers and the best order of making them are: cold resistance test, ratio and checking of taps, impedance, core-loss and exciting current test, heat run, insulation tests. The efficiency and regulation tests are made from the results of these tests.

Transformers should never be tested or subjected to potential unless they are filled with oil from which all moisture has been removed. The best results are given below.

**Temperature Measurement.** — The cold resistance must be very carefully measured and is used as a basis of calculating the temperature after the transformer has been standing in one place long enough for the windings to have reached the same temperature as the surrounding air. The current of from 10 to 15 per cent of the rated current of the transformer should be run through the windings and the drop measured with a voltmeter. At the same time the temperature of the windings is measured by a thermometer.

**Efficiency Test.** — This test gives information necessary for connecting transformers in a bank and have them operate in parallel or on polyphase. Direct current is sent through one winding of a transformer and a voltmeter connected across the other winding. If the current is

stopped, the voltmeter will give a deflection either positive or negative. For similar connection and direction of current on all the transformers on a bank the deflection should be of the same sign. A small current should be used as otherwise the throw of the voltmeter needle may be sufficient to bend it.

**Ratio of Turns.** — With no load on a transformer the ratio of voltages is the same as the ratio of the turns. Thus, with a known voltage applied to the low-tension winding, the ratio of turns of the two main windings and of the sections between taps can be checked up by connecting across the other terminals another voltmeter of proper range (using a potential transformer if necessary).

**Impedance Test.** — This test is important in order to calculate the regulation and in order to determine whether transformers will run in parallel with each other. One winding of a transformer is short circuited and a voltmeter, ammeter and wattmeter are connected in the circuit of the other winding. A voltage from 1 to 8 per cent of the rated voltage of this winding and of the proper frequency is impressed. The voltage is regulated so that readings are taken at values of current from 50 to 125 per cent of the rated current of the winding. The wattmeter reading will be in the neighborhood of 2 per cent of the rating of the transformer. The total impedance of the transformer will be  $Z = \frac{E}{I}$ . The

total effective resistance will be  $R = \text{Watts}/I^2$ , which will include the effect of eddy currents, and the total reactance will be  $X = \sqrt{Z^2 - R^2}$ . This reactance cannot be separated into primary and secondary reactance. The results of the test are usually plotted in two curves, one between volts and amperes and the other between volts and watts.

**Core-loss and Exciting Current Test.** — The alternator supplying the power for this test should give a sinusoidal e.m.f. wave, as any distortion in the shape may cause a variation of from 5 to 10 per cent in the core-loss. A peaked wave gives a lower core-loss than a sine wave. For this test the high-tension winding is left open and rated voltage at the proper frequency is impressed on the low-tension winding. A voltmeter, ammeter and wattmeter are connected in the low-tension circuit, the voltmeter having a range including the rated voltage of the transformer and the ammeter a range of approximately 15 per cent of the rated current of the machine. Readings are taken with a voltage of from 50 per cent to 125 per cent of the rated voltage of the transformer. Both ampere-volt and watt-volt curves are then plotted. If extreme accuracy is desired, the  $Rf^2$  loss should be subtracted to give true core-loss.

**Separation of Eddy and Hysteresis Losses.** — In certain special cases it is desired to investigate the iron of a transformer by separating the hysteresis from the eddy loss. Let

$W_1$  = the core-loss at normal voltage and frequency.

$W_2$  = the core-loss at half voltage and half frequency.

$W_e$  = eddy-current loss at normal voltage and frequency.

$W_h$  = hysteresis loss at normal voltage and frequency.

Then

$$W_1 = 2W_2 + 4W_e$$

$$W_h = 4W_2 - W_e$$

**Parallel Run Test.** — The test for polarity and ratio having shown nothing wrong in the transformers, they are connected two at a time. The

windings being connected in parallel to a generator and the windings in parallel with each other with an ammeter of about the capacity of the transformer connected in one lead between the voltage of the alternator is gradually increased from zero and the ammeter noted. This current should not be greater than 5 per cent of that winding at rated voltage. If a transformer windings in either member the same test should be made on these parallel.

n.—The heat run is made at the rated load of the transformer at an overload of 25 per cent or 50 per cent, depending on guarantees. The run may be made by connecting the transformer load such as a water rheostat (*q.s.*) but as there are other equally good methods, avoiding the waste of so much energy, this dead load is not used.

The other methods require two or three transformers to be used.

**Transformers "Bucking" (Fig. 22).**—The low-tension windings of the transformers are connected in multiple to a voltage of rated value and the high-tension windings are

so that their e.m.f.'s oppose each other, and are in series with the source of e.m.f., of rated frequency; a value of from 2 to 5 per cent of the rated voltage of the windings. The "loss supply" may be either an alternator, or a potential regulator of this source is adjusted so that current circulates in the windings and thereby induces heat in the low-tension windings. It should be realized that although the current in the rated voltage is 5 per cent of the current through the

each primary is generating its rated voltage and if there should be a dangerous potential strain or shock might result.

**Transformer Arrangement (Fig. 23).**—Three single-phase transformers are connected with their low-tension windings in delta to a three-phase supply of proper voltage.

The high-tension windings are also connected in delta with one corner to which the "loss supply" is connected preferably by an auxiliary transformer. The "loss supply" is adjusted so that the current flows in the primary winding.

**Heat Run.**—The time required for a heat run may be controlled by operating at an overload for a short while, or, if the transformer is a blast transformer, by operating without the blast until a temperature has been attained. Then the proper load is adjusted and the run continued until all temperatures remain practically constant, that is, within 1° C. in two hours. The voltage should be cut off once the resistance measurement quickly made to determine the temperature of the windings.

Fig. 22. Connections for Heat Run by Bucking

Fig. 23. Heat Run by Open-delta Method

Temperature Rise by Resistance is calculated from the formula

$$T = (234.5 + t) \left( \frac{R_h}{R_c} - 1 \right),$$

where  $T$  = temperature rise in ° C.;

$t$  = temperature in ° C., by thermometer, at which the cold resistance is measured;

$R_c$  = resistance in ohms at temperature  $t$ ;

$R_h$  = "hot" resistance in ohms at end of heat run.

The number 234.5 is the reciprocal of the resistivity temperature coefficient (referred to 0° C.), of 100 per cent conductivity copper, i.e., the reciprocal 0.00427. For any other conductivity,  $C$  per cent say, divide 234.5 by  $C$ . (See article on Resistance and Conductance.)

**Temperature Rise by Thermometer.**—In an air-blast transformer is desirable to measure by thermometer the temperature of the incoming and the outgoing air (from iron and coils), of the primary windings, and of the secondary windings. Spirit thermometers and not mercury thermometers should always be used for measuring the temperature of transformer windings.

In an oil-cooled transformer the temperature, by the thermometer, of the tank at top and bottom and of the oil in two or three places near the top should be taken.

**Insulation Tests.**—To test the insulation between turns and sections of coil double the rated voltage per section is impressed on each section for one minute. This test should be made at a high frequency, preferably at double the rated frequency. After this one and a half times normal voltage at rated frequency is applied for five minutes, to discover the effects of the double voltage test. These voltages should be applied and removed gradually.

**High-potential Test on Complete Transformer.**—To test the electric strength of the insulation as a whole the following high-potential test is made. Connect both terminals of the high-tension winding to one terminal of the high-potential transformer. Ground both ends of the secondary winding to the core and frame and connect to the other terminal of the high-potential transformer. Adjust a needle gap to arc at the desired test voltage and increase the voltage gradually until the gap arcs over. Decrease the voltage till the arcing ceases and hold the voltage as near as possible to the arcing point for one minute. The voltage should then be decreased gradually. The proper test voltages and spark-gap adjustments are given in the Standardization Rules of the A.I.E.E. (q.v.).

**Calculation of Efficiency and Regulation from Test.**—From the results of the preceding tests the efficiency and regulation of the transformer at various loads may be calculated by the methods given above, p. 1623 in the paragraph on *Efficiency and Regulation*, using the test data instead of the calculated quantities.

**TESTING OF THREE-PHASE TRANSFORMERS.**—In testing three-phase transformers the same methods are followed as with single-phase units. The only difference is in testing for polarity; owing to the mixing of the magnetic circuits special care must be exercised. The direct current must be sent in one direction through one primary phase and in the opposite direction through the other two, so that they will not neutralize one another. With a voltmeter similarly connected on the primary and secondary of each phase in turn, break up the direct current; if the connections are right the voltmeter on the secondary will deflect in the same direction as the steady deflection on the primary.

**Performance and Tests.** — (*See Standards*) Temperature rises upon which ratings are to be based. Efficiency at 25, 50, 75, 100, and 150 per cent transformation ratio. High-potential tests of insulation. Guarding effect of moisture and heat on insulation. Transformers shall contain no material which will be affected by moisture or by an occasional temperature of 95° C. Temperature is not maintained at any one time for a period of 24 hours. Transformers shall be capable of operating continuously with insulation being damaged thereby. Regulation of voltage. Regulation with load of rated kilovolt-amperes at 100 per cent and 90 per cent. State formula for regulation calculated. Reactance between primary bus and secondary. Transformers are to operate compound-wound or series-wound. Required reactance is usually specified by the manufacturer. (See converter.) Amount of air or water for cooling, and stated pressure. After the transformer has been tested, efficiency at full load shall be not lower than the guaranteed amount more than a stated percentage and after two years shall be not lower than the guaranteed amount by not more than 1 per cent.

#### INSTALLATION OF TRANSFORMERS

shall be on special foundations but merely a level floor of concrete of sufficient weight. Provision should be made for an electrical connection of the transformer to the ground.

**Oil- and Water-cooled Transformers.** — The operation of transformers in general, and high-voltage transformers in particular, is moisture, in that 0.1 per cent of moisture is sufficient for use. This may result either from rain or dripping water on the transformer or onto some of the parts, or from the condensation of moisture in the atmosphere on the various parts. For this reason transformers must be very carefully inspected, cleaned and dried before being put into service. If the operating potential is 15,000 volts, it will tell whether the transformer should be dried. For potentials above 15,000 the drying operation should be carried out in a special chamber.

**Methods of Drying.** — The best method is to pass a stream of dry air at 90° C. through and around the transformer for 24 hours in all transformers, for 72 hours in transformers of reasonable capacity and longer in special cases. The best drying is to short-circuit one winding of the transformer to the other member a voltage of from 1 to 2 per cent of the rated voltage winding so that a current of from  $\frac{1}{2}$  to  $\frac{3}{4}$  of the rated current of the winding. This current should be adjusted so that the temperature on the low-tension coils shows a temperature of 90° C.

**Preparation of Oil.** — No potential should be used on a water-cooled transformer unless it is supplied with a special oil. Oil forms the essential insulating medium as well as a cooling medium. It should be tested before using. Oil is considered good if it can withstand 40,000 volts between disks  $\frac{1}{2}$  inch in diameter. Transformers for 40,000 volts or less will operate satisfactorily if the dielectric strength has dropped to 25,000 volts, but if it has reached the oil should be dried, purified and retested. Oil of a voltage greater than 40,000 should not be used without special tests. 35,000 volts in the above described test apparatus.

purifying the oil is on the market (see *G. E. Bulletin No. 4134*). See *Oil, Transformer*.

Former tanks should be filled by pouring the oil through a fine-cloth allowing the oil to settle 12 hours before using. Rubber tubing used for carrying the oil as the sulphur in the rubber will eventually. The cover of the transformer should prevent any water dripping from the transformer but there should be a free exit allowed for gases which may be absorbed in the transformer stands in a moist atmosphere a special "breather" containing calcium chloride should be employed. In all transformers the level of oil should be well above the top of the transformer proper and this should be checked 3 days after the original filling to see whether the transformer has absorbed sufficient of the oil to lower the level a dangerous

of all sizes of oil-cooled transformers are designed to be suspended on poles or the sides of buildings or to be installed in manholes. These transformers are especially protected against the weather.

**Protection Against Overheating.**—It is most important to be sure of proper circulation of the cooling medium as the temperature of the oil will rise quickly to an excessive value in case of a failure of the fan. In this case the load must be reduced and kept at such a level that the temperature of the oil at the top does not exceed 80° C. If at any time the oil reaches an excessive temperature there will be a tendency for carbon to form on the transformer and coils, which will interfere with the proper operation.

An inspection should be made occasionally for this purpose and the oil removed. The oil should be sampled and tested each week and every six months thereafter. In taking samples of the oil care should be exercised that the vessel in which the sample is collected is thoroughly dried. The temperature of the oil in a self-cooled transformer should not exceed 80° C. and in a water-cooled transformer 65° C. Oil-cooled transformers should be in a well-ventilated compartment in which the air should be at least 5° above the outside atmosphere. An inspection should be made from time to time to see that there is no condensation on the inside walls.

**Operation for Multiple Operation.**—Transformers should never be connected in multiple on both the primary and secondary sides unless it is proved that the polarity is correct and that the ratio and regulation of the two transformers are the same.

**Transformers; Ducts and Blower Set.**—Air-blast transformers should be provided with a cover over an air duct of sufficient size to permit the required current to pass at a velocity of less than 500 feet per minute. The duct should be made of non-combustible material and should have smooth sides in order to offer no resistance to the current of air. Air is supplied to this duct by means of blowers of capacity to supply the proper quantity of air for a transformer at pressures from  $\frac{1}{2}$  to  $1\frac{1}{2}$  ounces (see *Blowers and Compressors*). Roughly the rating of the blower motor in horse-power is

$$\frac{\text{cubic feet of air per minute} \times (\text{pressure in ounces})}{1700}$$

1700

The air from the transformer at the bottom, flows vertically through the coils and out at the top, and also flows transversely through the iron, passing through the iron. Separate dampers at each outlet are provided in order to regulate the currents independently. The dampers are regulated so that the air is at a temperature 20° above the incoming air.

Since the transformers are so dependent on the air blast for their operation and safety, it is customary to provide a reserve blower set.

**Location.** — Care must be exercised to protect the transformers from moisture and dirt and particularly, since they are open at the top, to place them where water and dirt cannot drop in the open top. All terminals of the blast type of transformer are usually brought out below so that the primary and secondary cables may be laid in the air duct and all connections and inspection may be made from below. It is therefore desirable that the air duct be sufficiently large to enable a man to move about therein.

**Drying and Cleaning.** — In putting the transformer in operation, moisture must be removed before applying potential. This may be accomplished by running the blower set and forcing air through the transformer, which will be sufficient if the air is dry. Another method is to short-circuit one winding of the transformer and apply a low voltage of from 1 to 2 per cent of the rated voltage to the other winding, so that 75 per cent of full-load current flows through the windings. This is maintained for from 24 to 36 hours. Transformers of this type should be cleaned once a month by means of compressed air at 20 pounds pressure.

**Measurement of Temperature.** — In determining the temperature of the windings only that calculated from a resistance measurement is dependable, as the coils are so thickly wrapped in insulation that a thermometer does not show the true temperature.

**OPERATION OF TRANSFORMERS.** — Single-phase transformers may be used singly or in parallel on single-phase circuits, and in various combinations on polyphase circuits as described above. The polarity should be determined before making the connections.

**Parallel Operation on Single-phase Circuits.** — Single-phase transformers are very generally operated with the primaries in parallel on the supply circuit and their secondaries in parallel on the load circuit. In order to successfully operate in this manner two or more transformers, the transformers must have (1) the same ratio of transformation; (2) the same regulation; and (3) the same value of  $X/R$ , where  $R$  and  $X$  are the total resistance and reactance respectively of any one of the transformers. Transformers divide the load inversely proportional to their reactances, provided the ratio of reactance to resistance is the same in both cases. If transformers are purchased to operate in parallel with others, proper provision must be made in the design of the transformers, and this fact should be stated in the specifications.

In general, a 50-kilowatt transformer will have about twice the resistance and twice the reactance of a 100-kilowatt transformer of the same commercial line, and therefore these transformers will divide the load in proportion to their capacity. But this is not likely to be true of transformers of different lines made at widely different times.

If transformers not satisfying the above conditions are to be run in parallel, an impedance coil having a proper resistance and reactance may be connected in the circuit of one of them, thus establishing the necessary conditions for proper distribution of load, provided the ratios of transformation are the same.

**Transformers on Polyphase Circuits.** — See section above on *Transformer Connections*.

**WEIGHTS AND COSTS (Pre-war prices).** — The curves of Figs. 26 to 29 inclusive give approximate values of the weights and costs of several representative lines of single-phase transformers of the most usual common capacities, voltages and frequencies. These values are sufficiently accurate to be used

preliminary estimates, plans, theses, etc. The actual price of copper, commercial conditions and special requirements are from 40 to 50 per cent above those given by the tables.

The weight given is that of the transformer core and windings, but does not include the boxing for shipping or other accessories.

The cost is given in the form of dollars per kv.-a. of the lighting transformers of Fig. 26 this cost could be obtained in continuous operation with a temperature of 50° C. The transformers of Fig. 26 are rated on the basis of the characteristics of a lighting transformer of a maximum rise in temperature of 50° C. The prices include the cost of the oil.

The cost per kv.-a. and weight per kv.-a. of the transformers are roughly 90 per cent of the cost and weight per kv.-a. of the transformers having a combined capacity equal to that of the transformers shown.

The voltage of the secondary may vary in all cases without appreciably affecting the cost or weight given.

**FORMERS, INSTRUMENT.**—(See also *Transformers.*) Instrument transformers are either potential transformers or current transformers. Potential transformers are transformers of comparatively small size connected for shunt connection to the primary lines, designed to produce a voltage which represents the primary voltage with sufficient accuracy for use on instruments. Current transformers are transformers of comparatively small output arranged for series connection in the primary lines, and produce a secondary current which represents the primary current with sufficient accuracy for application to instruments. The insulation of both potential and current transformers is designed with reference to the voltage of the circuit on which the transformer is to be used. The most common voltage for the secondary of the potential transformer is 115 volts. The maximum current for secondary full load on the current transformer is 5 amperes. The secondary voltage of the current transformer is usually very low under normal operating conditions, being only sufficient to force the secondary current through a few instruments of low impedance.

**APPLICATIONS.**—Instrument transformers are used for three principal purposes: (1) to supply current and voltage to measuring apparatus; (2) to regulate circuit devices; (3) to operate circuit protective devices. In each case two principal advantages to be attained by the use of transformers are: (1) to protect the devices in the secondary circuit against the danger of a direct application of the primary voltage or current; (2) the use of measuring, regulating and protective devices designed to operate over the entire range of currents and voltages under various operating conditions, thus simplifying design and increasing reliability and accuracy and lowering cost.

**Accuracy and Reliability Required.**—Of the three applications given above, the use of transformers for measuring instruments, requires the highest accuracy in operation; in the operation of regulating devices the certainty of operation is more important; in the operation of circuit protective devices a moderate degree of accuracy is satisfactory, but certainty of operation is of the highest importance. It is, therefore, frequently desirable to use instrument transformers for the several purposes, even where convenience would suggest the use of a single transformer.

**DEFINITION OF CURRENT TRANSFORMER.**—The current transformer consists of a primary winding in which the line current flows, a magnetic circuit, and a secondary winding for connection to a load of instruments and other devices connected in series. The current flowing in the primary is usually determined by the characteristics of the transformer or by the amount of secondary current. If the secondary winding is short-circuited, the secondary current is equal to the primary ampere-turns, the slight difference being due to the magnetizing current. This exciting current is always of low power factor, while the secondary current depends on the resistance and inductance of the secondary circuit. While the reversed secondary ampere-turns are equal to the primary ampere-turns less the exciting ampere-turns, the secondary current is not usually arithmetical but vectorial. The secondary ampere-turns are less than and not in exact proportion to the primary ampere-turns. This is expressed by stating that the current ratio varies from the ratio of turns, and that there is a phase difference between the primary and reversed secondary currents. Since the secondary current depends on the relative amount of the exciting current and its phase with respect to the secondary current, they will vary with the imped-

ance of the secondary load and the current flowing in the secondary load impedance increases, the voltage across the secondary winding consequently the flux density in the magnetic circuit, grows larger. When the impedance becomes so great that the transformer magnetic circuit approaches saturation, the exciting current becomes so large that the secondary current is no longer proportional to the primary current and also differs from it appreciably both in wave form and phase position.

**Ratio and Phase Angle.**— For accurate comparison of a current transformer the exact ratio of the primary to secondary currents must be known. For power measurements the phase angle between the currents must also be accurately known. Refer to

$u$  = ratio of the number of secondary to the number of primary turns,

$I_p$  = primary current,

$I_s$  = secondary current,

$k$  = ratio of exciting current (referred to secondary current) to primary current,

$\alpha$  = phase angle between the exciting current and the secondary current,

$\theta$  = phase angle between the secondary current and the primary current (positive for lagging current).

$\beta$  = the "phase angle" of the transformer, i.e., the angle between the primary current and the secondary current reversed. If the secondary impedance load is higher than the primary impedance load, the secondary current (reversed) leads the primary current; if the power factor of the secondary is lower than that of the primary, the secondary current lags behind the primary current and  $\beta$  is negative.

Then the ratio of transformation is

$$\frac{I_p}{I_s} = u \sqrt{(\cos \theta + k \cos \alpha)^2 + (\sin \theta + k \sin \alpha)^2}$$

and the phase angle is

$$\beta = \tan^{-1} \frac{k \sin (\alpha - \theta)}{1 + k \cos (\alpha - \theta)}$$

The value of the ratio  $k$  for a given primary current and secondary current depends on the impedance of the load connected to the secondary; the greater the value of  $k$  and therefore increasing the secondary current, the greater the difference between the true ratio of the primary and secondary currents and the ratio of the secondary current to the primary current.

The true ratio  $\frac{I_p}{I_s}$  and the phase angle  $\beta$  also depend on the load.

In order to use these formulas for numerical comparison of a current transformer the amount and power factor of the exciting current and the conditions of load. Since this is difficult to predict, curves similar to Figs. 2 to 5 below, obtained by

**THEORY OF POTENTIAL TRANSFORMER**  
The theory of a potential transformer consists of a primary winding, a magnetic circuit,

winding is placed across the line, and the secondary winding is connected to instruments or other devices connected in multiple. The voltage primary is usually unaffected by the characteristics of the transformer secondary load. With the secondary open the secondary voltage is approximately equal to the primary impressed voltage divided by the number of turns in the primary to the number of turns in the secondary, the difference being due to the impedance drop produced in the exciting current. The impedance drop in the primary due

Current Transformer No. 1

Fig. 3. Phase Angle

Current Transformer No. 2

Fig. 5. Phase Angle

usually not in phase with the primary voltage; hence its relation from the primary voltage results both in a variation from the ratio of turns and in a difference of phase and reversed secondary voltages. This no-load ratio and error under load is due to the additional impedance of the primary and secondary windings and to the load impedance of the secondary. The drop in the secondary will be the current times the impedance of the secondary windings. Therefore the secondary voltage drops in these windings will be the actual secondary voltage and the impedance drop may be in almost any phase, whereas the drop due to the primary is a constant relation to the induced voltage, the phase angle and power factors may be either less than or greater than

Fig. 6

angle. — For accurate voltage measurements by means of the exact ratio of the primary to the secondary

terminal voltages must be known. For power meters the ratio between the two voltages must also be accurately known.

The relations of the quantities involved are shown in Fig. 6.

$$\text{Ratio} = \frac{E_p}{E_s} = u \left[ 1 + \frac{IR \cos \theta + IX \sin \theta}{uE_s} + \frac{I_0^2 R_p}{u^2 E_s} \right]$$

$$\text{Phase angle in minutes} = \frac{3438}{E_p} [IR \sin \theta - IX \cos \theta + I_0 X_p]$$

Where  $u$  = ratio of the primary to the secondary turns;  
 $R, X$  and  $Z$  = equivalent resistance, reactance and impedance of the transformer, respectively

$R_p, X_p$  and  $Z_p$  = resistance, reactance and impedance of the primary winding;

$E_p$  = primary impressed voltage;

$E_s$  = secondary terminal voltage;

$E$  = secondary induced voltage;

$I_s$  = secondary current;

$I = \frac{I_s}{u}$  = load current in the primary;

$I_0$  = exciting current.

It is assumed that,

$$\frac{R_p}{R} = \frac{X_p}{X}$$

because the reactance of the primary and secondary windings are directly determined. The third term in the expression in brackets, is very small and can be omitted with little error.

variations in the true ratio  $\frac{E_p}{E_s}$  with the power factor of the load on the secondary, see Figs. 7 and 9.

The phase angle  $\phi$  of a potential transformer, between the primary terminal voltage and the secondary terminal voltage, range from a positive angle (secondary voltage lags primary voltage) to a considerable negative angle (secondary voltage leads primary voltage), depending on the exciting current, power factor of the secondary load and the impedance of the transformer. At no-load condition this angle is nearly always negative (secondary voltage leads primary voltage) where the exciting current is large and of very low power factor. The general tendency of non-inductive secondary loads to vary in the positive direction (secondary voltage to lag primary voltage) leads to cause it to vary in the negative direction (secondary voltage to lead). It is frequently possible to bring  $\phi$  practically zero by varying the primary voltage and load by adding a non-inductive load. See Figs. 8 and 10 for actual variations in the phase angle between the primary terminal voltage and the secondary terminal voltage factor and volt-amperes of the load on the secondary.

**DESIGN.**—The general principles of design of potential transformers are the same as for distribution or power transformers. For instrument transformers, however, change the details of design to suit the degree of accuracy required.

**Design of Current Transformers.**—A very important factor in the design of current transformers is the

the operation of protective devices. When so used the failure transformer may cause destruction of expensive apparatus, and is designed to stand a higher insulation test than other types.

Again, the exciting current of the current transformer has the phase angle and errors of ratio. The flux density in the core is therefore kept very low for the ordinary metering conditions, errors within satisfactory limits. The resistance and leakage reactance of the primary winding do not affect the ratio of the transformer nor the relation between primary and secondary currents; their only effect is a voltage drop in the primary line. Resistance and leakage reactance

Fig. 8. Phase Angle

Potential Transformer No. 1

Fig. 10. Phase Angle

Potential Transformer No. 2

leakage between primary and secondary, constitute definite secondary load, and affect the phase angle and ratio of the current rating of a current transformer is always greater than continuous current to be carried by the lines of which it is a part. Overload capacity is required.

Therefore, current transformers, therefore, should include:

1. Adequate safety margin in insulation,

2. Adequate safety margin under the conditions of metering service (this is best satisfied by a moderate cross-section of magnetic circuit with a relatively large number of turns),

3. Adequate safety margin in leakage reactance in the secondary winding,

4. Adequate safety margin in reactance of the primary winding low enough so that the voltage drop does not cause an objectionable drop in voltage in the primary circuit. A current transformer is to be used in low-voltage circuits.

**Special Designs of Current Transformer**

poses special designs are useful. In stations where bus-bars while small power circuits, such as station the same bus-bars, current transformers must be operate on small current, while under enormous ex formers must at least remain in service long enou devices. Where the currents are not too low, trans bar as primary may be used. These resist m circuit, but the number of ampere-turns under th limited to the number of amperes flowing in the transformers have an accuracy suitable for meteri rated current of the line is comparatively large. are too low for satisfactory operation with a single formers of large size, great primary current capaci sometimes used.

A somewhat similar case arises where the cost of in high-tension circuits is prohibitive. A transfo bushing of an oil switch, the lead inside the bushi secondary being wound on a core which encircles th current is usually small, while the length of the r tively large, the accuracy of these transformers is narily confined to tripping devices or specially calli

**Design of Potential Transformers.** — The desi is very similar to that of a small distribution or po accuracy of ratio and small phase angle between pri the flux density in the core should be kept compar and leakage reactance of the primary and secondar these transformers are ordinarily connected to t insulation is sufficient if it equals that of good distri for the same voltage. The exciting current is us full load current than in power transformers, beca no moment, and good regulation is necessary. Th ever, is roughly dependent on the product of the ex resistance; hence too large an exciting current undesirable.

**RATING AND PRECISION.** — The volt-a transformers as given by many manufacturers is the most distant relation to the characteristics is no general correspondence between accuracies o various manufacturers for the same load. When with oil immersion for high-voltage circuits, their poor than in the small types without oil, because in cost of manufacture between good and poor tr tively small.

**Standard Voltage Ratings.** — The following ar for which the manufacturers usually list separate l 2300, 4600, 6900, 11,500, 23,00, 33,000, 44,000, 66,

The following are the voltages for which poten listed: 230, 460, 575, 2300, 4600, 6900, 11,500, 1, 66,000.

A transformer listed for one of these nominal vo operate satisfactorily on lines ten per cent above the

100 : 5	400 : 5	1500 : 5	4000 : 5	
150 : 5	500 : 5	2000 : 5	5000 : 5	

**Volt-Ampere Rating.**— Current transformers intended for use with measuring instrument usually have a secondary rating of 10 volt-amperes, and for use with more than one measuring instrument a rating of 20 volt-amperes, at rated secondary current.

Power transformers usually have a rating of 200 volt-amperes at rated secondary voltage.

**Correction.**— By properly proportioning the number of turns in the winding of a current transformer, it is possible to raise the secondary current to the rated value, with a given condition of load. It is usual to correct a current transformer for one-half its rated secondary capacity, with a power factor of 80 per cent and frequency of 60 cycles.

Ratio of turns in a voltage transformer differ from the marked ratio amount sufficient to make up the voltage drop in the transformer at full load. Voltage transformers are usually compensated for one-fifth per cent at full load, with a secondary power factor of 80 per cent, and at 60 cycles.

Phase displacement, however, cannot be compensated for, as it depends only on the constants of the transformer itself, but on the power factor of the load on the voltage transformer, and on the power factor of the load on the current transformer.

**Correction of Current Transformer.**— The variation of ratio and phase angle with load on the secondary of two typical 2300-volt, 20 : 1 ratio, current transformers is shown in Figs. 2 to 5. Figs. 2 and 3 show curves of ratio error obtained from tests on a current transformer (No. 1) of low primary and high ampere turns, and comparatively low secondary resistance and reactance. Figs. 4 and 5 show the results of similar tests on a current transformer (No. 2) where these values are not so strictly limited. It is noted that the scales of  $\frac{\text{true ratio}}{\text{marked ratio}}$  and of phase angle in Figs. 4

are 10 times those used in Figs. 2 and 3.

The series of curves was made with a different load on the secondary, loads consisting of a series of combinations of instruments, watt-hour meters, and other devices representing conditions in ordinary practice. Table I shows the ampere and power factor of the loads, designated by the letters

**Precision of Potential Transformers.**— The angle with the power factor of the load on the secondary of two typical 2300-volt, 23-cycle, 200-watt potential transformers is shown in Figs. 7 to 10. The ratio and phase angle obtained in test on a potential transformer the flux density is low, and the resistances and loadings are within moderate limits. Figs. 9 and 10 show the results on a transformer (No. 2) of the same rating in larger limits, resulting in inferior regulation and la

**GENERAL TESTS DURING MANUFACTURE.**— In the manufacture the insulation of every current or potential transformer is tested at a voltage greater than that at which it is to be used, the voltage selected being determined by the A.I.E.E. Standards. Manufacturers find it desirable to apply considerable safety margins to insure additional safety. A sufficient number of heating tests to assure safety of operation for a long life on accuracy should be made on all transformers. Tests for counting turns, short-circuits, etc.

**TESTING OF CURRENT TRANSFORMERS.**—  
**PHASE ANGLE.**— Where large numbers of current transformers are tested to a high degree of accuracy for ratio and phase angle, which use primary and secondary shunts, balancing coils, or zero reading instrument, are most rapid and satisfactory. The use of such an outfit is justified only where a large number of transformers are to be carefully tested. The phase angle may also be tested with two wattmeters or electro-dynamometers. Where a large number require an occasional check to determine that the transformer characteristics, a simple method which covers most cases with that of a standardized portable transformer is described below.

The uniformity among transformers of a certain rating is usually very good; in the case of a large lot of transformers it can be made only on a few representative ones.

**Demagnetization of Core Before Testing.**— Current transformers should be demagnetized before the test for ratio and phase angle. With small low-voltage current transformers demagnetization is done out by putting at least one-half-load primary current through the transformer with 10 ohms or more connected to the secondary terminals to be used. With large high-voltage current transformers with massive cores the resistance should be several times the impedance of the secondary winding. This resistance should then be removed in steps of one ohm or less.

When however current transformers are subjected to a test, the results for the correction of observations already taken should be in such a way as to avoid changing the magnetic flux density. The test results are secured. The secondary shunt should be that used in the working condition, and especially the secondary current is not allowed to flow in the primary or tertiary winding is open circuited. The current should be raised in steps from current point first, and raised to the higher points after the lower have been made.

frequency of Test Current. — In all current-transformer work where test are to be used for correction, the frequency used in test should be as that of the circuit in which the transformer is to be employed. Attention is only to check the condition of the transformer, any compensating frequency may be used.

Methods of Testing Current Transformers. — The following is a list of the details of one of these methods which has been found satisfactory.

Apparatus. — Referring to Fig. 11 a three-phase supply is used to excite the transformer with a single-phase secondary. The supply of the transformer under test is obtained from one phase of the same through a control resistance  $R_1$  and a step-up current transformer. The step-up transformer is omitted. Its input side is wound to the voltage of the supply (125 volts). The high-current winding is a heavy loose cable, of which one or more turns may be wound through the opening. By suitably selecting the number of turns, currents up to 1000 amperes are obtained. The primary shunt has a resistance such that the rated current gives a drop of 0.5 volt. It is arranged to carry

Fig. 11. Connections for Shunt Method

overload current for a short time for testing purposes. The secondary is adjustable, and is marked in percentage of a normal resistance. Several interchangeable scales the normal resistance corresponding to a percent may be made 0.06, 0.075, 0.08, 0.12, or 0.125 ohm. These of a primary 100-ampere shunt of 0.005 ohm resistance for transformer ratios of 1, 15:1, 16:1, 20:1, 24:1 and 25:1 rated ratios, while still direct reading on the secondary scale of the  $\frac{\text{true ratio}}{\text{marked ratio}}$  of the

A set of primary shunts rated 5, 10, 20, 50, 100, 200, 500, 1000, 2000 amperes will thus cover all probable ratios from 1:1 to 1250:1. A suitable calibrated mutual inductance whose current coil is in series with the secondary of the transformer under test, and whose potential coil is connected to the potential element of the sensitive electro-dynamometer  $D$ , whose secondary is in turn supplied from the secondary of the phase-shifting transformer mentioned above.  $Z$  is a double-throw single-pole switch.  $L$  is a secondary load suitable to represent the instrument combinations in practice.

**Procedure.**—The proper load is connected to the secondary of the transformer, and the primary current is adjusted to the desired value by the resistance  $R_1$ . This current may be read by the ammeter at  $A_4$  which is short-circuited after the current is adjusted to the right. The mutual inductance then acts as a shunt supplying to the dynamometer potential element the same current as with the secondary current of the transformer. The field current of the dynamometer is then adjusted so that the dynamometer reads zero for all positions of the handle. The position of maximum sensibility to changes in mutual inductance is then found. The switch  $Z$  is then thrown to the left, and the secondary shunt is adjusted by moving the drop resistor until the dynamometer reads zero. The phase of the dynamometer field current is then shifted 90 electrical degrees by moving the handle of the dynamometer to a definite distance. This is the position of maximum variation of the dynamometer reading. The mutual inductance is then adjusted until the dynamometer reads zero. The phase of the field current is then shifted to the original position, and a slight readjustment of the secondary current is necessary.

**Calculations.**—From the reading of the dynamometer the phase angle is determined by the formula

$$\beta = \tan^{-1} \frac{2\pi f M}{R_s}$$

where  $f$  is the frequency of the circuit in cycles per second,  $M$  the mutual inductance in henries, and  $R_s$  the resistance of the secondary shunt. Then the true ratio is expressed by the formula

$$\text{Ratio} = \frac{R_s}{R_p} \times \frac{1}{\cos \beta}$$

where  $R_p$  is the resistance of the primary shunt.

The correction factor  $\frac{1}{\cos \beta}$  for  $\beta = 1^\circ$  is 1.00017.

At these values it is negligible in comparison with the error in measurement work involving transformers and phase angles. If the angle is so great that this correction becomes important, it is inferior that it should not be used for any purpose.

**Speed of Operation.**—By this means a large number of points of ratio and the same number of points of phase angle can be determined with a single transformer helper to perform necessary calculations and a series of standardizing transformers in the circuit, it is quite practical to determine the ratio of transformers including from 6 to 12 points each of determinations of phase angle in an eight-hour day. This can be made practically as fast as the transformer current and secondary load adjusted.

**Standardized Transformer Method for Determining the Ratio of a Transformer.**—A portable transformer with a series-multiple connection, giving ratios of 5:1, 10:1, 20:1, 50:1, 100:1, practically everything up to 100 amperes. A secondary winding without primary, so arranged that one turn of the secondary is a ratio of 200:1, and more turns a corresponding ratio of 100 to 1000 amperes. In testing, the primary

t and the standardized portable transformer are connected in either ammeters, wattmeters or watt-hour meters may be used. In the case of watt-hour instruments, the last being susceptible of giving the higher

**Method of Ammeters with Standardized Transformer.** — The secondary of the standardized transformer is connected to a standard-type ammeter, and that of the transformer under test to a similar standard and a suitable secondary load. With a sufficient current flowing satisfactory readings on the ammeters, readings are made; the instruments are interchanged, and readings are repeated, to eliminate differences between the instruments. From the mean of the results and the ratio of the standardized transformer, the ratio of the transformer under test

**Method of Wattmeters with Standardized Transformer.** — The two secondaries are connected to the current coils of the wattmeters. Potential elements are placed in multiple and supplied with a definite voltage through a phase-shifting transformer. The phase shifter is adjusted so as to cause the wattmeter connected to the standardized transformer to read maximum. The instruments then are read as ammeters, using a standard transformer made with the same voltage applied to the potential element. By using a larger deflection is obtained for low-current values, and consequently more accuracy. If only transformers of moderate-current rating are tested, the current may be kept nearly in phase with the supply voltage by the resistance, the phase-shifting transformer may be omitted and the potential circuits excited from the supply voltage.

This method requires little apparatus or care beyond that necessary for instruments and transformers in good condition. It does not test but gives a check on ratio, whose error may readily be kept within 0.1%. This includes the error of comparison, using ordinary care, and the standard transformer. It is reasonably convenient and rapid, and is adapted for use in the laboratories maintained by most companies with light and power.

**Dynamometer Method of Determining Phase Angle of Current Transformers.** — Phase angle may be determined (where primary currents are known) by the use of similar types of dynamometer wattmeters whose current elements are connected in the primary and secondary circuits, and potential elements are supplied in multiple by a phase-shifting transformer. The phase of the voltage is shifted until the primary wattmeter is showing a quadrature relation of its current and voltage. If  $W$  is the reading of the secondary wattmeter,  $E$  the voltage applied to its current element, and  $I$  the current in its current coil

$$\beta = \sin^{-1} \frac{W}{EI}$$

The error of this method is very low with ordinary portable wattmeters, and satisfactory with sensitive reflecting dynamometers. It is the best method for the accurate determination of phase angle.

**Watt-hour Meter Method of Determining Ratio and Phase Angle of Current Transformers.** — This method is used by many operating companies for checking their current transformers. It consists of comparing a transformer under test with another of known characteristics. The advantages of this method are:

(1) No special apparatus required.  
(2) The apparatus is simple and rugged.

3. No special skill required to operate.
4. Transformers may be tested where they are installed.
5. Ordinary variations of voltage, frequency and load during the test do not affect the results.

**Apparatus.**—The primaries of the standard transformer (*S*) and the transformer (*T*) being tested, are connected in series with a variable resistor as shown in Fig. 12. The secondaries are connected through the desired

Fig. 12

to the current coils of the two watt-hour meters which are calibrated so that they can be read to  $\frac{1}{100}$  of a revolution. Ordinary portable standard watt-hour meters are generally used. In making the ratio test the voltage coils of the watt-hour meters are excited from the same phase which supplies the primaries of the current transformers, and in making the phase angle test, from one of the other two phases.

**Procedure.**—The double pole double throw switches are thrown to *AS* and *BT* and loads of the desired value are connected in the secondary circuit of the two transformers. Switch *P* is then closed and the primary current adjusted to the desired value. The switch *V* is now closed and the meter allowed to run until a reading is obtained. Then the switches *V* and *P* are opened and the other switches thrown to *AT* and *BS*. Another reading is taken with switches *V* and *P* closed. For convenience in calculation, the meters should be stopped when the one connected to *T* shows an even reading, say 1000 divisions. These readings give the data for calculating the ratio. For the phase angle measurement the same procedure is followed, except that the voltage switch is thrown to *A* instead of *V*, and the meters should be stopped when the one connected to *S* shows an even reading.

#### Calculations.—

Let  $R_s, R_T$  = ratio of the standard transformer and the transformer under test respectively;

$\alpha_s, \alpha_T$  = the respective phase angles (positive for reversed secondary leading primary);

$a_s, a_T$  = reading on meter *A* when connected to transformer *S* and *T* respectively;

$b_s, b_T$  = ditto for meter *B*;

$\cos \theta$  = effective power factor on the meter,

= 0.866 for the connection shown, with the voltage switch thrown to *A*.

$$R_T = R_s \sqrt{\frac{a_s b_s}{a_T b_T}}$$

$$\frac{R_T - R_s}{R_s} = \frac{1}{2} \left[ \frac{a_s - a_T}{a_T} + \frac{b_s - b_T}{b_T} \right] \text{ (approximately),}$$

$a$ 's and  $b$ 's are readings taken with the voltage switch thrown

$$\tan \alpha_T - \tan \alpha_s = \frac{1}{2 \tan \theta} \left[ 1 - \frac{\sigma_T \delta_T R_T^2}{\sigma_s \delta_s R_s^2} \right],$$

$$\text{minutes) } = \alpha_s \pm \frac{3438}{\tan \theta} \left[ \frac{\sigma_s - \sigma_T}{2\sigma_s} + \frac{b_s - b_T}{2b_s} - \frac{R_T - R_s}{R_s} \right] \text{ (approximately),}$$

$a$ 's and  $b$ 's are readings taken with the voltage switch thrown

st expression the + sign before the bracket should be used when with the voltage switch thrown to *A*, are working on leading l the - sign when the current is lagging. Or the sign may be determined from the fact that adding non-inductive resistance to the a current transformer tends to advance the phase of the secondary

ethods of Testing Current Transformers. — Many modifications : methods and other entirely different methods are in more or less use in various laboratories.

3 POTENTIAL TRANSFORMERS FOR RATIO AND ANGLE. — Where a large number of potential transformers are to potentiometer method of testing ratio is very satisfactory. In this ow-tension voltage is balanced against a part of the drop through ance in which current is maintained by the high-tension voltage. combined with the two-dynamometer method of testing phase n primary and secondary voltages. Where the number of trans- tested is not large, and where only a few ratios are to be tested compared with standardized transformers.

eter Method of Testing Potential Transformers. — The fol- escription of the apparatus and method of procedure which has tory results.

atus. — The general connections of such an outfit are shown in : supply is 3-phase for the excitation of the phase-shifting trans- ne phase is connected through a voltage regulator *Q* to the low- of the step-up transformer *T*<sub>1</sub>, which has a sufficient number of

connections to provide the range of voltages required for testing. This supply excites the high-tension side of the transformer  $T_2$  which is under test, and  $r_1$  and  $r_2$  are placed across the high-tension circuit in multiple with the high-tension

Fig. 13. Connections for Potentiometer Method

side of the transformer under test. They consist of non-inductive resistances, containing a non-adjustable portion constituting the greater part of  $r_1$ , a middle portion  $r_2$  subdivided into equal steps on which a contactor  $C$  travels, and a third part constituting the greater part of  $r_1$  on which taps are brought out at points suited to the various voltages to be used in test. One side of the secondary winding is connected to the end of  $r_2$  and the ground  $G$ ; the other is connected (for ratio test) through switch  $A$ , which is in the downward position, through a resistance and the moving element of the dynamometer  $D_1$  to the contactor  $C$ . By suitably proportioning the resistances  $r_1$ ,  $r_2$  and the steps of  $r_2$ , the outfit is made direct reading in terms of  $\frac{\text{true ratio}}{\text{marked ratio}}$  of the transformer.

**Precaution.**—Balance can only be secured by a proper connection with regard to polarity of the secondary of the transformer under test to the primary. If the reversed connection is used, double the secondary voltage is applied to the circuit through contactor and dynamometer. A sufficient resistance to protect the dynamometer should therefore be inserted when trying out each transformer to be tested. As soon as an approximate balance is obtained, this resistance may be reduced to secure sensitiveness.

**Determination of Ratio.**—The fixed coil of the dynamometer  $D_1$  is excited from the low-tension terminals of the transformer under test through the switch  $B$  in the downward position. Other secondary load may also be applied to the secondary terminals. With this load and the voltage and frequency suitably adjusted, and with the high-tension lead  $L$  connected to the proper tap on  $r_1$ , the contactor  $C$  is moved until the dynamometer  $D_1$  indicates nearly zero. If the resistance at which the dynamometer indicates zero lies between two steps of the contactor, the nearest may be taken or the readings of dynamometer on both steps may be noted and the result obtained by interpolation. If  $r_1$  and  $r_2$  are respectively the resistances from the contactor  $C$  to the high-tension and to the grounded lines, then

$$\text{True ratio} = \frac{r_1 + r_2}{r_2}$$

subject to a small error due to phase angle between primary and secondary voltages, which is negligible for a phase angle of a degree or less, provided

ce of the circuit from the contactor *C* through the dynamometer is equal to  $r_2$ .

**Elimination of Phase Angle.** — To obtain the phase angle the and *B* are thrown upward. The drop of primary voltage across  $r_1$  is added to the potential element of dynamometer  $D_1$ , while the secondary voltage is applied to the potential element of dynamometer  $D_2$ , both through their inductive resistances. The current elements of the dynamometers are in series and excited from the phase-shifting transformer *P*. When the excitation is shifted so that dynamometer  $D_2$  indicates zero, the phase angle between primary and secondary voltages is

$$\gamma = \sin^{-1} \frac{W}{VA}$$

where the watts indicated by the dynamometer  $D_1$ , *V* is the voltage and *I* applied to its potential and current elements respectively.

**Field of Operation.** — Ratio points may be taken at the rate of one point while operating, and phase-angle points at a somewhat slower rate. Point checks can be made practically as rapidly as the transformer is connected and the voltage, load and frequency adjusted. One check is required for ratio test, two for phase-angle test.

**Standard Transformer Method for Determining Ratio of Potential.** — The transformer to be tested should be placed in multiple with a standard transformer of the same rated ratio on the high-tension side, and standardized portable voltmeters should be connected to the two secondary terminals. The readings should be read, interchanged and read a second time to eliminate errors due to calibration of the voltmeters. It is not difficult to maintain an accuracy of about 0.2 per cent on ratio test by this method with carefully standardized transformers near the rated voltages of the transformer. More accurate determinations of ratio and determinations of phase angle if desired should be made in a thoroughly equipped laboratory, and the check results used simply to check the condition of the transformer.

**Standard Transformer and Resistance Method of Determining Ratio.** — Where a standard transformer of the same rated ratio and a voltmeter with suitable multiplier are available, good checking can be made according to the method shown in Fig. 14.  $T_1$  is a step-up transformer which furnishes the voltage for  $T_2$  and  $T_3$  are potential transformers of similar ratio,  $T_3$  being the transformer under test.  $V_2$  is a standard voltmeter.  $V_1$  is a good portable voltmeter or a laboratory standard. *M* is a multiplier of the resistance  $R_m$  that closing the switch *P* places the voltmeter and multiplier in series and reads nearly the same voltage as the primary supply as the voltmeter reads  $E_1$  and  $V_1$  is read.

Fig. 14. Connections for Voltmeter and Resistance Method

When the switch *P* is closed, and readings made with  $V_1$  and  $V_2$  are  $E_1$  and  $E_2$  respectively. Then the switch *P* is opened and *S* is closed.  $V_2$  is held at the reading  $E_2$  and  $V_1$  is read. If the resistance of  $V_1$  is  $R_v$ , its first reading  $E_1$  is the true ratio

$$\text{True ratio} = \frac{E_1 (R_m + R_v)}{E_2 R_v}$$

If the two readings are close together in the scale of  $V_1$ , no specially standardized instrument is necessary. The reading of  $V_1$  does not enter into the result, as it is only used to hold the primary voltage at the same point for the two readings. The accuracy of the method depends on the accuracy of reading of the instruments used, although the absolute values of the readings do not affect it. With care the error should not exceed 0.2 per cent.

**Mutual Inductance Method of Determining Phase Angle of Potential Transformer.** — The phase angle may be determined by the addition to a ratio-testing outfit described above of a mutual inductance whose primary is placed in series with  $r_1$  or  $r_2$  and whose secondary is in series with the circuit from the contactor  $C$  through the dynamometer  $D_1$  in a way similar to that described under current transformers. The primaries of two similar transformers may be placed in multiple, and the difference in their secondary voltages read on a low reading instrument. Where the phase angle is the same on both the transformers, this is an excellent method of comparison if the current drawn in the voltmeter is kept small by the use of a high-resistance instrument.

**Two Watt-hour Meter Method of Determining Ratio and Phase Angle of Potential Transformers.** — This is similar to the method used for current transformers (see page 1745) and consists in comparing the transformers to be tested with one whose characteristics are known. It has advantages similar to the method for current transformers and in addition all instruments are in the low-voltage circuit.

**Apparatus.** — In Fig. 15 the standard transformer is shown at  $S$  and the one under test at  $T$ . The connections to the two watt-hour meters and the

Fig. 15

loads are also shown. The watt-hour meters can be read to  $\frac{1}{100}$  of a revolution, portable standard watt-hour meters being most frequently used. The auxiliary transformer supplies current for the current coils of the watt-hour meters, and may be one of the main power transformers. The switch  $SW$  is a convenient means of starting and stopping both meters simultaneously. If ratio only is desired, the whole power supply may be taken from a 115-volt circuit, the auxiliary transformer being used to step up the voltage for the primaries of the instrument transformers.

**Procedure.** — The primary switch is thrown to  $V$  and the loads on the secondaries are adjusted to the desired values. The current in the current

meters is adjusted to about 5 amperes by means of the resistance  $R$ . The throw switches are now thrown to  $AS$  and  $BT$  and a reading is taken. Double-throw switches are thrown to  $BS$  and  $AT$  and another reading is taken. For convenience in calculation it is well to stop these readings when the meter connected to  $T$  shows an even number of divisions, say 10,000. These readings are used for calculating the ratio. For the phase-angle measurement the same procedure is followed except that the primary switch is thrown to  $V$ , and the meters should be stopped when the one connected to  $T$  shows an even reading.

**Calculation.**—The equations are the same as given for current transformers on page 1747, namely,

$$R_T - R_s = \sqrt{\frac{a_s b_s}{a_T b_T}}$$

$$\frac{R_T - R_s}{R_s} = \frac{1}{2} \left[ \frac{a_s - a_T}{a_T} + \frac{b_s - b_T}{b_T} \right] \text{ (approximately),}$$

where  $a$ 's and  $b$ 's are readings taken with the primary switch thrown to  $V$ ,

$$\tan \alpha_T - \tan \alpha_s = \frac{1}{2 \tan \theta} \left[ 1 - \frac{a_T b_T R_T^2}{a_s b_s R_s^2} \right]$$

$$\alpha_s \text{ (in minutes)} = \alpha_T \pm \frac{3438}{\tan \theta} \left[ \frac{a_s - a_T}{2a_s} + \frac{b_s - b_T}{2b_s} - \frac{R_T - R_s}{R_s} \right] \text{ (approximately).}$$

where  $a$ 's and  $b$ 's are readings taken with the primary switch thrown to  $A$ . They have the same meaning as given on page 1746. In the last expression, the + sign before the bracket should be used when the meters, with the primary switch thrown to  $A$ , are working on lagging current, and the - sign when the meters are working on leading current. Or the sign may be determined experimentally from the fact that the ratio of a transformer with a non-inductive load to a voltage transformer always tends to give a leading voltage.

**Method of Operation.**—The speed of operation is about the same as for current transformers by the same method as shown on page 1747.

**TESTING.**—Heating limits, insulation test, etc., should be in accordance with the Standards of the A.I.E.E. (*q.v.*).

The phase angle under definite conditions of secondary connected to a load of the highest class of commercial product, be defined substantially as shown in Figs. 2, 3, 7 and 8. Even better accuracy than that shown in Figs. 2, 3, 7 and 8 can sometimes be secured with considerable increase in cost and material. For less exacting service transformers of lower cost accuracy can be procured. The conditions to be fulfilled vary so widely that no definite general specifications cannot well be given.

**Work.**—Work, especially with current transformers and in cases where the accuracy is of great importance, on the result, abridged tests covering the performance under definite conditions may be required in connection with each individual transformer. In such cases very careful tests are made, however, the information from a single test is not reliable. The average of many determinations is apt to be more reliable than the result of one determination.

**INSTALLATION.**—Instrument transformers previous to installation should be kept in a cool, dry place. All handling should be done in such a manner as to avoid damage to the insulation, particular care being used on those types where the insulation is exposed. Oil-type transformers are usually shipped

without oil, and temporary wooden blocking is used, the blocking should be removed before installation. Transformers stored for a considerable time, or if they have been stored, should be thoroughly dried out before installing. The oil type should be filled with a good quality.

**Grounding of Transformers.** — Both current and potential transformers should be installed in a clean, dry place, preferably on a board in the case of low-voltage transformers, and those that are grounded, will clear all conducting or semiconducting material at least twice and preferably by three times the square root of the line voltage. The casings and frames should be grounded. The wiring should be grounded at such a point as to avoid the operation of instruments connected to the transformer.

**Resistance of Leads.** — Secondary leads should be given special attention should be given to making all connections connected to the secondary of current transformers. A lead of 0.2 ohm (200 feet of No. 10 wire) is usually used in the circuit of a current transformer operating watt-hour meters. A considerably greater length of leads may be used where watt-hour devices only are used because of the lower accuracy required. For transformers, the error due to drop in leads is proportional to the current passing through them, which is determined by the number of devices operated. For ordinary circumstances the error is 0.5 per cent; where special accuracy is desired, the error is negligible, or the accuracy test of the transformer should be made equivalent to the actual leads placed in series with the transformer should always be close together, enclosing as little area as possible.

**Fuses.** — Potential transformers should be fused at the source of the fuse should be designed to protect the line from the transformer, rather than to protect the transformer from the loads. The fuse should be of such resistance as to avoid errors in the ratio of transformation. A combination of a current capacity fuse and resistor is sometimes used. The resistor is rated to 20 or 40 amperes, while the fuse is designed to carry such a current.

**OPERATION.** — After the current transformer has been installed, need no other care than being kept clean. The secondary winding of the transformer must never be left open-circuited. If it becomes necessary to insert or remove instrument transformer secondary winding should first be carefully short-circuited. It has been open even momentarily while current flow through the transformer should be demagnetized; see above under "Demagnetizing." Transformers should always be considered as part of the live circuit and should be handled except to change connections. Even the secondary winding should be touched. When it becomes necessary to change connections the ground connection should be inspected to avoid short-circuit condition and is so made that it will not be disconnected. Grounded protective cases should be used to prevent attendants from coming in accidental contact with the transformer.

Potential transformers should receive the same care as current transformers. No power should be drawn from the secondary of a suitable load of instruments and the usual switch should be used in handling as with power

U.S. — In general, replacement or repair by the maker is to be preferred. Repairs made by the user where anything more than broken leads or small injuries are to be remedied. If repairs to magnetic circuit are attempted, care should be exercised to duplicate as exactly as possible the original construction especially in regard to number of turns and thickness of windings and exact assembly of punchings. After repairs are made the transformer should be carefully tested both for accuracy and for strength.

U.S. DIMENSIONS AND COSTS. — Current transformers in general for circuits from 115 to 110,000 volts range from 4 pounds to 1500 pounds weight with oil, and from a maximum dimension of 6 inches to a height of 30 inches with a diameter of 30 inches, depending on the quality of the transformer and the voltage of the circuit on which it is to operate. Potential transformers range over nearly the same range of sizes.

The cost of instrument transformers depends on the circuit voltage for which they are designed, and is also affected in the case of current transformers by the rating of the transformer. There is a considerable range between the prices of various manufacturers for transformers of the same rating; the prices are, however, associated with less accuracy or with less insulation strength.

The approximate cost of an instrument transformer of high grade represents about \$100 as per Figs. 2 and 3 for current transformers and Figs. 7 and 8 for potential transformers is as follows:

POTENTIAL VOLTAGE AND CURRENT TRANSFORMERS (1922)

Voltage of circuit	Insulation test voltage	Price in dollars	
		Operated dry	Operated with oil
230	5,000	20 to 25	.....
460	5,000	23 to 27	.....
575	10,000	25 to 30	.....

**TRANSIENT ELECTRIC PHENOMENA AND OSCILLATIONS.**

(See also *Alternating Currents; Capacity and Charging Currents; Electricity and Magnetism, Principles of; Inductance and Inductive Reactance; Transmission Lines.*)

**Establishment of a Direct Current in a Coil.** — Let  $E$  be a constant direct electromotive force,  $r$  the resistance of the coil,  $L$  the inductance of the coil (assumed constant); then  $t$  seconds after closing the circuit (placing the coil in series) the current in the coil is

$$i = \frac{E}{r} \left( 1 - e^{-\frac{r}{L}t} \right), \quad (1)$$

where  $e$  is the base of the natural logarithms and  $\kappa = \frac{r}{L}$ . See *Exponential Functions* for values of  $e^{-x}$ .

**Time Constant of a Coil.** — The time required for the exponent  $\kappa t = \frac{r}{L}t$  to reach the value unity, and therefore for the current to reach 63.2 per cent of its final value, is called the time constant of the coil, and is equal to  $\frac{L}{r}$ . The larger the time constant the longer the time required for the current to reach its steady value  $\frac{E}{r}$ .

**Decay of Current in a Coil when Coil is Short-circuited.** — Using the same notation as above, the current in the coil  $t$  seconds after short-circuiting it is

$$i = I_0 e^{-\kappa t}$$

where  $I_0$  is the current in it at the instant the short-circuit is made.

**Charging a Condenser Through a Resistance from a Source of Constant E.M.F.** — Let  $E$  be a constant e.m.f.,  $C$  the capacity of the condenser, the resistance in series with it, and let the condenser be originally uncharged. Then if the conductance of the condenser and the inductance of the circuit are both negligible, the voltage across the condenser, the current in the circuit and the charge on the condenser  $t$  seconds after the circuit is closed (thereby connecting the condenser, resistance and e.m.f. in series), are respectively

$$\left. \begin{aligned} v &= E(1 - e^{-\kappa t}), \\ i &= \frac{E}{r} e^{-\kappa t}, \\ q &= CE(1 - e^{-\kappa t}), \end{aligned} \right\} \quad (2)$$

where  $\kappa = \frac{1}{rC}$ . For values of  $e^{-x}$  see *Exponential Functions*.

**Time Constant of a Condenser and Resistance in Series.** — The time required for the exponent  $\kappa t = \frac{t}{rC}$  to reach the value unity, and therefore for the voltage and charge on the condenser to reach 63.2 per cent of their final values, is called the time constant of this circuit, and is equal to  $rC$ . The larger the time constant the longer the time required for the voltage across the condenser to reach the value of the e.m.f. impressed on the circuit.

**Discharge of a Condenser Through a Resistance.** — Using the same notation as above, and assuming negligible conductance in the condenser and negligible inductance in the circuit, the voltage across the condenser, the current

in the circuit and the charge on the condenser  $q$  it through a resistance  $r$ , the condenser being at the instant of short-circuit (but no current flowing),

$$\left. \begin{aligned} v &= V_0 e^{-\omega t}, \\ i &= -\frac{V_0}{r} e^{-\omega t}, \\ q &= CV_0 e^{-\omega t}, \end{aligned} \right\}$$

where  $\omega = \frac{1}{rC}$ .

**GENERAL EQUATIONS FOR LUMPED CAPACITY.**—Let the various quantities be as defined. The differential equations for this circuit are

$$\left. \begin{aligned} i &= gv + C \frac{dv}{dt}, \\ v &= e - ri - L \frac{di}{dt}, \end{aligned} \right\} \quad (4)$$

where  $i$  is the instantaneous current in the impedance coil (equal to the total displacement and conduction current through the condenser),  $v$  is the potential drop through the condenser in the direction of the impressed voltage, constant or varying.  $g$  represents the conductance of the condenser, i.e., the power dissipated in the condenser.

At any given instant, say at  $t = 0$ , let the impressed e.m.f. change from a previous value to a new value  $E \sin \theta$ , and let the current and voltage at this instant vary sinusoidally, i.e., at any instant  $t$  be  $E \sin(\omega t + \theta)$ , where  $\omega = 2\pi f$  and  $f$  is the frequency of the impressed e.m.f. (The solution for a constant impressed e.m.f.  $E$  is obtained by putting  $f = 0$  and  $\theta = \pi/2$  in the equations below.) Let  $i_0$  and  $v_0$  be the values of the current  $i$  and of the potential drop through the condenser at time  $t = 0$ .  $i_0$  and  $v_0$  may or may not be zero, and are determined by the state of the circuit previous to the change in the impressed e.m.f.

**Steady State Relations.**—The complete solution of (4) is that the current and voltage at any instant after the change in the impressed e.m.f. are each composed of two terms, (1) a term representing the transient state of the current and voltage respectively, and (2) a term, added to the first, which represents the steady state (or steady-state) solution of (4) is readily effected by the ordinary method of calculation (see *Alternating Currents*), and

$$\left. \begin{aligned} i &= \frac{E}{Z} \sin(\omega t + \theta - \phi), \\ v &= \frac{E}{\gamma Z} \sin(\omega t + \theta - \phi - \eta), \end{aligned} \right\}$$

where

$$\left. \begin{aligned} Z &= \sqrt{R^2 + X^2} & \text{and} & \phi = \tan^{-1} \frac{X}{R}, \\ R &= r + \frac{L}{\omega^2} & X &= \omega L - \frac{1}{\omega C}, \\ b &= \omega C, & \eta &= \tan^{-1} \frac{b}{\gamma}, \\ \gamma &= \sqrt{g^2 + b^2}, & \end{aligned} \right\}$$

oscillations. — The transient terms in the complete solution of equations (7) are as follows:

$$\left. \begin{aligned} i_1 &= e^{-\mu t} \left[ D \cos \omega_0 t - \left( \frac{D'}{\omega_0 L} + \frac{qD}{\omega_0} \right) \sin \omega_0 t \right], \\ \eta_1 &= e^{-\mu t} \left[ D' \cos \omega_0 t + \left( \frac{D}{\omega_0 C} + \frac{qD'}{\omega_0} \right) \sin \omega_0 t \right]. \end{aligned} \right\} \quad (7)$$

$$\left. \begin{aligned} \mu &= \frac{1}{2} \left( \frac{r}{L} + \frac{g}{C} \right) \quad \text{and} \quad q = \frac{1}{2} \left( \frac{r}{L} - \frac{g}{C} \right), \\ \omega_0 &= \sqrt{\frac{1}{LC} - q^2}. \end{aligned} \right\} \quad (8)$$

The constants  $\mu$ ,  $q$  and  $\omega_0$  are constants of the circuit, and are independent of the manner in which the transient oscillation is set up. The frequency of the "natural" oscillation is

$$f_0 = \frac{\omega_0}{2\pi} = \frac{1}{2\pi} \sqrt{\frac{1}{LC} - q^2}.$$

If  $q$  is small compared with  $\frac{1}{LC}$  the natural frequency is  $f_0 = \frac{1}{2\pi \sqrt{LC}}$ .

Because of the resistance of the coil and leakage of the condenser, these natural oscillations die out with time proportionally with  $e^{-\mu t}$ , or the amplitudes of the transient current and the transient voltage decrease by the fraction  $e^{-\mu t}$ .

The constants  $D$  and  $D'$ , which determine the amplitudes of the transient oscillations (7) are given by the following relations:

$$\left. \begin{aligned} D &= I_0 - \frac{E}{Z} \sin(\theta - \phi), \\ D' &= V_0 - \frac{E}{yZ} \sin(\theta - \phi - \eta), \end{aligned} \right\} \quad (9)$$

where  $I_0$  is the current in the coil and  $V_0$  the voltage across the condenser at  $t = 0$  at which any change is made in the circuit conditions, i.e., the switch is opened or closed, or e.m.f. short circuited.

**When Damping is Great.** — When  $q^2$  is greater than  $1 + (LC)$ ,  $\omega_0$  is imaginary and the oscillation therefore has an imaginary frequency, so that the transient terms die out without oscillating. Equations (9) still hold in this case and will give the *real* solution provided that in "cos" is changed to "cosh" (hyperbolic cosine), and "sin" is changed

to "sinh" (hyperbolic sine) and for  $\omega_0$  is taken the value  $\sqrt{q^2 - \frac{1}{LC}}$ . See *Hydrodynamics* for tables of "sinh" and "cosh." The expressions for  $\mu$ ,  $q$ , and  $\omega_0$  remain unaltered.

**Critical Damping.** — Where  $\omega_0 = 0$ , that is, when  $q^2 = 1 + (LC)$ , equations (7) for the transient current and voltage become

$$\left. \begin{aligned} i_1 &= \left[ D(1 - qt) - \frac{D't}{L} \right] e^{-\mu t} \\ \eta_1 &= \left[ \frac{D't}{C} + D'(1 + qt) \right] e^{-\mu t} \end{aligned} \right\} \quad (10)$$

where  $D$  and  $D'$  are given by equations (9).

**Complete Solution.** — The complete expressions for the current and voltage at any instant are in all cases

$$\left. \begin{aligned} i &= i_1 + i_2, \\ v &= v_1 + v_2 \end{aligned} \right\} \quad (11)$$

where  $i_1$  and  $v_1$  are given by equations (5) and  $i_2$  and  $v_2$  are given by equations (7); the latter changed as noted above when  $q^2$  is greater than  $1 + (LC)$  or reducing equation (10) when  $q^2 = 1 + (LC)$ .

**Discharge of a Condenser through an Impedance Coil.** — The above equations may be used to obtain the solution of the special case of a condenser charged to a voltage  $V_0$  and short-circuited at time  $t = 0$  through a coil having both resistance and inductance. Assume that at time  $t = 0$  the current through the condenser is zero. The "steady state" terms in this case are zero, and only the transient terms appear, viz.,

$$\left. \begin{aligned} i &= -\frac{V_0}{\omega L} e^{-\alpha t} \sin \omega t, \\ v &= V_0 e^{-\alpha t} \left( \cos \omega t + \frac{q}{\omega} \sin \omega t \right). \end{aligned} \right\} \quad (12)$$

where the values of  $\alpha$ ,  $q$  and  $\omega$  are as given above, equations (8). When  $1 + (LC)$  is greater than  $q^2$ , equations (12) apply directly; the current-time curve in this case is shown in Fig. 2. When  $1 + (LC)$  is less than  $q^2$  the circular functions become hyperbolic functions and  $\omega = \sqrt{q^2 - \frac{1}{LC}}$  and the current-time curve is as shown in Fig. 3. When  $q^2 = 1 + (LC)$ , equations (12) reduce to

$$i = -\frac{V_0}{L} t e^{-\alpha t} \quad \text{and} \quad v = V_0 e^{-\alpha t} (1 + qt). \quad (13)$$

Fig. 2.  $q < \frac{1}{\sqrt{LC}}$

Fig. 3.  $q > \frac{1}{\sqrt{LC}}$

**OSCILLATIONS IN TRANSMISSION LINES.** — Oscillations similar in nature to those discussed above occur in a transmission line when any change takes place in the load connections and particularly when high voltages are suddenly induced in the line by lightning discharges or when heavy currents are suddenly interrupted. The mathematical analysis of such cases is extremely involved, since account must be taken of the distributed nature of the inductance and capacity, and also of the fact that the possible periods of oscillations depend not only upon the line constants but also upon the constants of the apparatus at the two ends of the line. See article on *Transmission Lines*.

**BIBLIOGRAPHY.** — Steinmetz, C. P., *Transient Electric Phenomena and Oscillations; Electric Discharges, Waves and Impulses*; Pender, H., *Electricity and Magnetism for Engineers*; also *Bibliography* in article on *Radio Communication*.

**MISSION LINES.** — (See also *Capacity and Charging Current; Conduit Lines, Underground; Copper; Corona, Electric; Cross Arms; in Lines; Distribution and Transmission Systems; Inductance and Impedance; Insulators for Overhead Lines; Insulator Pins; Trolley Systems, Wind Pressure; Wires and Cables, Bare; Wires and Cables, Insulated; Buildings.*) Circuits designed for transmitting relatively large amounts from one fixed point to another are called transmission lines, while those carrying small amounts at numerous points are called distribution circuits. The type of construction is used for both kinds of lines when designed for the same voltage. The formulas used in the electrical design of distribution and transmission lines and in the mechanical design of wire included in this article; see also the articles on *Trolley Systems, Overhead Lines* for railway distribution, and *Wiring of Buildings* for formulas for building wiring. The construction details given in this article refer primarily to high-voltage lines designed to operate at or above 13,200 volts; for the construction of low-voltage lines see *Distribution Lines*. For a discussion of the characteristics of the various types of distribution and transmission systems see *Distribution and Transmission Systems*. **TERMS AND FUNDAMENTAL RELATIONS.** — The following definitions and relations apply to all types of transmission and distribution lines.

**Generator End and Load End.** — By the generator end of the line is meant the end which is connected to the source of power (either directly or through a transformer), and by the load end is meant the end which is connected to the load or station which is supplied with power over the line.

**Power Loss ( $Q$ ).** — By per cent power loss as used in this article is meant the percentage ratio

$$Q = 100 \cdot \frac{\text{total power lost in the line}}{\text{total power delivered at load end}} \quad (1)$$

Hence if  $P$  is the power delivered, then the total power supplied to the line and load is

$$P_0 = P \left( \frac{100 + Q}{100} \right). \quad (1)$$

**Per cent Voltage Loss ( $D$ ).**— By per cent voltage loss as used in this article is meant the percentage ratio\*

$$D = 100 \cdot \frac{(\text{voltage at generator end}) - (\text{voltage at load end})}{\text{voltage at load end}}. \quad (2)$$

Hence calling  $E$  the voltage at the load end, the voltage at the generator end is

$$E_0 = E \left( \frac{100 + D}{100} \right). \quad (3)$$

The per cent voltage loss allowed under various conditions is discussed in detail in the article on *Distribution and Transmission Systems*; the allowable voltage loss is usually between 1 and 20 per cent, the most common figure being 10 per cent.

In the case of a direct-current line with a single load at its far end, the per cent power loss and the per cent voltage loss are always equal, but in the case of an alternating-current line the per cent voltage loss may be either greater or less than the per cent power loss, depending upon the constants of the line and the power factor of the load, or may even be negative, i.e., there may be an actual rise of voltage at the load end above the voltage at the generator end; see below.

**Efficiency of Transmission.**— By the efficiency of transmission is meant the percentage ratio

$$100 \cdot \frac{\text{power output of line at load end}}{\text{total power input to line at generator end}}. \quad (4)$$

The per cent efficiency is related to the per cent power loss  $Q$  as follows:

$$\text{Per cent efficiency} = \frac{10,000}{100 + Q}. \quad (5)$$

**ELECTRICAL DESIGN OF DIRECT-CURRENT LINES.**— Two types of problems arise: (1) given a definite line with known constants, what is the power loss and voltage loss for a given load, and (2) to transmit a given amount of power a given distance with a given allowable loss, what will be the size and weight of the conductor required? In the following paragraphs are given the necessary formulas for the several cases.

**Two-wire Line; Concentrated Load at Far End.**— Let

$E$  = volts between wires at the load end of the line,

$P = \frac{EI}{1000}$  = kilowatts taken by load,

$I = \frac{1000 P}{E}$  = amperes taken by load,

$l$  = length of each line wire in feet,

$r$  = ohms per 1000 feet of conductor; see tables in article on *Wires and Cables, Bars*,

$R = \frac{rl}{500}$  = total resistance of line (both conductors), in ohms.

\* In the case of an alternating-current line the difference in the numerator of this ratio is the algebraic difference between r.m.s. values of the two voltages, not the vector difference.

ring relations then hold:

$$\text{kilowatts lost} = p = \frac{Rl^2}{1000} = \frac{rIl^2}{500,000} = \frac{2rIP^2}{E^2}, \quad (7)$$

$$\text{volts lost} = v = RI = \frac{rIl}{500} = \frac{2rIP}{E}, \quad (8)$$

$$\text{percent power loss} = Q = \frac{100p}{P} = \frac{rIl^2}{5000P} = \frac{200rIP}{E^2}, \quad (9)$$

$$\text{percent voltage loss} = D = \frac{100v}{E} = \frac{rIl}{5E} = \frac{200rIP}{E^2}, \quad (10)$$

$$\text{resistance of each conductor per 1000 feet} = r = \frac{500v}{Il} = \frac{QE^2}{200IP} = \frac{DE^2}{200IP}. \quad (11)$$

**Calculation of Size and Weight of Conductor for Concentrated Load.** From the value of  $r$  calculated from any one of the relations given in the preceding section, the size of wire may be found from the tables in the article on *Tables, Bare*; the next larger size of wire (next smaller gauge number) should be chosen when the calculated resistance lies between that of two sizes. The wire selected must also have sufficient current-carrying capacity.

*Tables, Bare; Wires and Cables, Insulated; and Wiring Tables.* For outside lines, however, the current-carrying capacity will be insufficient unless the allowable voltage loss is excessive. For an outside line, a wire smaller than No. 6 A.W.G. (or B. & S.) gauge is seldom used, on account of its lack of mechanical strength.

Weight per 1000 feet of the wire finally selected, then

$$\text{Total weight of conductor in pounds} = W = \frac{wl}{500}. \quad (12)$$

**Calculation of Total Weight of Conductor ( $W$ ); Two-wire Line.** For preliminary estimates it is sometimes convenient to calculate the weight of conductor directly, without reference to a wire table. The total weight of conductor for a two-wire line with concentrated load at its end is given

$$W = \frac{KP}{Q} \left( \frac{l}{E} \right)^2 \text{ pounds}, \quad (13)$$

where  $W$  is the weight of conductor in pounds,  $l$  the length of the line (length of each span at the load),  $Q$  the per cent power loss (= per cent voltage loss on d-c. line) and  $K$  a constant depending upon the material of the conductor. The units in which  $P$ ,  $l$  and  $E$  are expressed, viz.,

#### VALUES OF $K$ IN FORMULA 13

Material	$E$ in volts, $l$ in feet, $P$ in kilowatts	$E$ in kilovolts, $l$ in miles, $P$ in kilowatts
100 per cent conductivity).....	13.5	380
90 per cent conductivity)...	6.5	185
specific gravity $\delta$ having of $c$ per cent at 20° C. ...)	$\frac{13.5}{c}$	$\frac{3940 \delta}{c}$

Values of  $K$  given for copper and aluminum are about 5 per cent greater than the values to allow for stranding, higher working temperature, etc.; the conductivity corresponds to 1.724 microhms per centimeter cube at 20° C.

as the center of gravity is that point between which and the generator end of the line total line resistance is

$$R_p = \frac{R_1 l_1 + R_2 l_2 + R_3 l_3 + \dots}{l} \quad (16)$$

when the line conductor has the same cross-section throughout its length, then the center of gravity is at the distance,

$$l_p = \frac{l_1^2 l_1 + l_2^2 l_2 + l_3^2 l_3 + \dots}{l} \quad (16a)$$

at the generator end, where  $l_1, l_2, l_3$ , etc., are the distances of the respective loads from generator end.

The total voltage loss to the far end of the line is then

$$v = R_p I = \frac{r l I^2}{500} \quad (17)$$

where the distance  $l_p$  is in feet and  $r$  is the resistance of the conductor per 1000 feet, the second relation in (17) holding only when the conductor has the same cross-section throughout its length.

The total kilowatts lost in the line are

$$p = \frac{1}{1000} (R_{01} I_{01}^2 + R_{12} I_{12}^2 + R_{23} I_{23}^2 + \dots) \quad (18)$$

where, referring to Fig. 1,  $R_{01}$  = total resistance (both wires) from 0 to 1,  $R_{12}$  = total resistance (both wires) from 1 to 2, etc., and  $I_{01} = I_1 + I_2 + I_3 + \dots$  = the current in the line from 0 to 1,  $I_{12} = I_2 + I_3 + \dots$  = the current in the line from 1 to 2, etc. When the cross-section of the line conductor is the same throughout its length equation (18) may be also written

$$p = \frac{r}{500,000} (I_{01}^2 l_{01} + I_{12}^2 l_{12} + I_{23}^2 l_{23} + \dots) \quad (18a)$$

where the distances  $l_{01}, l_{12}, l_{23}$ , etc., are as shown in Fig. 1, and are measured in feet, and the resistance of the line conductor per 1000 feet.

**Calculation of Size and Weight of Conductor for Distributed Load.** — For a conductor of the same cross-section throughout, the required resistance per 1000 feet for a given voltage loss of  $v$  volts to the end of the line may be calculated from the formula

$$r = \frac{500 v}{l_p I^2} \quad (19)$$

where  $l_p$ , expressed in feet, and  $I$  are given by formulas (16a) and (15). The size and weight of conductor can then be found by reference to the wire tables in the article on *Wires and Cables, Bare*.

When the loads are far apart and the smaller loads are farthest from the generator, it is sometimes advisable to use different sizes of conductors for the various portions of the line. For a given voltage loss  $v$  to the end of the line, the minimum weight of conductor is obtained when the volts lost per unit length of conductor in each section of the line is proportional to the square root of the current in this portion of the line. For minimum weight of conductor then, referring to Fig. 1, the resistance per 1000 feet of wire in the section between 1 and 2, say, must be

$$r_{12} = \frac{r}{\sqrt{I_{12}}} = \frac{500 v}{l_{12} \sqrt{I_{12}} + l_{23} \sqrt{I_{23}} + \dots} \quad (20)$$

where the lengths are in feet; and similarly for the other sections. The weight of wire in each section may then be found by reference to the wire tables in the article on *Wires and Cables, Bare*, and the total weight  $W$  can then be computed. Vice versa, for a line proportioned in this manner the voltage loss to the end of the line for a given total weight of copper will be a minimum.

A line proportioned in this manner, however, does not give minimum power loss for a given total weight of conductor used. For a given total weight of conductor the total power loss will be a minimum when the power loss per unit length of conductor in each section of the line is directly proportional to the current in this section, i.e., when the

voltage loss per unit length in each section is the same, unit length of each section must be proportional to the load. Letting  $W$  be the total weight of the conductor in pounds, the minimum when the section from 1 to 2, say, has a weight

$$w_{12} = I_{12} \frac{500 W}{I_{12}^2 l_{12} + I_{23}^2 l_{23} + I_{13}^2 l_{13}}$$

where the lengths are in feet; and similarly for the other sections. The weight of each section may be obtained from the wire tables in *Bare*. When the sizes as found by the two formulas are compared, the choice will depend upon which is the more important factor, voltage loss.

**Three-wire Direct-current Line.**—When the loads are balanced, i.e., when the loads between each of the outer wires and the neutral are the same and are connected to the neutral, no current flows in the neutral wire. The formulas for a two-wire line then apply directly to the case of a balanced three-wire line, except that the  $E$  (= volts between wires) in the above formulas is the volts between the *outer* wires, and that the weight of the neutral wire in the above formula is the weight of the two outer wires, usually made equal in size to each outer wire, but sometimes expected it is sometimes made smaller. When the size of the neutral wire is the same as the outer wire the total weight of the three wires is more than that given by formula (13), when  $E$  is the volts between the outer wires.

The exact calculation of the voltage loss and power loss when the loads on two sides of the system are different and are connected to the neutral is somewhat complicated, but can always be effected by applying Kirchhoff's Laws for an electrical network; see *Electric Engineering*.

**SIZE AND WEIGHT OF CONDUCTORS FOR HIGH-VOLTAGE CURRENT LINES.**—As a rough guide in fixing the size of conductors for high-voltage lines the following facts should be noted; complete formulas for determining the conditions required are given later.

1. A power loss of approximately 10 per cent of the transmitted power is allowed.
2. A line voltage of approximately 1000 volts per mile is a good practice for long-distance lines not over 150 miles in length. For a line a line voltage of 10,000 volts would be employed for a line of 100,000 volts would be used. The maximum voltage (1914) employed is 150,000 volts and the maximum length is 240 miles.
3. On the basis of 1000 volts per mile of line, with a 10 per cent power loss, and copper at 15 cents per pound, the copper required for a three-phase line is \$4.00 per mile and for a single-phase or two-phase four-wire line \$5.33 per mile.

**Calculation of Total Weight of Conductor Required for a Line.**—The total weight of the conductor required for any line can be determined from the power delivered, power factor, line voltage and power loss.

\* These formulas are based on the assumption that the load is constant throughout the length of the line. In comparison with the load current, which condition is the case for the longest high-voltage lines; formulas for power loss taking into account the variation of load are given later.

$E$  = voltage between wires at the load end of the line,

$P$  = total power taken by all phases of the load,

$\cos \phi$  = power factor of load, as a decimal,

$l$  = length of line (= length of each line wire),

$Q$  = allowable total power loss in per cent of delivered power.

Then the total weight of all conductors is given by the formula

$$W = \frac{KP}{Q} \left( \frac{l}{E \cos \phi} \right)^2 \quad \text{pounds.} \quad (22)$$

where  $K$  is a constant depending upon the number of phases and wires, the material of the conductor and the units in which the various quantities are expressed, i.e.,

VALUES OF  $K$  IN FORMULA 22

Material and units	Single-phase or balanced 4-wire 2-phase*	Balanced 3-wire 3-phase
<b>Copper (98 per cent conductivity):</b>		
$E$ in volts, $l$ in feet, $P$ in kilowatts ...	13.5	10
$E$ in kilovolts, $l$ in miles, $P$ in kilowatts	380	280
<b>Aluminum (61 per cent conductivity):</b>		
$E$ in volts, $l$ in feet, $P$ in kilowatts ...	6.5	4.9
$E$ in kilovolts, $l$ in miles, $P$ in kilowatts	185	140
<b>Any material of specific gravity <math>\delta</math> having a conductivity of <math>c</math> per cent. at 20° C.:</b>		
$E$ in volts, $l$ in feet, $P$ in kilowatts ...	$\frac{141 \delta}{c}$	$\frac{106 \delta}{c}$
$E$ in kilovolts, $l$ in miles, $P$ in kilowatts	$\frac{394 \delta}{c}$	$\frac{295 \delta}{c}$

NOTE. — The values of  $K$  given for copper and aluminum are taken about 5 per cent lower than their theoretical values to allow for stranding, higher working temperatures, etc. 100 per cent conductivity corresponds to 1.724 microhms per centimeter cube at 20° C.

\* For a 3-wire 2-phase system with the middle conductor having a cross-section equal to  $\sqrt{2}$  times the cross-section of either outer wire multiply these constants by 0.85, taking for  $E$  the voltage (volts or kilovolts) between the middle wire and either outer wire.

**Calculation of Commercial Size of Conductor and Corresponding Total Weight.** — Formula (22) takes no account of the available commercial sizes of wire. These sizes differ successively by approximately 25 per cent in cross-section. The weight can also be determined by calculating the resistance of the required conductor per 1000 feet or per mile, and taking from the wire tables in the article on *Wires and Cables, Bars*, the nearest commercial size, neglecting the charging current, the required resistance per unit length of wire

$$r = \frac{K_1 Q (E \cos \phi)^2}{l P} \quad \text{ohms,} \quad (23)$$

where  $K_1$  is a constant depending on the number of phases and wires and the units in which the other quantities are expressed, as given in the table below.

From the wire table the corresponding weight ( $w$ ) per unit length of conductor having a resistance nearest to that calculated by formula (23) is obtained; the total weight of conductor, including all wires, is then

$$W = K_2 w l \quad \text{pounds,} \quad (24)$$

where  $K_2$  is a constant depending upon the number of phases and wires and the units in which  $w$  and  $l$  are expressed, as given in the table below.

VALUES OF  $K_1$  AND  $K_2$  IN FORMULAS 23 AND 24

Units	Single-phase	Balanced 4-wire 2-phase*	Balanced 3-wire 3-phase
$E$ in volts, $l$ in feet, $P$ in kilowatts, $r$ in ohms per 1000 feet and $w$ in pounds per 1000 feet.	$K_1 = 0.005$ $K_2 = 0.002$	$K_1 = 0.01$ $K_2 = 0.004$	$K_1 = 0.01$ $K_2 = 0.003$
$E$ in kilovolts, $l$ in miles, $P$ in kilowatts, $r$ in ohms per mile and $w$ in pounds per mile.	$K_1 = 5$ $K_2 = 2$	$K_1 = 10$ $K_2 = 4$	$K_1 = 10$ $K_2 = 3$

\* The values of  $K_1$  given in this column when used in formula (23) will give the resistance per 1000 feet or per mile of either outer wire in a 3-wire 3-phase system; the middle wire should, for the same energy loss per pound, have a cross-section 41 per cent greater than either outer, but when commercial sizes (B. & S. gage) are used, either a wire one gage number smaller (25 per cent greater cross-section) or two gage numbers smaller (60 per cent greater cross-section) may be used; in the first case the corresponding value of  $K_2$  is 0.81 times the values given in this column and in the second case 0.90 times the values given in this column.

**Current per Wire; Heating of Line Conductors.** — The size of wire as determined from formula (23) must be ample to carry the required current without overheating. Heating of the line conductors is seldom a limitation in outside overhead lines, but for inside wiring or underground cables the temperature rise may set a limit to the size of wire which may be used. It is therefore always wise to determine the current which the conductor must carry, and make sure that the wire is sufficiently large not to overheat; see articles on *Wires and Cables, Bare; Wires and Cables, Insulated; and Wiring of Buildings*, for tables of current-carrying capacity under various conditions.

The current per line wire in amperes may be calculated from the following formulas, in which  $E$  is the kilovolts between wires at the load end,  $P$  the kilowatts (all phases) delivered to the load, and  $\cos \phi$  the power factor of the load as a fraction.

$$\left. \begin{aligned} \text{Single-phase:} & \quad I = \frac{P}{E \cos \phi} \\ \text{Two-phase,* 4-wire, balanced:} & \quad I = \frac{P}{2 E \cos \phi} \\ \text{Three-phase, 3-wire, balanced:} & \quad I = \frac{P}{\sqrt{3} E \cos \phi} \end{aligned} \right\} \quad (25)$$

**Example: Calculation of Weight and Size of Conductor for a Three-phase Line.** — A load of 20,000 kilowatts is to be transmitted by means

\*  $E$  is here the volts between the two wires of the same phase. This formula also gives the current in each outer of a balanced 3-phase 3-wire line,  $E$  being the kilovolts between either outer and the middle wire; the current in the middle is  $\sqrt{3}$  times the current in each outer.

thead three-phase line of copper wire to a substation 50 miles away at 60,000 volts between wires, the frequency being 25 cycles per second and the power factor of the load 80 per cent with the current lagging; and the loss of 10 per cent of the delivered power to be allowed. From formula (22) the required total weight of copper is

$$W = \frac{285 \times 20,000}{10} \left( \frac{50}{60 \times 0.8} \right)^2 = 607,000 \text{ pounds.}$$

From formula (23) the required resistance per mile of conductor is

$$r = \frac{10 \times 10(60 \times 0.8)^2}{50 \times 20,000} = 0.231 \text{ ohm per mile.}$$

The nearest commercial size is 250,000 circular mils (stranded), which has a resistance of 0.228 ohm per mile at 77° F. (see *Wires and Cables, Bare*), and a weight of 680 pounds per mile. From formula (24) the total weight is then

$$W = 3 \times 4080 \times 50 = 612,000 \text{ pounds.}$$

The current corresponding to the given load is, from formula (25),

$$I = \frac{20,000}{\sqrt{3} \times 60 \times 0.8} = 241 \text{ amperes,}$$

which will cause a negligible temperature rise in the wire. See section on *Current-Carrying Capacity* in article on *Wires and Cables, Bare*.

**Choice of Size and Weight of Conductors for a Given Per cent Voltage Loss.** — The voltage loss in an alternating-current line depends not only on the resistance of the line, but also upon the line reactance, and in the case of long lines upon the electrostatic capacity of the line. It is therefore difficult to express directly in a simple formula the size or weight of the wire required for a given voltage loss. The most practical method of making such calculations is to assume first that the per cent power loss is equal to the given per cent voltage loss and calculate the size by formula (23); then using this size of wire calculate the per cent voltage loss by the formulas given below. If this calculated loss differs appreciably from the given voltage loss, choose the next smaller size of wire (accordingly as the calculated loss is greater or less than the given loss) and recalculate the voltage loss, and so on, until the required size of wire has been found.

### FACTORS WHICH AFFECT THE VOLTAGE AND POWER LOSS

**VOLTAGE LOSS.** — Due to the inductance and electrostatic capacity the per cent voltage loss in an alternating-current line is not so easily calculated as the loss in a direct-current line and is in general different from the per cent power loss. The amount dependent upon the inductance and capacity of the line varies with the frequency and the power factor of the load.

**Definition of Line Constants.** — The four fundamental line constants are resistance ( $r$ ) and inductance ( $L$ ) of the line conductors per unit length, capacitance ( $C$ ) and leakage conductance ( $G$ ) per unit length. For all but short transmission lines the mile is usually the most convenient unit of length. This unit will be used throughout the remainder of this article unless stated otherwise. Tables of resistance, inductance and capacity per 1000 feet are given respectively in the articles on *Wires and Cables, Bare*; *Inductance and Inductive Reactance*; and *Capacity and Charging Current*. In the inductance and capacity per mile or per 1000 feet may be used, and for any given frequency the reactance  $x (= 2\pi fL)$  and the capacity

susceptance \*  $b$  ( $= 2\pi/C$ ) for the corresponding unit of length. In the last two articles just mentioned are given full tables of reactance and of capacity susceptance per mile for frequencies of 60 and 25 cycles per second; dividing the numerical values given in these tables by 5.28 will give the corresponding quantity per 1000 feet. For any other frequency of  $f$  cycles per second, multiply the numerical values given in the tables for 25 cycles by the ratio  $f/25$ ; i.e., in 40 cycles the reactance is 1.6 times the reactance for 25 cycles.

**Allowance for Skin Effect in Conductors.** — For non-magnetic wires the increase in the conductor resistance due to the so-called skin effect is equal to 2 per cent when the quotient

$$(\text{cycles per sec.}) \div (\text{ohms per mile of conductor}) = 485. \quad (2)$$

For smaller values of this quotient the increase of resistance due to skin effect diminishes very rapidly; see article on *Skin Effect*. The skin effect is therefore practically negligible at 25 cycles for all copper conductors smaller than 7,000.00 circular mils, and at 60 cycles for all copper conductors smaller than 430.00 circular mils. The corresponding limiting sizes for aluminum are about 30 per cent larger. The skin effect is quite appreciable in copper or aluminum cables with a steel core; it is usual to neglect the conductivity of the steel core entirely in calculating the resistance of such cables.

**Apparent Resistance and Reactance in Unsymmetrical Arrangements of Wires.** — When the three wires of a three-phase line are so arranged that they form the three edges of an equilateral prism the reactance of each wire is the same as for one wire of a two-wire line. However, when the wires are arranged all in one plane, as is frequently done, the unequal mutual induction sets up a reactive electromotive force in each wire which is not in quadrature with the current in this wire; see equation (20) in the article on *Inductance and Inductive Reactance*. As a result, both the apparent resistance and the apparent reactance of each outer wire is different from its true resistance and reactance. Let  $r$  = the true resistance per mile of each wire in ohms,  $x$  = the reactance per mile of each wire in ohms, as given in the tables in the article on *Inductance and Inductive Reactance*; and  $f$  = the frequency in cycles per second, then the apparent resistances and reactances per mile of the three wires, No. 2 being the middle wire, are

$$\left. \begin{aligned} r_1 &= r + 0.00123f, & r_2 &= r, & r_3 &= r - 0.00123f, \\ x_1 &= x + 0.00070f, & x_2 &= x, & x_3 &= x - 0.00070f. \end{aligned} \right\}$$

The changes in the apparent resistances do not indicate any change in the power dissipated as heat in the wires but a transfer of energy from one wire to the other by the magnetic field surrounding the wires. These relations are deduced from equation (20) in the article on *Inductance and Inductive Reactance*, assuming sine-wave currents of the same effective value and differing in phase by exactly  $120^\circ$ . The assumption that the currents are exactly balanced cannot be strictly true, since the inequality in the apparent resistances and reactances of the three wires tends to unbalance the system, but the error just given may be taken as a fair approximation when the voltage loss in the line is not over 10 per cent, say. When the line wires are transposed these mutual induction effects are eliminated from the line as a whole, though the apparent impedances of the three wires in any one "exposure" of the transposition will be different; the transpositions, however, keep the currents balanced.

Similar effects take place in a two-phase three-wire line, see p. 1773.

**Leakage Conductance.** — The leakage current, even at very high voltages, is usually negligible in power transmission lines, but for telephone lines, the leakage is much greater, due to the large number of small insulators used, and has a very appreciable effect on both the attenuation and distortion of the voice currents. McMeen (*see article on Telephone Lines*) gives the following

\* The capacity susceptance to neutral as given in the tables (i.e., in micro-mhos per mile) is equal to the charging current in amperes per mile per million volts between the wire and neutral; the charging current for any other voltage to neutral is in proportion.

values of the leakage conductance of telephone lines, the conductance on one wire to neutral,

dry	$g = 0.004$ micromhos per mile.	} (28)
average	$g = 0.08$ micromhos per mile.	
wet	$g = 1.0$ micromhos per mile.	

leakage conductance from one wire to the other is one-half these values.

A megohms per mile equals  $1/A$  micromhos per mile.

If the voltage is sufficiently high on a power line to cause the formation of corona (see *article on Corona*), an appreciable leakage current passes from one wire to the other. Even for a sine-wave voltage this leakage current is by no means sinusoidal, since its instantaneous values are practically zero except at the peak of the voltage wave, and consequently the corona loss cannot be represented by a constant leakage conductance. Roughly, knowing  $p_c$  the average value of the corona loss from each wire in watts per mile corresponding to the given line voltage, the leakage conductance to neutral per mile due to the corona may be taken equal to

$$g_c = \frac{p_c}{V^2} \quad (29)$$

where  $V$  is the effective (r.m.s.) kilovolts to neutral.

**Voltage at Load End of Line on Open Circuit.**—In every current transmission line the voltage at the load end when this end is open is higher than at the generator end, although in short low-frequency lines this rise is inappreciable. In overhead lines for which the product

(cycles per sec.)  $\times$  (length of line\* in miles)  $< 10,000$ , (30)

the rise as a percentage of the delivered voltage is; to a close approximation the resistance of the wire is less than that of a No. 0 B. & S. copper

wire to  $\left(\frac{fl}{4000}\right)^2$ , where  $f$  is the frequency in cycles per second, and  $l$  the length of the line in miles. For example, in a 25-cycle line 160 miles long this rise is 1 per cent of the delivered voltage, in a 60-cycle line of the same length the load rise in voltage is 5.8 per cent of the delivered voltage. The percentage rise calculated by the above formula under the conditions stated is independent of the delivered voltage and of the size and spacing of the conductors, at least for all practical cases.

This rise in voltage, which is due to the charging current taken by the line, may be looked upon as a voltage drop at all loads, but when the load is appreciable the voltage drop due to the load current, unless leading, more than offsets this voltage rise. A leading load may increase the rise in voltage at the load end as the load increases.

**Synchronous Condensers (or Phase Modifiers) to Maintain Voltage at Load End.**—By making the line current at the load end lead the line voltage by the proper phase angle, it is possible to entirely offset the change in the load voltage which normally takes place as the load current increases. An overexcited synchronous motor connected in parallel with the load is sometimes used for this purpose, as described in *article on Motors, Synchronous*. A synchronous motor so used is called a synchronous condenser, since the current taken by it leads the line voltage. A striking example of the use of synchronous condensers for this purpose is in connection with the 150,000-volt, 240-mile

\* Length of each conductor.

line from Big Creek, Cal., to Los Angeles, constructed in 1913. Two separate lines are used, the total generator output is 70,000 kilovolt-amperes, and the voltage at the load end is controlled by two 15,000-kilovolt-ampere overexcited synchronous motors.

**METHODS OF CALCULATING VOLTAGE AND POWER LOSS IN A-C. LINES.**—The absolutely rigorous calculation of an alternating-current line requires that the distributed nature of the inductance and capacity be considered, i.e., that the line be considered as made up of an infinite number of sections such as shown in Fig. 7. However, simpler approximate methods may be employed for nearly all power lines such as are now used, and give results sufficiently accurate for all practical purposes. The accuracy of these approximate methods depends primarily upon the frequency and length of the line; the value of the product of these two quantities the simpler is the method which may be employed. Accurate calculation of even a short a-c. line with distributed load can be effected only by rather complicated network equations; see under *Kirchhoff's Laws* in the article on *Alternating Currents*.

**Limitations of Approximate Methods of A-C. Line Calculations.**—The approximate methods of calculating a-c. lines, in the order of their simplicity, may be designated as (1) the simple impedance method; (2) the single end-condenser method; (3) the middle condenser or "T" method and (4) the split condenser or "x" method; the "x" method is also called the "U" method. For short low-voltage lines, the simple impedance method, which neglects entirely the charging current, is usually sufficiently accurate. The single end-condenser method takes the charging current into account in a manner usually sufficiently accurate for all but the longest high-voltage lines. The "T" and "x" methods are still more accurate, but for exact calculations the rigorous method given on p. 1681ff should be used. In fact, it is always well to check an approximate solution by this exact method.

**Fundamental Assumptions on which Formulas Given Below are Based.**—All the formulas given below are based on the assumptions of pure sine-wave currents and voltages and a perfectly balanced\* system. By using the voltage to neutral instead of the voltage between wires, the formulas are also put in such shape that they may be applied directly to either a single-phase, a two-phase four-wire line or to a three-phase three-wire line, a two-phase four-wire line being considered as two separate single-phase lines. The fundamental idea in this method of treatment is that each line wire is considered as a separate circuit. The return wire shown in the various diagrams is therefore to be considered as having no impedance. This method of treatment of balanced polyphase circuits is strictly accurate (see *Alternating Currents*), but when the system is not balanced the circuit must be treated by the more general methods of network calculations; see section on *Kirchhoff's Laws in Symbolic Notation* in the article on *Alternating Currents*. Also, when the voltage and current waves are not sinusoidal, each harmonic must be treated separately as described in the article on *Alternating Currents*. The calculation of a two-phase three-wire line is treated separately, p. 1773.

**SIMPLE IMPEDANCE METHOD.**—This method is based upon the assumption that the electrostatic capacity of the line may be neglected entirely, and that the line may be considered simply as an impedance in series with the load, this impedance having a resistance equal to the total resistance of the line conductor and a reactance equal to the total inductive reactance of the line

\* The meaning of a "balanced" system is fully explained in the article on *Alternating Currents* (Q.V.).

Fig. 2 is a diagram of the circuit, and Fig. 2a is a complete vector of the current and voltage. When the wires are unsymmetrically arranged, the following assumptions are made:

Fig. 2.

Fig. 2a.

$$\begin{array}{lll} \overline{AH} = I, & \overline{BC} = V \sin \phi, & \overline{CE} = rI, \\ \overline{AC} = V, & \overline{CD} = rI, & \overline{AE} = V_0, \\ \overline{AB} = V \cos \phi, & \overline{DE} = rI, & \overline{FE} = V_0 - V \end{array}$$

volts to neutral at load end of the line (= volts between wires divided by 2 in case of a single-phase line, and volts between wires divided by  $\sqrt{3}$  in the case of a three-phase line),

$\frac{V}{II}$  = "equivalent" impedance of the load per mile of line,

power factor of the load at end of line,

$\sqrt{1 - \cos^2 \phi}$  = the reactive factor of the load;  $\sin \phi$  is to be taken positive for a lagging and negative for a leading current,

volts to neutral at the generator end of the line,

conductor resistance per mile of line in ohms; see tables in article on *Wires and Cables, Bare*,

conductor reactance per mile of line, in ohms; see tables in article on *Inductance and Inductive Reactance*,

$\sqrt{r^2 + x^2}$  = conductor impedance<sup>2</sup> per mile of line, in ohms,

$\frac{P}{P_0}$  = per cent power loss, as a percentage of delivered power,

$\frac{V_0 - V}{V_0}$  = per cent voltage loss, as a percentage of delivered voltage.

For diagram it is evident that the voltage at the generator end is

$$V_0 = \sqrt{(V \cos \phi + rI)^2 + (V \sin \phi + xI)^2}, \quad (31)$$

Another way of calculating an expression of the form  $\sqrt{a^2 + b^2}$  is to write it

as  $b \sqrt{1 + \left(\frac{a}{b}\right)^2}$  accordingly as  $a$  is greater or less than  $b$ ; the expression will then always lie between the numbers 1 and 2, and no difficulty need be had with decimal points. When  $b/a$  is less than 0.3, then the expression may be written  $b \left(1 + \frac{a^2}{2a^2}\right)$  with an error of less than 0.1 per cent, and when  $a/b$  is less than 0.3,

$b \left(1 + \frac{a^2}{2b^2}\right)$  with an error of less than 0.1 per cent. The error in the approximations diminishes very rapidly as the ratio of  $b/a$  or  $a/b$ , as the case may be, increases, being only 0.02 per cent when the ratio is 0.2.

which may also be written

$$V_0 = V \sqrt{\left(\cos \phi + \frac{r}{Z}\right)^2 + \left(\sin \phi + \frac{x}{Z}\right)^2} \quad (20)$$

where  $r$  and  $x$  are per mile of line.

The current at the generator end is the same as at the load end.

The per cent power loss is

$$Q = \frac{100 r I}{V \cos \phi} = \frac{100 r}{Z \cos \phi} \quad (21)$$

and the per cent voltage loss is

$$D = \frac{100 (V_0 - V)}{V} = 100 \left[ \sqrt{\left(\cos \phi + \frac{r}{Z}\right)^2 + \left(\sin \phi + \frac{x}{Z}\right)^2} - 1 \right] \quad (22)$$

The power factor at the generator end is

$$\cos \phi_0 = \left( \frac{100 + Q}{100 + D} \right) \cos \phi \quad (23)$$

**Relation between Impedance Drop and Voltage Loss.** — The total impedance drop, which is  $rI$  volts, should be carefully distinguished from the voltage loss, which is  $v = V_0 - V$  volts. The vector diagram, Fig. 2a, will make the difference clear. For a given impedance drop of, say,  $A$  per cent, the voltage at the load end of the line may be anything from  $A$  per cent less than the voltage at the generator end to  $A$  per cent greater than the voltage at the generator end. The determining factor is the difference between the power-factor angle ( $\phi$ ) of the load and the power-factor angle ( $\epsilon = \tan^{-1} \frac{x}{r}$ ) of the line; only when  $\epsilon - \phi = 0$

are the voltage loss and impedance drop the same. When  $\epsilon - \phi$  is greater than  $90^\circ$  (which may occur for a leading current, since  $\phi$  is then negative) the voltage at the load end will in general be higher than at the generator end although the impedance drop in the line may be very large. As a fair approximation, when the impedance drop is less than 20 per cent, that is, when  $r/Z$  is less than 0.2, the percentage voltage loss may be written

$$D = \frac{100 r}{Z} \cos(\epsilon - \phi) \quad (24)$$

$r$  and  $Z$  being the impedances of the line and load respectively, and  $\epsilon$  and  $\phi$  the power-factor angles of the line and load respectively.

**Example of Calculation by Simple Impedance Method.** — Take the case of a three-phase, 60-cycle line 50 miles long, the wires being No. 0000 A.W.G. (or B. & S.) stranded copper spaced symmetrically with 6 feet between centers, and let the load be 15,000 kilowatts at 60,000 volts between wires and at a power factor of 80 per cent with lagging current. The voltage to neutral is then  $60,000 \div \sqrt{3} = 34,600$  and the current per wire  $15,000 \div (\sqrt{3} \times 60 \times 0.8) = 180$  amperes. The resistance of each wire per mile is 0.269 ohm at  $77^\circ F.$ , and the reactance 0.728 ohm. The equivalent impedance of the load per mile of line is  $Z = 34,600 \div (50 \times 180) = 3.84$ .  $\cos \phi = 0.8$  and  $\sin \phi = \sqrt{1 - 0.8^2} = 0.6$ . Whence

$$\text{Per cent power loss} = Q = \frac{100 \times 0.269}{3.84 \times 0.8} = 8.76 \text{ per cent,}$$

$$\text{Per cent voltage loss} = D = 100 \left[ \sqrt{\left(0.8 + \frac{0.269}{3.84}\right)^2 + \left(0.6 + \frac{0.728}{3.84}\right)^2} - 1 \right] = 17.5\%$$

power factor at generator end =  $\cos \phi_0 = \left( \frac{100 + 8.76}{100 + 17.5} \right) \times 0.80 = 74.1$  per cent,

$$\text{Per cent impedance drop} = \frac{100 \sqrt{0.269^2 + 0.728^2}}{3.84} = 20.2 \text{ per cent.}$$

**Graphical Determination of Voltage Loss; Mershon's Chart (Fig. 3).** — The voltage loss may also be determined by means of the chart shown in Fig. 3, which was devised by R. D. Mershon. This chart is nothing more than a means of solving equation (37) graphically. To use the chart calculate

$$\text{the per cent resistance drop} = r \left( \frac{100 I}{V} \right), \quad (37)$$

$$\text{the per cent reactance drop} = x \left( \frac{100 I}{V} \right). \quad (38)$$

Start from the point on the curve marked "0" where this curve cuts the vertical axis corresponding to the load power factor; lay off horizontally the per cent resistance drop, and from the end of this horizontal line lay off vertically upward the per cent reactance drop; the per cent voltage loss is then given by the number on the circle through the end of this vertical line.

Taking the same example as given in the preceding section,  $(100 I) + V = 50 \times 50 \times 180 + 34,600 = 26.0$ , whence the per cent resistance drop is  $0.269 \times 0 = 7.0$  per cent and the per cent reactance drop is  $0.728 \times 26.0 = 18.9$  and hence from the chart the per cent voltage loss is 17.6 per cent.

**Calculations in Terms of Voltage at Generator End.** — When the volts to neutral at the generator end are given instead of the volts to neutral  $V$  at the load end, the calculations for a line of total resistance of  $R$  ohms per wire, and total reactance of  $X$  ohms per wire for a load of  $P$  kilowatts per wire\* at a power factor of  $\cos \phi$  at the load may be made in the same manner as above by first finding  $V$  by the formula,

$$V = A \sqrt{1 \pm \sqrt{1 - \frac{(R^2 + X^2) P^2 \times 10^6}{A^4 \cos^2 \phi}}}, \quad (39)$$

$$A = V_0 \sqrt{\frac{1}{2} \pm \frac{1000 P (R \cos \phi + X \sin \phi)}{V_0^2 \cos \phi}}. \quad (40)$$

The plus or minus sign in the formula for  $V$  arises from the fact that for a given amount of delivered power and given voltage at the generator end two different voltages at the load end are possible; for an inductive load the voltage corresponding to the minus sign will in general be less than 50 per cent of the voltage at the generator end, and the "minus" solution is therefore usually of no practical importance. The maximum power which can be delivered at the load end for a given voltage at the generator end is

$$P_m = \frac{V_0^2 \cos \phi}{2000 (\sqrt{R^2 + X^2} + R \cos \phi + X \sin \phi)}. \quad (41)$$

**Voltage and Power Loss in Two-phase Three-wire Line.** — Take the usual case of the three wires in the same plane, with the common wire midway between the two outers. Let  $r$  be the resistance per mile of each outer, and  $r_1$  the resistance per mile of the common wire, taken from the tables in the article on *Wires and Cables, Bare*, and let  $x_1$  be the corresponding reactances per mile taken from the tables in the article on *Inductance and Inductive Reactance*, for a spacing equal to the distance between the middle wire and each outer. Let  $E$  be the voltage between each outer and the middle wire,  $I$  the amperes in each outer,  $\cos \phi$  the power factor of the load, and  $l$  the length of the line. Assuming a balanced load, then the voltage between the two outers is  $\sqrt{2} E$  and the current in the middle wire is  $\sqrt{2} I$ , and the total power delivered to the load is  $(2 E I \cos \phi) \div 1000$  kilowatts. The per cent power loss is then

$$Q = \frac{100 (r + r_1) I l}{E \cos \phi}.$$

\* Calling  $P_1$  the total kilowatts delivered to the load, then  $P = P_1/2$  for a single wire line,  $P = P_1/3$  for a three-phase line and  $P = P_1/4$  for a two-phase four-wire line.

Fig. 3. Merzban's Chart for Calculating Drop in A-C. Line

equivalent resistances and reactances of the line for the two phases, assuming the volts in the two outer wires to be exactly equal in effective value and to differ in phase exactly  $90^\circ$ , are

$$R_1 = (r + r_1 - x_1 + 0.0014f)l, \quad X_1 = (x + x_1 + r_1)l,$$

$$R_2 = (r + r_1 + x_1 - 0.0014f)l, \quad X_2 = (x + x_1 - r_1)l,$$

where  $f$  is the frequency in cycles per second. When the wires are transposed only the  $0.0014f$  in the expressions for  $R_1$  and  $R_2$  go out, the other terms in the  $R$ 's and  $X$ 's remaining unaltered. The voltages at the generator end for the two phases are then

$$E_1 = E \sqrt{\left(\cos \phi + \frac{R_1 l}{E}\right)^2 + \left(\sin \phi + \frac{X_1 l}{E}\right)^2},$$

$$E_2 = E \sqrt{\left(\cos \phi + \frac{R_2 l}{E}\right)^2 + \left(\sin \phi + \frac{X_2 l}{E}\right)^2}.$$

Of course, if the voltages  $E_1$  and  $E_2$  are maintained equal at the generator end, which is usually the case, the assumptions of equal currents and equal voltages at the load end are correct, but the above formulas may be used to obtain an approximate value of the voltage loss in the two phases. The unbalancing due to the unequal equivalent impedances of the two phases renders the two-phase three-wire system undesirable except for cases in which the voltage loss is a small percentage of the voltage at the load, and the unbalancing therefore small.

**DWIGHT'S TRANSMISSION LINE CHART.**—The chart given in Fig. 3a, though approximate only, gives a simple and ordinarily sufficiently accurate means for calculating the voltage drop or size of wire for any alternating-current, overhead transmission line which is not over 100 miles long. When the resistance drop and the reactance drop are each under 15 per cent of the line voltage, the error in the voltage drop as calculated by this chart is less than 0.5 per cent of the line voltage.

To use the chart, lay a straight edge across it from the proper spacing point to the proper size of wire, and read on the vertical scale corresponding to the given power factor the volts per mile per ampere; call this  $V$ . Or, vice versa, when the volts drop per mile per ampere  $V$  is known, lay a straight edge across the chart from the proper spacing point to the given value of  $V$  as read on the vertical scale corresponding to the given power factor, and read the size of wire on the right-hand vertical scale. A value of  $V$  above the diagonal line on the chart corresponds to a "negative drop," that is, an actual voltage rise. Let  $V$  = volts drop per mile per ampere,  $E$  = volts between wires at the receiver end,  $U$  = kilovolt-amperes delivered to the receiver,  $l$  = length of line, in miles. Then,

$$\text{Total drop, in per cent of } E = \frac{100,000 U l V}{E^2} - 100 K \left(\frac{l}{1,000}\right)^2$$

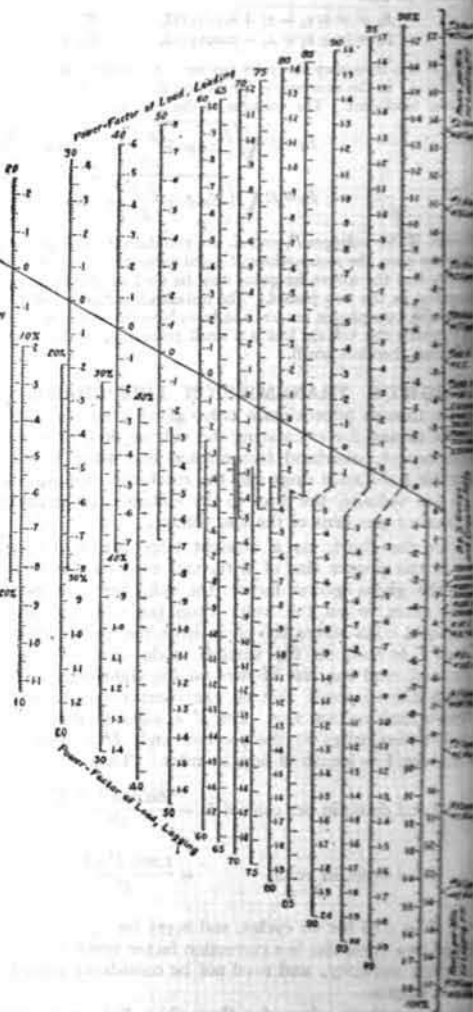

$$\text{Total drop, in volts} = \frac{1,000 U l V}{E} - E K \left(\frac{l}{1,000}\right)^2$$

where  $K = 2.16$  for 60 cycles, and  $0.375$  for 25 cycles. The last term in each of these two formulas is a correction factor which takes into account the effect of the line capacity, and need not be considered when the line is less than 30 miles in length.

When the three wires of a three-phase line are separated by distances  $a$ ,  $b$  and  $c$ , use as the effective spacing  $s = \sqrt{abc}$ . When the three wires are all in the same plane, and the middle wire is at the distance  $a$  from each of the others, use as the effective spacing  $s = 1.26 a$ .

The above formulas are for two-phase and three-phase lines. For a single-phase line use  $U$  in place of  $V$ .

# Transmission Lines; A-C. Calculations

3A. Dwight's Transmission Line Chart.

**Example.**—Length of line, 100 miles; effective spacing, 8 feet; No. 3 copper, & S. gauge; load, measured at the receiver end, 3,000 kv-a, 66,000 volts, 90 per cent power-factor lagging, 3-phase, 60 cycles.

Lay a straight edge from the 8-ft. spacing point for copper conductor, 60 cycles, to the point for No. 3 copper on the right-hand vertical scale. It crosses the 90 per cent power-factor line at  $V = 1.34$ .

$$\text{Per cent drop} = \frac{100,000 \times 3,000 \times 100 \times 1.34}{66,000 \times 66,000} - \frac{100 \times 2.16}{100} = 7.07\%$$

The voltage rise at no load is 2.16 per cent.

The regulation at the receiver end, or change in voltage from full load to no load, is 9.23 per cent of  $E$ . The exact values of the voltage drop and regulation as calculated by the formulas on page 1786 are 7.08 per cent and 9.40 per cent. If the power factor had been leading instead of lagging,  $V$  would have been 0.70, and the drop would have been 2.66 per cent, as against the exact value of 2.51 per cent. In the above example, the errors due to the chart are less than 0.2 per cent of line voltage.

**SINGLE END-CONDENSER METHOD.**—This method assumes that the total current at the load end is equal to the actual load current plus (vectorially) the charging current which would be taken by a single condenser shunted across the line at the load end, the capacity of this condenser being taken equal to the total capacity of the line. This method gives too low a voltage at the generator end by approximately the same amount that the straight impedance

Fig. 4.

$$\begin{aligned} \overline{AB} &= I, \\ \overline{AC} &= V, \\ \overline{AG} &= I \cos \phi, \\ \overline{GH} &= I \sin \phi, \\ \overline{HJ} &= \mu V \times 10^{-6}, \\ \overline{JK} &= \mu' V \times 10^{-6}, \\ \overline{HK} &= \mu'' V \times 10^{-6}, \\ \overline{AK} &= I_1 - I_0. \end{aligned}$$

Fig. 4a.

method gives it too high, and also gives the power loss too low by approximately the same amount that the straight impedance method gives it too high. By averaging the losses obtained by the two methods a close approximation to their true values is obtained.

Fig. 4 is a diagram of the circuit and Fig. 4a is a complete vector diagram of the voltage and current; voltages are shown by full lines and currents by dotted lines. The diagrams and formulas are for the general case of a line with leakage, but for nearly all practical cases the leakage may be neglected.

The effect of the electrostatic capacity of the line is to change both the numerical value and the phase angle of the line current. Or, the condenser and the load may be looked upon as forming together an equivalent load taking a current  $I_1$  at a power factor  $\cos \phi_1$  differing from the actual current and power factor of the load. Let

$V$  = volts to neutral at the load end of the line,

$I$  = actual amperes per wire at the load end,

$\cos \phi$  = actual power factor at the load end,

$\sin \phi = \sqrt{1 - \cos^2 \phi}$  = actual reactive factor at the load end,

$l$  = length of each line wire in miles,

$b$  = capacity susceptance to neutral per mile of line, in micromhos, see tables in the article on *Capacity and Charging Current*,

$g$  = leakage conductance to neutral per mile of line in micromhos, usually taken equal to zero in power lines, as explained above,

$y = \sqrt{g^2 + b^2}$  = dielectric admittance to neutral per mile of conductor, in micromhos. Note that for no leakage  $y = b$ .

The total leakage current, total charging current and total exciting current of the line are then respectively

$$I_g = gV \times 10^{-6}, \quad I_c = bV \times 10^{-6}, \quad I_e = \sqrt{I_g^2 + I_c^2}. \quad (42)$$

The total line current, i.e., the resultant of the actual load current and the exciting current, is

$$I_1 = I \sqrt{\left(\cos \phi + \frac{I_g}{I}\right)^2 + \left(\sin \phi - \frac{I_c}{I}\right)^2}. \quad (43)$$

On the assumptions of this method of calculation  $I_1$  is also the current at the generator end.

The power factor of the equivalent load formed by the actual load and the condenser is then

$$\cos \phi_1 = \frac{I \cos \phi + I_g}{I_1}, \quad (44)$$

and the reactance factor of this equivalent load is

$$\sin \phi_1 = \frac{I \sin \phi - I_c}{I_1}. \quad (45)$$

The formulas given above for the straight impedance method are then directly applicable, using for  $I$ ,  $\cos \phi$  and  $\sin \phi$  in those formulas the values of  $I_1$ ,  $\cos \phi_1$  and  $\sin \phi_1$  just calculated; i.e., the straight impedance method is to be applied not to the actual load but to the equivalent load formed by the actual load and a condenser having an admittance equal to the total admittance of the line.

**Example of Calculation by Single End-Condenser Method.** — Three-phase line, 50 miles long, No. 0000 A.W.G. stranded copper, 6 feet between centers, frequency 60 cycles, load 15,000 kilowatts, 60,000 volts between wires at load end, 80 per cent power factor at load. This is the same example as used above for the straight impedance method. Then  $V = 34,600$ ,  $I = 180$ ,  $\cos \phi = 0.8$ ,  $\sin \phi = 0.6$ ,  $l = 50$ ,  $b = 6.03$ ,  $g = 0$ ,  $r = 0.269$ ,  $s = 0.738$ . Then,

Charging current =  $I_c = 6.03 \times 50 \times 34,600 \times 10^{-6} = 10.4$  amperes,

Resultant current =  $I_1 = 180 \sqrt{(0.8)^2 + \left(0.6 - \frac{10.4}{180}\right)^2} = 174$  amperes,

Power factor of equivalent load =  $\cos \phi_1 = \frac{180 \times 0.8}{174} = 0.838$ .

$$\text{Factor of equivalent load} = \sin \phi_1 = \frac{180 \times 0.6 - 10.4}{174} = 0.561,$$

$$\text{Impedance of equivalent load per mile of line} = Z_1 = \frac{34,600}{50 \times 174} = 3.98,$$

$$\text{power loss} = Q = \frac{100 \times 0.269}{3.98 \times 0.828} = 8.16 \text{ per cent,}$$

voltage loss =  $D$

$$\sqrt{\left(0.828 + \frac{0.269}{3.98}\right)^2 + \left(0.561 + \frac{0.728}{3.98}\right)^2} - 1 = 16.30 \text{ per cent,}$$

$$\text{Power factor at generator end} = \cos \phi_2 = \left(\frac{100 + 8.16}{100 + 16.3}\right) \times 0.828 = 76.4 \text{ per cent.}$$

The per cent power loss and voltage loss obtained by the straight impedance method neglecting the line capacity are respectively 8.76 and 17.6 per cent. As the single end-condenser method gives these losses too low (for long loads) by approximately the same amount that the straight impedance method gives them too high, whence closer approximations to the true per cent power loss =  $(8.16 + 8.76) \div 2 = 8.46$  and per cent voltage loss =  $(17.6) \div 2 = 17.0$ .

**Effect of Synchronous Condenser.** — Formulas (43) to (46) directly to the calculation of the effect of a synchronous condenser at the middle of the line taking a current having an in-phase or energy component and a quadrature leading component equal to  $I_c$ . Fig. 4a then represents the relations of the currents and voltages, the vector  $JK$  being the component of the current taken by the synchronous condenser and  $HJ$  its in-phase component.

**CONDENSER OR T-CIRCUIT.** — This method of representing the line may be convenient to the circuit diagram of Fig. 5, which represents a synchronous condenser, having a leakage conductance  $b$  and a susceptance  $\theta$  in parallel with the total conductor resistance and inductance shunted across the middle point, the resistance and inductance on each side of this condenser being respectively to half the total conductor resistance and inductance.

The solution of Fig. 5 will show that the half of the line nearest the load is represented by a series impedance. Hence the voltage, current and power at the middle point of the line may be figured by the straight impedance method. Then, considering the voltage, current and power factor thus calculated at the middle point of the line, the second half of the line may be calculated by the single end-condenser method just described.

The proper values (which are somewhat complicated functions of the actual line constants and the frequency) to the constants of the "T" circuit shown in Fig. 5, may be made exactly equivalent, as far as the relations between the voltage, current and power at the two ends are concerned, to a line of any length and for any frequency. The "corrected" constants are entirely independent of the voltage, current and power at the load; see p. 1683.

**The "T" Circuit in Symbolic Notation.** — The solution of the circuit diagram of Fig. 5 is also given below in terms of complex quantities (see under Symbolic Notation in the article on Alternating Currents). Let

Fig. 5.

- $V$  = numerical value of volts to neutral at the load end of the line,  
 $I$  = amperes per wire at the load end of the line, taken as the vector of reference,  
 $\cos \phi$  = power factor at the load end of the line,  
 $V' = V \cos \phi + jV \sin \phi$  = volts to neutral at the load end of the line, referred to the current at the load end,  
 $z = r + jx$  = conductor impedance in ohms per mile of wire,  $r$  being the resistance per mile and  $x$  the reactance per mile,  
 $y = g + jb$  = dielectric admittance, one wire to neutral, in micromhos per mile of line, where  $g$  is the leakage conductance per mile and  $b$  the capacity susceptance per mile,  
 $l$  = length of each wire in miles.

Put

$$M = 10^9 y z^2 = [(gr - bx) + j(bv + gx)] 10^{-6} \mu. \quad (6)$$

Then the current at the generator end, in symbolic notation, is

$$I_0 = (1 + \frac{1}{2} M) I + 10^{-6} y l V, \quad (7)$$

and the volts to neutral at the generator end, in symbolic notation, are

$$V_0 = (1 + \frac{1}{2} M) V + z l (1 + \frac{1}{4} M) I. \quad (8)$$

Calling  $I_0'$  and  $I_0''$  the real and "j" components respectively of the current  $I_0$ , and  $V_0'$  and  $V_0''$  the real and "j" components of the voltage  $V_0$ , then the numerical values of the current and voltage at the generator end are

$$I_0 = \sqrt{(I_0')^2 + (I_0'')^2}, \quad \text{and} \quad V_0 = \sqrt{(V_0')^2 + (V_0'')^2}, \quad (9)$$

and the power input per wire at the generator end is

$$P_0 = V_0' I_0' + V_0'' I_0''. \quad (10)$$

In applying this last formula particular attention must be paid to the signs of the quantities involved, e.g., if  $V_0 = 1000 + j 300$  and  $I_0 = 100 - j 20$ , then  $V_0' = 1000$ ,  $V_0'' = 300$ ,  $I_0' = 100$  and  $I_0'' = -20$ , and  $P_0 = 1000 \times 100 - 300 \times 20$ . The power factor at the generator end is

$$\cos \phi_0 = \frac{P_0}{V_0 I_0}. \quad (11)$$

**SPLIT-CONDENSER OR "W" OR "U" METHOD.** — This method assumes that the line may be considered equivalent to the circuit shown in Fig. 6, which represents a single impedance in series with the load, the resistance and inductance of this impedance being equal respectively to the total conductor resistance and inductance of the line, and a condenser shunted across the line at each end; each condenser having a capacity and leakage conductance equal respectively to half the total capacity and half the total leakage conductance of the line.

Fig. 6.

An inspection of Fig. 6 will show that the calculation of the line up to the point  $A$  at which the condenser at the generator end is connected is exactly the same as for the single end-condenser method described above, except that the capacity and leakage of the end condenser are taken respectively as half the total capacity and half the total leakage of the line. The voltage at the point  $A$  is the same as the voltage at the generator end, but to find the current  $I_0$  at the generator end the exciting current  $I_0'$  of the condenser shunted across the line at the generator end must be added (vectorially) to the current  $I_1$  at  $A$ . Using the same notation as in the section above on the single end-condenser method, the total generator current is then

$$I_0 = I_1 \sqrt{\left(\cos \phi_0 + \frac{I_0'}{I_1}\right)^2 + \left(\sin \phi_0 - \frac{I_0''}{I_1}\right)^2},$$

where

$$I_0' = \frac{1}{2} g l V_0 \times 10^{-9} \quad \text{and} \quad I_0'' = \frac{1}{2} b l V_0 \times 10^{-9}$$

case of the "T" circuit, a "π" circuit, such as shown in Fig. 6, may be given vector constants as will make it exactly equivalent for any one frequency, as terminal conditions are concerned, to a line of any length whatever no matter his frequency may be; see p. 1787.

of the "π" Circuit in Symbolic Notation. — Using the same notation as above on the Solution of the "T" Circuit in Symbolic Notation, and call the quantity  $M$  by the same formula, viz., equation (46), the current and voltage at the other end in symbolic notation are respectively

$$I_0 = (1 + \frac{1}{2} M) I + 10^{-9} \rho (1 + \frac{1}{2} M) V, \quad (52)$$

$$V_0 = (1 + \frac{1}{2} M) V + zI. \quad (53)$$

ical values of these quantities, the power and the power factor are then to be found in the same manner as for the "T" circuit, viz., by formulas (49) to (51).

### CALCULATION OF A-C. LINES OF ANY LENGTH AND FREQUENCY.\* — The charging current (and also the leakage current) for any

a transmission line through only one conductor of the line between the sending and the receiving end. The charging current, voltage and current at any point therebetween taken into account in other words the charging current and leakage current are distributed not lumped in the above calculation.

shown three elements of a line, a resistance of zero being also included to complete the method of calculation separately each element is fully explained above, p. 1668.

to make clear the physical meaning of the various terms employed, the solution is first given in terms of instantaneous values. Following this the working formulas (1) in terms of exponentials, viz.,  $e^x$  and  $e^{-x}$ , (2) in terms of real hyperbolic functions, and (3) in terms of hyperbolic functions.

Equations of Transmission Line. — Let  $l$  = the distance in miles of any transmission line, measured from any arbitrarily chosen point (say from the sending end) to the point in question; let  $i$  = the instantaneous current in amperes in the conductor at this point, positive in the direction opposite to that in which  $l$  is measured (i.e., positive toward the load end); let  $v$  = the potential drop in volts between this point and the sending end; let  $r$  = the conductor resistance in ohms per mile,  $L$  = the inductance of the line in henries per mile,  $C$  = the capacity to neutral in microfarads per mile. This section is abstracted from the lecture notes of Dr. H. Pender.

Fig. 7.

Fig. 7a.

$$\begin{array}{ll} \overline{MN} = I, & \overline{MK}_0 = A e^{\alpha l}, \\ \overline{HK} = YV, & \overline{MH}_0 = B_0 e^{-\alpha l}, \\ \overline{MK} = A, & \overline{MN}_0 = I_0, \\ \overline{MH} = B, & \overline{H_0 K_0} = YV_0. \end{array}$$

and  $g$  = the leakage conductance to neutral in micromhos per mile. The following relations then hold at any point along the line,  $t$  being time in seconds measured from an arbitrarily chosen instant:

$$\frac{dv}{dt} = ri + L \frac{di}{dt} \quad (54)$$

$$10^8 \frac{di}{dt} = gv + C \frac{dv}{dt} \quad (55)$$

If the circuit is composed of two or more sections of different constants (e.g., an overhead section and an underground section, or a circuit formed by a step-up transformer, transmission line and a step-down transformer) then a similar set of equations holds for each section of the circuit, the constants  $r$ ,  $L$ ,  $g$ , and  $C$  being in general different for the several sections.

The complete solution of any two equations of the form given by (54) and (55) consist of an infinite series of terms for both  $v$  and  $i$ , corresponding terms in the two series being the following values:

$$i = \sqrt{Z_0} e^{-(\alpha - \beta)x} [A e^{i\omega t} \sin(\omega t + \beta t + \theta_1) + B e^{-i\omega t} \sin(\omega t - \beta t + \theta_2)] \quad (56)$$

$$v = \frac{\sqrt{Z_0}}{Y} e^{-(\alpha - \beta)x} [A e^{i\omega t} \sin(\omega t + \beta t + \theta_1 - \psi) - B e^{-i\omega t} \sin(\omega t - \beta t + \theta_2 - \psi)] \quad (57)$$

**Physical Interpretation and Names Given to the Various Constants.**—The constant  $\omega$  in equations (56) and (57) is equal to  $2\pi f$ , where  $f$  is the frequency of the oscillation represented by these equations. In the most general case any change in the circuit conditions, such as closing or opening a switch, or a lightning stroke in the vicinity of the circuit, may set up an infinite number of oscillations of different frequencies, the frequency being determined by the initial conditions at the instant the change is made. The current and voltage set up by each oscillation is represented by a set of terms of the form given by (56) and (57), and the resultant current and voltage will be respectively the sum of all the current terms and the sum of all the voltage terms. The oscillation of any given frequency, however, may be considered separately, as it is uninfluenced by the presence of the other oscillations. Moreover, in the case of a composite circuit, consisting say of a step-up transformer, transmission line and step-down transformer, if an oscillation of frequency  $f$  is set up in one part of the circuit it will also appear in all other sections of the circuit, though it may be greatly damped in these sections and therefore produce no appreciable effect.

**Attenuation Constant ( $\alpha$ ), Wave Length Constant ( $\beta$ ), Wave Length ( $\lambda$ ) and Velocity of Propagation ( $U$ ).**—Referring to equations (56) and (57) each oscillation sets up in each section of the circuit two waves, each of which has a wave length

$\lambda = \frac{2\pi}{\beta}$ ; the constant  $\beta$  is therefore called the "wave length constant;" it is a function of the frequency and of the constants  $r$ ,  $L$ ,  $g$  and  $C$  of the circuit. The two waves travel

along the line in opposite directions each with a velocity  $U = \frac{\omega}{\beta}$ ; in a composite circuit this velocity  $U$  is in general different for each section of the circuit. One wave may be looked upon as the "incident" and the other as the "reflected" wave. The amplitude of each wave diminishes by the factor  $e^{-\alpha}$  as the wave travels unit distance; the factor  $e^{-\alpha}$  is called the "attenuation factor" and the constant  $\alpha$  is called the "attenuation constant." The attenuation constant is a function of the frequency and the constants  $r$ ,  $L$ ,  $g$  and  $C$  of the circuit; see p. 1784.

**Surge Admittance ( $Y$ ) and its Power-factor Angle ( $\psi$ ).**—The constant  $Y$ , which is equal to the quotient of the amplitude (or r.m.s. value) of the incident current wave by the incident voltage wave, is called the "surge admittance" and its reciprocal is called the "surge impedance;" it is a function of the frequency and the constants  $r$ ,  $L$ ,  $g$  and  $C$  of the circuit; see p. 1784. The constant  $\psi$ , which is equal to the angle by which the incident current wave leads the incident voltage wave, is called the "power-factor angle of the surge admittance;" it is a function of the frequency and the constants  $r$ ,  $L$ ,  $g$  and  $C$ ; see p. 1785.

**Amplitude Constants ( $A$  and  $B$ ) and Phase-Angle Constants ( $\theta_1$  and  $\theta_2$ ).**—The constants are equal to the amplitudes of the incident and reflected current waves at the point from which the distance  $x$  is measured, and the constants  $\theta_1$  and  $\theta_2$  give the

two waves at this point ( $t = 0$ ) at the instant from which time is measured. Note that the incident current wave at  $t = 0$  leads the reflected current wave by  $\theta = \theta_1 - \theta_2$ . The determination of these constants for steady state conditions see p. 1785.

**Natural Damping Constant ( $\alpha$ ), Energy Transfer Constant ( $s$ ) and Composite Damping Constant ( $\alpha - s$ ).** — In the general case of a natural oscillation in a circuit the amplitude of each wave diminishes in unit time by the factor  $e^{-(\alpha - s)t}$ . This factor is called the "composite damping factor," and the constant  $(\alpha - s)$  is the "composite damping constant." The composite damping constant, like  $\alpha$ , is the same for all sections of a composite circuit. In the case of a line of constants throughout, not connected to any terminal apparatus, it can readily be shown that  $s = 0$ , in which case the amplitude of the oscillations diminishes in unit time by the factor  $e^{-\alpha t}$ ; this factor is therefore called the "natural damping factor" and  $\alpha$  is called the "natural damping constant," which for a section having the constants  $r$ ,  $L$ ,  $g$  and  $C$  per unit length,

$$\alpha = \frac{r}{2} \left( \frac{r}{L} + \frac{g}{C} \right) \quad (58)$$

is the "natural damping constant." Any section of a composite circuit for which the composite damping constant  $(\alpha - s)$  is less than the natural damping constant  $\alpha$  must receive energy from some other section; consequently a positive value of  $s$  for a given section means that energy is transferred into this section from some other section of the circuit. Similarly, a negative value of  $s$  for a given section means that energy is transferred from this section to some other section. The constant  $s$  may therefore be called the "energy transfer constant." The voltage and current in the circuit cannot increase indefinitely; therefore the constant  $s$  can never have a positive value greater than  $\alpha$ .

The composite damping constant  $(\alpha - s)$  is the same for all sections of a circuit, and the transfer of energy from one section to another by oscillations in a circuit will always be into the section in which  $\alpha$  is the larger from the section in which  $\alpha$  is the smaller. Neglecting the leakage conductance  $g$ , this means that energy will be transferred into section 1 from section 2, when  $\frac{r_1}{L_1}$  is greater than  $\frac{r_2}{L_2}$ , that is, energy

will be transferred from the section of the larger "time constant"  $\left( \frac{L}{r} \right)$  to that of the smaller "time constant"  $\left( \frac{L_1}{r_1} \right)$ . When the resistances are small, this means that in the limiting

case the energy ( $= \frac{1}{2} L_1 I_1^2$ ) of the magnetic field of the second section may go into the energy ( $= \frac{1}{2} C_1 V_1^2$ ) in the first section, producing therefore a very high voltage at the junction point when the inductance  $L_1$  of the second section is large compared with the capacity  $C_1$  of the first section. This accounts for the very high voltages sometimes observed during switching operations at the junction point of an overhead line with a transformer connected to a long overhead line.

**Steady State Conditions in a Transmission Line.** — From the above discussion it is seen that when a sufficient time (usually a small fraction of a second) has elapsed since the circuit was first energized, the only terms left in the general equations for the voltage and current in a given impressed sine-wave voltage of frequency  $f$  are those of the steady state, viz.,

$$V = \sqrt{2} \left[ A e^{\alpha t} \sin (\omega t + \beta t) + B e^{-\alpha t} \sin (\omega t - \beta t - \theta) \right] \quad (59)$$

$$I = \frac{\sqrt{2}}{Y} \left[ A e^{\alpha t} \sin (\omega t + \beta t - \psi) - B e^{-\alpha t} \sin (\omega t - \beta t - \theta - \psi) \right]. \quad (60)$$

The value of the current at any point is then equal to the sum of two vectors, the former leading the latter by the angle  $(\alpha \beta + \theta)$ . The value of the voltage is equal to the difference of these same two vectors. The phase angle between the voltage and current is equal to the phase angle between the sum and difference of the  $A$  and  $B$  vectors less the angle  $\psi$ .

Under steady state conditions time may be counted from any arbitrarily chosen interval, and the constants in (56) and (57) may be put equal to zero, and for convenience  $-\theta$  may

**Notation for Steady State Conditions.** — These relations are clearly shown in the vector diagram, Fig. 7a, which is a complete vector diagram of a transmission line with distributed capacity and leakage. The four constants  $\alpha$ ,  $\beta$ ,  $Y$  and  $\psi$  are constants of the line, independent of the load, and are expressed in terms of the ordinary line constants as follows: Let

$f$  = frequency in cycles per second,

$r$  = conductor resistance per mile, in ohms; see tables in article on *Wires and Cables, Bare*,

$x = 2\pi fL$  = conductor reactance per mile, in ohms, corresponding to the impressed frequency  $f$ ; see tables in article on *Inductance and Inductive Reactance*,

$z = \sqrt{r^2 + x^2}$  = conductor impedance per mile, in ohms,

$g$  = leakage conductance to neutral per mile of line, in micromhos; see above, p. 1667. For power lines  $g$  is usually taken equal to zero.

$b = 2\pi fC$  = capacity susceptance to neutral per mile of line, in micromhos, corresponding to the impressed frequency  $f$ ; see tables in article on *Capacity and Charging Current*,

$y = \sqrt{g^2 + b^2}$  = dielectric admittance per mile, in micromhos; when  $g = 0$ , then  $y = b$ ,

$\alpha = 10^{-3} \sqrt{\frac{yz - bx + rg}{2}}$  = the attenuation constant; for  $r$  and  $g$  small

compared with  $x$  and  $b$  this reduces to  $\frac{10^{-3}}{2} \left( r \sqrt{\frac{C}{L}} + g \sqrt{\frac{L}{C}} \right)$ .

$\beta = 10^{-3} \sqrt{\frac{yz + bx - rg}{2}}$  = the wave length constant; for  $r$  and  $g$  small

respectively compared with  $x$  and  $b$  this reduces to  $2\pi f \times 10^{-4} \sqrt{LC}$  which for an overhead line equals approximately  $\frac{2\pi f}{180,000}$ .

$Y = 10^{-3} \sqrt{\frac{y}{z}}$  = surge admittance; for  $r$  and  $g$  small respectively compared

with  $x$  and  $b$ , this reduces to  $10^{-4} \sqrt{\frac{C}{L}}$ . The reciprocal of the surge admittance is called the "surge impedance."

$\psi = \tan^{-1} \sqrt{\frac{yz - bx - rg}{yz + bx + rg}}$  = the power-factor angle of the surge admittance,

taken positive for  $gz < br$  and negative for  $gz > br$ . For  $r$  and  $g$  small compared with  $x$  and  $b$ , then  $\psi = 28.7 \left( \frac{r}{x} - \frac{g}{b} \right)$  degrees.

$U = \frac{2\pi f}{\beta}$  = velocity of propagation in miles per second; for a frequency

sufficiently high to make  $r$  negligible compared with  $x$ , and  $g$  negligible compared with  $b$ , this reduces to  $\frac{10^3}{\sqrt{LC}}$ , which for an overhead line with wires far apart is equal to the velocity of light in air, viz., 180,000 miles per second, approximately,

$\lambda = \frac{2\pi}{\beta} = \frac{U}{f}$  = wave length of each wave in miles; for a frequency  $f$  sufficiently high to make  $r$  negligible compared with  $x$ , and  $g$  negligible

compared with  $b$ , this reduces to  $\frac{10^8}{f\sqrt{LC}}$ , which for an overhead line is equal approximately to  $\frac{180,000}{f}$  miles.\*

at the vector diagram and in the formulas given below, let

$l$  = length of the line in miles,

$I$  = effective (r.m.s.) value of the amperes per wire at the load end,

$V$  = effective (r.m.s.) value of the volts to neutral at the load end,

$\phi$  = the power-factor angle at the load end, i.e.,  $\cos \phi$  is the power factor at the load end.  $\phi$  is taken positive for a lagging and negative for a leading current,

$I_0, V_0, \phi_0$  = corresponding quantities at the generator end.

**Solution by Vector Diagram (Fig. 7a).** — Having calculated the constants  $\alpha, \beta, Y$  and  $\psi$ , and knowing the current  $I$ , voltage  $V$  and power-factor  $\phi$  of the load,

Lay off  $\overline{MN} = I$  as the base line, and bisect it at  $G$ ,

At the angle  $(\phi + \psi)$  ahead of  $\overline{MN}$  lay off the line  $\overline{HK}$  equal in length to  $YV$ , so that it is also bisected by  $G$ ,

Then measure off  $\overline{MK} = A$  and  $\overline{MH} = B$ ,

Lay off at the angle  $57.3\beta l$  degrees ahead of  $A$  the line  $\overline{MK_0}$  equal in length† to  $Ae^{\alpha l}$ ,

Lay off at the angle  $57.3\beta l$  degrees behind  $B$  the line  $\overline{MH_0}$  equal in length to  $Be^{-\alpha l}$ .

Bisect  $H_0K_0$  at  $G_0$ .

Then the line  $\overline{MN_0} = 2\overline{MG_0}$  is equal to the current at the generator end,

The line  $\overline{H_0K_0}$  divided by  $Y$  is equal to the voltage at the generator end,

The angle between  $\overline{G_0N_0}$  and  $\overline{G_0K_0}$  less the angle  $\psi$  is the power-factor angle at the generator end.

Note that the voltage at the load end if drawn in the diagram would be at angle  $\psi$  behind the vector  $\overline{GK}$ , and at the generator end would be at the angle  $\psi$  behind  $\overline{G_0K_0}$ .

**Algebraic Solution for Steady-state Conditions.** — The vector diagram may be solved algebraically as follows: Calculate first the constants  $A$ ,  $B$  and  $\theta$  from the formulas:

$$A = \frac{1}{2} \sqrt{I^2 + (YV)^2 + 2YVI \cos(\phi + \psi)}, \quad (61)$$

$$B = \frac{1}{2} \sqrt{I^2 + (YV)^2 - 2YVI \cos(\phi + \psi)}, \quad (62)$$

$$\theta = \tan^{-1} \left[ \frac{2YVI \sin(\phi + \psi)}{I^2 - (YV)^2} \right]. \quad (63)$$

Note that  $\sin \theta$  has the same algebraic sign as the numerator of this fraction and  $\cos \theta$  has the same algebraic sign as the denominator of this fraction; this is the quadrant in which  $\theta$  lies.

Put  $A_0 = Ae^{\alpha l}$ , and  $B_0 = Be^{-\alpha l}$ . (64)

\* The above formulas for  $\alpha, \gamma, \alpha, \beta, Y, \psi, U$  and  $\lambda$  also hold for the transient or free oscillations in a single circuit, and also for each section of a composite circuit, provided these formulas  $r_1 = r(u-s)$   $L$  is substituted for  $r$  and  $g_1 = g + (u-s)$   $C$  is substituted for  $g$ .

† See the table in the article on *Exponential Functions* for values of  $e^{\alpha}$  and  $e^{-\alpha}$ , where  $\alpha$  is any number.

The current, voltage and power-factor angle at the generator end are, then, expressing all angles in degrees,

$$I_0 = \sqrt{A^2 + B^2 + 2AB \cos(114.6\beta l + \theta)}, \quad (65)$$

$$V_0 = \frac{I}{Y} \sqrt{A^2 + B^2 - 2AB \cos(114.6\beta l + \theta)}, \quad (66)$$

$$\phi_0 = \tan^{-1} \left[ \frac{2AB \sin(114.6\beta l + \theta)}{A^2 - B^2} \right] - \psi. \quad (67)$$

Note that the quadrant in which  $(\phi_0 + \psi)$  lies is determined by the algebraic signs of the numerator and denominator of the fraction in the brackets, just as in the case of the angle  $\theta$ .

#### Solution of Steady State Conditions in Terms of Hyperbolic Functions.

The above expressions for the current, voltage and power factor at the generator end also be put in the form,

$$I_0 = I \sqrt{\frac{\cosh(2\alpha l + \gamma) + \cos(114.6\beta l + \theta)}{\cosh \gamma + \cos \theta}}, \quad (68)$$

$$V_0 = V \sqrt{\frac{\cosh(2\alpha l + \gamma) - \cos(114.6\beta l + \theta)}{\cosh \gamma - \cos \theta}}, \quad (69)$$

$$\phi_0 = \tan^{-1} \left[ \frac{\sin(114.6\beta l + \theta)}{\sinh(2\alpha l + \gamma)} \right] - \psi, \quad (70)$$

where  $\theta$  and  $\gamma$  are given by the formulas

$$\gamma = \tanh^{-1} \left[ \frac{2YVI \cos(\phi + \psi)}{I^2 + (YV)^2} \right], \quad (71)$$

$$\theta = \tan^{-1} \left[ \frac{2YVI \sin(\phi + \psi)}{I^2 - (YV)^2} \right]. \quad (72)$$

The other quantities are as above defined. Note that  $\theta$  is the same angle as given by equation (63) and the quadrant in which it lies is to be determined as described in the note under (63). Also note that the constant  $\gamma$  given by (71) may be expressed in terms of  $A$  and  $B$ , given by (61) and (64), by means of the formula

$$\gamma = \log_e \left( \frac{A}{B} \right) = 2.303 \log_{10} \left( \frac{A}{B} \right). \quad (73)$$

**Formulas for Open Circuit and Short Circuit at Load End.**—When the line is open at the load end,  $I = 0$ , whence from equations (61) to (63),  $A = \frac{1}{2} IV$ ,  $B = \frac{1}{2} YV$ , and  $\theta = 180^\circ$  (since the denominator of the fraction is negative). When the line is short-circuited at the load end,  $V = 0$ , and  $A = \frac{1}{2} I$ ,  $B = \frac{1}{2} I$ , and  $\theta = 0^\circ$  (since the denominator of the fraction is positive). The current, voltage and power-factor angle at any point along the line may then be found in either case by substituting these values in equations (65) to (67) which reduce to the simple hyperbolic forms:

On open circuit	On short circuit
$I_0 = YV \sqrt{\sinh^2(\alpha l) + \sin^2(57.3\beta l)}$	$I_0 = I \sqrt{1 + \sinh^2(\alpha l) - \sin^2(57.3\beta l)}$
$V_0 = V \sqrt{1 + \sinh^2(\alpha l) - \sin^2(57.3\beta l)}$	$V_0 = \frac{I}{Y} \sqrt{\sinh^2(\alpha l) + \sin^2(57.3\beta l)}$
$\phi_0 = -\tan^{-1} \left[ \frac{\sin(114.6\beta l)}{\sinh(2\alpha l)} \right] - \psi$	$\phi_0 = +\tan^{-1} \left[ \frac{\sin(114.6\beta l)}{\sinh(2\alpha l)} \right] - \psi$

\* Tables of hyperbolic functions are given in the article on *Hyperbolic Functions*.

solution of Steady-state Equations in Complex Hyperbolic Functions.\* — all quantities other than the length  $l$  in symbolic notation (see Alternating the equations of the transmission line for steady state conditions only, may

$$I_0 = I \frac{\sinh(l\sqrt{yz} + B)}{\sinh B} \quad (74)$$

$$V_0 = V \frac{\cosh(l\sqrt{yz} + B)}{\cosh B} \quad (75)$$

symbols other than  $B$  have the same meanings as above, except that they are all as complex quantities and

$$B = \tanh^{-1} \left( \frac{I}{V} \sqrt{\frac{z}{y}} \right) \quad (76)$$

of  $\sqrt{yz}$  is the attenuation constant and the imaginary or "j" part is the constant.

Equally Equivalent "T" and "π" Circuits. — As noted above the middle "T" circuit, Fig. 5, or the split condenser or "π" circuit, Fig. 6, is rigorously the actual transmission line when proper values are assigned to the constants  $x'$  and  $y'$ . The corrected values  $x'$  and  $y'$  of the impedance per mile and of the admittance per mile are, in symbolic notation, as follows:

"T" circuit	"π" circuit
$x' = z \frac{\tanh\left(\frac{l\sqrt{yz}}{2}\right)}{l\sqrt{yz}}$ $y' = y \frac{\sinh(l\sqrt{yz})}{l\sqrt{yz}}$	$x' = z \frac{\sinh(l\sqrt{yz})}{l\sqrt{yz}}$ $y' = y \frac{\tanh\left(\frac{l\sqrt{yz}}{2}\right)}{l\sqrt{yz}}$

The tables above referred to are given tables of these correction fractions.

**FACTORS AFFECTING THE MECHANICAL DESIGN.** — In designing a transmission line the following factors, in addition to the line losses, must be considered: (1) right-of-way, (2) telephone circuits, (3) ground wires, (4) type of supporting structure, (5) type of insulators, (6) temperature range, (7) collection of ice, (8) wind velocity and wind direction, (9) requirements imposed by these several conditions are noted below; this is followed by the formulas and curves necessary for the required calculations.

**Right-of-way and Width of Right-of-way.** — The right-of-way should be as straight as practicable. Its width for a single line should be equal to the span of the conductors normally hang, plus twice the clearance under maximum wind, plus twice the safe clearance over possible buildings adjacent to the right-of-way. In some cases allowance must be made for swing of suspension insulators. Tables and charts of such functions have been published by Prof. A. E. Kennelly in *Complex Hyperbolic and Circular Functions*, Harvard University Press,

used, and extra width should be secured wherever extraordinarily long spans are made. For telephone lines on separate poles extra width will be required unless the power wires are high enough to swing safely over them. Where two power lines are on one right-of-way the towers for the two lines should be located directly opposite each other, especially on long spans, since the two lines are then placed close together with less danger of the wires of the two lines swinging together. However, it is usually desirable to have the lines far enough apart so that the towers of one line may fall without striking those of the other line. The right-of-way should be passable (or at least accessible) for patrolmen as well as for construction.

When it is necessary that the right-of-way cross railroads, roads or other lines the length of crossing should be reduced to a minimum by making the crossing at as near right angles as practicable. Rights-of-way through swamps often require expensive road building and expensive tower foundations, though small swamps (up to about 1000 feet across) can often be crossed in a single span. Steep side hills require extra expense for foundations and tower extensions and introduce a hazard of injury to tower from sliding earth, rocks, trees or snow. A right-of-way through forests requires expensive clearing.

It is usually advantageous to own and fence the right-of-way. However, when the right-of-way passes through farm lands, it is sometimes advantageous not to fence it in, but to have it cultivated and kept free from brush. Instead of purchasing a right-of-way, it is often sufficient to obtain easements covering the location of towers and suspension of wires. Easements should include the right to remove and trim trees under and adjacent to the line.

**Telephone Circuits for Power Lines.** — When the line voltage does not exceed 66,000 volts, the telephone circuits are usually carried on the same poles or towers as the power circuits, being placed below the power conductors. A separate line of wooden poles on the same right-of-way is usually employed when the voltage is higher than 66,000.

Where the telephone wires are on the same supporting structure as the power wires, sufficient clearance between the power and telephone circuits must be allowed to make the telephone line accessible for repairs and also to prevent the two circuits touching under abnormal conditions. On wood pole lines of short span (100 to 125 feet) the vertical clearance at the poles or towers ranges from 4 feet for 22,000 volts to 6 feet for 66,000 volts. On long span lines greater spacing is necessary to allow for safe clearance in the middle of the longest span due to the change in the sag of the power and telephone wires under all conditions of unequal ice loading and all variations of side deflection due to wind.

Telephone wires are ordinarily of copper, though copper-clad steel is sometimes used for long spans. For spans up to 125 feet No. 10 B. & S. copper may be used (though No. 8 is preferable) while for longer spans larger sizes (usually No. 8 or No. 6 or even No. 4) are necessary to allow for sleet load. A spacing of 12 inches between wires may be used for 125-foot spans, but a wider spacing is necessary for longer spans. Where inadequate spacing is used the telephone lines will frequently become crossed by the wind, unless they are strung with little sag, in which case they are overloaded and broken by sleet. With wide spacing and large sag higher poles must be used.

**Ground Wires.** — Grounded cables or wires are placed above the transmission line circuits to protect the latter from lightning discharges (see *Lightning Protectors*). They are usually grounded at each supporting structure except where short spans are used. The same care must be exercised to obtain clearances between conductors and ground cables or wires, as outlined above under telephone circuits. For tower lines having flexible towers and single-circuit towers having conductors arranged in a horizontal plane, two ground cables are

le, but for double-circuit tower lines either one or two may be used. As a rule a line drawn through the ground cable and any conductor should make an angle of more than 45 degrees with the vertical.

Clearances. — The following clearances require determination: conductor to edge of right-of-way; to tower; to ground wire; to telephone and other conductors.

Minimum clearance from the high-voltage wires to the surface of the ground is ordinarily 20 feet or more, and from the telephone wires on towers to the surface of the ground is 18 feet to ground. The minimum clearance from the high-voltage wires to the edge of the right-of-way or to the tower, under maximum swing of the wires and cables in the wind, should exceed the striking distance corresponding to the arc-over voltage of the insulators used. The minimum clearance between conductors, under extreme conditions of unequal ice loading (see above), should exceed the striking distance of the normal voltage by a factor of at least two. The normal clearance between conductors should be better than this, and is ordinarily from 10 inches to 1 foot per 10,000 volts.

Supporting Structure. — (See also *Poles for Overhead Lines; Cross-arms.*) Wood poles are usually the cheapest form of supporting lines up to about 66,000 volts. Most lines of voltage over 66,000 volts are supported on steel towers.

One line of poles or towers may support one, two and occasionally more circuits. Where several circuits are required two or more single-circuit tower lines with conductors arranged in a horizontal plane have the advantage that if an accident will usually be confined to one circuit, and that one can be safely repaired with another circuit alive, but this arrangement increases the maximum width of right-of-way. Where it is important to use the towers economically two-circuit towers having the conductors of each circuit in vertical planes on each side of the tower are used.

Towers are ordinarily placed from 100 to 200 feet apart and steel towers from 800 feet apart. The span for steel tower lines is ordinarily chosen to make the sum of all the items a minimum, and is usually within the limits mentioned.

Towers ordinarily used where the line is straight are designed to resist the weight of the conductors with sleet and the side pressure of wind on the towers to resist the tension in the conductors which is assumed to be vertically balanced. Such towers are called standard, straight line towers. Heavier towers designed to resist the unbalanced tension in the cables (which may occur if the cables are broken on the other side of the tower) are called anchor or dead-end towers, and are used at intervals of from 100 to 200 feet apart where the line is straight. Heavier towers designed to resist the lateral resultant of the tension in the cables are also used and are known as angle towers. For economy in design and manufacture angle towers (for any angle up to about 60°) are usually made of steel. Where towers are not very high, economy is often secured by using towers intermediate between square anchor and angle towers. On steep slopes extra strong poles guyed or braced in all four directions, with steel arms and double pins and insulators, are used for anchoring the line.

Insulators. — (See also *Insulators.*) Pin insulators are usually used up to 50,000 and suspension insulators for higher voltages. Suspension insulators are sometimes used for lower voltage where a high factor of safety is required. For the lower voltages the cost of the line is usually less for pin than for suspension insulators. The suspension insulator requires a higher tower

than the pin insulator, for the conductor is below the cross arm, and a long cross arm is also required to allow for the swing of the insulators in the wind.

**Conductors for Overhead Lines.** — (*See also Wires and Cables.*) Copper, aluminum or steel, or combinations of the two former with steel, are used for line conductors. The use of an all-steel conductor is limited to those cases where great mechanical strength is required, although some economy is claimed for it when high voltages are used and a conductor of large diameter is required on account of corona (*see Corona*). Conductors consisting of a steel center with copper or aluminum outside are used where long spans are desirable and mechanical strength of conductor is required, and may also be used where large diameter is required to prevent corona formation. The maximum stress in wires or cables should not exceed the elastic limit. This condition is ordinarily met if a factor of safety of two, based on the ultimate strength, is used.

**Distribution of Stress in Stranded Conductors.** — Conductors for long spans are usually stranded when larger than No. 6 B. & S. gage, on account of the tendency to crystallize at the points of support, due to swinging in the wind. However, the maximum size of solid conductor which may be used is dependent largely upon the kind of support; if these are designed to prevent sharp bends, solid conductors, larger than No. 6, may be used. One difficulty in the use of a stranded cable is that for a given total tension in the cable the wires in the various layers are not all stressed equally. In particular, the center wire or core, if of metal, takes more than its share of the tension. On this account the actual sag in the cable when suspended may differ from that calculated, unless an allowance is made for the unequal tension in the various wires composing the cable. One method of avoiding this difficulty is to stress the cable, before stringing it, to a tension per square inch corresponding to the elastic limit of the component wires; the center wire will then be given a permanent set and when the cable is again stressed each of the component wires will tend to take the same proportion of the total tension.

Cables having centers or cores of a different material than the outside strands should be so designed that both materials share the stress over the operating range of temperatures, to such extent as is possible. The properties of steel-core aluminum cables and the method of considering stresses therein are given in the article on *Wires and Cables, Bare*.

The distribution of stress among the wires of which conductors may be composed applies more particularly to long spans where clearances are important and it is necessary to use small deflections compared to lengths of spans. For all ordinary construction, having spans of 500 to 600 feet or less, a very slight change in either thickness of ice or amount of wind pressure on the conductor will affect results as much as the error resulting from not taking into consideration the distribution of stresses in conductors.

**Mechanical Characteristics of Conductor Materials.** — For purposes of design both elastic limit and modulus of elasticity of cables should be obtained from tests on samples of the cables actually to be used, since errors in these materially affect the accuracy of the calculations of deflections in spans. The modulus of elasticity of cables varies widely with the number of wires and their pitch or lay in the different layers. Table I shows the values of these quantities and also of the other mechanical properties of conductors commonly used in design, when specific test results are not available. See also the articles on *Aluminum*; *Copper*; *Strength and Elasticity*; *Wires and Cables, Bare*.

**Temperature Range.** — The maximum and minimum air temperatures which have occurred in any locality for a period of years can be obtained from the records of the United States Weather Bureau, or from similar records for other countries. The minimum air temperature recorded (which may be as

TABLE I  
CHARACTERISTICS OF WIRES AND CABLES

Copper	Aluminum	Steel
17,000	25,000-50,000	60,000-80,000
	11,000-14,000	35,000-40,000
	$7 \times 10^4 - 10 \times 10^4$	$22 \times 10^4 - 25 \times 10^4$
	$12.8 \times 10^{-4}$	$6.6 \times 10^{-4}$
3.09	0.97	2.67

Some of the northern states) will be the minimum temperature factor may be expected to reach. However, since the conductors are exposed to the direct rays of the sun, they will reach a maximum temperature in the summer considerably in excess of the Weather Bureau records, and will be above the temperatures in the shade.

Another important temperature which should be determined is that of the wire when coated with ice. As noted below, a sleet storm is usually followed by a sharp fall in temperature, and although the ice forms at 32° F., the wire may reach a much lower temperature while the ice is on it.

The following temperature ranges have been used in the design of certain lines:

	Maximum	Minimum
Eastern Canada.....	+120° F.	-40° F.
Mississippi Valley.....	+120° F.	-20° F.
Southern California.....	+140° F.	+10° F.

**Collection of Ice on Wires.**—Investigation of the records of the Weather Bureau leads to the conclusion that sleet and ice storms are generally followed by falling temperatures and high winds, and transmission lines should be designed to meet these conditions. Records indicate that under favorable conditions ice and sleet will collect on wires and cables to the same amount in any climate where freezing temperatures are obtained. Mild, moderate and cold climates differ in the frequency with which conditions are favorable. In general, sleet storms are most frequent in the moderate climates, since precipitation takes place more often at freezing temperatures. Destructive sleet storms occur in the eastern part of the United States at least as far south as Atlanta. One-half inch thickness of solid ice on wires and cables is generally assumed in designing transmission lines, but thicknesses of one-quarter and three-quarter inch are also assumed in the more favorable and unfavorable localities.

Ice and sleet generally collect quite uniformly on wires throughout their length. The collection is sometimes in the form of icicles but more often is ring-shaped in cross section, with the wire in the small end of the section. It frequently falls off non-uniformly in sections.

Clear solid ice weighs 57 pounds per cubic foot or 0.033 pound per cubic inch, but sleet or frozen snow such as often collects on wires weighs much less, sometimes as little as 8 pounds per cubic foot.

**Effect of Surface and Electric Potential on Collection of Ice.**—Local observations of single ice or sleet storms have shown that ice will sometimes collect on one wire or cable and not on an adjoining one. This has led to the conclusion that ice will not collect on certain kinds of wires, but more extensive observations indicate that ice will collect on any kind of wire under favorable conditions. Observations on wires carrying sufficient current to heat them and wires having potential near the critical corona voltage are not sufficiently extensive to warrant the conclusion that they will not collect ice and sleet.

**Wind Velocity and Wind Pressure on Wires.**—As noted in the article on *Wind Pressure*, the records of the United States Weather Bureau give nominal average velocities for five minute intervals, the true average velocities differ from the recorded velocities as follows:

Recorded velocity in miles per hour	10	20	30	40	50	60	70	80	90	100
Actual velocity in miles per hour	9.6	17.8	25.7	33.3	40.8	48.0	55.2	62.2	69.2	76.2

The Weather Bureau records give no indication of the "gust" velocities which may occur during the five minute periods, and which may greatly exceed the average velocity. Tests with a Dines pressure tube anemometer have shown that the extreme maximum is about 50 per cent greater than the average for short periods.

The extreme maximum wind velocity observed in Chicago in the whole thirty-six year period from 1873 to 1910 was 84 miles per hour (uncorrected) in February, 1894. A velocity of 76 miles per hour (uncorrected) was observed once in November, 1898, and a velocity of 73 miles per hour (uncorrected) was observed seven times. During the ten year period from 1894 to 1903 the maximum wind velocity in a few other representative localities was as follows, all velocities being the observed or uncorrected velocities: Bismark, N. D., 72; Eastport, Me., 75; Buffalo, N. Y., 90; New York City, N. Y., 78; Galveston, Tex., 84; Savannah, Ga., 76; Salt Lake City, Utah, 60. All the maxima range between 60 miles and 90 miles per hour.

The wind pressure on a cable is usually calculated from the formula

$$p = KV^2, \quad (1)$$

where  $p$  is the pressure in pounds per square foot of the projected area of the cable (including sleet and insulation, if any), and  $V$  is the actual velocity of the wind in miles per hour blowing perpendicularly across the span. The projected area, in square feet, of a one-foot length of cable is equal to the over-all diameter in inches divided by 12, where by over-all diameter is meant the diameter over the ice and insulation, if any. Buck's formula (see *article on Wind Pressure*) gives a value of 0.0025 for the constant  $K$ , whereas a value of 0.002 derived from the work of the Weather Bureau and experiments of Borda is also used.

**Maximum Loading.**—There is considerable difference of opinion as to what should be taken as the maximum loading in designing a transmission line. The Committee on Overhead Line Construction of the N.E.L.A. have proposed three different loadings, viz.: (A) No ice and a wind pressure of 15 pounds per square foot; (B) ice  $\frac{1}{2}$ -inch thick and a wind pressure of 8 pounds per square foot; and (C) ice  $\frac{3}{4}$ -inch thick and a wind pressure of 11 pounds per square foot. Class B loading gives greater stress than Class A loading for all sizes of wire in use. The difference is greatest for small sizes.

Several important lines have been designed on the assumption of a maximum loading of  $\frac{3}{4}$  inch of ice and wind pressure at 6 pounds per square foot, the temperature corresponding to this loading being taken as 0° F. In these same lines the clearance under unequal loadings was calculated on the assumption of five

s between anchor towers, with no ice on the third span of the lower conductor, and no ice on the first, second, fourth and fifth spans of the upper conductor, but with a loading of  $\frac{1}{4}$  inch of ice on all other spans the temperature being taken as  $32^{\circ}$  F. and no wind assumed.

**VERTICAL AND TRANSVERSE FORCES ON A SUSPENDED WIRE.**—The resultant force acting on one foot of a suspended wire is in general made up of three components, viz.:

- = weight of the conductor (including insulation, if any) per foot length, in pounds;
- = weight of the ice coating per foot length of the conductor, in pounds;
- = wind pressure per foot length of the conductor, in pounds.

The weight of the conductor per foot length may be taken directly from the tables in the articles on *Wires and Cables, Bars*, as can also the diameter of the conductor (over the insulation, if any). Let  $d$  be this diameter in inches and let  $t$  be the thickness of the ice coating, then the weight of the ice coating per foot length of the conductor is

$$i = 1.24 t (d + t). \quad (2)$$

Let  $p$  be the wind pressure per square foot of projected area, assumed or calculated from equation (1); then the wind pressure per foot length of the conductor, the horizontal component of the resultant force, is

$$h = \frac{p (d + 2t)}{12}. \quad (3)$$

The vertical component of the resultant force per foot length of conductor, which is equal to the resultant force for no wind, is

$$v = c + i. \quad (4)$$

The values of  $v$  and  $h$  for various ice thicknesses and various sizes of wires are given in Table II. The values of  $h$  are given in the table for a wind pressure of 10 pounds per square foot; these values of  $h$  are designated  $h_0$ ; for any other wind pressure of say  $p$  pounds multiply these values by  $\frac{p}{10}$ . Knowing  $v$  and  $h$  the resultant force  $w$  for any combination of wind and ice loads is readily determined by the formula

$$w = \sqrt{v^2 + h^2}. \quad (5)$$

TABLE II. VERTICAL AND HORIZONTAL LOADING FORCES\*

Pounds per Foot of Conductor

The horizontal component  $h_0$  is given for a wind pressure of 10 lb. per sq. ft.,for any other wind pressure of  $p$  lb. per sq. ft.,

$$h = \frac{ph_0}{10}$$

The resultant force for any ice thickness and wind pressure is  $w = \sqrt{v^2 + h^2}$

**CALCULATION OF SAG AND TENSION.** — A wire or cable suspended between towers takes the form of a catenary curve. In transmission-line practice the maximum deflection or sag is always small compared to the span, so that the curve is very flat. The shape of such a flat catenary curve does not differ appreciably from a parabola and, as the approximate parabolic formulas are much simpler than the more exact catenary formulas, they are used instead. The flatness of the curve allows of some further simplifications even in the parabolic formulas, viz., (1) the tension is considered uniform throughout the span, the slight excess of tension at the ends over that at middle being neglected, (2) the change of length of the wire due to elastic stretch or temperature expansion is taken as equal to the change of length of a wire equal in length to the horizontal distance between the points of support.

**Notation Used in Sag-tension Formulas.** — The following notation, given alphabetically, will be used throughout the discussion of sag and tension

- $A$  = cross section of the conductor (actual metal cross section) in circular inches = square of diameter in inches; 1 circular inch = 1,000 circular mils.
- $\alpha$  = coefficient of linear expansion of the conductor per ° F.; see Table above.
- $D$  = deflection, in feet, of the lowest point of the conductor when suspended from two points of support at the same elevation and at a distance  $L$  apart. ( $D$  is measured in the direction of the resultant transverse force.)
- $e$  = difference in elevation of the two points of support, in feet.
- $F$  = longitudinal horizontal component of the stress in the conductor, pounds. (The resultant stress in the wire at the insulator is equal to  $\sqrt{F^2 + H^2 + V^2}$ , where  $V$  is the weight of the conductor and ice between the insulator to the lowest point of the span, and  $H$  is the total ice pressure on half the length of span;  $H$  and  $V$  in this expression are usually negligible compared with  $F$ .)
- $h$  = wind pressure in pounds per foot length of conductor assumed perpendicular to the vertical plane through the two points of support, see equation (3) and Table II above.
- $L$  = length of span in feet, i.e., the horizontal distance between the two points of support in feet.
- $l$  = length in feet of the arc of the curve in which the conductor hangs, i.e., the length of stretched conductor between the two points of support.
- $M$  = modulus of elasticity of the conductor in pound-inch units; see Table above.
- $S = \frac{wD}{w}$  = sag of the lowest point of the conductor below the horizontal line through the lower point of support; for no wind  $S = D$ .
- $T_0$  = maximum allowable tension in the conductor in pounds per square inch of its cross section;  $T_0$  is usually taken as one-half the ultimate strength of the conductor; see Table I.
- $v$  = vertical force in pounds on a one-foot length of the conductor, including the weight of conductor and the weight of the ice, if any, on it; see equation (4) and Table II above.
- $w = \sqrt{v^2 + h^2}$  = resultant load in pounds on a one-foot length of the conductor.
- $Z = \frac{hD}{w}$  = side swing, in feet, of the middle point of the conductor, measured perpendicularly to the vertical plane through the two points of support.

rious symbols with the subscript "o" will be used to designate the various quantities under the conditions of maximum assumed see paragraph above on *Maximum Loading*.

**amental Equations of a Wire Span.** — As noted above, a perfectly suspended between two points of support hangs in a catenary. Assumption that the wire hangs in a parabola instead of in a catenary is very accurate for all practical calculations of wire spans, the error introduced on this assumption being less than 2 per cent of its true value. The sag is less than 0.06 times the length of the span (e.g., less than 60 feet for a 1000-foot span), and the error in the length of the wire calculated on this assumption is less than 0.002 per cent of its true value for the same limiting conditions. The formulae given below are all based on the assumption of a parabola.

**Deflection, Sag and Side Swing.** — For a given length of span  $L$ , weight  $w$ , and stress  $F$ , the deflection  $D$  for the points of support at the same elevation is given by the relation

$$D = \frac{wL^2}{8F} \quad (6)$$

When there is no wind this is also equal to the vertical sag, that is  $S = D$ . When there is wind,  $w$  is greater than the vertical loading  $v$ , and the vertical sag for the points of support at the same elevation is

$$S = \frac{vD}{w} = \frac{vL^2}{8F} \quad (7)$$

Equation (7) has the value given by equation (6). When one point of support is at an elevation  $\epsilon$  above the other, then the vertical sag of the lowest point of the conductor below the lower point of support is

$$S' = S \left( 1 - \frac{\epsilon}{4S} \right)^2 \quad (8)$$

Equation (8) is given by equation (7). The horizontal distance of the lowest point of the conductor from the lower point of support is

$$L' = \frac{L}{2} \left( 1 - \frac{\epsilon}{4S} \right) \quad (9)$$

The side swing  $Z$  of the middle point of the conductor, which is the point of maximum deflection, is the maximum distance from the vertical plane through the points of support, is

$$Z = \frac{hD}{w} = \frac{hL^2}{8F} \quad (10)$$

Equation (10) has the value given by equation (6).

**Length of Stretched Conductor.** — The length of conductor between the points of support for a given length of span  $L$ , loading  $w$ , stress  $F$  and elevation  $\epsilon$ , is

$$l = L + \frac{8D^2}{3L} + \frac{\epsilon^2}{2L} \quad (11)$$

Equation (11) has the value given by equation (6), that is,  $D$  is the deflection for the points of support at the same elevation, of span, loading and tension, but for the points of support at the same elevation.

**Effect of Changes in Loading and Temperature.**—When the loading or the temperature changes, the stress in the conductor will change to some new value,  $F_0$ , say, and the deflection will change to some new value, say  $D_0$ . Let the new loading be  $w_0$  and the new temperature be  $t_0$ , the initial temperature being  $t$ ; also let  $a$  be the coefficient of linear expansion,  $M$  the modulus of elasticity, and  $A$  the cross section of the conductor in millions of circular mils. Then, when the points of support remain fixed, the following relation will hold

$$\frac{8}{3L^2}(D^2 - D_0^2) = a(t - t_0) + \frac{1.273}{MA}(F - F_0).$$

The  $D$ 's in this equation are the same as given by equation (6) for a loading  $w$  and  $w_0$  respectively and stresses of  $F$  and  $F_0$  respectively. Note that equation (12) is independent of the difference in elevation of the two points of support, also that the two sets of symbols, with and without the subscripts, refer to any two sets of conditions.

**Stress-Deflection Charts (Fig. 8).**—In order to apply the above equations to the calculation of clearances under various conditions equation (6), namely

$$D = \frac{wL^2}{8F}, \quad (13)$$

and equation (12), which may be written

$$F = F_0 - \frac{2.10 MA}{L^2} D_0^2 - \frac{MAa}{1.273}(t - t_0) + \frac{2.10 MA}{L^2} D^2, \quad (14)$$

may be plotted for any given length of span as shown in Fig. 8, with deflection  $D$  as abscissas and the stress  $F$  as ordinates.

**Pull-up Curves.**—The curves representing the relation between  $D$  and  $F$  in equation (13) are equilateral hyperbolas, as many of these curves being drawn as there are loadings to be considered. These hyperbolas may be called "pull-up" curves, since they give the stress to which the wire must be pulled up for any given deflection. In Fig. 8 four pull-up curves are shown, one for the conductor only ( $w = 0.915$ ), conductor coated with  $\frac{1}{4}$  inch of ice but no wind ( $w = 1.19$ ), conductor coated with  $\frac{1}{2}$  inch of ice but no wind ( $w = 1.61$ ), and conductor coated with  $\frac{1}{2}$  inch of ice and a wind pressure of 6 pounds per foot of projected area of wire ( $w = 1.807$ ), this last being taken as the maximum loading.

**Loading Curves.**—The curves representing the relation between  $D$  and  $F$  in equation (14) are parabolas with vertical axes, as many of these curves being drawn as there are temperatures to be considered. These parabolas may be called "loading curves," since for a change in loading (at constant temperature) they give the relation which must exist between the new stress and new deflection produced. In order to plot these curves it is necessary to assume a maximum allowable tension, say  $T_0$  pounds per square inch, a maximum load-

Fig. 8. Stress-Deflection Chart for a 300,000-Circular-Mil, 19-Strand Copper Conductor on an 800-ft. Span

and the minimum temperature  $t_0$  at which this loading is assumed to occur

$$F_0 = \frac{AT_0}{1.273} \quad \text{and} \quad D_0 = \frac{w_0 L^2}{8 F_0}$$

For a given temperature  $t$  all the terms in the right-hand member of (14) are constant except the last term, which varies as  $D^2$ . In Fig. 8 the maximum tension  $T_0$  is taken as 30,000 pounds per square inch, the maximum loading as 1.807 pounds per foot length, and the minimum temperature under loading as  $0^\circ$  F. Then  $F_0 = 7065$  pounds and  $D_0 = 20.5$ , which fixes the  $0^\circ$  loading curve, and the other points on this curve are calculated from (14) by putting  $t = 0$ . For any other temperature, equation (14) gives the same shaped parabola as for  $0^\circ$ , but each point of the curve is shifted downward a distance  $\frac{MA\alpha}{1.273}$  for each degree increase of temperature. Hence it is only necessary to calculate the  $0^\circ$  loading curve, and the loading curve for any other temperature can be readily plotted by the use of a pair

of **Stresses and Deflections.** — In stringing cable it is essential that the deflection be correct for the stringing temperature, otherwise the stress will be

either too safe or the ground less

use to maximum exceeded amount.

Proper stringing temperature and temperature are plotted as deflection curves are

and no ice. such curves

30-foot span Fig. 8. For the cable is

1000 lbs., then it is in a deflection

(sag) of 10 feet provided the supports are at

100 pounds, independent of the difference of elevation of the two points of

there is a difference of elevation of 30 feet, say, between the two points, then from equation (8a), the cable should be drawn up until the lowest point below the lower point of support is

$$S' = 19.25 \left( 1 - \frac{30}{4 \times 19.25} \right)^2 = 7.17 \text{ feet,}$$

the cable will then be 3800 pounds.

**Calculation of Change in Deflection and Stress with Loading Temperature.\*** — When for  $F$  in equation (12) is substituted its value

from equation (13) there results a cubic equation in  $D$ . This cubic equation can be solved directly by means of Tables III and IV given herewith. (Pender, *Electrical World*, Vol. 66, p. 314, 1915.) The procedure is as follows: using the same notation as above, calculate,

$$b_1 = \frac{1273 F_0}{MA}$$

$$b_2 = \left( \frac{w_0 L}{0.155 F_0} \right)^2$$

$$b_3 = 1000 a(t - t_0)$$

$$b = \frac{1273 w L}{MA}$$

$B$  = numerical value of  $[b_1 - (b_2 + b_3)]$ ,

$$x = \frac{b}{B\sqrt{B}}$$

TABLE IV.—VALUES OF  $y$  IN TERMS OF  $x$ 

$$b_1 < (b_2 + b_1)$$

ke  $y$  from table.  
 when the deflection is

$$D = yL\sqrt{B},$$

the stress is,

$$F = \frac{wL^2}{8D}$$

note that  $b_1$  may be greater or less than  $(b_2 + b_1)$ ; in either case  $B$  is to be a positive and equal to the numerical value of  $b_1 - (b_2 + b_1)$ . Also note that is the elongation, in feet per 1000 feet, of a straight wire when subjected stress of  $F_0$  pounds.

is the number of feet per 1000 feet of wire, by which the length of the wire degrees and loading  $w_0$  exceeds the horizontal distance between the points support (when these are at the same elevation).

is the elongation, in feet per 1000 feet of wire, due solely to a change in temperature from  $t_0$  to  $t$  degrees.

$b$  is the elongation, in feet per 1000 feet of wire, due to a stress equal  $wL$  (=its own weight plus the total ice and wind, if any, at the temperature.)

**Example.** — To find the sag at which a No. 6 B. & S. stranded copper wire must be strung at 60° F. on a 400-ft. span so that the wire will have a factor of safety of two at 0° F. when loaded with ice 0.5 in. thick all around the wire and with a wind pressure of 8 lb. per square foot of projected area. The breaking strength of the wire is 4980 lb., cross-section 105,500 circ. mils, modulus elasticity  $16 \times 10^6$ , and coefficient of expansion  $9.6 \times 10^{-6}$ .

The data and calculations are then as follows:

$$\begin{aligned} F_b &= 2490 & M &= 16 \times 10^6, \\ w &= 0.323, & L &= 400, \\ w_0 &= 1.26, & t - t_0 &= 60 \\ A &= 0.1055, & \alpha &= 9.6 \times 10^{-6}. \end{aligned}$$

Then

$$b_1 = \frac{1273 \times 2490}{16 \times 10^6 \times 0.1055} = 1.878,$$

$$b_2 = \left( \frac{1.26 \times 400}{0.0155 \times 2490} \right)^2 = 1.705,$$

$$b_3 = 1000 \times 9.6 \times 10^{-6} \times 60 = 0.576,$$

$$b = \frac{1273 \times 0.323 \times 400}{16 \times 10^6 \times 0.1055} = 0.0975.$$

Noting that  $b_1$  is less than  $(b_2 + b_3)$ ,

$$B = 1.705 + 0.576 - 1.878 = 0.403,$$

$$x = \frac{0.0975}{0.403 \sqrt{0.403}} = 0.382,$$

and, from Table IV,  $y = 0.0308$ . Whence

$$D = 0.0308 \times 400 \sqrt{0.403} = 7.82 \text{ ft.}$$

This is the sag at 60° F. with no ice or wind.

The sag at 0° F. with no ice or wind is found in exactly the same way, so that for these conditions  $b_3 = 0$ , and  $b_1$  is greater than  $(b_2 + b_3)$ , giving for  $B$  value

$$1.878 - 1.705 = 0.173,$$

and for  $x$  the value

$$\frac{0.0975}{0.173 \sqrt{0.173}} = 1.355,$$

and  $y$  from Table III is then 0.0367, and

$$D = 0.0367 \times 400 \sqrt{0.173} = 6.10 \text{ ft.}$$

**Stress and Deflection in Spans of Unequal Length.** — By stringing cables according to the stress determined for each particular length of span, the maxi-

able tension will be reached in all spans under maximum loading. Under other loading conditions the tension will be unequal where the spans are not the same. This is shown in Fig. 10 which is plotted for the conditions as stated in the title of Fig. 8, but for spans of from 600 to 2400 feet length. Fig. 11 shows the corresponding deflections.

equal stresses on the two sides of the insulator will tend to bend the insulator pin, but any motion of the point of support will tend to equalize the stresses. When suspension insulators are used, the stresses are practically

since the insulator is free to move, it should be free to move in the direction of the motion of the insulator necessary to equalize the stresses. When suspension insulators are used, the cable is strung at a corresponding sag length.

When the cable is thus strung under minimum temperature and loading will need the assistance in the spans and be assumed the longer spans, under temperature the longer spans have a sag of the value on the side of the maximum tension

ed with maximum loading, and the shorter spans will have a sag calculated value. The actual stresses and deflections can be calculated by the method given in the following section.

**Calculation of Stresses in Unequally Loaded Spans.\*** — When suspension insulators are used, any tendency of the stresses in two adjacent spans to be unequal will produce such a deflection of the insulator, in the direction of the span with greater stress, as will establish equilibrium in the line. This deflection will occur (1) when adjacent spans carry unequal ice loads, (2) when there are unequal ice breaks on one side of the insulator, and (3) to a slight extent with unequal temperature when the adjacent spans are unequal in length, as noted in the following method of calculating the "equilibrium" stresses in the corresponding sags is applicable to all cases of initially unbalanced stresses irrespective of their cause. The method may also be used to calculate the stresses and sag in spans supported on pin insulators, provided the motion of the pin and of the pole or tower is known or can be calculated.

Fig. 10.

Fig. 11.

\* From lecture notes by Dr. H. Pender.

**Change of Stress Due to Change in Length of Span.** — When the length  $L$  of the span (i.e., distance between points of support) increases by  $\lambda$  inches, due to a horizontal displacement of the insulators (without slipping of the wire), the stress in the wire is increased by the same amount as would be produced by a fall in temperature of

$$t - t' = \frac{\lambda}{12 \alpha L} \quad \text{or} \quad t' = t - \frac{\lambda}{12 \alpha L} \quad (15)$$

degrees Fahrenheit, where  $t$  is the actual temperature and  $t'$  may be called the "equivalent" temperature corresponding to the change in length  $\lambda$ . In the equation  $\lambda$  is the actual increase in the distance between the points of support in inches,  $\alpha$  the temperature coefficient of linear expansion per °F., and  $L$  the original length of the span in feet. For example, in an 800-foot span of copper wire an increase of 1 inch in  $L$  corresponds to a drop of temperature of  $t - t' = (12 \times 9.6 \times 10^{-6} \times 800) = 10.85$  degrees, and an increase in length of 4 inches corresponds to a drop of temperature of  $t - t' = 10.85 \lambda$  degrees.

Hence the stress-deflection chart for any given length of span, see Fig. 8, may be used directly to determine the stress in the wire after any change in the length of the span, due to the deflection of the insulator. For example, consider an 800-foot span of 300,000-circular-mil, bare, copper conductor, at 32° F., without ice or wind, initially stressed to 4170 pounds, and let the length of the span be increased 4 inches as the result of the deflection of the insulators by this amount. This increase in length of span will then give the same stress in the wire as would be produced if the temperature fell from 32° to  $t' = 32 - 4 \times 10.85 = -11.4$ °. The point at which the loading curve (Fig. 8) corresponding to a temperature of  $-11.4$ ° crosses the pull-up curve for conductor only gives the new stress, viz., 4700 pounds.

**Horizontal Pull of Insulator.** — Referring to Fig. 12, let  $m$  = the horizontal distance in inches (measured along the span) which any insulator is deflected from the vertical, taken positive when to the right, say, and negative when to the left. Let  $x$  = the length of the insulator string in inches, i.e., distance from point of attachment to tower to point of attachment to wire;  $V$  = total weight of wire and ice between the lowest point of the wire in the span to the left of the insulator and the lowest point of the wire in the span to the right of the insulator plus one-half the weight of the insulator;  $H$  = total wind pressure on the length of wire between the middle points of the two adjacent spans, plus half the wind pressure on the insulator; and put  $W = \sqrt{V^2 + H^2}$ . Then the horizontal component of the pull of the insulator toward the left along the line of the span is \*

$$P = \frac{m}{\sqrt{x^2 - m^2}} \cdot W. \quad (16)$$

For example, consider two adjacent spans of 300,000-circular-mil copper, each 800 feet long and with points of support at the same elevation. Let the span to the left be free of ice and let the one to the right have a  $\frac{1}{2}$ -inch ice coating. Assume the insulator to be 60 inches long and to weigh 100 pounds. Then is no wind  $H = 0$ ,  $V = 1.19 \times 400 + 0.915 \times 400 + 100/2 = 892$  pounds. Hence for deflections of the insulator of less than 12 inches the horizontal pull of the insulator is  $P = (892 \times m) + 60 = 14.9 m$ , or 14.9 pounds per inch deflection.

\* When  $m$  is less than 50 per cent of  $x$  this may be written, with an error of less than 2 per cent,

$$P = \frac{m}{x} W. \quad (16')$$

**Stresses in a Series of Spans When Points of Support are not ed.** — Referring to Fig. 12, let the left-hand end of span No. 1 be anchored, assume the insulator at the right-hand end to be deflected a horizontal distance of  $m_1$  inches, due, for example, to a change in the loading on the succeeding

Fig. 12.

ns (or to a change in temperature when the spans are of unequal length). In equation (15) calculate the "equivalent" temperature  $t_1'$  corresponding to this change in length, and from the pull-up curve in Fig. 8 corresponding to assumed loading  $w_1$  of this span find the stress on this curve corresponding to a temperature of  $t_1'$  degrees; call this stress  $F_1'$ .

Next calculate the transverse and vertical loads on the insulator, viz.,  $H_1$  and  $V_1$ , and the resultant load  $W_1 = \sqrt{V_1^2 + H_1^2}$ , as explained in the preceding section. Then from equation (16) or (16a) calculate the horizontal pull  $P_1$  of the insulator. The stress in the second span, assuming the value of  $m_1$  chosen at start is correct, must then be

$$F_2' = F_1' + P_1. \quad (17)$$

is then determined from  $F_2'$  on the pull-up curve. From equation (15) the corresponding increase in the length of span No. 2 must then be

$$\lambda_2 = 12 \sigma L_2 (t - t_2'), \quad (18)$$

where  $L_2$  is the length of the second span. The corresponding deflection of the insulator at the right-hand end of span No. 2 must then be

$$m_2 = m_1 + \lambda_2. \quad (19)$$

Always taking the insulator deflection positive when to the right, say.

Using the values of  $\lambda_2$  and  $m_2$  thus found, calculate the  $\lambda_3$  and  $m_3$  in exactly the same manner as  $\lambda_2$  and  $m_2$  were calculated, and similarly for the succeeding spans until the next anchor tower is reached. For the anchor tower at the right-hand end of the  $n$ -th span, say, the deflection of the insulator must be zero, viz.,

$$m_n = 0. \quad (20)$$

$m_n$  as calculated comes out greater than zero, then the assumed value of  $m_1$  is too great; if  $m_n$  comes out less than zero the assumed value of  $m_1$  is too small. By calculating  $m_n$  for two or three assumed values of  $m_1$ , and plotting  $m_n$  as ordinates against  $m_1$  as abscissas, the correct value of  $m_1$  will be where this curve crosses the axis of abscissas. Using this correct value of  $m_1$ , the stresses and deflections in each span may then be accurately calculated by the process first given, using the Stress-Deflection Chart, Fig. 8. The complete process is as shown by an example.

**Example.** — Consider the case of three spans between anchor towers, (Fig. 12) all of the same length, 800 feet, and all supports at the same elevation, 30,000-circular-mil copper being used for the conductor. Let the temperature be  $32^\circ$  F., and let the middle span have a  $\frac{1}{4}$ -inch ice coating but the other two spans have no ice on them; also assume no wind. The Stress-Deflection Chart given in Fig. 8 then applies directly, provided the wires are strung in accordance herewith. Assume that each insulator weighs 100 pounds and has a length of

60 inches. Then for an increase of  $\lambda$  inches in the length of any span, the "equivalent" temperature is, from equation (15),

$$t' = 32 - 10.85 \lambda$$

or if the equivalent temperature rise  $t'$  is known

$$\lambda = 0.092 (32 - t').$$

The horizontal pull of any insulator for a deflection of  $m$  inches (small compared with the length of the insulator) is, from equation (16a),

$$P = 14.9 m.$$

In the following table are given the calculations for assumed values of  $m_1$  of 1, 2, 3 and 4 inches, and in Fig. 13 are plotted the corresponding calculated values of  $m_2$  against  $m_1$ . It is seen that the relation between  $m_2$  and  $m_1$  is practically a straight line cutting the horizontal axis at  $m_1 = 2.4$ , which is therefore the correct value of  $m_1$ . The calculations for  $m_1 = 2.4$  inches are given in the last column of the table. Hence the stresses and deflections in the two end spans (without ice) are  $F_1' = F_2' = 4460$  pounds and  $D_1' = D_2' = 16.3$  feet respectively, and the stress and deflection in the middle span loaded with  $\frac{1}{4}$ -inch of ice are  $F_3' = 4496$  pounds and  $D_3' = 21.1$  feet respectively, the deflections being read directly from Fig. 8 corresponding to the proper stresses and loadings ( $w$ ).

**LOCATION OF TOWERS AND DETERMINATION OF CLEARANCES.**—The height of towers is determined so as to give some specified minimum clearance from conductor to ground for some length of span chosen as a nominal standard on the basis of level ground. In practice the ground is rarely level and the towers are actually located to conform to the irregularities of the ground. In locating towers of a given height the spans are made as long as possible consistent with maintaining the ground clearance. The irregularities of the ground are ordinarily advantageous and permit of slightly longer spans on the average than could be obtained with the same height of towers on level ground.

**and Plan of Right-of-Way.** — In order to locate towers properly sary to have a profile of the right-of-way. Profiles are conveniently standard ruled profile section paper to a vertical scale of 20 feet to the horizontal scale of 200 feet to the inch. Three profiles are desirable; the center of the tower line and one on each side, say at each edge of 17, as shown on Fig. 14 at *A*, *B* and *C*. The two side profiles indicate t and direction of the slope of the ground across the line, which must i for in determining ground clearance and foundation or tower

f the right-of-way is of course also necessary for determining the cont angles in the line, and the clearances from the conductor to the edge it-of-way when the conductor is deflected horizontally by the wind. n is shown at the bottom of Fig. 14.

**Templates for Locating Towers.** — Three templates are required, one for rance with maximum sag, marked *M* in Fig. 14, one for uplift at inimum sag, marked *N*, and one for maximum side swing, marked *Z*. ut from thin celluloid and are to the same horizontal and vertical ed for the profile and plan of the right-of-way.

curvature of the catenary or parabola in which the wire hangs de- on the tension and loading and not on the length of the span or on ce in elevation of the points of support, all spans having the same l loading can be drawn (for any one predetermined scale) from a late, irrespective of their lengths or of the differences in elevation of of support. However, when the elevations of the points of support same, the lowest point of the curve is shifted from the middle of the l the lower support, but the axis of the curve remains vertical.

**Construction of Maximum Sag Template *M*.** — The maximum sag on the Stress-Deflection Chart, Fig. 8, and may be the deflection ng to the maximum temperature, and conductor only, e.g., 21.4 feet may be the deflection corresponding to 32° F. and the maximum

Wind will increase this deflection but will not increase the *vertical*  $S_m$  this maximum sag. Then the equation of the maximum sag template *M*, is

$$y = \left( \frac{4 S_m}{L^2} \right) x^2, \quad (21)$$

he length of the particular span for which the maximum sag is  $S_m$ , in of the curve is its lowest point and the axis of *y* is vertical; all are in feet. Three parabolic curves are given by this template; the presents the position of the cable and is drawn on the basis of the 1 under the maximum load; the middle curve is a similar parabola pper curve a distance equal to the minimum allowable clearance to e bottom curve is another similar parabola below the upper curve e equal to the height of cable above ground at the support.

**Construction of Minimum Sag Template *N*.** — The minimum sag is rom the Stress-Deflection Chart, and is usually the deflection cor- o the minimum temperature and conductor only, e.g., 15.1 feet in l this sag  $S_n$ ; then the equation of the minimum sag template, or is

$$y = \left( \frac{4 S_n}{L^2} \right) x^2. \quad (22)$$

**Construction of Maximum Side-swing Template *Z*.** — The maxi- wing occurs at time of maximum wind pressure and may be at

Fig. 14. Chart Showing Use of Templates in Locating Towers and Determining Clearances

imum temperature or may be at  $32^{\circ}$  F. when covered with ice. In the latter case the side swing depends on the shape (circular or elliptical) of the covering and its specific gravity. For a circular covering of solid ice one particular thickness (usually but not necessarily the maximum thickness) gives the greatest side swing. For example, in Fig. 8, the maximum side swing occurs  $D = 21.7$  and  $w = 1.807$ , and its value is, see equation (16),  $Z = (0.815 \times 21.7) \times 1.807 = 9.8$  feet, 0.815 being the wind pressure per foot of wire. Calling the maximum side swing  $Z_m$ , then the equation of the side swing template, or template  $Z$ , is

$$y = \left( \frac{4Z_m}{L^2} \right) x^2. \quad (23)$$

**Locating Towers by Means of Template  $M$ .**—Choose a starting point, as shown for example in Fig. 14, at station  $0 + 00$ , elevation 500.0 feet for the first tower location. The template  $M$  is then placed over the profile and shifted until its axis is vertical and the lower curve is at station  $0 + 00$ , elevation 500.0 feet, and the middle curve is tangent to the ground profile as shown. The proper location for the second tower is at the point where the lower curve again intersects the ground profile, or at station  $8 + 00$ , elevation 506.0 feet, in the example. The operation is then repeated for the next tower. Adjustments in length of spans are usually necessary to meet local conditions, in order to avoid locating towers in roads or swamps and to bring towers at angle points. Adjustments which increase the ground clearance are of course allowable.

The position of the conductors with maximum sag may be drawn on the profile on the top curve of the template.

**Uplift on Insulator; Use of Template  $N$ .**—An insulator sustains the weight of the lengths of conductor from the insulator to the lowest point of the span on each side. If the conductor leaves the insulator horizontally on one side, the lowest point of that span is at the insulator, which then sustains no weight due to that span. If the conductor has an upward inclination where it leaves an insulator, it is exerting an uplift equal to the weight of a length of conductor extending from the insulator along the span produced in the reverse direction to the lowest point of the parabola. Where the conductor has a downward inclination on one side and upward on the other side of the insulator, there must be a weight or uplift on the insulator equal to the difference between the weight of conductor on one side and uplift on the other.

Suspension insulators when used hanging downward to sustain weight are capable of resisting uplift. Where uplift occurs the conductor may be dead ended or may be tied down or weighted down.

The method used for locating towers ordinarily precludes uplift under the loading which gives maximum sag, but uplift may occur when the loading is less. To determine this the minimum sag is drawn on the profile with template  $N$ . The minimum sag curve is drawn between points of support, keeping the axis of the parabola vertical as before.

**Side Swing of Suspension Insulators.**—Let  $l_1$  = the length of conductor between the lowest point in the span to the left of the insulator and the lowest point in the span to the right of the insulator, and let  $l_2$  = the distance between the middle points of these two spans, both in feet. Also let  $w$  = the weight of the conductor and ice per foot length, and  $h$  = the wind pressure per foot length (see Table II). Then the vertical pull on the insulator is  $wl_1$  and the transverse horizontal force is  $M_1$ . Also let  $w_1$  = the weight of the insulator and  $h_1$  = the total wind pressure on it. Then the insulator is deflected sidewise from the vertical by approximately the angle

$$\theta = \tan^{-1} \left[ \frac{M_1 + 0.5 h_1 l_1}{wl_1 + 0.5 w_1 l_1} \right]. \quad (24)$$

Usually the weight of the insulator and the wind pressure on it are negligible compared with the weight and wind pressure on the conductor, in which case

$$\theta = \tan^{-1} \left( \frac{h_1}{w_1} \right). \quad (11a)$$

When the points of support are at the same elevation  $h_1 = h_2$  and

$$\theta = \tan^{-1} \frac{h}{p}. \quad (11b)$$

Calling  $X$  the length of the insulator in feet then the transverse horizontal deflection of the insulator is  $X \sin \theta$  feet.

For example, consider the side swing of the third insulator (from the left) in Fig. 14. Then  $h_1 = 470$ ,  $h_2 = 850/2 + 600/2 = 725$ ,  $w = 1.61$  (for 300,000-circular-mil conductor with  $\frac{1}{2}$  inch of ice), and  $h = 0.82$  (for wind pressure of 6 pounds per square foot). Whence, neglecting the weight of the insulator and the wind pressure on it,

$$\theta = \tan^{-1} \frac{0.82 \times 725}{1.61 \times 470} = 38^\circ.$$

If the insulator is 5 feet long, the transverse horizontal deflection is then  $5 \sin 38^\circ = 3.1$  feet.

If the angle of swing as thus determined is excessive the cables and insulators will be lifted up into the cross arms at times of low temperatures and high winds. The remedy is the same as in case of direct uplift.

**Side Clearance; Use of Template Z.** — Where a right-of-way of definite width is obtained it is necessary to determine whether the conductor will swing beyond the edge of the right-of-way. Therefore after the towers have been located by the use of the profile they should be marked on the plan and the side swing marked in from template Z, as shown in Fig. 14. In determining the side swing, the swing of the insulator (if suspension type) must be allowed for, as well as the side swing of the conductor. Adequate margin should be allowed between the extreme position of conductor and the edge of the right-of-way, so that a safe clearance will be preserved from any structures erected adjacent thereto. Where extraordinarily long spans must be used, an adequate extra width of right-of-way should be obtained in the first place.

**Loss of Clearance Between Conductors Due to Unequal Ice Loading.** — Where one span is loaded with ice and the one immediately below it is not, the clearance is reduced. This condition may sometimes arise due to the ice falling off the lower wire before it falls off the upper wire. Where the wires are directly over each other the normal clearance must be great enough to prevent the crossing of wires under these conditions. For ice loading without wind, clearance under unequal loading is most easily obtained by offsetting the wires horizontally for the required clearance instead of increasing the vertical clearance. However, to prevent crossing of the unequally loaded wires when deflected by wind pressure, this horizontal offset must be considerable, as the clearance must then be obtained between the wires in their inclined positions.

If the conductors to which Fig. 8 refer are normally 10 feet apart vertically on an 800-foot span, the sag would be 17.5 feet without ice at  $32^\circ$  F., 19.0 feet with  $\frac{1}{4}$ -inch ice, and 20.9 feet with  $\frac{1}{2}$ -inch ice at  $32^\circ$  F. Consequently, if two cables are used one above the other, and ice should form on the upper but not on the lower, then, assuming fixed points of support (pin insulators), the clearance would be reduced by 3.4 feet for  $\frac{1}{4}$ -inch ice, and 1.5 feet for  $\frac{1}{2}$ -inch ice, making the clearances 6.6 feet and 8.5 feet respectively, instead of 10 feet.

## Transmission Lines; Erection

Where suspension insulators are used the reduction of clearance from loading is greater. If one span is loaded with ice and the adjacent same wire are not loaded, the sag of the loaded span will be increased; insulators will swing toward that span. Similarly if one span is loaded and adjacent spans are loaded, the sag will be decreased. The minimum clearance occurs where by one span of the upper wire is loaded and is immediately above the only unloaded span of the lower wire. The actual reduction is readily calculated by the method given above in the section on *Calculation of Stresses in Unequally Loaded Spans*, p. 15. The amount of reduction depends on the number of spans between anchor towers, and the distance from the anchor towers which the unbalanced loading occurs. For a 300,000-circular-mil copper cable on 800-foot spans with unequal loadings on sections of one, two, three and five spans (see assumed conditions of unequal loading and the loss of clearance below):

Fig. 16.

Number of spans between anchor towers	1	2	3
Upper conductor; $\frac{1}{4}$ -inch ice on spans Nos. 1 <sup>a</sup> ...	1	1	2
Lower conductor; $\frac{1}{4}$ -inch ice on spans Nos. 1 <sup>a</sup> ...	...	2	1, 3
Sag of middle span of upper conductor, feet....	19.0	20.5	21.1
Sag of middle span of lower conductor, feet.....	17.5	15.9	15.5
Loss of clearance in middle span, feet.....	1.5	4.6	5.6

<sup>a</sup> The other spans assumed to have no ice load.

**Stresses and Deflections Due to Broken Conductors.**—When a conductor breaks in a span supported by suspension insulators, the insulator is pulled up into line with the cable, throwing the cable into the unbroken part of the cable equal to the length of the cable. The slack divides between the unbroken spans, increasing the deflection. The stresses and deflections of the unbroken spans may be calculated by the method given above in the section on *Calculation of Stresses in Unequally Loaded Spans*, p. 1803, calling the span in which the break occurs span *n*.

**ERECTION OF TRANSMISSION LINES.**—The preliminary work in erecting a transmission line includes the clearing of the right-of-way; of buildings (if necessary), building roads, bridges, fences, gate posts, etc., so that the right-of-way is passable. If the telephone line is to be supported on separate structures, this is generally built in advance of the main line during the rest of the construction.

After the towers are in place and the insulators placed, the wires are strung. The reels are distributed and spaced according to the weight on each. The reels of heavy cable are supported on reel jacks. The wire and cable is usually drawn out on the ground and carried over the supporting structures. Heavy cables are drawn over rollers attached to the towers at approximately the final point of support. The

out of wires and cables is usually done with horses, but under favorable conditions a traction engine or hoisting engine can be used. Where lines parallel railroads they have been pulled out successfully with locomotives. Care should be taken in drawing out the cable so as not to scratch or injure it by sharp bends or faulty cable grips, or by dragging it over sharp stones. See also the article on *Wires and Cables, Bare*.

After the cable is drawn out and is in place on the sheaves on the towers, it should be adjusted to the proper sag by using dynamometers for measuring the tension. In order to have uniform tension in all spans when pulling several at one time, the cable should be free to move at all points of support. Wires and cables should be clamped or tied in place while under the proper tension corresponding to the temperature at time of stringing. Wind loads on cables or wires are generally not of an amount during wire stringing to require allowance for additional tension. Splicing sleeves are twisted by hand wrenches in the smaller sizes and by splicing machines for the larger sizes.

At anchor towers loose jumpers must be bent to shape and not left so that they may ground on the tower due to twist of cable, pressure of wind or weight of sleet.

Where ground wires or telephone wires are also on the tower, it is equally important that they be strung at the proper tension; otherwise they may crack and ground the conductors.

Suspension towers (i.e., those intermediate between the dead-end towers) are ordinarily not strong enough to stand the strain of dead-ended cables during high winds and heavy sleet storms; consequently care must be used if cables are temporarily dead ended on them during construction.

**Transposition of Transmission Lines.**—(See also *Telephone Lines*.) Transpositions are not necessary for the proper operation of an isolated transmission line, but are used to diminish the inductive effects of the transmission line on neighboring circuits. The number of transpositions required depends principally on the sensitiveness and proximity of other circuits, especially telephone lines and on the distance that such lines parallel the transmission line, and also to a lesser degree on the current and voltage of the transmission line.

Where the voltage of transmission is 2200 or less the length of exposure (i.e., distance between two successive transposition points) is usually insufficient to require transpositions and, when the voltage is over 60,000, the lines are often at sufficient distance from nearest telephone line to make transpositions unnecessary. For voltages above 2200 and not over 60,000 a telephone line is ordinarily run the whole distance on the same poles or towers with a transmission line, thereby making transpositions necessary. Transpositions on such transmission lines are ordinarily located three miles or more apart, the telephone line also being transposed every 500 or 600 feet.

Each transposition of a three-phase line ordinarily consists of a spiral of one-third of a turn. Three transpositions give a complete spiral and bring the phases back to their original position. A line is ordinarily transposed by giving it one or more complete spirals, the transpositions being located so as to divide the line into approximately equal sections. For one complete spiral two transpositions dividing the line into thirds are sufficient, though the equivalent of a third transposition is necessary at one end if the phases are to have the same relative position in the station wiring at each end.

Special poles or towers are usually necessary at transposition points.

**TESTS AND INSPECTION OF TRANSMISSION LINES.**—Tests on transmission lines include testing of the several parts; conductors, insulation, pins, clamps, ties, towers, etc., and are described in the articles on *Wires and*

ulators for Overhead Lines; Poles for Overhead Lines, Cross Arms; be efficiency and other electrical characteristics of transmission lines put with such certainty that tests are not necessary to determine them, though the calculations are occasionally checked by observations on actual operation.

When the line is completed it should be carefully inspected to see that all joints are made, all insulators put on, etc. Moreover, before starting continuous operation, it is advisable to apply voltage in order to make sure that the line is properly circuited, short-circuited or grounded.

When two or more transmission lines are to be in parallel, or where a new line is to be connected to points already connected by other lines, it is necessary to test out the corresponding phases before connecting in multiple, especially if any of the lines are to be transpositions.

**IRON.** — Patrolmen are usually located between ten and twenty miles depending on the character of the country. The cooperation of the local people along the line must be obtained in order to prevent damage by cutting insulators, throwing wires over the conductors, blasting rocks or trees on the line, etc. Patrolmen should inspect the line regularly and keep away from inflammable material from the poles and towers. They should also check the condition of the foundations, towers, poles, insulators and conductors. In addition they should make minor and emergency repairs on the line.

Switches are often installed at each patrolman's house. By manipulating the switches any section of line may then be tested for faults.

The maintenance of a line includes resetting foundations that have shifted; leveling of foundations with earth to proper depth after heavy rains; painting towers before they are affected by rust; renewal of rusted ground rods; replacement of cracked or partially defective insulators that have not held; sagging of any cable where sag has changed due to stretch of cable, etc. In addition, during emergency repairs, etc.

**Connections.** — A good telephone line is essential and the patrolman should report by telephone at regular intervals. As a convenience in the country, telephones are installed or connections are provided for a portable telephone at intervals of three or four miles along the line. For the higher voltage lines, protection must be provided for the person using telephone. This protection includes insulated stools, telephone insulating transformers, telephone lightning arresters and fuses.

**TRANSMISSION LINES.** — To obtain an accurate estimate of the cost of a transmission line the cost of the various elements should be separated. The following over-all costs based on before-the-war prices are given as a rough guide in preliminary estimating.

**Right-of-Way.** — The cost of the right-of-way for a low-voltage line is a nominal amount for a line on public roads, to \$10,000 per mile or more for a wide right-of-way in thickly settled districts. A right-of-way 100 feet wide requires approximately 12 acres per mile, which for farming land at \$200 per acre amounts to \$2400 per mile. Land values may be expected to be considerably higher for right-of-way than for farming, especially if a road or a desired crossing a farm diagonally.

**Right-of-Way for high-voltage tower lines** should be estimated liberally as they usually have long spans and few angles, and cannot be diverted around trees, rocks and obstructions as readily as short-span wooden-pole lines.

**Size and Cost of Conductor on Total Cost.** — The size and material of conductors greatly affect the cost of a line. A circuit of 3

No. 0000 cables costs about \$1500 per mile with copper at 14.4 cents per lb and \$2000 per mile at 19.2 cents per pound. The cost of smaller cables is proportionally less; No. 0 being about one-half, No. 3 about one-fourth and about one-eighth the cost of No. 0000. Thus the copper cost of a three line will range from about \$205 per mile for No. 6 at 15.6 cents per pound \$2000 per mile for No. 0000 at 19.2 cents per pound.

For the same power loss in the line aluminum conductors usually cost 10 per cent less than copper.

**Total Structural Cost of Wooden Pole Lines.** — The structural cost of a wooden-pole transmission line ordinarily ranges from about \$1500 per mile for an 11,000-volt line with 3 No. 6 wires to about \$4000 per mile for a 55,000-volt line with 3 No. 0000 wires, excluding the cost of right-of-way. To the structural cost and cost of right-of-way should be added the charges for engine contractor's services, superintendence, tools and equipment, etc., which amount to from 20 to 40 per cent of the structural cost.

**Total Structural Cost of Tower Lines.** — The cost of light tower line for 55,000 volts with 3 No. 0000 wires may be as low as for a wooden pole line about \$4000 per mile. For 110,000 volts with three 300,000-circular-mil. wires the cost may be about \$8000 per mile or more. The cost of towers proper varies greatly according to the views of the designers as to what risks are proper design, that is, the severity of assumed wind and ice loadings, and the margin of safety. The cost of foundations is very small when simple steel structures are used in very firm ground, but foundations add greatly to the cost of a line when concrete or steel structures are used, so designed as to make the strength and holding power of the foundations actually equal to the strength of the tower under reasonably unfavorable conditions of ground. See article *Towers for Transmission Lines*.

**TRIGONOMETRIC FUNCTIONS.** — (*See also Derivatives; Integrals; Geometrical; Trigonometry.*) The trigonometric functions of an angle are defined as the ratios of one side of a right triangle having the given angle to another of the various sides of a right triangle having the given angle. Referring to Fig. 1, let  $B$ ,  $P$  and  $H$  be the three sides of the triangle. Then the trigonometric functions of the angle  $x$  are

abbreviated  $\sin x = \frac{P}{H}$ ; cotangent of  $x$ , abbreviated  $\cot x = \frac{B}{P}$ ;  
 abbreviated  $\cos x = \frac{B}{H}$ ; secant of  $x$ , abbreviated  $\sec x = \frac{H}{B}$ ;  
 abbreviated  $\tan x = \frac{P}{B}$ ; cosecant of  $x$ , abbreviated  $\csc x = \frac{H}{P}$ .

and  $H$  are limited to the three sides of a right triangle, the above are directly applicable only to angles lying between  $0$  and  $90^\circ$ . They, however, may be extended by considering the point  $A$  (Fig. 2) as

Fig. 1.

Fig. 2.

circle of radius  $OA$  with the center at  $O$ . Let  $XX'$  be the horizontal diameter and  $YY'$  the vertical diameter of this circle, and call  $P$  the perpendicular distance from  $A$  to the line  $XX'$  and  $B$  the horizontal distance from  $A$  to the vertical diameter.  $P$  and  $B$  are considered positive when  $A$  lies above  $XX'$ , negative when  $A$  lies below  $XX'$ ;  $B$  is considered positive when  $A$  is to the right of  $YY'$  and negative when  $A$  is to the left of  $YY'$ . The four quarters of the circle are called quadrants, and are the first, second, third and fourth quadrants as indicated. The trigonometric functions of an angle  $x$  lie in the quadrant in which the point  $A$  lies. In Fig. 2 the angle  $x$  lies in the second quadrant.

**ALGEBRAIC SIGNS OF THE FUNCTIONS**

	Sine	Cosine	Tangent
first quadrant.....	+	+	+
second quadrant.....	+	-	-
third quadrant.....	-	-	+
fourth quadrant.....	-	+	-

**Period.** — From the above definitions it is evident that adding  $2\pi$  radians or  $360^\circ$  to an angle does not change the value of any of its functions, that is, the functions repeat themselves every time the angle increases by the  $2\pi$  radians or  $360^\circ$ . They are therefore said to have a period equal to  $2\pi$  radians or  $360^\circ$ .

**Functions of Angles in Any Quadrant in Terms of Angles in First Quadrant.**—

$\sin(-x) = -\sin x,$	$\sin(90+x) = \cos x,$
$\cos(-x) = \cos x,$	$\cos(90+x) = -\sin x,$
$\tan(-x) = -\tan x,$	$\tan(90+x) = -\cot x,$
$\sin(180-x) = \sin x,$	$\sin(180+x) = -\sin x,$
$\cos(180-x) = -\cos x,$	$\cos(180+x) = -\cos x,$
$\tan(180-x) = -\tan x,$	$\tan(180+x) = \tan x,$
$\sin(270-x) = -\cos x,$	$\sin(270+x) = -\cos x,$
$\cos(270-x) = -\sin x,$	$\cos(270+x) = \sin x,$
$\tan(270-x) = \cot x,$	$\tan(270+x) = -\cot x.$

**Table of Trigonometric Functions.** — By making use of the above relations the functions of any angle may be obtained from a table giving the values of the functions for angles between  $0$  and  $90^\circ$ . Such a table is given below. For  $\sec$ ,  $\csc$  and  $\cot$  take the reciprocals of the  $\tan$ ,  $\cos$  and  $\sin$  respectively.

**Example of Use of Table.** —  $\sin 21.6^\circ = 0.3681$ ,  $\cos 21.6^\circ = 0.9299$ ,  $\tan 21.6^\circ = 0.3959$ ;  $\sin 107^\circ = \sin(180^\circ - 107^\circ) = \sin 73^\circ = 0.9563$ ,  $\cos 107^\circ = -\cos 73^\circ = -0.2924$ ,  $\tan 107^\circ = -\tan 73^\circ = -3.2709$ .

actions. — If  $a = \sin x$ , then  $x$  is the angle whose sine is  $a$ ; this may be symbolically  $x = \sin^{-1}a$ , which is read “ $x$  equals the angle whose sine is  $a$ .” The angle  $x$  is also called the “anti-sine” or the “inverse sine” of  $a$ . The same notation is used for the other functions; for example,  $x = \cos^{-1}b$  expresses the relation that  $x$  is the angle whose cosine is  $b$ . At least two “inverse functions” must be known to completely determine the quadrant in which the angle lies; for example, if  $x = \sin^{-1}0.5$  then  $x$  may be either  $30^\circ$  or  $150^\circ$ ; if we also have  $x = \cos^{-1}0.866$ , then  $x$  must equal  $30^\circ$ , while if  $x = \sin^{-1}0.866$ , then  $x$  must equal  $150^\circ$ .

Values may be taken from the table given above by finding the angle in the table corresponding to the function in the table. *Example:*  $\sin^{-1}0.319 = 180^\circ - 18.6^\circ = 161.4^\circ$ .

— The expression  $(1 - \cos x)$  is called the “versine” of  $x$ .

**Among Functions of the Same Angle. —**

$$\begin{aligned} x &= \frac{\sin x}{\cos x} = \frac{1}{\cot x}, & \sin^2 x + \cos^2 x &= 1, \\ x &= \frac{1}{\cos x}, & 1 + \tan^2 x &= \frac{1}{\cos^2 x}, \\ x &= \frac{1}{\sin x}, & 1 + \cot^2 x &= \frac{1}{\sin^2 x}, \\ \sin(-x) &= -\sin x, & \sin(-x) &= -\sin x, \\ \cos(-x) &= \cos x, & \cos(-x) &= \cos x, \\ \tan(-x) &= -\tan x, & \tan(-x) &= -\tan x. \end{aligned}$$

**Difference of Two Angles. —**

$$\begin{aligned} \sin(x+y) &= \sin x \cos y + \cos x \sin y, \\ \cos(x+y) &= \cos x \cos y - \sin x \sin y, \\ \tan(x+y) &= \frac{\tan x + \tan y}{1 - \tan x \tan y}, \\ \sin(x-y) &= \sin x \cos y - \cos x \sin y, \\ \cos(x-y) &= \cos x \cos y + \sin x \sin y, \\ \tan(x-y) &= \frac{\tan x - \tan y}{1 + \tan x \tan y}. \end{aligned}$$

**Products of the Functions of Two Angles. —**

$$\begin{aligned} \sin x \sin y &= \frac{1}{2} [\cos(x-y) - \cos(x+y)], \\ \sin x \cos y &= \frac{1}{2} [\sin(x+y) + \sin(x-y)], \\ \cos x \sin y &= \frac{1}{2} [\sin(x+y) - \sin(x-y)], \\ \cos x \cos y &= \frac{1}{2} [\cos(x+y) + \cos(x-y)]. \end{aligned}$$

**Double an Angle. —**

$$\begin{aligned} \sin 2x &= 2 \sin x \cos x, & \cos 2x &= \cos^2 x - \sin^2 x, \\ \tan 2x &= \frac{2 \tan x}{1 - \tan^2 x}. \end{aligned}$$

**Half an Angle. —**

$$\frac{1 - \cos x}{2}, \quad \cos \frac{x}{2} = \sqrt{\frac{1 + \cos x}{2}}, \quad \tan \frac{x}{2} = \sqrt{\frac{1 - \cos x}{1 + \cos x}}$$

**Three Times an Angle. —**

$$\begin{aligned} \sin 3x &= 3 \sin x - 4 \sin^3 x, & \cos 3x &= 4 \cos^3 x - 3 \cos x, \\ \tan 3x &= \frac{3 \tan x - \tan^3 x}{1 - 3 \tan^2 x}. \end{aligned}$$

**TRIGONOMETRY.** — (See also *Trigonometric Functions.*) Any triangle completely defined when, (1) two sides and the included angle are known (2) one side and two angles are known, (3) three sides are known. Let sides and angles of a triangle be designated as in Fig. 1.

1. Given two sides  $a$  and  $b$ , and the included angle  $\gamma$ . Then

$$c = \sqrt{a^2 + b^2 - 2ab \cos \gamma}$$

$$\sin \alpha = \frac{a}{c} \sin \gamma$$

$$\beta = 180 - \alpha - \gamma.$$

Fig. 1.

2. Given the side  $a$  and the two angles  $\beta$  and  $\gamma$ . Then

$$\alpha = 180 - \beta - \gamma$$

$$b = a \frac{\sin \beta}{\sin \alpha}$$

$$c = a \frac{\sin \gamma}{\sin \alpha}.$$

3. Given the three sides  $a$ ,  $b$  and  $c$ . Put

$$s = \frac{1}{2}(a + b + c)$$

Then

$$\sin \alpha = \frac{2}{bc} \sqrt{s(s-a)(s-b)(s-c)}$$

$$\sin \beta = \frac{b}{a} \sin \alpha$$

$$\gamma = 180 - \alpha - \beta.$$

**Relations Between Sides and Angles.** — The following relations between the sides and angles of a triangle are sometimes useful:

$$\frac{a}{\sin \alpha} = \frac{b}{\sin \beta} = \frac{c}{\sin \gamma}$$

$$\cos \alpha = \frac{b^2 + c^2 - a^2}{2bc}$$

$$\sin \frac{\alpha}{2} = \sqrt{\frac{(s-b)(s-c)}{bc}}$$

$$\cos \frac{\alpha}{2} = \sqrt{\frac{s(s-a)}{bc}}$$

and similar relations for the other two angles.

y wire is usually of hard-drawn copper but sometimes of steel, ended from insulators some 16 to 30 feet above the ground, and continuous contact surface to a trolley wheel or bow attached to rock. There are two classes of trolley construction, the span wire bracket; each may have either simple or catenary suspension.

**Span and Side-bracket Construction.**— In the simple span wire the trolley wire is supported by wires stretched across the tracks or building walls. The side-bracket construction resembles the first except that instead of the supporting wire being stretched between poles it is stretched between two supports on the same pole. In both of these constructions, the trolley wire is supported at intervals of 100 feet and sags considerably between supports, making it necessary for the trolley to have a constant vertical vibration as the cars move.

**Catenary Construction.**— The speed attained upon modern electric roads is difficult to obtain satisfactory service with a trolley wire which dips between supports and sags and sways with every impulse. The catenary system was devised to meet this condition. In general, it consists of a messenger wire suspended horizontally from a sagging messenger wire. The supporting wires are suitably insulated and firmly held in place. The supporting system is generally employed for interurban single- or double-track roads of the catenary type, but for some conditions cross-span construction becomes necessary. The latter method of support differs only in the substitution of a cross-span for the bracket arm and doubling the number of poles for double-track.

**CHOICES OF VARIOUS TYPES OF CONSTRUCTION.**— The trolley system is used on urban railways, wherever the unsightliness or exposed construction is not considered objectionable. It is used on rural and suburban lines wherever the current taken by the trains is not economically carried on copper wires. In recent years it has been used in connection with the alternating-current systems of electric traction on city lines.

Span construction is the most slightly for double-track city railways, where lateral brackets are used, side-pole construction being generally used for single-track lines. Span-wire construction is used where, for any reason, it is practicable to have the poles near the tracks or where, as is common in Europe, the span wires are supported from the walls of buildings. The objection against overhead lines is often due to the excessive loading of the wires, which is both unsightly and dangerous.

**ELECTRICAL DESIGN OF CONDUCTORS.**—In designing the trolley system careful attention must be given to both the electrical and mechanical features. In this section will be treated the electrical features, and in the following section the mechanical features. The electrical design of railway distribution systems involves the consideration of potential drop, heating of conductors and feeder economy. The heating of conductors is seldom an important factor in railway feeder design, as it is usually necessary to use low current density to keep down the drop of potential. A discussion of the heating of conductors will be found under *Wires and Cables, Bare*. The trolley system being sufficient to meet the conditions imposed by the allowable potential drop (*see below*), it will be economical to make it greater if the saving in the cost of energy which will result, is greater than the increased interest and other charges on the additional investment.

**Allowable Potential Drop.**—The total potential drop is limited by the necessity of running the cars at a certain speed and by the need of keeping the car lights brilliant. The potential drop in the ground conductors, i.e., the track rails and bare negative feeders, is further limited by the danger of electrolysis by current leaking into the earth (*see article on Electrolysis*).

The drop in the grounded conductors under maximum-load conditions is limited by law in Great Britain to 7 volts between any two points of the system. In Germany the maximum drop in the grounded conductors is limited to 1 volt per kilometer (1.61 volts per mile). In the United States the legal limit is a matter of local option and is, in general, less severe than in Europe.

**Calculation of Potential Drop.**—The method of calculation of potential drop depends upon the following conditions: (1) whether the current is direct or alternating; (2) whether the load is concentrated at one point, sparsely distributed or evenly distributed; (3) the distribution of metal in the feeder circuit and (4) whether the section is being fed by one or by two or more substations. Calculations for alternating-current lines differ from those for direct-current lines only in taking into account the inductance, as described below. On trolley railways it is usual to assume the load to be evenly distributed, it being stated as a given number of amperes per foot (*see article on Railways, Energy Requirements and Motor Capacity for*). If the load is actually concentrated at equidistant points, the drop will exceed that calculated on the assumption of

uniform distribution by about  $\frac{100}{N}$  per cent. On interurban and trunk lines the cars are usually concentrated at one or two points between substations making the assumption of uniform distribution impracticable. In such cases the loads should be located so as to give the worst conditions, and calculations made as for any network.

Where electrolytic damage is to be guarded against, the drop of potential in the track rails themselves has to be calculated, as well as the total drop in the rails and feeders.

**Resistance of Trolley and Track.**—Values of the resistance of trolley wires to direct current will be found in the article on *Wires and Cables, Bare* and values of the resistance of rails to direct current will be found in the article on *Rails, Steel*. It should be noted that the resistances of the trolley and positive feeders are in parallel and that the track rails and negative feeders are in parallel. Also note that in the case of high-voltage systems a considerable portion of the current returns through the earth and not through the rails, and consequently the drop in the rails is due only to that part of the current which returns through them. For preliminary calculations, however, the full current may be assumed as returning through the rails.

formulas for Direct-current Trolley Circuits. — The following formulas to certain typical circuits which frequently occur in practice. Let

$I$  = total current in amperes taken by all cars on section considered,

$L$  = total length of section in 1000 feet,

$V_p$  = total drop in volts, in positive conductors between substation bus and far end of line,

$V_n$  = total drop in volts in negative conductors between substation bus and far end of line,

$V = V_p + V_n$  = total drop in volts in both positive and negative conductors,

$r_p$  = resistance in ohms of all the positive conductors in multiple per 1000 feet of line,

$r_n$  = resistance in ohms of all the negative conductors in multiple per 1000 feet of line,

$r = r_p + r_n$  = total resistance in ohms per 1000 feet of line,

$l$  = distance in 1000 feet, from far end of line to any point  $P$ ,

$v$  = drop to the point  $P$ , subscripts used as for  $V$ .

Uniformly Distributed Load, Uniform Conductor, Fed from One Station. — Then

$$v = \frac{rI^2 l}{2L}$$

$$V = \frac{rIL^2}{2}$$

These formulas are applicable to either the positive or negative conductors considered separately or to both in series.

Uniformly Distributed Load, Conductor Tapered to give Minimum Weight of Metal, Fed from One Substation. — For minimum weight the tapering must be such that at any point  $P$

$$r = \frac{3V}{2l\sqrt{L}\sqrt{l}}$$

the cross-section, if all the conductors are of the same metal, must increase as the square root of  $l$ . The drop to the point  $P$  is

$$v = \frac{V\sqrt{l}}{L}$$

These formulas also apply to either the positive or negative conductors considered separately or to both in series.

Uniformly Distributed Load, Conductor Divided into Sections of Constant Resistance, Fed from One Substation.

The drop from  $P_n$  to the far end of line is

$$\frac{I}{2L} \sum_{s=1}^n r_s [P_n^2 - P_{(n-s)}^2]$$

This formula is applicable to either the positive or negative conductors. The subscript  $n$  is here the general form of the subscript corresponding to each section represented by  $r_s$ ,  $P_n$ , and  $P_{(n-s)}$  in Fig. 1.

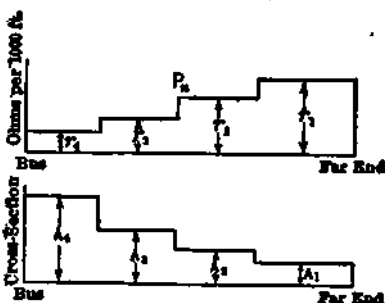

Fig. 1.

**Concentrated Load, Section Fed from One End.**—Fig. 2 shows 4-track road with 4 trolley wires and 3 feeders with the tracks cross-bonded intervals. The solution given below is a general one, and may be applied in any case from 1 track and 1 trolley wire up. Let all distances be expressed in 1000 feet and let

$N_f$  = number of feeders in section considered, e.g., for the section  $AB$ ,  $N_f = 3$ , and for the section  $BD$ ,  $N_f = 2$ ,

$N_c$  = number of contact conductors, trolley wires or third rails in section considered, e.g., four are shown in Fig. 2,

$N_t$  = number of tracks in section considered,

$R_f$  = resistance of each feeder per 1000 feet,

$R_c$  = resistance of each contact conductor per 1000 feet,

$R_t$  = resistance of each track per 1000 feet (1 rail or 2 rails in multiple depending upon whether 1 or 2 rails are used for return conductors).

$$n = N_c + \frac{R_c}{R_f} N_f \quad \text{for the section considered.}$$

Then for the section in which the load may be, the resistance of the positive conductors from the load to the end of that section in the direction of the substation, e.g., the resistance from  $L$  to  $B$ , is

$$R_c M_1 \left[ 1 - \frac{(n-1) M_1}{nM} \right].$$

The resistance of the positive conductors in any section such as  $BA$  is

$$\frac{R_c D}{n}.$$

(Note that the value of  $n$  for this section is not the same as for the section  $BA$ .)

The resistance of the negative conductors from the load to the first cross bond in the direction of the substation, e.g., the resistance from  $L$  to  $F$ , is

$$R_t l_1 \left[ 1 - \frac{(N_t - 1) l_1}{N_t d} \right].$$

The resistance of the remaining portion of the negative conductors, e.g., from  $F$  to  $E$ , is

$$\frac{R_t d}{N_t}.$$

(Note that if negative feeders are used, each negative feeder having a resistance of  $R_f'$  per 1000 feet, then for  $N_t$  in the last two formulas substitute  $n' = N_t + \frac{R_f'}{R_f} N_f'$ , where  $N_f'$  is the number of negative feeders for that section.)

The total resistance from the load to the substation is the sum of the resistances as above calculated.

Fig. 2.

**Concentrated Load, Section Fed from Both Ends, Substation Voltage at the Two Ends the Same.**—The most convenient method of solving such problems is to plot an "equivalent-resistance-distance" curve as shown in Figs. 2 to 5. By "equivalent resistance" is here meant that distance by which the total current taken by the load must be multiplied to give the total drop in voltage between the load and either substation. For example, if the substation voltage is 600 at each end, the voltage across the load is 550 and the current taken by the load is 200 amperes, then the equivalent resistance is  $R = \frac{600 - 550}{200} = 0.25$ . This method avoids the determination of

distribution of the current in the various parts of the network, and the distance when once determined can be applied to any load.

In Fig. 3 is shown a single track and single trolley.  $S_1$  and  $S_2$  are substations;  $L$  is a load placed arbitrarily between corresponding points  $P_1$  and  $P_2$  on the positive and negative conductors respectively. Let

$a$  = resistance of the conductors between the points  $S_1P_1P_2S_1$ ;

$b$  = resistance of the conductors between the points  $S_2P_1P_2S_2$ .

These resistances are the resistances of the transmitting conductors and do not include the internal resistances of the substations and load. Then the equivalent resistance is

$$R = \frac{ab}{a+b}.$$

Fig. 3.

Fig. 4.

Fig. 4a.

In Fig. 4 is shown a 4-track road with 4 trolleys, both track and trolley on-bonded. Fig. 4a is a simplified diagram of Fig. 4, corresponding points being designated by identical letters.

$S_1$  and  $S_2$  are substations;  $L$  is a load placed arbitrarily between points  $P_1$  on the positive system and  $P_2$  on the negative system;  $C_1$  and  $C_2$  are ties between positive conductors and  $B_1$  and  $B_2$  ties between negative conductors.

Let

$a$  = resistance of loop  $S_1C_1P_1LP_2B_1S_1$ ,

$b$  = resistance of loop  $C_1P_1C_2C_1$ ,

$c$  = resistance of contact conductor  $C_1P_1$ ,

$d$  = resistance of contact conductor  $C_2P_2$ ,

$e$  = resistance of loop  $B_1P_2B_2B_1$ ,

$f$  = resistance of track  $B_1P_2$ ,

$g$  = resistance of track  $B_2P_2$ ,

$h$  = resistance  $\frac{d^2}{b} + \frac{g^2}{e}$ ,

$i$  = resistance  $\frac{c^2}{b} + \frac{f^2}{e}$ ,

$j$  = resistance  $S_2C_2P_1LP_2B_2S_2$ .

These resistances are the resistances of the transmitting conductors and do not include the internal resistances of the substations and load. The equivalent resistance is

$$R = \frac{aj - ah - ji - 2\left(\frac{fg}{e} \times \frac{cd}{b}\right) + \frac{f^2d^2 + c^2g^2}{eb}}{a + j - h - i - 2\left(\frac{fg}{e} + \frac{cd}{b}\right)}$$

#### Concentrated Load, Section Fed by Feeders from Both Ends.

Fig. 5 shows a simple case with feeders for the positive conductors only.

Fig. 5 shows a simple case with feeders for the positive conductors only. A general formula is available for such a circuit. Any such network can, however, be calculated by Kirchhoff's Laws (q.v.), using the numerical values of the resistances for the various resistances. The equivalent resistance from the substations to the load is then the drop in voltage for a load of one ampere.

**Ways of Reducing Total Drop.** — Three methods are employed for reducing the total drop in the trolley and rails, viz:

1. **Plain or "Non-boosted" Feeders.** — Copper feeders, usually bare, may be connected to the trolley wire,

third rail or track rails at frequent intervals. If the resistance of the trolley is high compared with that of the rails, which is usually the case, the feeders should be used to reinforce the trolley wire and not the track. In general, the most economical use of additional copper is to connect it in parallel with that side of the circuit having initially the higher resistance.

2. **Boosted Feeders.** — An insulated feeder may be tapped into the trolley wire or third rail at one point, and connected to a booster at the sub-

Fig. 5.

The principle of this method is to increase the activity of the feeder, i.e., let it carry more current and thereby reduce the current in the trolley wire. It is necessary only where the resistance of the line is so low that a moderate-feeder does not take its full share of current. It is not much used because line resistance is already low and the load is small, the drop will usually be enough naturally, and if the load is great, the booster and feeder will be too large in order to produce any effect, as to be prohibitive in cost and cost of operation.

3. **Floating Battery**, i.e., a battery connected across the line so as to charge when the line potential is high and discharge when it is low. This scheme is little used on account of the high cost of operating and maintaining a battery. It is difficult to imagine under what conditions such a system would be commercially practicable, but if anywhere, it would be on a long line with load and small feeders. Typical calculations for floating batteries are given in *London's Storage Battery Engineering*, Chap. XLIV.

**Systems of Reducing Drop in the Negative Side of Circuit.** — Owing to the necessity of preventing the leakage of current from track rails into the earth, it may be necessary to reduce, not the total drop in the negative system, but the drop in the grounded portion of the negative. This may be accomplished by the use of insulated feeders connected to the track rails so as to drain the current from the latter and thus reduce the drop in the rails, regardless of the drop in the feeders themselves. Such feeders may be used with or without a booster. With boosters, this method is probably the most economical way of reducing the drop in return rails where a large reduction is necessary to prevent electrolysis.

**Negative Feeder with Booster.** — In the case where the load is uniformly distributed over the line, the size of booster which must be installed in the substation may be determined as follows:

- $i$  = amperes entering negative feeder system per foot of line,  
 $r$  = resistance of negative feeder system per foot,  
 $R$  = total resistance of the feeder connecting the booster to the negative feeder system,  
 $I$  = total amperes entering negative feeder system from the motors,  
 $I_0$  = amperes to be taken off by booster,  
 $\frac{I - I_0}{a}$  = distance from substation to the point at which the current in the negative feeders is to be zero,  
 $l_1$  = distance from booster tap to point in negative feeders where current is zero,  
 $l_2$  = the distance from the booster to the end of the line.

then the booster voltage is

$$RI_0 - \frac{1}{2} ar(l_1^2 - l_2^2).$$

The output of the booster is, of course, the product of the current and voltage. The total drop is

$$\frac{1}{2} ar(l_1^2 - l_2^2 + l_2^2).$$

See *Del Mar's Electric Power Conductors*, Chap. V, for a more complete treatment. Formulas and Constants for Alternating Current Trolley Circuits. — The information is available on the effective or a-c. resistance (see *Alternating Currents*) and reactance of steel rails. As a rough approximation the a-c. resistance of a rail at 25 cycles per second may be taken as 4 to 5 times its d-c. resistance and the reactance of the rail as approximately the same as that of one wire of a pair of No. 0000 wires at a distance apart equal to the height of the

trolley wire above the track i.e., roughly as 0.4 ohm per mile. As a matter of fact the a-c. resistance depends upon the shape of the rail, its magnetic quality, the value of the current and the frequency; to a lesser extent inductance, and therefore the reactance, depends upon these same items.

Data from Tests on N. Y., N. H. & H. R.R. — The following data were obtained by A. W. Copley from tests on the New York New Haven Hartford Railroad and reported in the Trans. A.I.E.E., 1908, Vol. 27, (2) p. 11. An analysis of these tests is also given by H. Pender in the Elec. World, Vol. 53, p. 1457. Copley's results showed that a considerable portion of current entering the track from the load leaked to the earth. The combined resistance  $r$  of any number of trolley wires, and track rails and earth, as determined by Copley, can be represented by the following formula

$$r = \frac{\beta_1 r_1 + \beta_2 r_2}{100}$$

where  $r_1$  = the resistance of each trolley wire separately,  $\beta_1$  = the per cent of the total current in this wire,  $r_2$  = the a-c. resistance of each rail separately and  $\beta_2$  = the per cent of the total current in this rail. Similarly, the combined reactance  $x$  of any number of trolley wires and track rails and earth return can be represented approximately by the formula

$$x = \frac{\beta_1 x_1 + \beta_2 x_2}{100}$$

where  $x_1$  = the reactance of a given trolley wire,  $x_2$  = the reactance of a rail and  $\beta_1$  and  $\beta_2$  as above.

Pender gives the following values for trolley wire and rail separately, based upon Copley's tests:

Item	Resistance, ohms per mile		Reactance, ohms per mile	
	25 cycles	15 cycles	25 cycles	15 cycles
Single trolley wire, No. 0000 B. & S....	0.26	0.26	0.35	0.23
000 B. & S....	0.33	0.33	0.38	0.25
00 B. & S....	0.42	0.42	0.39	0.25
Single rail, 100 pounds to the yard.....	0.16	0.13	0.44	0.26

\* For the trolley wire 25 ft. above the track, changing the height of the trolley wire 5 ft. up or down changes these values by less than 5 per cent.

The combined resistance and reactance respectively of the trolley wires and earth are given in the following table:

For any other weight of rail the a-c. resistance of the rail itself may be taken as roughly inversely proportional to the weight per yard. The reactance of the rail, however, is practically independent of its cross-section, for the magnetic flux within the rail is relatively small compared with the total flux surrounding the rail (see Inductance).

Formulas for Single-phase Calculations. — The calculation of power lost and drop in voltage between a load and the power house are calculated in the same manner as in the case of an ordinary single-phase a-c. tra-

## RESISTANCE AND REACTANCE PER MILE OF ROAD

100-pound Rails

Number of tracks.....			1	2			4
Number of trolley wires.....	1		1	2			4
Number of rails.....	1		2	4			8
Percent of total current returning through rails.....	25		40*	58*			75*
Miles per second.....	25	15	25	15	25	15	25
Combined resistance of trolley wires, track and earth per mile of road							
No. 0000 B. & S. trolley.....	0.30	0.29	0.29*	0.28*	0.16*	0.15*	0.086*
0000 B. & S. trolley.....	0.37	0.36	0.36	0.35	0.20	0.19	0.11
00 B. & S. trolley.....	0.46	0.45	0.45	0.44	0.24	0.23	0.13
Combined reactance of trolley wires, track and earth per mile of road, all three sizes of trolley wire.....	0.49	0.30	0.47*	0.28*	0.27*	0.18*	0.17*

The figures marked thus \* are taken directly from the paper by Copley, whose tests confined to No. 0000 trolley wires; the other values are calculated by Pender.

The percentages of total current returning through the rails are test results on the N. H. & H. R.R., and refer to relatively long sections (over 3 miles); a greater portion of current flows in the rails in the immediate vicinity of the load and power house. The proportion of the total current which will return through the earth will depend upon the nature of the soil and ballast; for any other division of current the resistance and reactance can be obtained from the approximate formulas given above. The proportion of current returning through the earth on the N. Y., N. H. & H. R.R. has been greatly reduced since the above data were obtained, by the use of the three-wire system shown in Fig. 6.

Transmission line (see *Transmission Lines*). For a concentrated load (e.g., a single locomotive) the calculation is as follows: Let

$V$  = volts between trolley wire and track;

$P$  = kilowatts at the locomotive delivered to locomotive;

$\phi$  = power factor of load taken by locomotive;

$l$  = distance in miles, between power house and locomotive;

$r$  = combined resistance in ohms, per mile of trolley wire, rails and earth return;

$x$  = combined reactance, in ohms, per mile of trolley wire, rails and earth return;

$R = rl$ ;

$X = xl$ .

Then the current taken by the locomotive is

$$I = \frac{1000 P}{V \cos \phi} \quad \text{amperes,}$$

power lost is

$$p = \frac{R I^2}{1000} \quad \text{kilowatts,}$$

Drop in voltage between the power house and locomotive is

$$v = \sqrt{(V \cos \phi + R I)^2 + (V \sin \phi + X I)^2} - V \quad \text{volts,}$$

the power factor at the power house is

$$\cos \phi_0 = \frac{1000 (P + p)}{V^2}$$

**Example.** — 2000 kw. at 25 cycles per second are to be supplied a locomotive at 90 per cent power factor and 10,000 volts at a distance of 10 miles from the power house. The circuit consists of a No. 0000 trolley wire and two 100-lb. track rails. Then  $V = 10,000$ ,  $P = 2000$ ,  $\cos \phi = 0.9$ ,  $\sin \phi = 0.435$ ,  $I = 20$ ,  $r = 0.29$  (assuming only 40 per cent of the current returning through the rails),  $x = 0.47$  (same assumption),  $R = 0.29 \times 20 = 5.8$ ,  $X = 0.47 \times 20 = 9.4$ . Whence

$$I = \frac{1000 \times 2000}{10,000 \times 0.9} = 222 \text{ amperes,}$$

$$p = \frac{5.8 \times (222)^2}{1000} = 286 \text{ kilowatts,}$$

$$v = \sqrt{(10,000 \times 0.9 + 5.8 \times 222)^2 + (10,000 \times 0.435 + 9.4 \times 222)^2} = 10,000 + 2130 \text{ volts,}$$

$$\cos \phi_0 = \frac{1000(2000 + 286)}{222(10,000 + 2130)} = 0.848.$$

**Scheme of Connections Used by N.Y., N.H. & H.R.R.** — The distribution system is shown diagrammatically in Fig. 6 where  $A$  is the trolley

Fig. 6.

wires,  $B$  the track rails and  $C$  a feeder. These three sets of conductors are connected at intervals of about two miles through auto-transformers  $D$ ,  $E$  and  $F$ . The difference of potential between  $A$  and  $B$ , and between  $B$  and  $C$  is 11,000 volts and between  $A$  and  $C$  is 22,000 volts. The effect of this arrangement is to practically give a transmission voltage of 22,000 with 11,000 volts at the trolley, and to greatly reduce the current in the grounded conductors with a consequent reduction of disturbances to telephone lines.

**MECHANICAL DESIGN OF OVERHEAD SYSTEM.** — The various parts of the overhead system will first be described, and then the various methods of construction, span wire, catenary, etc. The American Electric Railway Engineering Association has adopted specifications for overhead line material which cover most of the mechanical details pertaining to ordinary trolley lines.

**Parts of Overhead Trolley Construction.** — The trolley wire is attached to an "ear" by soldering, clamps or other means; the ear is bolted to a "tension" which may or may not be provided with an insulating portion. The suspensions are carried by span wires which in turn are fastened to the poles or brackets, or may be fastened directly to the bracket. If the "ear" is not insulated, "strain" insulators are inserted in the span wire between the suspension and its point of attachment to the poles or brackets. A slightly different suspension, called a "pull-off," is used on curves. At turnouts "trolley" wire

to be used to guide the trolley wheel. These various parts are illustrated in accompanying cuts.

Fig. 7

**Trolley Bars.**—Figs. 7 to 10 are for round wire. Fig. 7 shows the standard straight-line ear of the A.E.R.E.A. It is made of cast bronze of approximately the following composition:

Copper.....	84 per cent
Zinc.....	10
Tin.....	3
Lead.....	3

100 per cent

The ear shown in Fig. 8, which has a deep groove into which the wire is soldered, is a type in common use. These ears may be provided with rings as in Fig. 9

Fig. 8.

Fig. 9.

Fig. 10.

Fig. 11.

Types of Trolley Ears for Round Wire

which guy wires are attached to relieve the strain at curves and for steadying the line at intervals. Fig. 10 shows the type of ear used at points where the

Fig. 12

trolley is spliced, which should always be at an ear. Fig. 11 shows an ear with a terminal for a feeder connection.

Figs. 12 to 14 are designed for grooved or figure "8" trolley wire. Special grooved or figure-8 wire affords a smoother running surface for the trolley wheel or bow as the ear only grips the upper part, leaving the lower part absolutely even. This construction is practically essential for bow trolleys. The design shown in Fig. 12 is the standard of the A.E.R.E.A. It is made of cast bronze, which must conform with A.S.T.M. standards.

**Soldering Trolley Wire to Bars.**—The strain should be taken off the wire by a U-shaped clamp catching hold of it on each side of the bar. The

Fig. 13.

Fig. 14.

Types of Trolley Bars for Figure "8" Wires

soldering iron should weigh about 8 or 9 pounds, and should have a good fitting half way round the wire. Special precautions should be taken not to have the iron unnecessarily hot.

**Suspensions for Straight Line Work.**—Fig. 15 shows an uninsulated suspension with ear attached for straight line work. Fig. 16 shows a suspension with strain insulators at each end; this is also used on curves for double-track

Fig. 15.

Fig. 16.

Fig. 17.

Fig. 18.

Fig. 19.

Fig. 20.

Types of Suspensions

work. Figs. 17 and 18 show solid insulated suspensions for span wire and side-bracket construction, respectively. These types are frequently used, and are quite satisfactory if the insulating material used in their construction is properly made. Fig. 19 shows a section of an assembled cap and cone suspension. Fig. 20 shows a cap and cone suspension with ear attached. The cap and cone are made separate. This type is preferred by some engineers on account of the possibility of replacing injured bolts and insulation without removing the whole suspension. This advantage is partly offset by the greater liability to trouble due to multiplicity of parts, and this type of suspension is now little used.

**Strain Insulators.**—Fig. 21 shows a "globe" strain insulator, the type most commonly used. Fig. 22 shows a "Brooklyn" strain insulator. This type is used on wooden pole and light iron pole construction to draw span wire taut. It is also required even for heavy iron pole construction if spans are long and temperature variation great. Bolts may be provided at both ends if an extra amount of adjustment is required. A globe strain and a Brooklyn strain may be used in series where extra insulation is required.

Fig. 21.

Fig. 22.

Fig. 23.

Fig. 24.

Strain Insulators

Pull-offs

**Pull-offs.**—Fig. 23 shows a cap and cone pull-off for single-curve construction and Fig. 24 a cap and cone pull-off for double-track curve construction.

pull-offs of the same type as the uninsulated and solid insulated suspension in Figs. 15, 17 and 18 are also used.

**Trolley Frogs.** — A trolley frog is a malleable iron casting used at crossings where trolley wires from different tracks unite. Its function is to hold the diverging wires together and afford a smooth running path to the trolley wheel when a car passes or enters a switch. A common type is illustrated in Fig. 25. Frogs are made for various angles of divergence, and both right and left hand. The usual angles are 8, 15 and 20 degrees.

Fig. 25. Trolley Frog

**Load and Tension in Overhead System.** —

Attention must be paid to designing the span and structure in such a manner that it

will stand the extra tension due to the contraction of the wires at low temperatures and the extra loads due to wind and sleet, and a sufficient allowance must be made in the height of the trolley wire to take care of the extra sag experienced at high temperatures. With a simple trolley construction the stresses in tension and sag may be calculated by a direct application of the principles given in the article on *Transmission Lines*; in the case of catenary construction, the additional load due to trolley wire, clips, etc., is treated in the same way as a sleet or wind load.

**Suspension.** — The following discussion applies primarily to span-wire and bracket construction; catenary construction is treated in a separate article below. Details of standard parts are given in the A.E.R.A. Engineering Manual.

**Height of Trolley Wire Above Rail.** — The height of wire varies from a minimum of 16 feet and a maximum of 22 feet, the usual height being 18 feet. It is usual to raise the wire at railroad crossings to a height of 20 feet or more above the top of rails. Catenary construction should be used where the clearance exceeds 150 feet.

Fig. 26. Simple Pull-off Arrangement

Fig. 27. Simple Pull-off Arrangement

**Setting of Poles.** — Bracket-arm poles on tangent construction should be set back from the track centerline by a distance not exceeding 3 inches, and span-wire poles in hard ground by a distance of from 4 to 5 inches. In soft ground a rake of 12 inches is not uncommon.

Center poles should be set vertically except at curves, where they should be set away from the curve along the perpendicular to the tangent at that point.

**Anchorage.** — At both ends of every grade and curve, there should be a trolley wire anchorage. If there are not many grades and curves, anchorages should be provided at intervals of from  $\frac{1}{4}$  to  $\frac{3}{4}$  of a mile. An anchorage is made

by means of a steel cable running from the trolley wire to one or more anchor poles through an anchor ear and strain insulators.

**Curves.**—At curves in the track the trolley wire should be made to follow the curve by means of pull-offs or wires pulling the trolley wire outward as shown in Figs. 26 and 27.

Wherever possible the pull-off wires should be radial to the trolley wire. This, however, requires a large number of poles, and is therefore impracticable in cities. In such cases, the bridle, bow-string or backbone construction shown in Figs. 28, 29, and 30 is resorted to. In this construction the pull-off wires

Fig. 28. Bridle Construction at Curve

instead of being anchored to individual poles are fastened to a wire which is stretched between poles. While this construction is almost universally used in cities, it is more expensive to maintain than single pull-offs, and is therefore not favored for interurban lines.

A combination of the two types of construction is shown in Fig. 31. Figs. 28 to 31 are from G. E. Co. publications.

**Spacing of Pull-offs at Curves.**—The number of pull-offs should be sufficient to keep the wire within about  $2\frac{1}{2}$  inches from the theoretical curve. This may be accomplished by spacing the successive ears in accordance with the following relations:

Let  $L$  = distance between pull-offs in feet,

$R$  = radius of curve in feet,

$a$  = offset of wire in inches from theoretical curve, midway between pull-offs, the ears being assumed to lie on the theoretical curve.

Then,

$$L = \sqrt{\frac{2aR}{3} - \left(\frac{a}{6}\right)^2}$$

or

$$L = 0.815 \sqrt{aR},$$

with an error less than  $\frac{1}{2}$  per cent for all radii greater than 40 feet.

If  $a$  is to be  $2\frac{1}{2}$  inches, then

$$L = 1.29 \sqrt{R} \text{ approximately.}$$

If the ears are set exactly on the theoretical curve, the wire will depart  $2\frac{1}{2}$  inches from the correct position half way between the two ears; if the ears are set  $1\frac{1}{2}$  inches from the curve, the mid-point of the wire will be only  $1\frac{1}{2}$  inches when  $L$  is taken equal to  $1.29 \sqrt{R}$ .

**Offset of Trolley Wire at Curves.**—It is usual, at curves, to offset the trolley wire from the center of the track ( $a$ ) because the trolley wheel is tilted inward due to the elevation of the outer rail, and ( $b$ ) because in order to keep the wheel on the wire, the latter must be so placed that the projection of the pole on the plane of the track is always tangential to the wire.

Fig. 29. Bow-string Construction at Curve

Fig. 30. Backbone Construction at Curve

Fig. 31. Combination Construction at Curve

(a). The former offset, measured horizontally toward the inside of the curve, equals  $k \tan \theta$ , where  $k$  is the normal height of the wire above the top of rail and  $\theta$  is the angle of elevation between the plane of the track and the horizontal. For standard gauge and wire 18 feet above the top of rail this offset is about 1.5 inches for every inch of elevation.

(b). The latter offset, also measured horizontally toward the center of curve, is calculated as follows, assuming the curve to be longer than the wheel base itself; for shorter curves the offset will be less. Let

$R$  = radius of curve,

$L$  = horizontal distance of center of trolley wheel to center of trolley base usually about 11 feet,

$G$  = distance from center of car to center of truck.

In the case where the trolley base is located over the truck center, as on cars with two trolleys, the offset is

$$R - \sqrt{R^2 - L^2}.$$

If the trolley base is located over the car center as on cars with one trolley, the offset equals

$$R - \sqrt{R^2 - G^2 - L^2}.$$

The total offset is the sum of the offsets (a) and (b).

**Curves of Small Curvature.**—If the curvature\* is less than 1°, the poles are frequently spaced closer together and no pull-offs used. The following table gives the practice of the Denver and Interurban R.R. Co., which may be considered typical, the divergence of the wire from the theoretical curve being kept within 3½ inches.

#### SPACING OF POLES ON CURVES, INTERURBAN ROAD

Degree of curvature of track	Pole spacing, feet	Divergence of trolley wire from track center, inches	Degree of curvature of track	Pole spacing, feet	Divergence of trolley wire from track center, inches
Tangent	120	0	6	60	2.87
1	120	1.87	7	50	2.34
2	110	3.37	8	50	2.64
3	90	3.06	9	50	2.94
4	80	3.37	10	50	3.24
5	70	3.06			

**Turnouts.**—(See also *Railways, Location and Permanent Way* for the location of the trolley frog at turnouts may be determined as follows. Referring to Fig. 32, from switch point  $A$  draw a line to center point  $D$  of track frog distance  $BC$  and from switch point  $B$  draw a line to center point  $E$  of arc  $AEC$ . The intersection of these two lines at  $F$  will be the proper location of the frog. While certain variables, such as super-elevation of the outer rail on the curve, length of wheel base and projection of trolley pole

Fig. 32

\* The degree of curvature of a track is the angle which subtends a chord 100 feet long, between points on the center line of the track.

from center of car, may necessitate slight variation of setting, this will be found so nearly correct that a very small alteration, which determined by experiment, will compensate for the variable con-

comparing table gives the distance from track switch back frog with which each trolley frogs may be most easily used:

Minimum frog distance given with which the 15° frogs are to be set to best advantage corresponds to a turnout radius of 40 feet when suburban cars, using trolley wheels, run over it.

It is advisable to use 15° rather than 20° frogs throughout the city even where the minimum frog distance is less than 20 feet.

Track-frog distance	Divergence angle of trolley frog
Up to 22 feet.....	20°
From 20 to 30 feet.....	15°
Above 28 feet.....	8°

#### TABLE OF TRUNK & INTERURBAN RAILWAY CONSTRUCTION. CATENARY SUSPENSION

\* No copper or steel supporting wire above the copper contact wire.  
 † No supporting wire above the N-000 phono-electric contact wire.  
 ‡ D catenary with D inch messenger cable supporting the smaller one.  
 (messenger cables composed of 7 strands in all cases.)

suspensions. — (See also p. 1841.) The number of suspensions depends upon the speed at which the cars are to be run and upon whether a bow or wheel is used. The three-point suspension in which, with 150 feet spacing, the poles are 50 feet apart has been found ample for wheel collectors at speeds up to 40 m.p.h. With the sliding pantagraph or bow trolley an eleven-point suspension has been found sufficient, with 150 feet pole spacing.

Hangers. — (See also p. 1842.) Where only one horizontal wire is suspended from the messenger cable, the hangers should hang loosely from the messenger and should be screwed fast to the trolley wire. This permits the trolley wire to pass slightly as the trolley passes under it, thereby making the wire flexible along its entire length. Where a steel contact wire is clipped to the messenger conductor, the hangers are usually rigidly attached at both ends, and the application of horizontal wires assures uniform flexibility, regardless of the speed.

Method of Equipment or Erection. — Work should be done, as far as practicable, with the aid of a construction train at least five cars long and equipped with the necessary scaffolds. With such a train the following daily results are attainable:

	Men	Number erected
Erecting poles.....	26	117
Erecting brackets.....	18	150
Stringing catenary.....	17*	7 miles
Stringing and splicing trolley wire.....	12*	7 miles
Clipping messenger and trolley.....	13*	3½ miles

\* Exclusive of train crews.

**EXAMPLES OF CATENARY CONSTRUCTION.** — The following examples are given to illustrate in greater detail the methods employed in the construction of overhead trolley systems.

**New Haven & Hartford R.R.** — The various types of catenary systems successively adopted by this company are all for high-speed traffic. The construction consisted of a simple catenary system made rigid by

Fig. 33

the use of two steel messenger cables with equilateral triangular steel pipe hangers of different lengths, joining them to the copper trolley wire. This having proved to be too rigid was modified by the addition of a steel contact wire supported from the copper wire by clips midway between hangers. Consideration of the economy and the desirability of securing better lightning protection led to the adoption of a compound catenary, that is one in which one messenger cable is supported from another by suspension insulators, the upper cable being made rigid. The copper wire is supported horizontally by suspensions of suitable length from the lower steel cable and a steel contact wire clipped to the

copper wire midway between hangers as shown in Fig. 33. Both of the above types of construction involve the use of heavy lattice steel bents spaced 300 feet apart.

Pennsylvania R.R. — While both types remain in successful operation on the N. Y., N. H. & H. R.R., a less expensive one was developed for the New York Connecting Railroad and the Philadelphia & Paoli Branch of the Pennsylvania Railroad. This construction is especially suitable where there is opportunity to use guy poles instead of lattice bents. In this construction pairs of guyed steel poles, one on each side of the track, are spaced 300 feet apart. The two poles of a pair are joined by two messenger cables as shown in Fig. 34, making a small catenary system across the tracks with a vertical sus-

Fig. 34

pension rod over the center of each track. The upper of these cables has a diameter of  $\frac{3}{4}$  inch and the lower of  $\frac{1}{2}$  inch. The vertical rods are  $\frac{3}{8}$  inch in diameter and terminate in malleable iron clamps. An insulator consisting of three 10-inch porcelain disks is attached to each of these clamps and the main messenger cables suspended therefrom over the center of each track. These messenger cables consist of  $\frac{1}{4}$ -inch double galvanized extra strong steel. The usual No. 2-0 grooved copper wire is suspended from this messenger cable by hangers 30 feet apart and a No. 3-0 phonographic contact wire is clipped  $1\frac{1}{4}$  inches below the copper wire.

The hangers used for supporting the copper wire are shown in Fig. 35. They are made of hot-galvanized steel.

To prevent side swaying of the lower wires in heavy winds a steady-brace is installed between poles and wires. These consist of steel wires insulated from the structure by strings of three porcelain insulators similar to those used to support the messenger cable. The contact wires themselves are insulated from the structure by single wooden strain insulators 6 inches long.

On the curves, steadies or pull-offs are used, but the hangers between the main messenger cables and the copper wires are spaced 15 feet instead of 30 feet as on tangents and the suspension rods are differently bolted as shown in Fig. 35.

Fig. 35

e guys are  $1\frac{1}{4}$ -inch rods attached to the poles through collars provided buckles. They are anchored in reinforced concrete blocks 8 feet or  $w$  ground and protected from the ground by 3-inch boiler tubes.

3. **Milwaukee & St. Paul R.R.** — The 3000-volt trolley system of & St. P. R.R., comprising 660 miles of electrified trunk line, has two contact conductors suspended by alternate hangers from the same

This enables 2000 amperes to be collected by a copper-shod pantograph at a speed of 60 m.p.h. The return circuit has an aerial which is connected to the track rails every 8000 feet, preventing the : of dangerous voltages at rail joints in case of broken bonds.

**Construction.** — In yards, wire cross-spans between poles, are used the messenger cables the insulators being suspended from the by  $\frac{1}{4}$ -inch soft-steel cable. A horizontal steady-wire insulated slightly above the level of the contact wire supports the steady- which the contact wire is clipped. On curves, an additional insulated : is attached to the messenger wire at the poles. The messenger n reduced from  $\frac{3}{4}$  inch to  $\frac{1}{2}$  inch and the hangers are spaced 15 feet : and 10 feet on curves. A copper contact wire is not required.

**Sections.** — Main-line conductors are usually divided into m cross-over to cross-over. Wherever conditions permit, sections are y staggering the contact wires laterally and running the two wires out 18 inches apart, each to a separate insulator. The ends are o avoid catching the pantograph.

a. — Turnouts are made by means of steel deflectors or frames the diverging wires at a fixed angle apart.

in **Spans.** — The stresses in the  $\frac{3}{4}$ -inch cable of the original onstruction of the N. Y., N. H. & H. R.R. are as follows on a tangent in:

Condition	Temperature, ° F.	Sag, ft.	Stress, lb.
Normal.....	60	6.42	7,550
Normal.....	-10	5.71	8,550
Steel and wind.....	-10	6.46	14,750

s in the  $\frac{3}{4}$ -inch cable of the original triangular construction of the l. & H. R.R. are as follows on a tangent 140-foot span:

Condition	Temperature, ° F.	Stress, lb.
Normal.....	60	4930
Normal.....	-10	7100
Steel and wind.....	-10	8400

in the copper wire and contact wire are negligible. Steel is assumed : wire to a depth of one-half inch and the wind is assumed to exert of  $\frac{3}{4}$  of 8 pounds per square foot.

**Hangers.**—The longest hangers of the original triangular construction of the N. Y., N. H. & H. R.R. (140 feet apart) have a length of 15½ inches measured between centers of wires. The shortest hangers are 4¼ inches long. For main-line construction they are made of ¾-inch rods, for yards, of ½-inch rods.

**SPECIFICATIONS.**—(See also article on Specifications.) Specifications for trolley wire are given under *Wires and Cables, Bare*, and for insulators and *Insulators for Overhead Lines*. The specifications of the American Electric Railway Engineering Association, which refer to overhead trolley systems, are as follows:

Specifications for Overhead Line Material (for 750 Volt Direct-Current Direct Suspension).

Railroad Specifications for Electric Light, Power Supply and Trolley Line Crossing Steam and Electric Railways.

These two specifications aggregating 87 pages contain a great deal of valuable data, including drawings of various detail parts and general layouts.

**OPERATION.**—The operation of overhead lines for low-speed cars presents few difficulties owing to the adaptability of the trolley pole and wheel at all speeds. With high-speed cars the case is different as the collector vibrates rapidly and the line must be kept uniformly level, smooth and elastic throughout and all special work must be maintained in first-class condition. If the collector vibrates in resonance with the loops in the contact wire, an increase in the number of supports will usually cure the trouble.

**Prevention of Formation of Sleet.**—Sleet may be prevented from forming on the wires by greasing the latter with petroleum jelly and if it does form it may be easily removed by any of the numerous commercial forms of sleet cutters.

**Wear of Trolley Wheel, Bow and Trolley Wire.**—The wear of trolley wires is not serious either with wheel or bow collectors. On the lines of the Indianapolis & Cincinnati Traction Co., a copper trolley wire lost less than 1 per cent in weight after it had experienced 39,000 car movements, each car taking an average of about 40 amperes by an aluminum slider.

The vertical wear of the steel contact wire on the N. Y., N. H. & H. R.R. was 0.028 inch in thirty months, which is practically 4.5 per cent per year of the total diameter of the wire (one-half taken to permit wire to be held in clips) which even on this vertical diameter basis, indicates a life of over 20 years; but as a matter of fact it will be much more than this, for the reason that as the vertical diameter lessens the breadth of contact increases throughout, thus diminishing the rate of vertical wear. There is practically no corrosion on the under side of the wire where there is much traffic, for the wire is covered with a film of grease deposited by the pantograph shoe (*W. S. Murray*). The upper part, however, rusts and rain water washes the rust on to the roofs of the cars (*Amberg*).

**Change in Length of Trolley Wire.**—The change in length of copper due to changes in temperature is one of the greatest difficulties in the maintenance of overhead work. A drop of 100° F. in temperature will cause a copper bar to contract approximately 1 inch for every 100 feet of length. If it be restrained at the ends this will cause an additional stress of 2500 pounds in a No. 0000 trolley. (See *Transmission Lines*.)

European catenary lines are usually maintained at constant tension by means of weights pulling on the free ends of the trolley wire at the end of every section.

**Flashing.**—Considerable trouble has been experienced with flashing on high-voltage d-c. lines. This has been largely overcome by placing a permanent shunt across the station buses to shunt out the harmonics set up by the trolley.

of the machine armatures. In addition to the above, flash suppressors consisting of electrically operated switches that kill the field of the excited d-c. generators, thereby killing the d-c. voltage instantly. Arcs are also used on the high-voltage commutators.

**TESTING OF TROLLEY CIRCUITS.** — Trolley lines have to be tested, (1) for resistance, and (2) for insulation from ground. The resistance may be tested by grounding one end of the wire to the track rails and circulating current at reduced voltage. The drop in the overhead lines may be tested by using another trolley wire, a telephone wire or the earth as a lead. If the earth is used, the connections to ground should be sufficient from the track rails to be outside the zone of potential disturbance (see *Analysis of Underground Structures*).

**REPAIRS OF TROLLEY CIRCUITS.** — The repair methods of four ways are given below.

**Philadelphia Rapid Transit Co.** — The overhead line organization is in the hands of the Superintendent of Overhead Lines and is divided into maintenance sections, emergency crews, a pole crew and one special crew on electric switch and signal maintenance.

The maintenance and construction crews and the pole crew are under separate foremen. The emergency crews and the electric switch and signal crew report to the Superintendent of Overhead Lines.

The maintenance and construction foreman has four crews, each consisting of a foreman, one helper and a driver. The pole gang consists of the foreman, one helper, five helpers and two drivers. There are also two men who work on sidewalks and metal awnings in connection with the pole work. There are nine emergency stations, seven of which are manned for 24 hours and two for twelve hours per day. These stations care for approximately 100 miles of line each, taking care of line troubles, traffic blockades and street cleaning of the line repairs in the district. They, however, when needed, can be called in other districts. The movements of these emergency crews are coordinated by telephone by an emergency operator at headquarters to whom all line trouble is reported and who keeps a log sheet showing all movements of these crews. They do not leave their stations except on his orders.

At each of these emergency stations are equipped with two-ton auto trucks and telescopic towers. Four stations are each equipped with two-horse power wagon and four horses. One of these wagon stations has also a truck equipped for handling wrecks but not line troubles.

In addition to the above there are tower trolley cars for heavy work located at each of these stations.

**United Railway Company.** — The maintenance and construction organization consists of three gasoline power line wagons, one three-ton horse-drawn truck, one single truck line car, and one double truck line car, with hoist and windlass. The gasoline power wagons and line cars are all manned by one foreman, two line men, a driver or trolley man.

The emergency station is located in the center of the city and serves twenty miles of city line. Its equipment includes three gasoline power line wagons, one gasoline wrecking and hose jumper wagon. These men are on duty for emergency work during the day time and four at night.

The emergency station is the headquarters for all equipment.

**Traction System.** — The line is divided, for overhead maintenance into districts averaging 90 miles in length. A line foreman and his assistants are assigned to each district and are given a tower line car with crew.

Light maintenance work is handled from gasoline motor car equipped with collapsible tower, the regular line car being used only for the heavier work.

**N. Y., Westchester & Boston Ry.** — This line has 54 miles of 11,000-volt contact wire. The general foreman has one day foreman, one night foreman, one lineman and one assistant lineman. They use a work train consisting of gasoline-electric locomotive and work car, the former carrying the workmen. (Zogbaum.)

Engineering Manual and Standards of A.I.E.E.

**BY SYSTEMS, UNDERGROUND.**— (See also *Trolley Systems*,

This system is little used on account of its cost, the installations at New York, Washington and London being the only notable ones. A special feature of all these systems is the underground conductor which is carried from the car by a "Plough" extending through a continuous slot in the track.

**TRUCK SYSTEM.**— The most successful construction is the latest type, a brief description of which is given below.

**Description.**— The street is excavated and cleared of obstructions to a depth of about 5 feet 6 inches and a depth of about 3 feet and cast-iron yokes are set in the excavation about 5 feet apart. The track and slot are supported on these yokes and the whole system made solid with concrete. The concrete fills the excavation from the foundation to near the top of the rails forming a tunnel under the slot free from masonry. The conductors are suspended in this tunnel, by special strain insulators, no part of the electrical system being in contact with the ground. The use of two insulated conductors avoids trouble in case of grounding.

The yoke shown in Fig. 1 is made in three parts. The lowest part rests on the floor of the excavation is a 6-inch steel I-beam, 4 feet long.

Two castings 6½ inches thick are riveted to this, serving to support one track and one slot rail. Fig. 1 shows the slot rails in place on the track rail. The slot rails are carried on a timber stringer which extends from yoke to yoke along the whole line. The stringer is held to the yokes

Fig. 1.

by angle iron plates the ends of which project beyond the stringer and have washers to accommodate bolts running through the yoke. These bolts serve the dual purpose of fastening the rails to the stringers as they also pass through the slot rail which bears upon the foot of the rail. The rails are further secured by bolts running to the center of the yoke. The slot rails are bolted directly to the track rails by long bolts every 30 inches.

**Boxes.**— A pair of cast-iron boxes are laid across from the slot rail to the track rail and bolted to them every 15 feet as shown in Fig. 2.

These contain the insulators which support the contact conductors. On the inside each box is a wooden block, resting on these blocks and bolted to them is a wooden edge which holds the conductors. The top of the box is bolted to the track rail with a cast-iron nut which is flush with the top of the track rail.

Fig. 2.

**Work.**— When the track is laid the tunnel which is formed by the concrete

is formed with collapsible sheet iron, fitting closely to the center of the yokes and run from yoke to yoke. The space from the bottom

of the insulator boxes to the road foundation is formed with boards. Concrete is then poured into the excavation completely filling every part but the top and its offsets at the insulator boxes. The concrete is poured to within a height of a paving block of the rail tops. When the concrete is hard, the sheet-iron form is collapsed and pulled along to the next section. The forms at the bottom of the insulator boxes being collapsible are drawn out through

Fig. 3.

the handholes and are used again elsewhere. The depth of the complete tunnel is 18 inches from the base of the slot rails. A view of an older New York City construction is shown in Fig. 3, which is taken from an article in the *Street Railway Journal*.

**THE LONDON SYSTEM** has alternate long and short yokes, the long ones fulfilling the same function as the New York ones, the short ones serving merely to give additional support to the slot rails. No stringers are used, the rails resting on hard-wood blocks at the yokes only.

**THE BUDA-PEST CONSTRUCTION** has the slot in the track rail, thus saving considerable iron, but necessitating an excessively wide slot to accommodate the wheel flanges.

**COSTS.** — The type of construction in New York City cost from \$50,000 to \$100,000 per mile of track, exclusive of feeders, depending upon the conditions under which it was installed. Due to the high cost of this system, its use has not been extended.

**MEASUREMENT OF UNITS.** — By the magnitude of any quantity is meant the magnitude of this quantity as compared with some other quantity of the same nature; e.g., a length of 10 inches means a length which is ten times as long as one inch. To measure a quantity, then, it is necessary either (1) to choose first some fixed magnitude of the same nature which may be used as a standard of reference, or unit, or (2) to define the quantity in such a way that the unit of measurement may be derived from the arbitrarily selected quantities involved in the definition.

**MECHANICAL AND DERIVED UNITS.** — Units which are chosen arbitrarily as "fundamental" units; those which are derived from a set of fundamental units are called "derived" units. All mechanical units can be derived from a set of three fundamental units; the three units ordinarily chosen as fundamental are those of length, mass and time. In relations involving temperature changes, an arbitrary unit of temperature is also chosen; to express electrical and magnetic quantities at least one electrical or magnetic unit is arbitrarily chosen; to express photometric quantities the unit of luminous intensity is arbitrarily chosen. These arbitrarily chosen non-mechanical units are called "auxiliary fundamental" units.

**ENGLISH AND METRIC SYSTEMS OF UNITS.** — There are two systems of units in use in English speaking countries, the English and the metric systems. The latter system is used universally by physicists and engineers in all countries and also forms the basis of the electrostatic and electro-

tromagnetic systems of electric units used by engineers as well as physicists. The English system of mechanical units, however, is used almost universally by English speaking peoples, in engineering, in commerce and in the arts; it is also the basis of the system of thermal units used largely by engineers. Engineers, however, are coming to use the metric system to a greater and greater extent for all purposes.

In both the English and the metric systems length, mass and time are chosen as the fundamental quantities. In the English system the fundamental units for these three quantities are respectively the foot, the pound (avoirdupois) and the second; this system is therefore also called the foot-pound-second system. In the metric system the corresponding units are the centimeter, the gram and the second; this system is therefore also called the centimeter-gram-second, or c.g.s., system. The magnitudes of these fundamental units have been fixed arbitrarily by law; see below.

**Absolute and Gravitational Units.** — Two different units of force (and units derived therefrom) are used in both systems, viz.: (1) the unit of force defined as that force which will give unit acceleration to unit mass, and (2) the unit of force is defined as that force which will give to unit mass an acceleration equal to the acceleration of a freely falling body under the influence of "gravity" or the pull of the earth alone (see *Mechanics, Principles of*). The first unit is called the "absolute" unit of force and the second the "gravitational" unit of force, and derived units based on these two units are called absolute and gravitational units respectively. The gravitational units are not defined unless the latitude and elevation of the point at which the acceleration due to gravity, usually represented by the symbol " $g$ ," is specified. By international agreement (*Troisième Conf. Gen. des Poids et Mes., 1901, p. 66*) the value  $g_0 = 980.665$  cm. per sec. per sec. ( $= 32.1739$  feet per sec. per sec.) has been chosen as the standard value for the acceleration due to gravity; this value of  $g$  may be called the "gravitational acceleration constant." The value 980.665 was chosen to represent the value of  $g$  at  $45^\circ$  latitude and sea level, but measurements give a slightly different value of  $g$  at this latitude and elevation; the value 980.665, however, is retained as the standard value of  $g$ .

The gravitational unit of force in the English system is called the pound and in the metric system the gram, the same names being used for the unit of force as for the unit of mass. This arises from the fact that unit mass has a force exerted upon it by the earth, i.e., has a weight, numerically equal to its mass, when the force is expressed in terms of this gravitational unit. (This is exactly true only at the latitude and elevation for which  $g = g_0$ , but the variation with both latitude and elevation is usually negligible in engineering work \*) The absolute unit of force in the English system is called the poundal, but is practically never used; the absolute unit of force in the metric system is called the dyne, and is the unit of force commonly used by scientists. In engineering work the common units of force are the gravitational units, pound or gram and their multiples and submultiples.

The relation between the absolute and gravitational units of force are:

$$\begin{aligned} 1 \text{ pound} &= 32.1739 \text{ poundals,} \\ 1 \text{ gram} &= 980.665 \text{ dynes.} \end{aligned}$$

**Weight and Mass.** — The word weight is used in two different senses, viz.: (1) to mean the force with which the earth attracts a piece of matter

\* The force acting on a mass of 1 pound at sea level at the equator is 0.9972 pound, and at sea level at either pole of the earth is 1.002651 pound. An increase of elevation of 10,000 feet diminishes the force acting on a mass of 1 pound by only 0.00096. See Landolt, Börnstein and Roth, *Physikalisch-Chemische Tabellen*.

designate a given mass or quantity of matter; in other words, weight designate both force and mass. As commonly employed the term *weight* has its second meaning; that is, by a "weight of 10 pounds" a piece of matter which has a mass of 10 pounds. A weight (2nd sense) of 10 pounds has a weight (1st sense) of 10 pounds at 45 degrees latitude (practically), but at any other latitude and elevation it has a weight (1st sense) slightly different from 10 pounds, and on the sun, for example, it would have a weight (1st sense) many times 10 pounds.

In connection it should be noted that a beam-balance when used in the way to compare two pieces of matter measures weight in the second sense; it would "read" the same whether the measurement were made on earth or on the sun), that is, a beam-balance as ordinarily used compares masses, not forces. A beam-balance, however, is frequently used in testing (in connection with a Prony brake, see *Index*) to compare a force produced by a weight with the pull on a standard mass (or "weight") due to gravity. If great precision is desired the reading of the balance should then be corrected for the value of "g" at the place of observation, but in ordinary practice the inaccuracy of the balance is likely to be much greater than the correction factor. For values of "g" at various places see reference to the bottom of preceding page.

**UNITS OF THE FUNDAMENTAL UNITS.** — The physical units upon which the c.g.s. system of units is based, and the legalized units of the foot and pound used in Great Britain and the United States are defined below.

**Unit of Length.** — The standard meter (100 centimeters) is the distance between two lines on a platinum-iridium bar carefully preserved at the Bureau of Weights and Measures, at Sevres, France, when the bar is kept at a temperature of zero degrees centigrade throughout. In the United States the yard (3 feet) was defined by Act of Congress, July 28, 1866, as

$$1 \text{ U.S. yard} = \frac{3600}{3937} \text{ meter,}$$

and the British imperial yard is defined by law as

$$1 \text{ British imperial yard} = \frac{3600}{3937.079} \text{ meter.}$$

For engineering purposes the U. S. and British yards may be considered as

**Unit of Mass and Force.** — The standard kilogram (1000 grams) as a unit of mass is a cylinder of platinum preserved at the Bureau of Weights and Measures, at Sevres, France. The U. S. pound avoirdupois is defined by law (Act of Congress, 1866) as  $\frac{1}{2.2046}$  kilogram, but in 1893, the Superintendent of

Weights and Measures, with the approval of the Secretary of the Treasury, defined the pound to be

$$1 \text{ U. S. pound} = \frac{1}{2.204623} \text{ kilogram.}$$

The British imperial pound has the same value.

The relations between pound and kilogram hold whether these units are used as units of mass or as units of force, the unit of force being defined in

both cases as the pull of the earth on unit mass at 45 degrees latitude and level.

**Standard of Time.**—The standard second universally adopted is the  $\frac{1}{86,400}$ th part of a mean solar day. The solar day is the interval of time between two successive transits of the sun across a meridian of the earth at the point of observation; this interval varies in length at different times during the year, but the average length of the interval for one year is constant as far as can be determined by any known methods of observation.

**STANDARDS OF THE AUXILIARY FUNDAMENTAL UNITS.**  
The standards of temperature, dielectric coefficient, magnetic permeability, and luminous intensity ordinarily used are defined below.

**Standard of Temperature.**—Two units of temperature, or temperature scales, are commonly employed, viz., the centigrade and the Fahrenheit scale. The relation between these two units results solely from the manner in which they are defined.

$$1 \text{ degree centigrade} = \frac{9}{5} \text{ degrees Fahrenheit.}$$

Due to the difference in the zeros of the two scales, a temperature of  $t_f$  degrees Fahrenheit corresponds to a temperature of

$$t_c = \frac{5}{9} (t_f - 32) \text{ degrees centigrade,}$$

and vice versa,

$$t_f = \frac{9}{5} t_c + 32 \text{ degrees Fahrenheit.}$$

**Standards of the Auxiliary Fundamental Electrical Units.**—Three systems of electrical and magnetic units are in use, viz., (1) the c.g.s. electrostatic system, (2) the c.g.s. electromagnetic system, and (3) the practical system. In the c.g.s. electrostatic system the dielectric coefficient  $k$  of air at  $0^\circ\text{C}$  and 760 mm. mercury pressure is arbitrarily chosen as unity. In the c.g.s. electromagnetic system the magnetic permeability of air under the same standard conditions is arbitrarily chosen as unity. In the practical system a certain standard of the unit of resistance (called the ohm) is arbitrarily chosen (see *Units, Practical Electrical*); this unit resistance was originally designed to be equal to  $10^9$  times the unit of resistance in the c.g.s. electromagnetic system and within the limits of ordinary experimental error this relation may still be considered exact.

**Use of the Prefixes "Stat" and "Ab."**—To designate the electrostatic and electromagnetic units in the electrostatic and electromagnetic systems (or units respectively the prefixes "stat" and "ab" may be used with the name of the corresponding practical unit. For example, the c.g.s. electrostatic unit of quantity may be called the statcoulomb and the c.g.s. electromagnetic unit of quantity may be called the abcoulomb. For the names and definitions of the various electrical and magnetic units see the article on *Electricity and Magnetism Principles of*.

**Standards of Luminous Intensity.**—Two standards are in use, the international candle and the hefner, the latter being used chiefly in Germany. See article on *Photometric Quantities* for the specifications for these units.

**EXPERIMENTALLY DETERMINED CONVERSION FACTORS.**—By conversion factor is meant the numerical factor which gives the magnitude of one unit for any given quantity in terms of any other unit for the same quantity.

e, in the expression 1 yd. = 3600/3937 meter, the factor 3600/3937 is the conversion factor between the yard and the meter.

For two units for the same quantity based on two different sets of chosen units which are defined independently, the conversion factor is obtained only by experiment. The more important experimentally determined conversion factors are given in the paragraphs immediately following.

**g and Water-column Pressure.** — To convert pressure per unit height of mercury column the density of mercury must be known. Scheel (*Zeitsch. f. Instrk. de.*, 1898, Vol. 18, p. 138) give the density of mercury at 0° C. as 13.59545 grams per (cm.)<sup>3</sup>. Using the standard value of the gravitational acceleration constant,  $g_0 = 980.665$ , the relation between the centimeter and 1 cm. of mercury column at 0° C. is then

1. mercury column at 0° C. = 13332.6 dynes per sq. cm.

density of water as 1 gram per (cm.)<sup>3</sup> at 4° C.,

m. water column at 4° C. = 980.665 dynes per sq. cm.

**Cal Equivalent of Heat.** — Very useful units of energy are those which express the mass of a standard substance and temperature, viz., the heat (erg) required to raise the temperature of a specified mass of water through a certain number of degrees; see *Heat and Thermal Properties*. The experimentally determined relation between the mean small calorie (i.e., the one-hundredth part of the heat required to raise the temperature of 1 gram of water from 15 to 100 C. at 760 mm. mercury pressure) and the erg is

1 mean small calorie =  $4.1834 \times 10^7$  ergs.

See also Davis, *Steam Tables and Diagrams*, N. Y., 1912. From this table the relations (fixed by definition) given above between the yard and the meter, the pound and the kilogram, the value of the gravitational constant  $g_0$ , and the two temperature scales, Marks and Davis, are obtained from the relation

1 British thermal unit = 777.52 foot-pounds.

The British thermal unit as here used is defined as the  $\frac{1}{180}$  th part of the heat

required to raise the temperature of 1 pound of water from 32° F. to 212° F. at 760 mm. mercury pressure. See also *Heat and Thermal Properties*.

The experimentally determined conversion factor between the energy unit based on units of temperature and mass, and the energy unit based on the units of length, mass and time, i.e., the unit of mechanical work, is called the mechanical equivalent of heat."

**Relation between the Three Systems of Electrical Units.** — The experimentally determined, between the c.g.s. electrostatic system and the c.g.s. electromagnetic system is that

1 abfarad =  $9 \times 10^{21}$  statfarads,

in consequence of the definitions of the various terms is equivalent to 1 abcoulomb =  $3 \times 10^9$  statcoulombs, the erg being the unit of energy in both systems.

The experimental relations between the c.g.s. electromagnetic system and the c.g.s. electrostatic system are

1 abcoulomb = 10 coulombs,

1 erg =  $10^{-7}$  watt-seconds, or joules,

the erg being the unit of energy in the c.g.s. electromagnetic system and watt-second or joule the unit of energy in the practical system.

Relation between the International Candle and the Hefner. — experimentally determined relation is

$$1 \text{ hefner} = 0.9 \text{ international candle.}$$

**MULTIPLES AND SUBMULTIPLES OF UNITS.** — Multiples and submultiples of the metric units are designated by the following prefixes; relations are *definitions* and are therefore absolutely exact.

$$\text{micro} = \frac{1}{1,000,000} \quad \text{or } 10^{-6}$$

$$\text{milli} = \frac{1}{1,000} \quad \text{or } 10^{-3}$$

$$\text{centi} = \frac{1}{100} \quad \text{or } 10^{-2}$$

$$\text{deci} = \frac{1}{10} \quad \text{or } 10^{-1}$$

$$\text{deka} = 10 \quad \text{or } 10^1$$

$$\text{hecto} = 100 \quad \text{or } 10^2$$

$$\text{kilo} = 1,000 \quad \text{or } 10^3$$

$$\text{myria} = 10,000 \quad \text{or } 10^4$$

$$\text{mega} = 1,000,000 \quad \text{or } 10^6$$

The multiples and submultiples of the English units are given in bold type in the tables below.

**CALCULATION OF CONVERSION FACTORS.** — The conversion factors noted above, which are either definitions or results of experiment, form the basis for the calculation of the conversion factors for the various derived units. The method of procedure is first to express one of the pair of units, *A*, in terms of its component units (length, mass, time, temperature, capacity, or resistance, and luminous intensity), then express the magnitude of each of these units in terms of the corresponding component units of *B*; the resultant numerical factor is the conversion factor. For example, let it be required to find the conversion factor between pressure in pounds per square foot and pressure in dynes per square centimeter.

$$1 \text{ lb. per sq. ft.} = \frac{(1 \text{ lb. force})}{(1 \text{ ft.})^2}$$

$$1 \text{ lb. force} = \frac{1}{2.204612} \times (1 \text{ kilogram force}).$$

$$1 \text{ kilogram force} = 1000 \times (1 \text{ gram force}).$$

$$1 \text{ gram force} = 980.665 \times (1 \text{ dyne}).$$

Therefore

$$1 \text{ lb. force} = \frac{1000 \times 980.665}{2.204612} \times (1 \text{ dyne}).$$

Also

$$1 \text{ ft.} = \frac{1}{3} \times (1 \text{ yd}).$$

$$1 \text{ yd.} = \frac{3600}{3937} \times (1 \text{ meter}).$$

$$1 \text{ meter} = 100 \times (1 \text{ cm}).$$

$$1 \text{ ft.} = \frac{1}{3} \left( \frac{3600}{3937} \right) \times (100) \times (1 \text{ cm.}).$$

$$\frac{1 \text{ lb. force}}{(1 \text{ ft.})^2} = \frac{1000 \times 980.665 \times (3 \times 3937)^2}{2.204622 \times (3600 \times 100)^2} \times \frac{(1 \text{ dyne})}{(1 \text{ cm.})^2}$$

$$= 478.799 \times \frac{(1 \text{ dyne})}{(1 \text{ cm.})^2}.$$

$$\frac{(1 \text{ dyne})}{(1 \text{ cm.})^2} = 1 \text{ dyne per sq. cm.}$$

$$1 \text{ pound per sq. ft.} = 478.799 \text{ dynes per sq. cm.}$$

**SIGNAL FORMULAS.** — Instead of writing the expression for a quantity in words, it is frequently convenient to express it in algebraic symbols. A specific symbol for each of the fundamental or auxiliary fundamental quantities is used. For example, let  $L$  stand for a length of 1 centimeter,  $M$  for a mass of 1 gram, and  $T$  for a time interval of 1 second; then the unit of force in the c.g.s. system (the dyne) may be written

$$F = MLT^{-2},$$

$$1 \text{ dyne} = (1 \text{ gram}) \times \frac{(1 \text{ cm.})}{(1 \text{ sec.})^2}.$$

Such a formula, such as  $F = MLT^{-2}$ , where each letter represents the magnitude of the quantity for which it stands, is called a "dimensional formula" or "dimensional number," or a quantity which is the ratio of two units of the same dimension. An angle, such as an angle, has zero dimensions and does not appear in a dimensional formula.

Dimensional formulas are useful for two purposes, viz., (1) as a systematic method of calculating conversion factors and (2) as a check of algebraic formulas by substituting various relations. Unless one has a large number of conversion factors, it is probably simpler to use the direct method given in the preceding section. Certain quantities, for example, work and torque, may have the same dimensions although they are physically entirely different. In such cases, although the quantities are physically different their conversion factors are the same. The second use of dimensional formulas is based on the fact that in any set of terms connected either by equal signs, plus signs or minus signs, all terms must have the same dimensions.

A complete list of the dimensional formulas for the various mechanical, electrical, and photometric quantities see Hering, C., *Conversion Tables*, etc. In the tables below are given, in the parentheses after the dimensional formulas of the mechanical quantities in terms of length, mass, and time, designated by  $L$ ,  $M$  and  $T$  respectively. For the electrical and magnetic quantities the dimensions are expressed in terms of electric potential, quantity of electricity  $Q$  and time  $T$ . In the c.g.s. electromagnetic system  $Q$  may be expressed in terms of  $L$ ,  $M$ , and  $T$  by the formula

$$Q = L^{\frac{1}{2}} M^{\frac{1}{2}} T^{-1};$$

In the electrostatic system by the formula

$$Q = L^{\frac{3}{2}} M^{\frac{1}{2}} T^{-1};$$

and the dimensional formula for energy is  $L^2 M T^{-2}$ .

**TABLES OF CONVERSION FACTORS.\*** — The following tables the most commonly required conversion factors for mechanical, electrical, magnetic quantities. See *Heat and Thermal Properties* for special heat (other than energy) and *Photometric Quantities* for the special photometric

## LENGTH (L)

cm. = centimeter.

ft. = foot.

in. = inch.

km. = kilometer.

m. = meter.

mi. = mile.

mm. = millimeter.

yd. = yard.

**UNITS, PRACTICAL ELECTRIC.** — (See also *Electricity and Magnetism, Principles of; Units and Conversion Factors.*) Following the recommendation of the Chicago International Electrical Congress of 1891, the following Act was passed by Congress. (Act approved July 13, 1894.) *As enacted, etc.* That from and after the passage of this act the legal units of electrical measure in the United States shall be as follows:

*First.* The unit of resistance shall be what is known as the international ohm, which is substantially equal to one thousand million units of resistance of the centimeter-gram-second system of electromagnetic units, and is represented by the resistance offered to an unvarying electric current by a column of mercury at the temperature of melting ice fourteen and four thousand five hundred and twenty-one ten-thousandths (14.4521) grams in mass, of a constant cross-sectional area, and of the length of one hundred and six and three-tenths (156.3) centimeters.

*Second.* The unit of current shall be what is known as the international ampere, which is one-tenth of the unit of current of the centimeter-gram-second system of electromagnetic units, and is the practical equivalent of the unvarying current, which, when passed through a solution of nitrate of silver in water in accordance with standard specifications, deposits silver at the rate of one thousand one hundred and eighteen millionths (0.001118) of a gram per second.

*Third.* The unit of electromotive force shall be what is known as the international volt, which is the electromotive force that, steadily applied to a conductor whose resistance is one international ohm, will produce a current of one international ampere, and is practically equivalent to  $\frac{1000^{\circ}}{1434}$  of the electromotive force between the poles or electrodes of the voltaic cell known as Clark cell, at a temperature of fifteen degrees centigrade (15° C.), and prepared in the manner described in the standard specifications.

*Fourth.* The unit of quantity shall be what is known as the international coulomb, which is the quantity of electricity transferred by a current of one international ampere in one second.

*Fifth.* The unit of capacity shall be what is known as the international farad, which is the capacity of a condenser charged to a potential of one international volt by one international coulomb of electricity.

*Sixth.* The unit of work shall be the joule, which is equal to ten million units of work in the centimeter-gram-second system, and which is practically equivalent to the energy expended in one second by an international ampere in an international ohm.

*Seventh.* The unit of power shall be the watt, which is equal to ten million units of power in the centimeter-gram-second system, and which is practically equivalent to the work done at the rate of one joule per second.

*Eighth.* The unit of induction shall be the henry, which is the induction in a circuit when the electromotive force induced in this circuit is one international volt while the inducing current varies at the rate of one ampere per second.

**SECTION 2.** That it shall be the duty of the National Academy of Sciences to prescribe and publish, as soon as possible after the passage of this act, such specifications of detail as shall be necessary for the practical application of the definitions of the ampere and volt hereinbefore given, and such specifications shall be the standard specifications herein mentioned.

**NOTES ON THE ABOVE DEFINITIONS.** — The specifications mentioned above were prepared by a committee, and their report, based on the best

t had been done up to that time, was accepted and adopted by the Academy of Sciences on February 9, 1895.

on is called to the wording of the definitions of the three fundamental

international ohm is based upon, but *not stated to be equal to*,  $10^9$  s of resistance; it is, however, *definitely defined* in terms of a column of

international ampere is one-tenth of the c.g.s. unit of current, and is be represented *sufficiently well for practical purposes* by the current visits a definite mass of silver per second under specified conditions.

international volt is the e.m.f. which will cause an international ampere-rough an international ohm, and is stated to be represented *sufficiently acical purposes* by a definite fractional part of the e.m.f. of the Clark

ent investigation has shown that the figures for the silver voltameter 'lark cell are not equivalent. The e.m.f. of the Clark cell is really :ernational volts at  $15^\circ$ .

**ICAL STANDARDS.** — The Act of July 12, 1894, is still in force tage has been taken of the manner of stating how the international e practically realized to use as a standard of e.m.f. the Weston normal l of the Clark cell (*see Cells, Standard*).

l resistance coils (*see Resistors, Standard*) are used as secondary of resistance. These are usually accurately adjusted by the makers. t accuracy is required these standard resistances should be sent to i of Standards for calibration. Much more accurate results can be o an ordinary laboratory by using properly calibrated secondary than by attempting to construct primary standards in accordance efnitions in the above Act.

of a voltameter for the calibration of current-measuring instruments r seldom employed. A more accurate method for ordinary laboratory determine, by means of a properly calibrated potentiometer (q.v.), drop produced by the current through a standard resistance.

**UNLOADERS, COAL AND ORE.** — (See also *Cranes; Motors, Industrial Applications of; Power Stations.*) Coal and ore unloaders may be divided into two distinct classes, namely, the stiff-leg type and the bridge type. They are adapted to electric drive and each possesses certain advantages under conditions for which it is designed. Unloaders range in capacity from three to fifteen tons per bucket load. The capacity in tons per hour varies within wide limits, but records have been established where under normal operating conditions four 15-ton equipments unloaded 10,000 tons in five hours. The power required naturally also varies under different conditions, but an average of from 0.4 to 0.5 kilowatt hour per ton is not uncommon.

**STIFF-LEG UNLOADERS** (Fig. 1) are mainly used at receiving docks for unloading ore from the boat to railway cars or to a large concrete trough from which it is in turn transferred to the storage yards by means of ore bridges. The machine, as seen from Fig. 1, consists essentially of a massive pantograph, the short leg of which forms an integral part of the carriage *C*. This leg is rigidly vertical, hence the stiff leg *L* which carries the bucket *B* must always be vertical. The weight of the moving parts of the link motion is nearly counterbalanced at *W* by the main hoist, rotation and bucket motors and their respective drums. The motor house on the carriage *C* contains the trolley motor and the magnetic control panels for all the above motors. The carriage is

Fig. 1. Stiff-leg Unloader

mounted on trucks and moves back and forth on the girder runway *G*. The girder structure supports a hopper with rotating gates which receives the ore from the bucket *B* and distributes it slowly to the weighing larry which in turn deposits it in the ore car underneath or in the concrete trough *T*. Cables from the main hoist drum at *W* are attached to the rear of the carriage. The operator rides in the bucket leg and has absolute control of lowering, opening, closing, bucket rotation, hoisting and trolleying movements. The entire girder structure is mounted on trucks and can be run along the dock at will by means of the bridge movement motor. Magnetic control is employed throughout and all motors except leg-rotation and bridge-movement motors are arranged for dynamic braking.

**Cycles of Motor Movements.** — The service of the main hoist and opening and closing motor is intermittent with continuous repetition of cycle often at the rate of one round trip per minute for several consecutive hours. The leg rotation motor is used chiefly in cleaning up the bottom of the boat between hatches and involves rapid and frequent reversals at irregular intervals. The trolley motor cycle includes acceleration, free running, retardation, reversal and repeat with every bucket load hoisted. The ore-gate motor operates intermittently whenever ore is distributed to the weighing larry. The larry travel and hopper-gate motors both operate on a continuously repeated cycle of short duration. The bridge-movement motor is used only at irregular intervals for locating the bucket over the hatches.

**Motor Equipment.** — The following table shows the motor equipment of a modern unloader of the stiff-leg type. The main-hoist motor has a continuous rating, but all the others are rated on an intermittent basis.

MOTOR EQUIPMENT, 15-TON STIFF-LEG UNLOADER

no.	H.P.	R.p.m.	Volts, d-c.	Application	Type of motor
	135	350	230	Main hoist	Compound wound
	75	500	230	Trolley	Compound wound
	75	500	230	Bucket { Opening Closing	Compound wound
	100	450	230	Ore gates	Compound wound
	100	450	230	Larry	Compound wound
	100	450	230	Bridge movement	Compound wound
	20	750	230	Leg rotation	Series wound
	30	750	230	Larry hopper	Series wound

BRIDGE-TYPE UNLOADERS (Figs. 2 and 3) can be divided into two classes, viz., the "man-trolley" and the "rope-trolley." In the former existing and conveying motors together with a cab containing the control ment and operator are mounted on a carriage which runs the length of the x, as shown in Fig. 2. In the rope-trolley unloader the motors are located stationary motor house and power is transmitted to the hoisting drum and age by means of cables, as shown in Fig. 3. The operator is also located in stationary cab as seen.

Fig. 2. "Man-trolley" Bridge Unloader

Fig. 3. "Rope-trolley" Bridge Unloader

MOTOR EQUIPMENT, 625-FOOT "MAN-TROLLEY" BRIDGE UNLOADER

3	55	430	250	Closing and hoisting	Series wound
1	25	430	250	Travel	Series wound
1	11	...	250	Bucket twist	Series wound
1	15	...	250	Car-loading drums	Shunt wound

**TYPE OF MOTOR.**—The selection of the most suitable type of motor for coal and ore bridge work must be determined for each specific installation by local considerations. In general the requirements are not quite as severe as those commonly included under the term "steel mill service," and standard industrial motors in a few instances have been used for high-speed bridges with good success. As a rule, however, especially for ore bridges, the mill-type motor is recommended, since even under the best conditions the short cycle, rapid and frequent acceleration, severe vibration, dirt and moisture, all demand the most rugged construction.

The question of alternating- or direct-current motors is usually one of comparative first costs, costs of maintenance and operation. Where adjustable speed under variable load are required the induction motor with its constant speed characteristics is somewhat at a disadvantage if compared with the direct-current motor equipped with interpoles and best available control. For dynamic braking the direct-current motor also offers fewer complications in the control. Furthermore, for the rack movement or trolley travel the acceleration losses are less for the series direct-current motor. On the other hand, the efficiency of transformation and distribution of power is considerably higher for alternating-current for direct-current systems so that the apparent gain due to the characteristic of the series motor may be more than offset by the simplicity and ruggedness of the induction motor, the elimination of motor-generator sets, equalizer sets and in some cases even of static transformers.

**ES.**—(See also *Boilers; Gas Engines; Pipes; Power Stations; Steam Steam Turbines.*) The following types of valves are used to control of fluids in pipes.

**Gate Valve.**—The opening in this valve is perpendicular to the axis of the pipe and is closed by a disk which moves across the opening. A gate valve offers little resistance to the flow of the fluid, since when fully opened it leaves a straight passage the full diameter of the pipe (see *Pipe and Piping*).

**Globe Valve.**—In this valve the opening is in a partition parallel to and perpendicular to the axis of the pipe. The opening is closed by a mushroom-shaped disk which is screwed down against the partition. The name "globe" comes from the globular form of the casing. The passage through a globe valve has the general shape of the letter S, and consequently offers considerable resistance to the flow (see *Pipe and Piping*). It is simpler in construction than a gate valve, and the contact surfaces are more easily ground.

**Elbow Valve.**—This valve has the inlet and outlet at right angles to each other and may therefore be installed in place of an elbow. The opening is at right angles to the inlet. The closing mechanism may be either of the gate or globe type.

—This type of valve consists of a conical plug with a hole through the center perpendicular to its axis, mounted in a suitable casing. The valve is opened by turning the plug so that the hole is in line with the pipe and is closed by turning the plug a quarter turn. Cocks are frequently used on blow-off piping.

**Stop Valve.**—A stop valve is any valve that is controlled by hand or other means, and used to stop the flow of fluid in a pipe.

**Check Valves.**—A check valve is any valve which opens automatically when the pressure in the normal direction reaches a predetermined value, but closes when the pressure is less than this amount or is in the opposite direction.

Ordinary forms of check valves resemble a globe valve without a partition. The closing device may be a disk, ball or cup. When the disk is free to swing about an axis like a hinge the valve is called a "swing check," "hinge valve," or "butterfly valve." When the disk or other device is lifted by the pressure of the fluid the valve is called a "lift-check valve." A check valve placed at the suction pipe of a pump is called a "foot valve."

**Safety Valves.**—Lift check valves provided either with a helical spring or a weight and lever mechanism to hold the valve closed under normal pressure are called safety valves; the former type is called a pop safety valve, the latter a lever safety valve. The pop safety valve has practically supplanted the other type, since it closes more promptly and is less liable to leak.

**Back-pressure Valves.**—Check valves used to relieve excessive back pressure in engine exhaust pipes are called "back-pressure valves," and when used in connection with condensers to relieve excessive pressure are called "atmospheric valves."

**Throttling Valves** are used when it is desired to obtain steam at a pressure lower than that of the boiler. In this type of valve the opening is relatively small, and the steam in expanding through this small opening has its pressure reduced. The size of opening for various rates of flow is maintained automatically by adjusting the force produced on the closing mechanism by the pressure on the pressure side of the valve against the force produced on this mechanism by a helical spring. The size of the opening then adjusts itself automatically in this balance irrespective of the rate of flow.

**SELECTION OF TYPE OF VALVE.** — For low-pressure work standard cast-iron valves with bronze seats have been more than satisfactory. They are now made of a great many types, all of which give very good results. The solid wedge gate is perhaps the earliest and the best known. The parallel wedge type and the parallel two-gate type are also well known and largely sold. Globe valves are not usually used for steam work on account of the resistance offered to the passage of the steam, but for throttle valves and stop valves are still the standard. For high-pressure work and especially with superheated steam the use of the steel body valve with steel seats and disks has become standard and many varieties of valves are now on the market, some of which are doing excellent work. Nickel-bronze and nickel are also used for seats and stems with good results. In choosing a valve for high-pressure and high-temperature work, great stress should be laid on the absence of chance for unequal expansion in the body and gates. The metal should be so plain that what expansion occurs will be equable in all directions and the gates designed that they cannot spring out of true under different degrees of heat. Such mechanism as may be used between the gates in a double-gate valve press them up against the seats should be as carefully designed as the body of the valve, as small deflections in this part of the mechanism will prevent tightness. The most satisfactory valves for this work have been of the double wedge type, although there are good parallel seat and solid-wedge valves on the market which have stood severe tests.

**ELECTRICAL OPERATION OF VALVES.** — (*See also Motors, Industrial Applications of.*) The advantages of electrical motor operation for valves is emphasized not only by the fact that such valves must be closed in a very short time, which would be impossible with hand control, but also by the fact that remote control is very often essential, as, for example, in hydroelectric power developments where it becomes desirable to control the gate valves in the control switchboard. The service of valve motors is exceedingly intermittent and may vary from comparatively short intervals, such as once every hour, weeks or even months. Due to the intermittent nature of the service, efficiency or power factor need not be considered in this kind of motor application, the main consideration being the most reliable system of operation.

**Size of Motor.** — The proper size of a motor for driving a valve will vary with the duty and conditions under which the valve operates. A small valve may only require a one-horse-power motor, whereas very large valves, such as the Stoney-Gate valves at Panama, require 40-horse-power motors. The required motor capacity also depends to a large extent on the pressure on the valve. When opening the valve, the torque is a maximum shortly after the time of unseating, that is, after the wedges have been released and the actual motion begins. The torque then drops some until the valve has opened about one-fourth, after which it takes comparatively little power to complete the opening. When closing the valve, friction only needs to be overcome in starting; there is no pressure on the valve until it has begun to close. After the valve is about three-fourths closed the pressure causes the torque to increase rapidly. At the end of the closing cycle the torque does not, however, reach the value it did during the period of starting.

**Type of Motor.** — Either direct- or alternating-current motors may be used. With the former the series- or compound-wound type is generally used as it gives a high starting torque. With the latter the squirrel-cage induction motor is most widely used for small- and medium-size valves, principally on account of its simplicity. To overcome the sticking when opening, the drive is sometimes provided with a "lost motion" so as to give a hammer blow. For alternating

ators this is furthermore of value in that it permits the motor to speed and gain in torque before the load comes on.

**Equipment.** — Where the size of the motor permits, the simplest control is to throw the motor directly on the line without the use of resistances. The automatic overload circuit breaker which should protect under normal operating conditions, must be prevented from tripping during the rush of starting current. This is readily accomplished either by short-circuiting the overload coil of the circuit breaker or by opening the circuit to the coil. The former is the preferable method as this will leave the motor under load protection even though the coil is short-circuited. A push button is provided for this purpose.

Limit switches which will open the circuit when the gate has reached its limit should always be provided. As a further precaution against excessive closing torque the motors should preferably be geared to the shafts through efficient and reliable friction clutches.

If the motors are too large to be thrown directly on the line, starting resistance must be provided. With direct-current series motors a permanent magnet and a running resistance are often provided. The permanent resistances are fixed in the circuit and should be so dimensioned as to give the torque required. The running resistance is short-circuited at start-up so the motor current drops to any desired value, at which time a current switch opens the shunt circuit of the contactor used for short-circuiting the running resistance. This running resistance should be such as to prevent excessive starting load and to limit the torque should the valve seat itself before the motor is connected. The same general scheme may be used with alternating-current motors, but with these there is no danger of exceeding the synchronous

**for Indicating Valve Positions.** — When it is desired to indicate on the switchboard the position of the gate throughout its range of travel, this may be done by placing a number of sliding contacts on the inside of the switch housing. These contacts are then connected with a row of indicator lamps installed on the switchboard, and as the limit switch travels across the board the lamps will light successively.

A more comprehensive system, much more comprehensive, is used in connection with the motors at the Panama Canal. In connection with each limit switch there is a "synchronizing transmitting device." This consists merely of a generator which is mechanically connected to and revolves with the limit switch. This generator is electrically connected to a small motor which is mounted on the switchboard and there mechanically connected to some sort of indicating device, such as a pointer. When the generator at the valve revolves, the motor on the switchboard will follow in synchronism thus indicating the exact position of

Jour.*, 36, p. 136, 1914.

**VECTORS.** — (*See also Complex Quantities.*) Any quantity which requires for its complete specification a magnitude and a direction is called a vector quantity. Such a quantity may be represented graphically by a line having length equal to the magnitude of the quantity and a direction parallel to the direction of the quantity. Such a line is called a vector. Its direction is, in general, specified by the angles which it makes with three arbitrarily chosen lines or axes of reference. Vectors which lie in the same or in parallel planes are called co-planar vectors; the direction of a vector in the plane in which it lies (or parallel planes) may be specified by the angle which it makes with a single line of reference in this plane.

Quantities which are completely specified by magnitude and "sense" (whether positive or negative) are called scalar quantities. Forces, velocities, displacements, etc., are vector quantities, while time, work, mass, etc., are scalar quantities.

**Vector Addition and Subtraction.** — Since vector quantities cannot be completely specified by ordinary numbers, the various operations of arithmetic such as addition, subtraction, multiplication and division have no meaning when applied to such quantities. Analogous processes, however, are of great value in dealing with them. For example, the resultant of two forces which make an angle with each other is, by the ordinary parallelogram of forces, equal to the diagonal of the parallelogram formed by drawing from the free ends of the two lines representing the forces, lines parallel to these forces. That is, the resultant of  $OA$  and  $OB$  in Fig. 1 is the diagonal  $OC$ . Both the length  $OC$  and direction (the angle  $AOC$ ) of the resultant is fixed by this construction. The resultant  $OC$  is called the vector sum of  $OA$  and  $OB$ . Similarly, the vector sum of  $OA$  and  $AB$  is equal to  $OB$ , or vice versa,  $AB$  may be called the vector difference of  $OB$  and  $OA$ . The angle  $XAB$  gives the direction of this vector difference when  $OA$  is subtracted vectorially from  $OB$ . When  $OB$  is subtracted vectorially from  $OA$  the vector difference also has the same length or magnitude, but is in the opposite direction, i.e., makes an angle  $180^\circ - \angle XAB$  with  $OA$ .

Fig. 1

**Components of a Vector.** — Any vector may be considered as made up of any number of vectors which when added vectorially, as described above, give a resultant vector equal to the given vector. It is frequently convenient in analyzing problems involving vectors to resolve each vector into two components, one parallel to and the other perpendicular to the axis of reference. The first component is usually referred to as the horizontal component and the second as the vertical component. It is readily proved that the horizontal component  $H$  of the resultant (or vector sum) of any number of vectors is equal to the algebraic sum of the horizontal components  $h_1, h_2$ , etc., of the individual vectors, i.e.,

$$H = h_1 + h_2 + \text{etc.}$$

and the vertical component  $V$  of the resultant is equal to the algebraic sum of the vertical components  $v_1, v_2$ , etc., of the individual vectors, i.e.,

$$V = v_1 + v_2 + \text{etc.}$$

The length of the resultant is then

$$S = \sqrt{H^2 + V^2}$$

akes with the axis of reference the angle  $\sigma$  where

$$\tan \sigma = \frac{V}{H}$$

**ical Representation of a Vector.**—The geometrical representation  
plex quantity (*see Complex Quantities*) is a vector, i.e., the line repre-  
complex quantity has both magnitude and direction. Any vector  
may, therefore, be represented by a complex quantity, and the opera-  
ector addition and subtraction may be carried out by the ordinary  
of algebraic addition and subtraction of complex quantities. For ex-  
o vectors  $A$  and  $B$  may be represented by the algebraic expressions

$$\begin{aligned} \underline{A} &= h_1 + jv_1, \\ \underline{B} &= h_2 + jv_2, \end{aligned}$$

and  $h_1$  and  $v_1$  and  $h_2$  and  $v_2$  are the horisontal and vertical components re-  
and the dots under  $A$  and  $B$  signify that  $\underline{A}$  and  $\underline{B}$  are vector quan-  
ie vector sum of  $\underline{A}$  and  $\underline{B}$  is then

$$\underline{S} = \underline{A} + \underline{B} = (h_1 + h_2) + j(v_1 + v_2),$$

the magnitude

$$S = \sqrt{(h_1 + h_2)^2 + (v_1 + v_2)^2},$$

ngle

$$\sigma = \tan^{-1} \frac{v_1 + v_2}{h_1 + h_2}.$$

**ication and Division of a Vector by a Number.**—Multiplying a  
a real number  $n$  means taking a vector  $n$  times as long; dividing

$v/n$  means taking a vector  $\frac{1}{n}$  of the length of the original vector. The

ultiplying a vector by an imaginary number  $jn$  is defined as a vector  
e length of the original vector and making a positive angle of  $90^\circ$   
original vector. The result of dividing a vector by an imaginary

is defined as equivalent to multiplying the vector by  $\frac{1}{jn} = -j\frac{1}{n}$

equivalent to a vector  $\frac{1}{n}$  of the length of the original vector and  
egative angle of  $90^\circ$  with the given vector. Hence the multiplication  
of a vector  $h + jv$  by a complex number  $n + jn$  is equivalent to  
lgebraic multiplication or division of two complex numbers (*see*  
*quantities*).

**Product of Two Vectors.**—Multiplication, in the ordinary sense,  
ector by another has no meaning, since a vector is not a number but  
oth magnitude and direction. In the analysis of the more com-  
blems of mechanics and electricity, certain expressions arise, how-  
are analogous to ordinary multiplication. One of these expressions  
quantity equal to the product of the magnitude of the two  
the cosine of the angle between them. This product is called the  
luct of the two vectors. The scalar product of the two vectors  $A$   
 $B \cos \theta$  where  $\theta$  is the angle between them. If the vectors are  
is complex quantities

$$\begin{aligned} \underline{A} &= h_1 + jv_1, \\ \underline{B} &= h_2 + jv_2. \end{aligned}$$

the scalar product is

$$a_1a_2 + a_3a_4.$$

Note that this has no relation to the algebraic product of the two expressions  $a_1 + ja_3$  and  $a_2 + ja_4$ .

**Vector Product of Two Vectors.** — Another expression which arises is a vector quantity at right angles to the plane of the two vectors and equal in magnitude to the product of the magnitudes of the two vectors by the sine of the angle between them. This product is called the vector product of the two vectors.

**Example.** — The vector product of the vector  $A$  by the vector  $B$  (Fig. 4) is  $AB \sin \theta$ , and is in the direction in which a right-handed screw, to the axis of which  $A$  is conceived to be fixed, is advanced when  $A$  is turned through an angle of less than  $180^\circ$  into coincidence with  $B$ . From this definition it follows that the vector product of  $B$  times  $A$  is equal but *opposite* to the vector product of  $A$  times  $B$ . When  $A$  and  $B$  are expressed as complex quantities the vector product of  $A$  times  $B$  is

$$A_1B_2 - A_2B_1.$$

Note that the algebraic product of the expressions

$$a_1 + ja_3 \text{ and } a_2 + ja_4 \text{ is } a_1a_2 - a_3a_4 + j(a_1a_4 + a_2a_3).$$

The real and imaginary parts of this expression are *not* equal to the scalar and vector products.

**ON, LAWS OF.** — (See also *Illumination, Laws of; Photometricities; Photometry.*) Light enters the eye through the *cornea*, a thin, trans-  
 curved wall, and passes successively through the *aqueous humor*, the  
 the *biconvex lens*, and the *vitreous humor* to an image on the rear wall  
*na*. The cornea and lens possess the image-forming function, and accom-  
 ion to distance is given by the varying curvature of the lens. The humors  
 optical contact and preserve the size and form of the eye. The contraction  
 ilation of the pupil gives automatic accommodation to the intensity and  
 ity of light in the field of view. The retina adapts itself automatically  
 ibility to the flux density of the light falling upon it; while comfortable  
 covers a range of brightness of ten billion to one, the sensibility of the  
 varies in the ratio of one hundred million to one.

The retina comprises an elaborate structure of microscopic nerve terminals  
 as rods and cones. In its periphery rods predominate, but the ratio of  
 to rods increases steadily toward the axial region of *fovea*, where the cones  
 y predominate. The directly visualized image falls on the fovea and the  
 less of perception diminishes markedly in passing to the periphery. At  
 ow intensities rod vision predominates. At moderate and high intensi-  
 ine vision predominates. In the former state the relative sensibility to  
 ue end of the spectrum is emphasized, in the latter state the relative sensi-  
 to the red. As an optical system the eye has a chromatic aberration of  
 imately two diopters.

**ELEMENTS OF VISION.** — Visual sensations in general are characterized  
 intensity, extensity, quality and duration. Intensity refers to the aspects  
 ion measurable photometrically, such as brightness and contrast, determi-  
 ux density at the retina. Extensity involves the perception of contour,  
 ertive, relief, detail and distance. Quality discriminates between sensa-  
 of color and non-color. Duration relates to the growth, fatigue, persist-  
 and intermittency of visual sensations.

**Intensity Relations.** — For a given quantity of radiant energy, the luminous  
 ion (light) varies with the wave frequency of the radiation, with its  
 ity and with the time of exposure  
 eye to it. The eye is most sen-  
 and the ratio of light to energy  
 maximum at a wave length of  
 0.000558 mm. in the green part  
 e spectrum. Here the ratio of  
 to radiation is about 0.0015 lumen  
 per watt of radiation. From  
 ave length the luminous equiv-  
 of radiation decreases rapidly

rd both shorter and longer wave lengths. It is about 0.000006 lumen  
 watt at wave lengths 0.00040 and 0.00073 mm. The data on the complete  
 : for ratio of light to radiation are given in the following table and in  
 1. These data are the means for about 200 subjects collected by Ives,  
 ing, Coblenz and Hyde in four different laboratories. These data are  
 cable to all moderate and high intensities. At very low intensities a  
 ar curve displaced toward shorter waves obtains.

**Purkinje Effect.** — Transition from vision at low intensity to high  
 lves relative loss of sensibility to blue and gain of sensibility to red, so that  
 lights of reddish and bluish hue respectively show a ratio of intensities  
 h varies with the brightness of the field of view. This is known as the  
 kinje effect. In fields above a brightness of one lumen per square foot the

shift is slight. Photometric comparisons involving color differences should be made only in bright fields.

**Intensity Sensibility.** — For an eye viewing a field of a given brightness there exists for each brightness to which the eye is adapted (1) a minimum brightness just perceptible, (2) a ratio of brightness (contrast) just perceptible, (3) a maximum brightness just tolerable.

Field brightness	Difference fraction	Discrimination factor	Threshold limit	Class limit
0.000001 m.l.	(1.00)	1.0	0.00000093 m.l.	20.1 "
0.00001	(0.66)	1.5	0.0000042	40.7 "

rief summary of the data on threshold limit, discrimination and glare given in the table at bottom of page 1888.

example, an average eye adapted to a field brightness of 0.1 m.l. can just contrast of 1.037 : 1—the discrimination is about half (27/57) its maximum

The deepest shadow in which it can see anything is 0.0017 m.l. in less and the brightest tolerable high light is 800 m.l.

#### 1. Threshold, Discriminating Power and Glare Sensibility at Various Levels.

illuminating engineer is chiefly concerned with four quite distinct brightnesses, namely:

- 0.001 m.l. (E.N.) Exteriors at night, street lighting.
- 0.01 m.l. (I.N.) Interiors at night, interior artificial lighting
- 1.0 m.l. (I.D.) Interior daylight lighting.
- 1.0 l. (E.D.) Exterior full daylight lighting.

glare sensibility ( $G$ ) is a linear function of log field brightness ( $B$ ) such that

$$\begin{aligned}\text{Log } G &= 3.23 + 0.32 \text{ log } B, \\ G &= 1700B^{0.32}.\end{aligned}$$

reshold sensibility ( $T$ ) is also a linear function of log field brightness at the highest intensities (over 0.1 lambert) such that

$$\begin{aligned}\text{Log } T &= 0.66 \text{ log } B - 2.10, \\ T &= 125B^{0.66}.\end{aligned}$$

ility to contrast is nearly constant (about 2 per cent) over the wide of intermediate intensities with which vision is chiefly concerned.

#### RATE OF INCREASE AND DECREASE OF THRESHOLD SENSIBILITY

Time	$B_0 = 0, B = 15 \text{ m.l.}$ Sensibility decrease	$B_0 = 25 \text{ m.l.}, B = 0$ Sensibility increase
1 second	2.1 times	1.6 times
2 seconds	4.2 times	2.6 times
5 seconds	16.2 times	7.6 times
10 seconds	58 times	14.4 times
10 minutes	170 times	20.9 times

**Effect of Alternate Exposures.** — If an eye is fully adapted to a given brightness, then suddenly exposed to a dark field it gains rapidly in sensibility as shown in the table on page 1889, while if adapted to darkness and then exposed to a bright field it loses sensibility but at a lower rate.

Since the loss of sensibility in a given interval is greater than the recovery, the net result of a succession of exposures to alternate light and darkness is a considerable depression of mean sensibility.

**Color of Various Sources.** — In monochromatic analysis white light is mixed with light of a pure spectral hue to match the color to be analyzed. L. A. Jones gives the following color analyses of common light sources.

Source	Color	
	White	Hue
1. Sunlight . . . . .	100	472
2. Average clear sky . . . . .	60	472
3. Standard candle . . . . .	13	593
4. Hefner lamp . . . . .	14	593
5. Pentane lamp . . . . .	15	592
6. Tungsten glow lamp at 1.25 w.p.c. . . . .	35	592
7. Carbon glow lamp at 3.8 w.p.c. . . . .	25	591
8. Nernst glower at 150 w.p.c. . . . .	31	556
9. Nitrogen filled tungsten:		
at 1.00 w.p.c. . . . .	34	576
at 0.50 w.p.c. . . . .	45	554
at 0.35 w.p.c. . . . .	53	548
10. Mercury-vapor arc . . . . .	70	460
11. Helium tube . . . . .	33	538
12. Neon tube . . . . .	6	605
13. Crater of carbon arc:		
at 1.8 amperes . . . . .	59	584
at 3.2 amperes . . . . .	62	581
at 5.0 amperes . . . . .	67	551
14. Acetylene flame (flat) . . . . .	36	595

**Intensity Relations.** — Intensity is perceived largely through differences in brightness and color, by varying visual angles and by acuity, or the power of resolving detail. Acuity follows a logarithmic relation to brightness and to the strength of sensation. The same practical lower limit, say from one to two lumens per square foot, affords a fair normal basis of acuity. Above this the gain in acuity is relatively much less than the increase in illumination. Acuity, however, is not independent of color, due to the chromatic aberration of the eye. Retinal images formed by approximately monochromatic light are sharper than those due to a rich spectrum. Luckeish (see *Elec. W.*, Vol. 1, p. 1252) gives the data in Fig. 3 for the relative acuity with various colors. For near vision blue light is more readily focussed, whereas for distant vision red light is more readily focussed.

Fig. 3

are.—The effectiveness of illumination is depressed to a marked / disturbing influences grouped under the term glare, which may be ately defined as the relative overbrightness of part of the field of view.

Glare, caused by the slowly changing adaptation of the eye when from a dim region into a brilliantly lighted one, causes only temporary

t. Persistent glare, in addition to the depression of visual functions, ighly injurious. No complete quantitative analysis of glare has yet

e. The following qualitative relations have been well established:

re effect, or reduction of visual effectiveness, increases as the glaring roaches the eye. Glare increases as the ratio of the distance of the ace to that of the visualized object from the eye diminishes. The t which a light source ceases to be glaring depends on its intensity, and position in the field of view.

e increases with the quantity of light received from the source.

e increases with the brilliancy of the glaring source and with its de- strait to objects visualized. An automobile headlight is exceedingly night, but not glaring by day. Any light source giving an after- cessive in brilliancy. Glare due to this cause is accentuated by the eacy of the eye to wander from the object of vision and fix on the urce, causing a fatigue of attention.

e increases as the retinal image of the glaring source approaches the ie field of view. Depression of vision from side light is due in part and in part to the dilution of the central image by light scattered

Glare due to bright walls and backgrounds is largely of the latter glare from bright sources situated at an angle from the line of vision 6 degrees is generally negligible.

f practical cases of glare are due to directly visible light sources of and brilliancy, to scattered light from side sources and backgrounds ect reflection of bright images by glazed surfaces in the immediate

t. Prevention should be sought by the proper location and shading roces, by creating suitable contrasts between the field and its s and by avoiding the use of glazed surfaces, especially highly-sized

. — Below certain frequencies intermittent sensations retain a distinctness and produce a flicker effect. If a critical frequency is e sensations blend into a continuous effect equal in intensity to the ity over the complete cycle. Examples are the rotating sectored e electric lamp operated by alternating current. The vanishing e flicker increases with the degree of variation from maximum to 1th the solid angle subtended by the object viewed and with the its brightness. The vanishing frequency of flicker is higher for or colored light. Within the common limits of practice the vanish- y is between 30 and 45 cycles per second. Electric lamps display le flicker in themselves or in illuminated objects at frequencies cycles.

r **Color Relations.** — Non-colored sensations are white gray, and r sensations differ in brightness in hue and in tone. The hue of termed by the spectral position of its predominant component. int depends on the degree of dilution with white or black. Thus pink and claret may agree in hue, but differ essentially in tone. ions are equal in brightness when they may be rapidly alternated f view without the appearance of flicker.

esis and Analysis of Colors may be accomplished by mixing red, ue in proper proportions, or by diluting the predominant hue with e of white or black. A color may be specified by the synthesis

necessary to reproduce it. Tri-chromatic specification gives the mixing proportions of red, green and blue. Mono-chromatic specification gives the spectral hue and the degree of dilution. The tri-chromatic analysis as determined by the colorimeter (see *Photometry*) is of greatest practical utility. In this system the proportions of red, green and blue found in average daylight, though not equal, are taken as 33.3 per cent each to fix three color scales. The mixing proportions of these colors on the scales so established which reproduce a given light serve to specify it and to compare its color composition with daylight.

**Relation of Color of Light to Appearance of Objects.**— Objects appear in the colors which they reflect or transmit to the eye. To produce true color effects light must possess all the components necessary to reproduce objects and possess them in proper proportions. If the spectrum is deficient in parts or its components differ greatly from the proportions in daylight it will in general produce distorted color effects:

**Artificial White Light.**— With the exception of the carbon dioxide vacuum tube no artificial illuminant approaches closely the color value of daylight. White light may be approximated by synthesis by combining the light of two sources, one excessive in red and the other excessive in blue, as the incandescent electric lamp and the mercury arc. A closer realization may be obtained from any incandescent lamp by means of a selective absorption screen which removes the excess of red and green light. The latter method involves a sacrifice of efficiency.

**SUMMARY OF CONDITIONS FOR BEST VISION.**— The minimum brightness of objects viewed should not be less than 0.0015 candle per sq. inch nor more than 1.5 candles. In terms of the illumination of ordinary paper these values correspond roughly to limits of 1 to 1000 foot-candles. The value best adapted to any condition varies with the individual, the close application, the nature of the surroundings and the general degree of difficulty. For reading by daylight 100 foot-candles is approximately the best condition.

#### ILLUMINATION IN FOOT-CANDLES

Nature of illuminated surface	Foot-candles at floor level	
	Minimum required	Good practice
Roadways and yard thoroughfares.....	0.02	0.05-0.10
Storage spaces, stairways, passageways, and exits and elevator entrances.....	0.25	0.50-1.00
	Foot-candles at the work	
Work not requiring discrimination of detail....	0.50	1.00-2.00
Rough manufacturing and assembling.....	1.00	2.00-4.00
Machining and bench work.....	2.00	3.00-6.00
Fine manufacturing and office work.....	3.00	4.00-8.00
Special fine work, drafting, engraving, sewing..	5.00	7.00-15.00

cial light approximately from 4 to 10. The degree of illumination is strongly influenced by the contrast between objects visualized and surroundings. The high diffusion of daylight and the flatness of the conic it gives account in large measure for the higher illumination desired. Seeing the objects viewed should be brighter than the surroundings, contrast should not exceed 10 : 1. The illumination provided for work close application should be in inverse ratio to the reflecting power of dominant surfaces. Directly visible light sources may generally be shaded to a brightness of 2.5 candles per square inch with advantage to vision. As outlined under *Glare* should be observed.

Accompanying table indicates the range of artificial illumination in foot-candles which has been found satisfactory under practical conditions.

Resolution. — Vision is aided by the sharp definition of details down to an angle of 1 in 10,000. Reading is easiest with type subtending an angle of 1 in 100. For comfort it should not be larger than 1 : 20 nor less than

Contrasts in intensity are best at about 1 : 10, but should not be less than 1 : 5. Contrasts as slight as 98 : 100 are readily perceivable in good light.

Intensity of light on the working area is important. Excessively bright light creates an annoying glare and interfere with the fixation of vision.

Stability of light is essential, as flicker causes rapid fatigue.

Spectrum. — A well-balanced spectrum is required for the true revelation of colors. Fatigue is most rapid in the extreme blue end of the spectrum. Violet radiations may cause injury if present in unusual quantity. Imparting a strongly dominant yellow-green hue gives the highest visual

Resolution. — Complete diffusion tends to eliminate shadows, with the result of relief. The value of moderate shadows varies greatly with the conditions, but is greatest where color distinctions are lacking.

**EFFICIENCY.** — The resultant of all conditions affecting vision is the somewhat loose term visual efficiency. This concept must take into account the fundamental discriminations of brightness, detail and color and the maintenance of these faculties in use. Tests of visual acuity have been proposed as a working criterion of visual efficiency. As applied to the momentary vision this criterion is unsatisfactory as it invites a semi-conscious effort to offset fatigue. An ideal criterion must take account of the degree of acuity in work, of the ease with which fixation of vision and attention are sustained, and of the general requirements of ocular hygiene. (*Ill. Eng. Soc., Vol. 8, p. 40.*)

**VOLTMETERS.**—(See also *Ammeters; Wattmeters.*) A voltmeter is an instrument for measuring the potential difference, or voltage, between the two points to which its two terminals are connected. Any type of ammeter (q.v.) may be used as a voltmeter, but when designed for this purpose the coil which carries the current is made of a number of turns of fine wire, so that the moving element will be deflected by a very small current (from 10 to 200 milliamperes, for full-scale deflection, depending upon the type) and to limit the current to this value a high resistance, contained within the case of the instrument, is usually inserted in series with the coil. The high resistance may be provided with taps brought out to additional binding posts, so that the same instrument will give full-scale deflection for say 75, 150 and 300 volts, depending upon which binding post is used in conjunction with the terminal marked "0" or "+." The range of a voltmeter may also be indefinitely extended by the use of multipliers (see below) or potential transformers (see *Transformers; Instrument*).

**Current Taken by, and Resistance of, Voltmeters.**—The current taken by voltmeters of various types for full-scale deflection, and the resistance per volt of full-scale deflection are usually as follows:

Type of voltmeter	Milliamperes for full-scale deflection	Ohms per volt of full-scale deflection *
Iron-vane type.....	83 to 60	12 to 17
Moving-coil type.....	20 to 10	50 to 100
Electrodynamic type.....	83 to 40	12 to 25
Hot-wire type.....	250 to 187	4 to 5.3

\* For example, a moving-iron type voltmeter having a 150-volt scale would have a resistance of from  $12 \times 150 = 1800$  to  $17 \times 150 = 2550$  ohms. The current taken by the instrument would be from 83 to 60 milliamperes. Lower ranges in moving-iron and in electrodynamic voltmeters require larger currents for full-scale deflection, in order to keep down errors due to frequency.

When a d-c. voltmeter is connected to any two points on a network, its reading is in general lower than the previous potential difference between the points, because the voltmeter draws some current from the network. Let the voltmeter reading be  $V_1$ . If the voltmeter be now shunted by a resistance equal to its own, a second reading  $V_2$ , lower than  $V_1$ , will be obtained. The potential difference  $V$  can then be found from the formula,

$$V = V_1 V_2 / (2V_2 - V_1).$$

The above method gives correct results not only when the voltmeter is connected directly to the points but also when it is connected through "pressure wires" of appreciable resistance.

**Temperature and Inductance Errors.**—In order that a voltmeter calibrated at one temperature shall read correctly at all other ordinary temperatures, it is necessary that its total resistance shall change with temperature but only the small amount necessary to offset the resultant effect of temperature change in the springs, magnets, or other operative parts. To secure this condition, the resistance included in series with the active winding (which latter is usually made of copper wire) must have a very low temperature coefficient.

in, constantan, and various other alloys may be used for this purpose; *Resistance*. The total resistance of a permanent-magnet moving-coil meter, or of a voltmeter of the electrodynamic type should increase about 1 per cent per degree C. if its readings are to be independent of temperature. Added resistance in an a-c. voltmeter is wound non-inductively, either as a coil or on a card. The total impedance is then only slightly greater than the total resistance for well-designed voltmeters used at ordinary lighting frequencies. At higher frequencies the voltmeter will read lower than its higher impedance. If the reading is correct at the calibration frequency  $f_1$ , the reading at frequency  $f_2$  may be corrected by multiplying by  $\frac{1}{1 + 2\pi^2 L^2 (f_2^2 - f_1^2) / R^2}$ , where  $R$  is the resistance,  $L$  the inductance. The terms  $f_1^2 L^2 / R^2$  and  $2\pi^2 f_1^2 L^2 / R^2$  are each small in comparison with unity. In cases the term  $f_2^2$  may be neglected.

**Multipliers and Potential Transformers.** — A voltmeter multiplier is an external resistor placed in series with the voltmeter. These resistors are made of high-resistance alloys having a low temperature coefficient, and are wound non-inductively. If  $r$  and  $R$  are the resistance of the voltmeter and multiplier respectively,  $v$  and  $V$  the value of one scale division in volts and with multiplier respectively, then

$$V = v(R+r)/r.$$

$(R+r)/r$  is frequently called the "multiplying power" of the multiplier voltmeter in question.

For voltages above 750 volts potential transformers are to be preferred to resistors for a-c. circuits; see *Transformers, Instrument*.

**Electrostatic Voltmeters.** — When the current taken by the ordinary form of voltmeter is an appreciable fraction of the load current or when the frequency is high, as in radio work, an electrometer (see *article on Electrometers*) or electrostatic voltmeter may be used. The ordinary electrostatic voltmeter is in principle the same as an electrometer, but is provided with a pointer and is so constructed as to be more readily portable than the ordinary electrometer which is read by means of a telescope and scale. Repulsion electrostatic voltmeters are also used, the principle of operation being the repulsion of two conductors charged with electricity of the same sign, as in a gold-leaf electrometer.

Resistor multipliers are sometimes used with electrostatic voltmeters; see *Electrometers*.

**Checking of Voltmeters.** — A voltmeter may be checked by comparing it with a standard voltmeter whose correction curve is known, or it may be checked directly by means of a potentiometer and standard cell; see *Potentiometer*. Electrostatic and electrodynamic voltmeters for alternating-current work should be checked on direct or alternating current; a moving-iron voltmeter should be checked by comparing it, on alternating current, with one of the other types which has been previously checked on direct current. Electrostatic voltmeters are employed commercially only for high voltages, and therefore must be checked on alternating current.

**Applications in Use and Installation, Costs, Bibliography, etc.** — See *articles on Ammeters*.

**WATER WHEELS AND THEIR SETTINGS.** — (See also *Hydraulic Principles of; Power Stations, Hydroelectric; Water Wheels, Speed Regulation*.)

—A water wheel is a machine for converting the energy of falling water into mechanical work. The old-fashioned undershot and over-shot wheels are now seldom used. In modern water wheels, usually called hydraulic turbines, the energy of the water is gradually transformed into kinetic energy as the water passes through a set of guides and vanes.

Work is the product of force times distance, and power is the rate of doing work. Let  $f$  be the total force in pounds exerted by the water on the runner of a turbine, let  $L$  be the distance in feet travelled by a point on the runner located at the center of pressure, and let  $t$  be the time in seconds for this point to travel this distance. The power developed by the water is then

$$P = \frac{f}{550} \cdot \frac{L}{t} \quad \text{horsepower}$$

The power developed by falling water may also be expressed in terms of the rate of flow in cubic-feet per second,  $Q$ , and the net effective head  $h$ , in feet. The potential energy of  $Q$  cubic-feet of water at an elevation of  $h$  feet is  $62.4 Qh$  foot-pounds. Hence for a rate of flow of  $Q$  cubic feet per second the theoretical power developed is:

$$P = \frac{62.4 Qh}{550} = \frac{Qh}{8.814} \quad \text{horsepower}$$

It is important to note that in this equation  $h$  is not the difference in elevation between the intake and discharge levels, but is equal to this gross head  $H$  less the sum of the heads corresponding to the friction losses in the conduit system and the residual velocity where the water is returned to the stream.

All the energy developed by the water as it passes through the turbine is not converted into useful work. The ratio,  $e$ , of the power output of the turbine measured on the turbine shaft, to the theoretical power of the water, is the efficiency of the turbine. The output of the turbine may then be expressed by the equation:

$$P_0 = \frac{Qhe}{8.814}$$

**Speed of Rotation.** — In the conversion of energy by an hydraulic turbine the factor  $\frac{L}{t}$  in equation (1) is the *linear speed* of the runner at the center of pressure.

If the linear speed is zero, it is evident that the power must be zero. If the linear speed is too great, approximately equal to the spouting velocity of the water corresponding to the head on the turbine, the pressure of the water on the runner is zero and again no power is produced. It is evident, therefore that at some linear speed between these limits the power and the efficiency will be the greatest. In other words, the linear speed of the runner must be a fixed percentage (theoretically about 50 per cent) of the spouting velocity of the water, in order to obtain the best efficiency. Therefore, since the *speed of rotation* or revolutions per minute (commonly termed "speed" of the runner) varies directly as the linear speed, it increases with the head (and spouting velocity), if the diameter is constant. It also decreases as the diameter (and capacity) increases.

Consequently, for a given type of runner, low heads and large capacities require a low speed and, conversely, high heads and small capacities require high speeds. It is the object of turbine builders to keep the speed within

enable limits to suit the characteristics of the generators and other machinery and for this purpose many types of runners have been developed.

**CLASSIFICATION OF TURBINES.**—Modern hydraulic turbines are of two types: reaction turbines and impulse turbines. The basic difference between the two types is in the runner.

**Reaction Turbines.**—A typical low-head reaction turbine and runner are indicated in Figs. 1 and 2. The water enters the runner through the guide

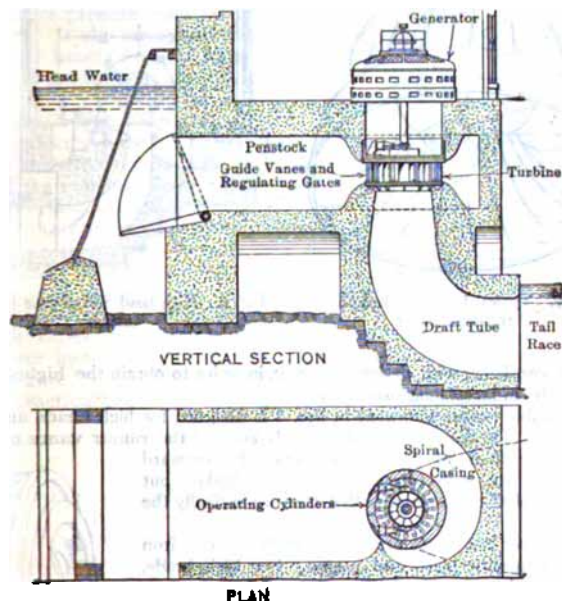

Fig. 1. Low-head Spiral-case Reaction Turbine

es and regulating gates. It passes inwards and downwards through the guide vanes to the draft tube.

Power is developed by the pressure and reaction of the water on the runner vanes, the runner being completely filled. Modern reaction turbines are adapted to all heads up to about 800 feet where the units are large.

**Impulse Turbines.**—A typical impulse turbine and runner are indicated in Fig. 8. The pressure head is first converted into velocity through the nozzle at the end of the penstock, and power is developed by the impulse of the water acting upon the buckets on the rim of the runner.

The impulse turbine must never be submerged, it being necessary to allow the water to fall away freely from the buckets. Small impulse turbines are adapted to all heads. For all capacities they are used exclusively for heads greater than about 800 feet.

**CHARACTERISTICS OF REACTION TURBINES — The Runner.**— Reaction runners vary in shape and design depending upon the conditions under which they are to be used. The runner indicated in Fig. 2 is designed for a low-head, large-capacity turbine. The diameter is made as small

Fig. 2. Typical Low-head Reaction-turbine Runner

Fig. 3. High-head Spiral-case Reaction turbine

possible, consistent with desired capacity, in order to obtain the highest speed. This results in large, long runner vanes.

The double runner indicated in Fig. 4 is designed for high heads and small discharges. The diameter is relatively larger and the runner vanes narrower and smaller than in the former type. In outward appearance the two types are quite dissimilar; but the action of the water and path of flow are basically the same.

Runners for low heads are usually made of cast iron or cast iron with plate-steel blades. For high heads, cast steel or bronze are often used to reduce the wear of the metal resulting from the high velocities.

No uniformity exists among turbine manufacturers in the methods of measuring the diameters of reaction runners. For this reason it is never possible to compare the diameter of a runner with that of another make; or even with a runner of another type of the same manufacturer. Diameters are therefore employed only for comparison of runners of the same type and, as relative diameters only are used, it is never necessary to know the actual points to which the diameter is measured when selecting the type and size of runner for a given installation.

The capacity of a runner is specified as a certain full gate capacity at a given head and speed.

**The Gates.**— In modern installation, wicket-gates are used because they present the least resistance to flow when in a part open position. Cylindrical gates, consisting of a steel cylinder, moving axially over the opening to the

Fig. 4. Typical High-head Double-discharge Reaction-turbine Runner

inner, are sometimes adopted for small installations and those designed to operate normally at full gate. Cylinder gates are not efficient when operated at open, owing to the sharp contraction at the bottom of the cylinder.

Wicket gates are actuated by the governor or hand control through rods and levers. The gates of the turbine indicated in Fig. 1 are controlled by two operating cylinders located in the turbine pit. Oil is admitted by the governor to the cylinders and the resulting movement of the piston rods revolves slightly a shifting ring to which are connected the individual gate-links for opening the gates.

**The Draft Tube.** — The function of the draft tube is to utilize, by suction and negative pressure below the turbine, the head between the turbine and the tail race. It also serves to reclaim as much as possible of the velocity head of the water issuing from the runner, which is sometimes very great. They are increased gradually in area towards the outlet where the average velocity is usually from 3 to 10 feet per second, the higher velocities being for the higher head installations.

The velocity of the water, when leaving the runner, is not strictly axial but, due to imperfect reaction and skin friction, has a swirling motion in the direction of the rotating runner. It is only the component of this velocity in the axial direction which can be reclaimed by the ordinary form of draft tube. It is for the purpose of reclaiming more of the residual velocity that a spiral type of draft tube has recently been developed. It is, however, adaptable economically only to special cases because of its relatively larger size.

Because of the draft tube, turbines can be set well above tail water in order to be convenient at all times for inspection.

Draft tubes are sometimes constructed of steel plate; but more often, for the larger installations, they are shaped in the concrete of the power house structure.

The practical limit of the draft head is given by the equation:

$$K = A + \frac{v_2^2 - v_1^2}{2g} - s \quad (4)$$

where  $K$  = the maximum allowable draft head in feet, measured from the lowest tail water level to the center line of gates, for vertical turbines; or to the highest point of the discharge space of the runner, for horizontal turbines.

$A$  = the pressure of one atmosphere in feet of water, normally about 34 feet at sea level. It decreases with the altitude. Two feet should be subtracted from the normal weight to allow for reductions during meteorological disturbances.

$v_1$  = the average velocity of the water in feet per second at the exit of the runner, measured at the point of minimum internal diameter of the runner band.

$v_2$  = the average velocity at the end of the draft tube.

$s$  = a margin allowed for disturbances during load changes and vapor tension, ordinarily adopted as five feet, but should be larger for long draft tubes, low pressure heads and sudden load changes.

Friction in the draft tube will increase  $K$ , but is too small for consideration.

**Settings.** — Reaction turbines are adaptable to many types of settings, and the choice of type is governed by the relative cost compared with the efficiency of the turbine and ease of operation. Typical examples of turbine settings are indicated in Figs. 1, 3, 5, 6 and 7. The following are some of the more common types of settings, of which many combinations are possible.

a. The turbines may be horizontal or vertical; that is, set with horizontal or vertical shaft.

b. One or more runners on the same shaft may be used.

c. For multiple runner turbines, there may be a separate draft tube for each runner, or each pair of runners may have a single draft tube located between them.

d. The turbines may be set in an open forebay or flume with shaft extending vertically to a generator above water surface, or horizontally through the wall to a generator on the opposite side.

e. The runners may be enclosed in a casing or prolongation of the pipe line. Such casings may be spiral or cylindrically shaped.

The tendency is towards single runner vertical turbines for low heads, and horizontal or vertical turbines with one or two runners for medium and high heads. More than one runner is seldom now used for vertical installations.

The open flume setting is common for very low-head installations utilizing small turbines. Such a setting is indicated in Figs. 5 and 6. In open flumes of ample size, the water approaches the turbine with low velocity and without disturbance. Consequently this type of setting possesses the highest degree of efficiency.

As the head becomes higher or the diameter of the turbine larger, the structural problems of open-flume construction become increasingly difficult. It is finally necessary to effect a reduction in size of conduit and a corresponding increase in velocity of flow, and some type of closed casing is then necessary.

Fig. 5. Open-flume Setting for Horizontal Turbine

A cylindrical casing is indicated in Fig. 7. This type of casing cannot be made hydraulically efficient. Because of its shape, the water cannot enter the turbine with the absence of disturbance, so essential to best efficiency of operation. Cylindrical casings are less expensive than spiral casings, but are seldom

Fig. 6. Open-flume Setting for Vertical Turbine

Fig. 7. Horizontal Cylinder-case Double-runner Setting

now used for large units, except to effect a reduction in first cost at the expense of efficiency. They are usually made of plate steel or formed in the contour of the toe of the dam.

Fig. 8. Impulse Turbine

A typical spiral casing is indicated in Figs. 1 and 3. The areas of water passages are proportioned for constant velocity at all sections, the area decreasing gradually as the water is drawn into the runner. This allows the water to enter the turbine with a minimum of disturbance consistent with the high velocities used. Spiral casings are common to all large, modern installations. They are usually made of concrete for large units up to heads of 60 or 80 feet, and of cast iron, cast steel or riveted plate steel for higher heads. Plate steel is considered inferior to the other materials for casings, but is often less expensive.

**CHARACTERISTICS OF IMPULSE TURBINES. — The Runner. —** As is shown a typical impulse runner, consisting of cast-steel or bronze bolted to the periphery of the wheel body. The buckets receive the water from the jet and destroy its velocity, the water falling inertly to the tail race.

The total head between the runner and the tail race is lost. In an impulse turbine there is one ratio of runner diameter to jet diameter which gives the best efficiency. This ratio varies from about 12 to 15 depending upon the capacity of the unit. A ratio as low as 8 is practical under special conditions, with a sacrifice of a few per cent in efficiency.

**Nozzles. —** The flow of water through the nozzle is controlled by a governor-actuated needle valve as indicated in Fig. 8.

Deflecting turbines are commonly used for high-head installations with long penstocks in which the flow cannot be arrested quickly when a sudden reduction in output is required. For this reason deflecting nozzles, by-pass valves and deflectors are used in order to eliminate the possibility of water-hammer. Deflecting nozzles are provided with a ball joint, and when a sudden reduction in output is required, are made to deflect by the action of the governor, with the result that only part of the jet remains in contact with the buckets and the power output is reduced. The needle valve then partly closes slowly, and the jet is returned to its normal position.

A deflecting deflector acts on much the same principle as the deflecting nozzle. It is a governor-actuated, hinged, curved vane which, upon a reduction in output, moves into and deflects part of the jet from the buckets. The deflector then returns to its normal position as the needle valve slowly closes.

The most recent method of regulation consists of by-pass valves of various sizes which are usually operated by the governor synchronously with the needle valve to an extent sufficient to retain a constant penstock flow when the penstock is slowly closed automatically. Fig. 8 indicates a typical by-pass valve of the needle type.

**Runners. —** One or more runners may be used on the same shaft and one or two buckets may be provided for each runner; but the usual arrangement, for medium capacity units, consists of a single runner with a single nozzle. Impulse turbines may be horizontal or vertical; but vertical installations are avoided where possible because the water cannot fall away as readily without interference.

#### REGULATING CHARACTERISTICS OF HYDRAULIC TURBINES.

$R$  = speed of runner, in r.p.m.

$H$  = total effective head, in feet.

$P$  = theoretical horsepower developed.

$K$  = a constant, called the "unit speed" of the runner.

$K$  = unit speed of a reaction turbine at a given speed and gate opening,

$$\frac{R\sqrt{P}}{H\sqrt{H}^{1/2}} = K \quad (5)$$

By calling  $K$  the "unit speed" it is that  $K$  is equal to the speed  $R$  of the runner when the head is 1 foot and the power output  $P$  of 1 horsepower.

**Impulse turbine,**

$$\frac{R\sqrt{P}}{H\sqrt{H}^{1/2}} = 3.67, \quad (5a)$$

indicates the usual unit speed of impulse runners to be about 3.67.

**Values of Unit Speed.** — In equation (56), if  $k$  and  $P$  are unity,  $R = K$ , the speed of the runner when generating. Turbine builders use the value of  $K$  as unit speed at full gate opening as a basis for representing the speed characteristics of the various types of runners. For each type of runner there is one unit speed near which occur the best efficiencies for ordinary conditions of operations. High-speed runners are those requiring a high full-gate unit speed for best efficiencies and vice versa. The practical maximum unit speed in the standard modern reaction-type runner, without considerable sacrifice of efficiency, is about 95. Special runners have been developed recently, both in this country and abroad, which are claimed to operate satisfactorily at a unit speed of 150 or over, and several small units have been installed. With unit speeds greater than 95, considerable saving can be made in the cost of generators because a large single runner unit operating at 95 unit speed under a low head requires a speed of revolution much too low for economical generator design.

**Efficiency.** — The methods of calculating, from test data, the performance of an hydraulic turbine are too complicated to be given in the limited space here.

Fig. 9. Efficiency-power Curves of 46 In. Runner

available. Typical efficiency curves of a large reaction-type runner at two different heads are given in Fig. 9, and a typical efficiency curve for an impulse-type runner in Fig. 10.

It will be noted that the efficiency and power falls off quite rapidly as the head reduces. It is not possible to obtain a runner which will have good efficiencies for a wide range of heads for a constant speed.

The use of test data for the determination of probable turbine operating characteristics under practical conditions is influenced by the following considerations:

a. Other conditions being the same, the efficiency and capacity of a runner increases with its size, owing principally to the smaller influence of defects in fabrication and roughness of the water passages.

Fig. 10. Efficiency-power Curves of an Impulse Water Wheel

setting of the turbine may differ from that of the test, a condition then has a marked influence on efficiency and power.

efficiency and capacity decrease with service, particularly if there is in the water to wear the runner and increase clearances.

turbine manufacturers have patterns for only a part of the possible runner moreover the best speed of the runner is not always the best speed for expensive type of generator. Consequently, in many installations, it is desirable to sacrifice a certain amount of adaptability and efficiency in order to reduce the first cost of the installation.

**Factors Affecting Choice of Runner.**—Complete data for the final selection of the type and size of runner most suited for a particular installation is in the possession of turbine builders only, and advice from that source can usually be obtained.

The type of runner and turbine setting should be adopted which will have the characteristics for the conditions under which it must be operated for the greater portion of the time, and also possess reasonable characteristics for unusual conditions.

Among the influences governing the choice of type are:

1. Period of low-stream flow, during which maximum efficiency is essential.  
 2. Period of high-stream flow, during which maximum capacity only is essential.  
 3. Degree of fluctuation in head. The runner must have sufficient capacity at low head and also have reasonable efficiencies at mean and high heads.

4. Nature of the load characteristics, or the part-gate-opening periods. The efficiency must be quite rapidly for small gate openings and best efficiency is not usually obtained at full power.

5. Other conditions affecting the type of turbine setting.

**TESTING OF HYDRAULIC TURBINES.**—The "Testing Code" of the American Society of Mechanical Engineers has been adopted by most hydraulic turbine manufacturers as a basis for comparing actual operating characteristics with those published by the manufacturer. The object of the test is to determine the

efficiency, equation (3), at fixed speed under different conditions of load and (where possible) head; the capacity of the unit; and its general performance.

Tests under varying heads are not always possible in power development, and it is sometimes not even possible to test under the effective head stated in the guarantee. It is permissible, however, to test under other heads, differing by not over 10 per cent from the contract head, provided the speed is changed in proportion to the square root of the head. The operating characteristics under contract head and speed can then be computed from the result of the tests under test head and speed.

The power input is given by equation (2). The quantity of water  $Q$ , may be measured in a number of ways, the principal of which are,

- a. Weirs in the head or tail race.
- b. Current meter measurements in the head or tail race.
- c. Pitot tube in the penstock or conduit.
- d. Floating screen in an open conduit.
- e. Venturi meter in the penstock.
- f. Titration or chemical method, in which a salt solution is introduced at the inlet and measured in concentration in the tail race.

The net head,  $h$ , is the difference between the elevation corresponding to the pressure in the penstock near the entrance to the turbine casing (or water surface immediately above the turbine in open flumes) and the elevation of the tail water, this difference being corrected by adding the velocity head in the penstock at the point of measurement and subtracting the residual velocity head at the end of the draft tube.

The output,  $P_0$ , is usually measured electrically if the turbine-driven generator has been previously tested. One of the many forms of Prony brakes may be used for small units.

**BIBLIOGRAPHY.**—Some of the more modern books treating of hydraulic turbines are: Lof and Rushmore, *Hydro-Electric Power Stations*; Mead, D. G., *Water Power Engineering*; Taylor and Braymer, *American Hydro-Electric Practice*. The following are recent articles in the technical journals. Galbreath, J. D., *The Design of Hydro-Electric Power Plants*, Trans. A.S.C.E., 1915; Grant, B. F., *Chemical Hydrometry and its Application to the Testing of Hydraulic Generators*, Trans. A.S.C.E., 1916; Kennison, H. R., *Comprehensive Plotting of Water Turbine Characteristics*, Proc. A.S.C.E., Aug., 1919; Rogers, F. H., *Economical Operation of Water Turbines*, Elec. W., April, 1919; *Recent Utilization of Water Power*, Mech. Eng., Sept., 1920; Hillburg, A. G., *Design of Turbine Draft Tubes*, Eng. Rec., Nov., 1915; *The Kaplan Hydraulic Turbine*, Mech. Eng., Sept., 1920; *Tests of Appalachian Turbines*, Elec. W., March, 1913; *Tests of Holwood Turbines*, Eng. Rec., March, 1915.

**WATER WHEELS, SPEED REGULATION OF.** — (See also *Hydroelectric Power Stations, Hydroelectric; Water Wheels and Their Settings.*) In special cases close speed regulation of water wheels is unnecessary, for example in pulp grinding, certain chemical processes and operating air compressors. Even in these cases experience has shown that better results may be obtained when wheels are controlled by properly designed governors. For work, where the power is applied through the medium of belting, the method of regulation is simplified by the large inertia effect of the pulleys.

**SPEED VARIATION IN HYDROELECTRIC PLANTS.** — For generators, which perhaps comprise the majority of installations, the necessity of speed regulation is required because the value of the electrical energy produced is greatly lessened if the voltage and frequency are not uniform. In the best large modern power plants speed variations greater than one per cent are exceptional. In smaller plants, since there are usually proportional load fluctuations, it is more difficult to maintain close speed control.

**METHOD OF REGULATION.** — A change of load requires a change in quantity of water passing through the turbine in order that the power will equal the new demand. This is effected through a change in the gate opening by the action of the governor.

When a change in load demand occurs, and the turbine is not able at once to alter its output to correspond, the surplus or deficiency of power will be absorbed or stored by the inertia of the rotating elements of the turbine and generator. The turbine will give up or receive energy only by means of a change in speed. Thus the manifestation of a change in load demand is a change in the speed of the

rotating elements. Turbines are sensitive to very slight changes of speed and start almost at once to adjust the gate opening; but this cannot be done immediately. Consequently during the time required to make the adjustment, the change in the output of the rotating elements, corresponding to the surplus or deficiency of power, must be made without too great a change in speed. Therefore the necessity of the rotating elements or "fly wheel effect" is fixed by the capacity of the turbine to store energy, the expected load change and the gate-closing speed of the governor. The influences to be overcome in obtaining good regulation are:

1. The inertia of the rotating elements.  
2. The sensitiveness of the governor, or the fact that the speed must first return to normal before the governor action starts.

The governor cannot change the gate opening instantly. A common rule for open flume settings or short penstocks is about two seconds. For long penstocks, the speed of the governor must be much slower to prevent excessive water hammer.

In the case of long penstocks, a change in penstock velocity, resulting from a change of gate opening, necessitates a variation in head at the turbine to accelerate the water to the new velocity. This change in head is exactly opposed to that desired for speed regulation.

**Flume Setting.** — In Fig. 1, assume the power demand, for an open flume setting, to be represented by the line *ABCD*. After the instant *X*, the power demand changes, the output of the unit is insufficient and the deficiency must be made up by the inertia of the rotating elements. Consequently the speed falls off as indicated. At *Y* the speed change is sufficient to affect the governor and the gates begin to open. The rate of gate opening is not constant, but will vary according to the characteristics of the governor. Under open flume conditions, the head is practically constant during the change in gate opening. The power output may be represented by the line *EFG*, which, for open

furnes, may be assumed to vary uniformly. The area  $BCFE$  represents the total deficiency in energy,  $\Delta K$ , to be supplied by the fly-wheel effect of the unit. At  $Z$  the output is equal to the demand and, as indicated, no further reduction in speed occurs. As the speed is still below normal, the governor will continue to open the gates and the power will further increase. The excess output over demand, after time  $Z$ , will add to the speed of the unit until, at time  $W$ , the speed is again normal but the output is in excess of the demand. The speed will then rise above normal and the governor will start closing the gates. There is seen to be a tendency for the output to fluctuate above and below the new power demand. This feature is called "hunting" of the governor. In actual practice this does not occur to an objectionable extent, as the governors are provided with a compensating device or "anti-racing" mechanism which has the effect of dampening these fluctuations, and the speed is soon brought permanently to normal. This condition requires, however,

that the capacity of the unit be somewhat in excess (usually 5 per cent to 10 per cent) of the maximum output to which the demand may suddenly change, otherwise there would not be available the necessary excess capacity to bring the speed back to normal after a sudden increase in demand to maximum demand occurs.

**Long Penstock Settings.**—In Fig. 2, assume the power demand for a plant with a long penstock to be represented by the line  $ABCD$ . As in the previous case, the speed begins to be retarded at  $X$ , the moment of the load change, and at  $Y$  the governor action starts. The variations of gate opening and penstock velocities are indicated in the diagram. Part of the total head available for power is consumed in increasing the penstock velocity and the net head on the turbine decreases momentarily as indicated. The net result of the slowly accelerating velocity, combined with considerable reduction in net head, may be a momentary reduction in output as indicated by the output line. This reduction in net head, at the critical time when an increase in power output is most needed, is the chief influence opposed to good regulation with long penstocks. The velocity soon picks up, however, and the power output increases about as indicated by the line  $EFG$ .

As in the case of open-flume installations, the speed of the unit is a minimum at  $Z$ , when the output equals the demand; but the gate opening, penstock velocity and output continue to increase until the speed reaches normal at time  $W$ . The gates then start to close. The time interval between the sharp breaks in the head, penstock velocity, and output lines correspond to the time required for the wave of penstock velocity change to travel from the turbine to the upper end of the penstock and back again.\* The deficiency in output  $\Delta K$ , is indicated by the area  $BCFE$ .

For sudden decreases in load demand the characteristics indicated in Figs. 1 and 2 are simply reversed.

**Water Hammer.**—Water hammer is a term used to indicate the increase

Fig. 1

\* See article by N. R. Gibson, referred to in Bibliography.

where  $h$  = the rise or fall, in feet.

$v$  = the velocity change in the pipe line corresponding to the change in load, in feet per second.

$a$  = the area of the pipe line, in square feet.

$A$  = the area of the surge tank, in square feet.

$L$  = the length of the pipe line, in feet.

$g$  = the acceleration due to gravity = 32.16.

The value  $v$ , for use in this equation, is the difference between the original pipe line velocity and the velocity required for the new load, the latter corresponding to the head on the turbine at the time of the maximum deviation of the water surface in the tank from normal. Its value therefore depends upon the turbine characteristics and the value of  $h$ . Consequently the solution of the equation can best be accomplished by the cut-and-try method.

Restricted orifices are usually provided between the pipe line and the tank to dampen the surges and prevent them from continuing indefinitely or piling up due to the action of the governor in endeavoring to compensate for the resultant head changes.

Friction in the pipe line and in the restricted orifices have considerable influence on the action of the surge tank and the foregoing equation gives results too large for loads thrown off, and considerably too small for loads thrown on. For more exact methods of design the reader is referred to R. D. Johnston's article on surge tanks referred to in *Bibliography*.

**Relief Valves.** — Relief valves are serviceable only to compensate for sudden decreases in load demand. They are appliances attached to the lower end of the penstock and are designed to open automatically when a sudden decrease in demand occurs. By this means, a sudden large decrease in penstock velocity is avoided, the surplus water not needed for power being by-passed through the relief valve to the tail race. After the output has been adjusted, the valve slowly close. They are sometimes actuated by the rise in pressure; but are preferably synchronously opened by the governor to an extent corresponding to the closure of the turbine gates, the penstock velocity remaining nearly constant during the load change. Relief valves are very wasteful of water. Deflecting nozzles and jet deflectors of impulse turbines, described in *Water Wheels and their Settings*, also serve the same purpose.

**CALCULATION OF SPEED REGULATION. — Open Flume Settings.**  
—In Fig. 1, let:

$P_0$  = the initial horsepower output.

$P_1$  = the new power demand after time  $X$ .

$T_1$  = the time interval, in seconds,  $XY$ , after load change before the governor action starts.

$T_2$  = the speed of the governor or time, in seconds,  $FZ$ , for the governor to adjust the gates to the new load demand.

$R_0$  = the normal speed of the unit in revolutions per minute.

$R_1$  = the speed of the unit at time  $Z$  corresponding to maximum deviation from normal.

$s$  = the percentage change in speed of the unit.

$K$  = the foot-pounds of kinetic energy in the rotating elements at speed  $R_0$ .

$\Delta K$  = the energy change in the rotating elements due to change in speed from  $R_0$  to  $R_1$ .

$I$  = the fly-wheel effect of the rotating elements in foot-pound units, usually expressed in pounds at one foot radius, i.e., the weight which, at a radius of one foot, would have an equivalent moment of inertia.

$N$  = the regulation constant of the unit.

For open flume settings, the average horsepower deficiency during the time interval  $XZ$ , assuming  $EF$  to be a straight line, is,

$$p = \frac{(\rho_1 - \rho_0)T_1 + (\rho_1 - \rho_0) \frac{T_2}{2}}{T_1 + T_2}$$

The total deficiency in work for the interval  $XZ$ , which must be supplied from the inertia of the rotating elements, is:

$$\Delta K = 550(T_1 + T_2)p$$

Therefore, 
$$\Delta K = 275(\rho_1 - \rho_0)(2T_1 + T_2) \quad (1)$$

From the laws of mechanics,

$$K = \frac{2I\pi^2R^2}{g60^2} = 0.00017IR^2$$

∴ 
$$\Delta K = 0.00017I(R_1^2 - R_0^2)$$

Therefore, 
$$R_1 = \sqrt{R_0^2 + \frac{\Delta K}{0.00017I}}$$

From definition, 
$$s = \frac{100(R_1 - R_0)}{R_0}$$

Therefore, 
$$s = \frac{\sqrt{R_0^2 + \frac{\Delta K}{0.00017I}} - R_0}{0.01R_0} \quad (2)$$

By neglecting  $T_1$ , which is small, Meade has shown that equation (2) may be written, for small speed changes, in the following approximate form:

$$s = 81,000,000 \frac{T_2}{IR_0^3} (\rho_1 - \rho_0) \quad (3)$$

For full load change, equation (3) may be written,

$$I = \frac{81,000,000 T_2 \rho_P}{S R_0^3} = N \frac{\rho_P}{R_0^3}$$

∴ 
$$N = \frac{81,000,000 T_2}{S}$$

Therefore, 
$$N = \frac{R_0^3 I}{\rho_P} \quad (4)$$

For open-flume plants or plants with negligible length of penstock as indicated in Fig. 1, of the article on *Water Wheels and Their Setting*,  $I$  usually has a value such that  $N$  will be at least 5,000,000.

A quick acting governor and a large fly-wheel effect make for good regulation. If the fly-wheel effect is too small for the required regulation, the speed of the governor must be increased or additional fly-wheel effect provided either in the form of a separate fly-wheel or by increasing the weight of the rotating parts of the generator. Either method requires additional expense and the choice should be made to obtain the greatest economy.

**Plants with Long Penstocks.** — For plants with long penstocks, the out-slip line,  $BEF$ , Fig. 2, and hence the deficiency of output,  $\Delta K$ , cannot be

expressed by a simple equation. The fluctuations in head and penstock wheel are affected by the considerations of water hammer and stand pipe or surge valve characteristics. Each must be computed and plotted, from which the power output line can be determined from the turbine characteristics. The area  $BEFC$  or deficient work,  $\Delta K$ , can then be computed for use in equation (1).

**HYDRAULIC-TURBINE GOVERNORS.**—The governor proper is the device for automatically opening and closing the gates as the load on the turbine varies. The requirements to be met are (1) sensitiveness to small variations in speed, (2) quickness in action, (3) steadiness and accuracy in moving the gates the proper amount, (4) ability to operate continuously with a minimum amount of attention.

**Types of Governors.**—There are two general classes of governors: (1) the "mechanical" type, which takes energy from the turbine itself, as required, through a belt or gearing, and by means of friction clutches applies this energy at suitable times to the operation of the turbine gates; (2) the "hydraulic" type, in which stored energy in the form of compressed air is made available when required to move the turbine gates through the medium of a liquid (usually oil) acting against the piston in a hydraulic cylinder. The energy in the compressed air is thus transmitted by the liquid through a suitably controlled valve to do the work of moving the turbine gates, when necessary, and the energy of the air is afterwards restored by pumping the same liquid back into the tank. The operation of restoring the energy by pumping is gradual; while the operation of moving the turbine gates, by utilizing the energy of the compressed air, may be as rapid as desired.

Governors of the mechanical type were the first in the field, and, being simple and cheaper to construct, have been very widely used. They have certain objectionable features, however, which have prevented them from being adopted under any conditions which require extreme nicety in speed regulation. Consequently, governors of the hydraulic type are almost exclusively used in large and important power plants. When properly designed, they are capable of giving extremely accurate speed regulation and are thoroughly reliable. Some governors are sometimes operated continuously night and day for weeks, or even months.

**Connections between Turbine and Governor.**—The connections between a hydraulic turbine governor and the gates must be strong, direct and free from lost motion; otherwise the governor cannot perform its functions properly. Modern governors are built in many different types, so as to be readily adapted for connections to any standard make of turbine. It is generally advantageous to have the hydraulic cylinder of the governor located near the turbine gates, although for very large units the control mechanism of the governor may be more conveniently placed on the floor above. For small turbines, which are occasionally located in comparatively inaccessible places, it is sometimes necessary to place the governors at a considerable distance and connect them with the turbine gates by means of rods and levers. Occasionally several turbines are connected in this manner to a single governor.

**Distant Control.**—Large governors are frequently provided with suitable electric devices by means of which the speed of the wheel may be adjusted from any distant point, thus permitting alternators driven by independent turbines being brought to the same speed and angular position for parallel connection.

**Rating of a Governor.**—A hydraulic governor is usually rated in terms of the energy, expressed in foot-pounds, which is developed by one stroke of the piston, and the time, in seconds, required for a complete stroke (i.e., to completely close or open the gates). The size of governor required for a given size

depends so largely upon the type of gate, head, etc., that no general be given here.

**Conditions for Governor.** — The following is taken from the standard of one of the large governor manufacturers:

Governors are each guaranteed to develop the energy, expressed in foot-pounds below, and if not called upon to develop a greater amount of energy in that named, will completely open or close the gates to which they are attached in the following number of seconds:

..... Governor, ..... Foot-Pounds, ..... Seconds, .....

Governors are further guaranteed: (a) to stand substantially steady speed does not vary; (b) to be dead beat in action and not to hunt; (c) to act with maximum promptness for all load changes within the capacity of the turbines to which they are attached; (d) to maintain the speed steady within one per cent under uniform load upon the turbines to which they are attached; (e) to begin to adjust the turbine gates when the speed has varied more than one per cent; (f) after sudden decrease of load to bring the speed back in ..... seconds; (g) to operate perfectly in parallel with other governors of the same make.

**WATTHOUR METERS.** — (See also *Ampere-hour Meters; Electrodynamic meters; Wattmeters.*) A watt-hour meter consists essentially of (1) a small electric motor, which may be either of the commutator type, mercury or disc type, or induction type, (2) a brake system composed of a disc of non-magnetic material (usually copper or aluminum) mounted on the armature spindle and so arranged that its edge rotates between the poles of one or more permanent magnets, and (3) a system of gears with numbered dials forming a suitable registering mechanism for indicating the number of revolutions of the armature or disc. One winding, called the "potential" coil, connected across\* (in shunt with) the load and the other winding, called the "current" coil, is connected in series\* with the load, the connections being the same as for an indicating wattmeter; see *Wattmeters*.

**Principle of Operation.** — Motor-type meters are so constructed that the average torque exerted by the motor is proportional to the average power taken by the load. The brake system is so designed that the opposing torque due to the eddy or Foucault currents induced in the disc as it rotates between the poles of the permanent magnets, is proportional to the speed of the disc. When the disc acquires a given speed the driving torque must be just equal to the opposing torque, and must therefore be proportional to the speed. Hence the speed of the disc is proportional to the average power, and therefore the total number of revolutions which the disc makes during any interval will be proportional to the total energy input during this interval, whether the power remains constant or varies. To determine the energy input to the load in watt-hours or kilowatt-hours it is therefore only necessary to take the difference between the dial readings at the beginning and end of the given interval, and multiply by the proper constant if the meter is not direct reading.

**Sources of Error.** — In a d-c. watt-hour meter the chief sources of error are the friction of the brushes (which is more or less variable), friction of the bearings of the motor and gear train, and air friction, the brush friction being by far the most important. In a-c. watt-hour meters, the lack of exact 90° phase relation between the impressed voltage and the magnetic flux due to the current in the potential coil may cause additional errors which vary with the frequency and power factor and also with the distortion of the wave form; in well-designed modern meters these errors are practically negligible. Instrument transformers (see *Transformers, Instrument*), introduce additional sources of error which may be undesirably large if the transformers are not properly designed. Details and methods for overcoming, or of correcting for, these errors are described below.

**Classification According to Service.** — Watt-hour meters may be classified according to the service in which they are used, viz., (1) service meters for use in residences or factories, (2) switchboard meters for use in central stations and (3) meters for use in individual power installations and isolated plants. Meters for house service are generally front-connected, separately-sealed devices which can be installed and sealed to prevent tampering. Switchboard meters are generally back connected and of such design as to match other switchboard devices. "Meter-boards," equipped with the necessary auxiliary or protection devices, are frequently used with house meters, in order to insure proper connections and sealing.

**COMMUTATOR TYPE OF WATTHOUR METER.** — The commutator type of meter is now used only on direct-current circuits, although built

\* Either directly or through suitable instrument transformers; see *Transformers, Instrument*.

tion meter was so highly perfected large numbers were used for alternating current also. The motor consists of a set of stationary coils, commonly field coils, which carry the current, and an armature wound with small coils which is connected across the terminals of the load or in shunt with the circuit; generally a series resistance is used to absorb part of the line voltage. The connection to the armature is by a commutator and brushes, as in the ordinary commutator type of shunt motor. Special attachments are provided for very large capacities, such as double armatures, astatically connected and damping magnets inclosed in a laminated iron shield in order to prevent field errors where heavy currents are used and heavy short-circuits are not.

It should be noted that the operation differs from that of an ordinary shunt motor in that the speed increases with increase of field strength, since its back e.m.f. is much less than 50 per cent of the line voltage.

On account of the inductance of the windings of the commutator meter, it does not operate accurately on a-c. circuits unless properly compensated, the percentage error being greater the less the power factor.

**Adjustment for Friction; Light-load Adjustment.**—Friction in a well-adjusted watt-hour meter will be very small and will be noticeable only on light loads, 10 per cent and below. To compensate for this friction, a "light-load coil" is added, which is an auxiliary or compounding coil. This coil is connected in series with the armature. It is placed adjacent to the main field so that its field strengthens the main field and produces a slight torque which is a part of the power and just sufficient to compensate for friction.

**Design of Construction, Bearings, etc.**—In the design of the modern watt-hour commutator type of watt-hour meter, great thought has been given to the mechanical construction in order to obtain small air gaps between the field and field coils, light-weight armatures and commutators and brushes which will have very small friction and yet stand the wear and carry the load of the armature without undue sparking and pitting of the contact parts. In the most approved design the field coils are wound with copper strips and the armature winding is enamel-covered wire wound on a sphere mounted on a spindle of light steel tubing. The lower bearing carries all of the weight and the upper bearing is a guide bearing, as all shafts are vertical shafts. The lower bearing consists of a steel pivot mounted on the spindle or armature shaft, running on a jewel bearing. In a good grade of sapphire is used for the jewel and is cupped and polished so as to provide a bearing with as little friction as possible. Of late years a great deal of attention has been given to the bearings and in some cases, on high-capacity meters with astatic armatures and a corresponding weight, diamond jewels are being used with excellent results. A diamond jewel will last much longer than the sapphire before wearing to increase the friction and thereby change the accuracy of the meter especially at light loads. See also section below on *Data on House-*

**Design of Commutator Watt-hour Meters.**—Commutator-type direct-current meters are built in capacities ranging from 5 to 10,000 amperes, 100 to 250 volts. Meters of this type are furnished with double current circuits for three-wire circuits, the maximum ampere capacity for three-wire meters being 10,000 amperes. Special meters have been supplied for 1200- and 2400-volt circuits.

—Tests on direct-current commutator meters show that a meter should start on two per cent of full load and should give accu-

grades about as follows:— To within  $3\frac{1}{2}$  per cent from 5 per cent to  $\frac{1}{2}$  full load, 2 per cent from  $\frac{1}{2}$  to full load. The Meter Code (see *Bibliography*) requires d-c. watt-hour meters to run continuously on normal voltage and 2 per cent rated current, and for higher loads to be accurate within the following limits:

Per cent rated current . . . . .	5	10	20	50	100	150
Maximum deviation, per cent . . . . .	7.5	3.0	2.0	2.0	2.0	2.0

For a summary of the meter accuracies required by commission regulations, city ordinances, and state statutes, see Circular No. 56 of the Bureau of Standards, 1st ed., pages 234-5.

The Mercury-motor Watt-hour meter is manufactured for direct-current service. The motor element consists of a mercury chamber in which is submerged a copper armature. The line current enters and leaves the mercury through electrodes diametrically apart. Since mercury has about fifty-five times the resistivity of copper, the major part of the current traverses the armature. The mercury thus performs the function of the commutator and brushes of the commutator-type meter. A shaft attached to the armature passes through the chamber to prevent the mercury from escaping when the meter is inverted. Externally, this shaft carries a worm which engages with the register train, and an aluminum damping disc moving in the field of a permanent magnet. The copper armature is notched radially to direct the current flow in such a manner as to obtain the greatest torque, and carries a float so proportioned that there is a slight upward thrust. In consequence, the lower bearing is a ring-jewel, while the upper end of the shaft is carried in a ring-stone end-stone bearing. A laminated iron electromagnet having many turns of fine wire is covered across the line, and sends through the copper armature a magnetic flux which varies in proportion to the line voltage. The driving torque is thus proportional to the power supplied to the load. The damping at small and moderate loads is nearly all caused by the drag disc, but at full load and overloads the fluid friction of the mercury increases at such a rate as to cause a drop in the percentage registration curve unless compensated. Compensation is effected by passing the line current through a few turns of heavy wire around the voltage electromagnet.

**Compensation for Friction, Light-load Adjustment.**— For effecting light-load compensation for friction, a thermal device is used in some cases, and it is also possible to obtain compensation by shunting part of the potential current through the armature. The thermal device employed is a thermocouple shunted around the mercury chamber, and heated from a resistor connected in series with the potential circuit. The small electromotive force generated in the thermocouple sends a small current through the armature which is sufficient to overcome the friction of the moving parts.

**Application of Mercury Meters.**— Mercury-motor meters, on account of the low resistance of the current circuit, are particularly well adapted for use with external shunts, since but a small potential drop in the shunt is required. They are therefore used in comparatively large numbers for switchboard work where large currents are used and where external shunts can be conveniently installed. They are much less subject to derangement by vibration than commutator meters.

**Details of Construction.**— The preceding description applies to the mercury-motor meter extensively used in the United States. Other designs differ in mechanical construction and in methods for obtaining light-load adjustment. The chief difference in mechanical construction is in the motor element, where a mercury chamber of non-metallic compound is used in some cases, and a German silver chamber enameled on the inside in other designs. Armatures differ in

ne designs use a copper disc and others a copper drum or thimble. See below on *Data on House-Type Meters*.

**city of Mercury Watt-hour Meters.** — Direct-current mercury meters themselves independent of ampere capacity, as external shunts are used, giving a capacity as high as 60,000 amperes have been furnished. Meters for voltages up to 600 volts are regularly furnished and special meters are supplied for 1200- to 3000-volt direct-current railway circuits.

**acy.** — The mercury-motor watt-hour meter above described is stated to have a load-accuracy curve at normal voltage which deviates from a straight line less than 1.5 per cent over a range of load of 5 per cent to 200 per cent

**INDUCTION WATTHOUR METER (Fig. 1).** — This type of meter, the elements of which are illustrated in Fig. 1, has a laminated soft-iron

Fig. 1. Diagram of Induction Watt-hour Meter

between them and is cut by the alternating flux due to each wind-

**Mode of Operation.** — There are thus set up in the disc currents which flow in concentric circles, the induced currents in the disc, the two windings being in quadrature for a load of unity power factor only, unless a suitable phase compensator is used; see below). The current induced by the current coil passes under the pole of the potential coil and therefore through a magnetic field which is approximately in phase with it, and similarly part of the current induced by the potential coil passes under the pole of the current coil and therefore through a magnetic field which is approximately in phase with it; for power factors less than unity the phase difference between these currents and the magnetic fields through which they pass is the same as the difference in phase between the load current and the voltage across the load; hence a torque is produced on the disc having an average value proportional to the load supplied through the meter; see *Electricity and Magnetism*. A braking system similar to that employed in the commutator motor (see above) causes the speed of the disc to be proportional to this torque, and therefore the number of revolutions of the disc is proportional to the energy supplied.

**Phase Compensation; Lag Coil.** — In order to make the induction watt-hour meter record correctly, especially for power factors less than unity, it is necessary to cause the flux at the tip of the potential pole to lag 90 degrees behind

the voltage impressed on the potential coil. A method of securing this condition is to mount on the potential pole a closed winding the resistance of which can be varied by a resistance wire soldered to the terminals. This closed winding is sometimes called the "lag coil." In many designs it is a metal plate in the form of a closed loop.

**Compensation for Friction; Starting Plate.** — The light-load adjustment can be obtained by placing a short-circuited loop of copper adjacent to the potential pole so that it can be shifted in a plane at right angles to the axis of the potential coil. This loop has induced in it currents which produce a field of phase with the flux from the potential coil, and the reaction between the two produces on the disc a slight turning moment independent of the current in the current coil. The amount of compensation can be varied by shifting the position of the light-load coil, or starting plate, as it is sometimes called.

**Details of Construction.** — The induction watt-hour meter is manufactured in several different types all based on the same principle of operation but differing in mechanical construction and electrical characteristics. The general type of construction is to mount the iron core and windings on a metal frame which carries the bearings for the armature, the core and windings being combined as a single unit in some designs, whereas in others the current and potential coils with their iron cores are mounted separately on a common frame or on the meter case. The other details of design consist of mounting the registering train and damping magnets and arranging the full-load, light-load and power factor adjustments so that they are readily accessible. See also section below on *Data on House-Type Meters*.

**Polyphase Induction Meters.** — The polyphase induction meter for commercial use is nothing more than two single-phase meters with a common spindle connecting the two armature discs. The measurement of power on the meter is based on the two-wattmeter method for three-wire, three-phase and quarter-phase work (see *Wattmeters*), and a slight modification of the element meter is used quite extensively for four-wire, three-phase work. This modification consists of making a third current circuit by adding a winding on the current coils of both elements. Such a construction is quite accurate even on badly unbalanced voltages, the most accurate arrangement for such work being three separate single-phase meters, or a single meter which contains the single-phase elements.

**Capacity of Induction Watt-hour Meters.** — Induction watt-hour meters are supplied in standard capacities ranging from 5 to 300 amperes. Meters are generally used with self-contained potential circuits up to 600 volts and for higher voltages and current capacities potential and current transformers are used with 5-ampere 110-volt meters. When transformers are used, either multiplying constant for the dial alone can be used in connection with the ratio of transformation of the transformers, or the ratio of the transformer can be included in the meter constant (see below), so that the register is direct reading with the transformers of proper ratio. For three-wire, single-phase circuits it

Fig. 2. Calibration Curve of Induction Watt-hour Meter

to obtain a special form of current transformer with double primary and a single secondary winding for connection to the meter.

**accy.** — Modern induction watt-hour meters are susceptible of a higher accuracy than the commutator or mercury-motor meter. Fig. 2 shows characteristic curve of an induction watt-hour meter. It is possible to make, by special calibrations a combination of induction watt-hour meters and current transformers which will be accurate to within 1 per cent over the range of commercial operation. The Meter Code (see *Bibliography*) requires a-c. watt-hour meters to run continuously, at rated voltage and frequency and unity power factor, with 2 per cent of rated current, and for higher currents to be accurate within the following limits:

Rated current. . . . .	5	10	20	50	100	150
Maximum deviation. . . . .	3.0	1.5	2.0	2.0	1.5	3.0

Meters must also be adjusted for measurement on power factors of 75 per cent and 100 per cent to within 2 per cent and 4 per cent respectively. Other requirements for accuracy can be found in the Meter Code.

**PREPAYMENT METERS.** — Standard watt-hour meters are sometimes made into a device whereby the circuit through the meter and load is closed by the insertion of a coin into the device, and remains closed only until a predetermined amount of energy has been recorded by the meter, when the meter again opens automatically. When so equipped the meter is called a prepayment meter. The prepayment device may be either inserted in the meter, or it may be placed in a separate attachment electrically connected to the meter.

**DIFFERENT TYPES OF WATTHOUR METERS.** — The descriptions of meters given above refer particularly to the types manufactured in the United States. Meters of the same general types are manufactured abroad, and there are certain other types. Among the latter, the Aron clock meter is worthy of mention. In this meter the potential coils are carried on two pendulums in such a manner that they swing close to the coils carrying the line current. One pendulum must be retarded as the other is accelerated and to do this the connections are so made that the instantaneous polarity of the pendulum coils is always opposite while the current coils are always alike. The meter has an iron core and has no commutator and is, therefore, a very accurate device, although somewhat complicated and delicate of adjustment for commercial work.

**WEIGHTS AND DIMENSIONS OF SERVICE-TYPE METERS.** — General data on service-type meters of different types are tabulated below. These data are approximately representative of modern practice in this country. The weights and dimensions given refer to meters of 5 to 25 amperes rating, and are exceeded for meters of greater rating.

**INSTALLATION OF WATTHOUR METERS.** — For laboratory tests the meter should be mounted on a firm support and set level. These conditions should be obtained when the meter is permanently mounted for service; see below *Installation*. For laboratory tests a bank of lamps or some form of rheostat or "phantom load" may be used for a load. The instructions given below apply to both laboratory and service tests.

**INSTRUMENTS.** — For d-c. measurements a portable ammeter and a portable watt-hour meter may be used; for a-c. measurements a portable wattmeter or portable watt-hour meter may be used. Two facilities should be provided, one sufficient to take care of the full

load of the meter and the other small enough to read the light load with a high degree of accuracy.

The use of a portable watt-hour meter is now recognized as the standard method for testing watt-hour meters up to 100-ampere capacity. There is question as regards the accuracy of this method, since it is not necessary that the load be constant. With the portable watt-hour meter, indicating instrument and stop watches are unnecessary, and personal errors in reading are thus reduced.

When indicating instruments are employed, a reliable stop watch is essential for taking the meter speed. As a matter of safety, it is advisable to have at least two stop watches, one to serve as a check on the other in test. The same care cannot be used in the handling of these watches and in giving them final checks with some local jeweler's standards. In checking the stop watch it is advisable to check at different points of the dial.

**Precautions.** — In order to insure accuracy, d-c. meters should not be tested until they have been connected in circuit with the voltage on for fully 15 to 20 minutes before the test is made. This enables the heating effect of the current in the potential circuit to become constant. If the meters are tested before this consecutive readings may not check.

The testing instruments should not be allowed to measure the losses of the potential circuit of the meter under test, or vice versa. In order to avoid this the current circuits of the testing instrument should be connected in series with the meter under test, while the potential circuits of the testing instrument and of the meter under test must both be connected across the line at the same place and between the generator and the nearer instrument.

A number of revolutions should be taken so that the time of observation is at least from 40 to 60 seconds. If the time is materially less than 40 seconds undeniably large errors in the measurement of time are probable; a time interval longer than 120 seconds is generally unnecessary.

**Test Constant.** — In checking a watt-hour meter the speed of the meter

ately, since too long a time would be required to obtain a suitable reading on the dials of the register. The relation between the number of revolutions of the disc and the corresponding dial reading may be expressed by a multiplier, called the "test constant," which depends only upon the relation between the disc and dial. Various manufacturers express this constant as follows, viz.:

**General Electric Test Constant ( $K$ ).**—The number of watt-hours indicated by the register per revolution of disc; its value is marked on the disc.

**Westinghouse Test Constant ( $K$ ).**—Westinghouse meters (except type CW-6) are all adjusted for a certain speed at rated full load, which is marked on the nameplate. Meters of modern manufacture have a speed of 3600 r.p.m. and older forms of 50 r.p.m. Let  $N$  be the number of revolutions of the disc corresponding to a rating of  $P$  kilowatts, then the test constant  $K$  (number of watt-seconds per revolution of disc), as given in the instruction manual issued by this company, is  $K = 60,000 P/N$ . For type CW-6 (direct-current meters) the test constant is the number of watt-hours per disc revolution.

**Port Wayne Test Constant ( $C$ ).**—For type  $K$  meters the number of watt-hours for 36 revolutions of the disc; for types  $K_1, K_2, K_3, K_4$  and  $K_5$  the number of watt-hours for 1 revolution of the disc; the constant is marked on the disc.

**Duncan Test Constant ( $K$ ).**—The number of watt-hours per revolution of disc; it is marked on the meter name plate.

**Langamo Test Constant ( $K$ ).**—The number of watt-seconds per revolution of disc; it is now marked on the name plate in the D-5 mercury meters and on the register of the type  $H$  induction meters.

**Conversion Formulas.**—Let  $R$  = number of revolutions of disc,  $S$  or  $T$  = seconds for  $R$  revolutions,  $K$  or  $C$  = meter constant as defined above; the power corresponding to the speed of the meter is:

Type of meter	Meter watts
General Electric	$\frac{3600 KR}{S}$
Westinghouse	$\frac{KR}{T}$
Port Wayne, Type $K$	$\frac{100 CR}{S}$
Port Wayne, Types $K_1, K_2, K_3, K_4$ and $K_5$	$\frac{3600 CR}{S}$
Duncan	$\frac{3600 KR}{S}$
Langamo	$\frac{KR}{S}$

**Accuracy.**—The meter watts as thus calculated divided by the watts read on the test meter, and multiplied by 100, gives the per cent accuracy. If the per cent accuracy is less than 100 the meter is running slow; if more than 100 it is running fast. The term "per cent accuracy" is open to

some objection, and "per cent registration" is coming to be preferred. An entirely satisfactory name has yet been found for this quantity.

**Adjusting Speed of Meter.** — If the error in the meter reading at full is in excess of the permissible error the speed should be altered by adjusting position of the permanent magnets or shunting part of their flux by the method provided therefor. If the error at light load, say 5 per cent load, is excessive light-load adjustment should be altered to bring the speed to its correct value.

**Method of Using the Portable Watt-hour Meter.** — The dial of the portable meter reads directly in revolutions of the meter disc. At the instant a mark on the disc of the service meter passes some arbitrarily chosen fixed point note the dial reading of the portable meter. Count the number of revolutions of the disc of the service meter, and at the instant when a suitable whole number of revolutions are completed note the dial reading of the portable meter. Let  $R_0$  be the difference in the two dial readings of the portable meter,  $K_0$  the test constant of the portable meter,  $R$  the number of revolutions of the service meter and  $K$  its test constant. Then the per cent accuracy is  $KR/K_0R_0$ . Of course the test constants of the two meters must be expressed in the same manner, i.e., as watt-hours per revolution or as watt-seconds per revolution.

**Testing of Three-wire and Polyphase Meters.** — A three-wire meter may be tested as a two-wire meter by connecting the current coils in series. A three-wire meter will then read twice the number of watts actually supplied to the test load. By using two sets of instruments three-wire meters may be tested as actually used.

A polyphase meter is most readily tested as a single-phase meter with the current circuits in series and the potential circuits in parallel. The reading of the meter is then twice the number of watts actually supplied to the test load.

**INSTALLATION OF WATTHOUR METERS.** — A watt-hour meter should always be mounted on a firm support, should be set with the dial face and in a place where it will not be liable to be injured or subjected to undue strain. A firm support is particularly essential, as continual vibration of the meter may cause it to "creep," since vibration tends to lessen the friction, and the resulting compensation may then be excessive.

Meters should not be installed closer than about fifteen inches between centers, and should not be too close to conductors carrying heavy currents in the vicinity of iron girders, posts, water or steam pipes.

A check on its accuracy should always be made after the installation of a meter.

**Determination of the Capacity of Meter.** — Before installing a meter some tests or accurate estimates should be made to determine the correct capacity of meter, as it is not advisable to run a meter continuously above its rated capacity, and too large a meter means in general poor accuracy on light loads. As a rough guide, the capacity of the meter should be one-half the total connected load for ordinary residences, three-fourths the total connected load for stores and offices, and  $1\frac{1}{2}$  times the connected load for elevator, hoist, and motor taking a large starting current. When several such motors are connected to a meter, the diversity factor will often permit the use of a meter capacity less than their combined current capacity.

**Precautions in Connecting Polyphase Meters.** — Direct-current and single-phase alternating-current meters are comparatively simple to install and connect properly, but all installations on polyphase circuits require considerably more care and knowledge to insure proper connections. Polyphase meters must be connected properly in regard to phase relations, and otherwise very inaccurate results will be obtained, which may not be apparent on casual examination of the meter. The manufacturer's instructions should

very carefully and the phase relations traced out to make sure that correct. Practically all instrument transformers are now marked in inductive manner to indicate the relative instantaneous polarity of the secondary windings, in order to facilitate making connections.

**TENANCE, REPAIRS AND DEPRECIATION.** — It has been an experience that except for the very smallest central stations or power companies it is economy to maintain some systematic method of caring for all meters on the system. For ordinary house service except very large installations, readings are taken about once a month and meters are examined and tested as required. Commutator-type and motor meters should undoubtedly be tested and put in good condition once a year; induction meters may be left for two years and perhaps be examined, as the very slight change in accuracy is not enough to warrant the expense of the test. With very large capacity meters, where the money involved is large, frequent tests are made and in some cases a check and adjustment is made, and whenever necessary the meter is completely overhauled and a spare meter installed in the meantime.

— In making repairs on watt-hour meters, it is practically necessary to have a considerable equipment and a department for this class of work. If a department is available it is preferable to return meters to the factory for all repairs except those of a minor nature, such as cleaning of contacts on direct-current meters and inserting new jewels and pivots for commutator bearing. Manufacturers will usually supply repair parts at reasonable prices. Quite extensive repairs can be made by the central stations if they are equipped. In service the attention and care necessary vary with the type of meter, induction meters being by far the cheapest to repair and under conditions such meters require the least attention of any type.

**OF WATTHOUR METERS.** — Ordinary service type commutator meters for direct current range in price from \$16 to \$170. Switching commutator meters in capacities from 800 to 6000 amperes range in price from \$50 to \$500. Shunted type commutator meters range from \$100 for a meter to \$200 for one of 5000 amperes capacity.

Motor meters usually have external shunts. The meter itself is of 5000 ampere capacity and sells for about \$16 in the service type and \$55 to \$70 in shunted type. Prices of shunts for these meters are approximately \$10 for a 500-ampere, \$30 for a 500-ampere, \$40 for a 1000-ampere and \$100 for a 5000-ampere meter.

Single-phase service-type induction meters are sold for about \$35; larger capacities and polyphase meters range from \$35 to \$70. Induction meters sell for \$40 to \$100; they are 5-ampere, 110-volt meters and are used for use with instrument transformers, q.v.

These prices are approximate, and should be used only as a rough guide. The cost of installing and connecting the meter varies considerably with the local conditions or requirements. Where no protective devices are used, and the utility company furnishes the main line cutout and cutout box, the installation cost may be about \$2. Where the company furnishes the main line cutout and box, with protective devices to prevent tampering, the installation cost will be about \$10.

**METERS.** — (See also *Ammeters; Electrodynamometers; Electrometers; Wh; Voltmeters; Watthour Meters.*) A wattmeter is a device for electric power and is particularly useful for measuring alternating-current. Usually some form of electro-dynamometer is used in which the load current  $i$  in the circuit or a known part of it is sent through one winding, the current coil; and a small current in phase with the e.m.f. across the terminals of the load is sent through the other winding, or potential coil; see Figs. 1 and 2. For voltages above 150 to 750 volts, potential transformers (see *Transformer*) are usually employed. In some cases specially-constructed multipliers, or multipliers, are employed in testing work up to 25,000 volts and higher. The moving coil is generally used for the potential circuit because it is convenient to carry through it a small current than a large one.

**Principle of Operation.** — In an instrument constructed and used as above the current in the current coil is practically proportional to the load current  $i$  at each instant and the current in the potential coil is practically proportional to the voltage  $e$  across the load at that instant. Hence the instantaneous torque acting on the moving element at this instant is proportional to the instantaneous power. The average torque acting on the moving element during each cycle of the current and voltage is then proportional to the average power. If the free period of the moving system is large compared with the period of the current and voltage, then the steady reading will also be proportional to the average power.

**CONSTRUCTION OF WATTMETERS.** — The electro-dynamometer instrument is built in several forms, e.g., the original Siemens electro-dynamometer in various forms in which the moving coil is brought back to zero position by a torsion head from which the reading is obtained; deflection instrument in which the moving coil is allowed to advance through an angle until it is arrested on it by the currents in the instrument windings is balanced by a spring torque developed in a spring or equivalent device. In the latter instrument the position of the moving coil is usually read by means of a pointer passing over a scale, graduated to read directly in watts or kilowatts. In very sensitive instruments for laboratory use a beam of light and scale like those used with mirror galvanometers is employed. (See also *Electrodynamometers.*)

Instruments of the electro-dynamometer type of instrument, induction wattmeters, operating on the same general principle as the induction watthour meter (see *Watthour Meters*), are sometimes used for switchboard and even for kilowatt-hour meters, but they are not so generally useful through wide ranges of frequency and voltage as electro-dynamometer instruments.

In limited conditions electrostatic wattmeters (see *Electrometers*) are occasionally used; in this general class of wattmeters for special purposes included the cathode-ray oscillograph or Braun tube (see *Braun Tube*).

Wattmeters, having two or more sets of current and potential windings, are made for use on polyphase circuits. They are described below under *Measurement of Three-phase Power.*

**Different Types of Wattmeters.** — Reflecting electro-dynamometers for laboratory use are made for currents up to 100 or 200 amperes and for voltages from a fraction of a volt up to 150 volts. Such instruments are specially constructed for larger currents and higher voltages.

**Electrodynamometers.** Such instruments are chiefly useful for measuring power in circuits of low voltage and of low power factor where even

the small power required to operate the instrument makes the use of ordinary portable instruments inconvenient or impossible.

Portable wattmeters are usually made to give a full-scale deflection about two-thirds of the product of their rated amperes and volts, i.e., an instrument rated as 5 amperes and 150 volts would usually have a 500-watt full-scale deflection. For determining core losses and other service where the power factor is low, wattmeters may be had giving full-scale reading with one-third or even one-fifth of the product of the rated amperes and volts. It is customary to supply such wattmeters with a certificate showing the values of the equivalent phase angle  $\alpha$  (see below) that have been determined, so that they may be used where a high degree of precision is required on low power factor work.

Portable wattmeters are made in ranges up to 200 amperes and 750 volts. Extra potential terminals are often supplied so that the instruments may be used on more than one voltage, e.g., 125 or 250 volts. Double current windings are also supplied, with a switch or links for changing the current range, and it is also usual to construct wattmeters having two current ranges and two voltage ranges. This construction greatly increases the usefulness of the instrument and is particularly useful when applied to the low power factor wattmeter. It makes it possible to use them for higher power factors by using say the 5-ampere, 250-volt range for a load of 5 amperes at 125 volts.

Portable wattmeters for currents larger than 200 amperes and voltages larger than 750 volts have been successfully constructed but are not generally used because the higher ranges can usually be taken care of with 5-ampere wattmeters in connection with calibrated instrument transformers.

Switchboard wattmeters are made single-phase up to 200 amperes and 750 volts, and polyphase up to 50 or 100 amperes and up to 750 volts. The higher ranges are usually taken care of by using 5-ampere wattmeters in connection with instrument transformers.

**METHODS OF CONNECTING WATTMETER TO LOAD; CORRECTION FOR POWER LOST IN WATTMETER.** — A wattmeter may be connected to the load which it is to measure in either of the two ways illustrated in Figs. 1 and 2. When connected as in Fig. 1 the current through

Fig. 1. Includes Loss in Potential Circuit

Fig. 2. Includes Loss in Current Circuit

the current circuit is equal to the sum (vector sum in the case of alternating currents) of the current taken by the load and that taken by the potential circuit of the wattmeter; hence the wattmeter will read the sum of the watts taken by the load and the watts lost in the potential circuit. The loss in the potential

circuit is equal to  $\frac{E^2}{R_p}$ , where  $R_p$  is the resistance of the potential circuit and  $E$  is the voltage across the load. For precise work this correction should always be made, unless the wattmeter is "compensated"; see below.

In the second scheme of connection, Fig. 2, the current through the current circuit is the same as that taken by the load, but the voltage across the

it is higher than the voltage across the load by the voltage drop through the current circuit of the instrument, and the wattmeter reads too high by an amount equal to the watts lost in the current circuit. This loss is equal to  $R_c I^2$ , where  $R_c$  is the resistance of the current circuit and  $I$  the load current. This loss is usually less than the loss in the potential circuit which occurs when the first scheme of connection is used. If no correction is made for the wattmeter loss the scheme of connections shown in Fig. 2 should therefore be used. If the greatest precision is required, especially when a small-capacity wattmeter is used, the connections shown in Fig. 1 should be used, and a correction should be applied. The resistance of the potential coil is usually stated on the case of the instrument.

When a voltmeter is connected to the load across  $AA'$  in Fig. 1, while the wattmeter reading is being taken, a correction should also be made, if applicable, for the power taken by the voltmeter. Calling  $R_v$  the resistance of the meter and multiplier, if any, and  $E$  the voltage across the load, the loss in the voltmeter is  $\frac{E^2}{R_v}$ . In most cases the potential circuit losses in the watt-

meter and voltmeter are best determined by a direct measurement with the wattmeter, using the test voltage and leaving the current circuit open. If the voltmeter is connected across  $BB'$  in Fig. 2, then the power lost in it is not measured by the wattmeter, but the voltmeter reading is not exactly equal to the voltage across the load, but equals the load voltage plus the resistance drop or impedance drop, added vectorially, in the case of an alternating-current circuit through the current circuit of the wattmeter.

**Compensation for Wattmeter Loss.**—In the so-called compensated wattmeter a stationary compensating coil inside the instrument is connected in series with the potential coil, this compensating coil being so placed that the current through it produces on the moving element a torque equal and opposite to that produced by this same current when it passes through the current coil. A compensated wattmeter should always be connected to the circuit, as shown in Fig. 1; when so connected no correction for the loss in the wattmeter is necessary.

**SOURCES OF ERROR.**—Due to the unavoidable inductance in the potential circuit of a wattmeter, the current in the moving coil is not exactly in phase with the e.m.f. impressed on the circuit; in addition there are other inherent defects in wattmeters, such as eddy currents in windings, supports, etc., which tend to make commercial wattmeters more or less imperfect. These imperfections are more serious as the frequency of the circuit is raised and the power factor is lowered.

For precision testing under service conditions when the best obtainable accuracy is required, it is often desirable to apply corrections to wattmeter observations to eliminate the errors due to phase displacement, or its equivalent, in the potential circuit; when instrument transformers are used, additional phase displacement occurs, rendering such corrections especially important. In other cases where corrections cannot well be applied, it is useful to consider the magnitude of the error that will occur under any given conditions, in order to select suitable instruments and transformers and to arrange the burdens connected to the secondaries in such a way as to produce as near as may be the desired results. In many cases indications that would otherwise be considerably in error may be made to give results of satisfactory accuracy by correcting for phase displacement in the wattmeter, and particularly in the instrument transformers.

There are many ways in which the necessary corrections may be determined and verified but the following has been found satisfactory in practical work

**Equivalent Phase Angle of Wattmeter.**—All the errors in wattmeter may be considered as due to a certain phase displacement between the current in the potential coil and the impressed e.m.f. of the circuit. This equivalent angle of phase displacement may be due to a variety of causes, but can be determined for any given instrument from the following relations. Consider a wattmeter in which the current in the potential circuit lags or leads behind the e.m.f. impressed on the potential circuit, the meter being in all other respects perfect. If such a meter is used to measure the watts  $P$  supplied by a current at a voltage  $E$ , this current lagging behind  $E$  by an angle  $\theta$ , the wattmeter will read  $P_2 = EI \cos \theta_2$  watts, where  $\theta_2 = \theta - \alpha$ . Hence if a wattmeter is used to measure a known load of  $P$  watts with  $I$  amperes and  $E$  volts, and the wattmeter reads  $P_2$  watts, the equivalent phase angle of the wattmeter may be defined by the relation

$$\alpha = \cos^{-1} \left( \frac{P}{EI} \right) - \cos^{-1} \left( \frac{P_2}{EI} \right).$$

This angle  $\alpha$  is to be taken positive when the wattmeter reads too high on an inductive load and negative when it reads too low on an inductive load.

For a given wattmeter and given potential coil this equivalent phase angle is practically constant for all currents, voltages and load power factors, provided the frequency remains constant.

In the best portable and reflecting instruments  $\alpha$  is usually + and very small. In a portable instrument built for a 125- to 150-volt circuit, when used on a 60-cycle circuit,  $\alpha$  may have a value of from +2 minutes to as much as +4 minutes. The phase angle varies directly as the frequency and inversely as the voltage rating.

The phase angle of a wattmeter may be compensated by shunting a condenser of capacity  $C$  around a portion  $R$  of the resistor in the potential circuit. If the equivalent inductance of this circuit be  $L$ , the relation for compensation is

$$C = \frac{L}{R^2}.$$

**Correction for Phase Angle of Wattmeter and of Instrument Transformers.**—Let  $\alpha$  = the phase angle of the wattmeter, as defined above,  $\beta$  = phase angle of the current transformer,  $\gamma$  = the phase angle of the potential transformer (see *Transformers, Instruments*),  $P_2$  = wattmeter reading corrected for scale error and multiplied by the product of the corrected ratios of the current and potential transformers,  $E$  = voltmeter reading corrected for scale error and multiplied by the ratio of the potential transformer, and  $I$  = ammeter reading corrected for scale error and multiplied by the corrected ratio of the current transformer. Then the apparent power factor is

$$\cos \theta_2 = \frac{P_2}{EI},$$

and the true power is

$$P = P_2 \frac{\cos(\theta_2 + \alpha + \beta + \gamma)}{\cos \theta_2}.$$

The angle  $\theta_2$  is to be taken positive when the current lags behind the voltage and negative when the current leads. Note that  $\alpha$ ,  $\beta$  and  $\gamma$  may also be positive or negative angles. Values of the correction factor  $\frac{\cos(\theta_2 + \alpha + \beta + \gamma)}{\cos \theta_2}$

given in Tables I and II. Note carefully the conditions, stated at the head of each table, to which each table applies.

On three-phase systems (see pp. 1032 and 1033), when badly unbalanced

rections should be applied separately, as above, to each wattmeter. When circuit is balanced a single correction based on  $\cos \theta_2$  for the whole circuit be used.

**Example No. 1.** — Given a single-phase circuit with lagging current in which the wattmeter reading corrected for scale error and multiplied by the correction ratios of current and potential transformers equals 24,520 watts, and the product of the voltmeter and ammeter readings, similarly corrected, equals 35,600 amperes. Then  $\cos \theta_2 = \frac{24,520}{35,600} = 0.689$ . If the equivalent phase angle  $\alpha$

of the wattmeter is  $+4'$  and if from examination of characteristic curves the current transformer phase angle  $\beta$  is found to be  $+48'$  and the potential transformer phase angle  $\gamma$  is  $-10'$ , then  $\alpha + \beta + \gamma = +42'$ , and from Table I, the correction factor is 0.9871. Whence the true power equals  $24,520 \times 0.9871 = 24,204$  watts.

**Example No. 2.** — Given a single-phase circuit with leading current, in which the wattmeter reading, corrected as in example No. 1, equals 12,266 watts the product of the voltmeter and ammeter readings, similarly corrected, is 24,532 volt-amperes. Then  $\cos \theta_2 = \frac{12,266}{24,532} = 0.5$ . If the equivalent

phase angle  $\alpha$  of the wattmeter is  $+5'$ , the phase angle  $\beta$  of the current transformer is  $+2^\circ 33'$  and the phase angle  $\gamma$  of the potential transformer is  $+38'$ ,  $\alpha + \beta + \gamma = +3^\circ 16'$  and therefore from Table II the correction factor to be used is 1.0971. Whence the true power equals  $12,266 \times 1.0971 = 13,457$  watts.

**Errors Due to Stray Fields.** — Stray magnetic fields influence the reading of a wattmeter in much the same way as such disturbances influence the readings of other electrical instruments; see *Ammeters*. In unshielded instruments errors due to stray fields may be quite large. Considerable errors are often introduced by the effect of neighboring instruments on one another. To avoid these errors, high-grade American wattmeters are magnetically shielded.

**ACCURACY OF WATTMETERS.** — The question of the accuracy of electrical instruments is discussed in detail in the article on *Ammeters*. High-grade portable wattmeters may be obtained having a stated accuracy of 0.25 per cent of full-scale value for single-phase or 0.5 per cent for polyphase wattmeters. It is not practicable to obtain as high accuracy in the latter, on account of the impossibility of making both elements of the polyphase wattmeter follow the same scale law. This theoretical disadvantage of the polyphase wattmeter is more than offset in practical use by its greater convenience and reduction in number of observations necessary, and its service accuracy, especially on fluctuating power, may even exceed that of single-phase wattmeters used for polyphase measurements. High-grade switchboard wattmeters may be obtained having a stated accuracy of 1 per cent of full-scale value. Of course the higher the degree of accuracy demanded the more costly is the meter.

**TESTING OF WATTMETERS.** — Wattmeters are usually tested by being compared with other standard wattmeters, which have in turn been calibrated by special methods and their behavior under various conditions determined. For examining the effect of low power factor on wattmeters, shifting transformers or generators having shifting fields are conveniently employed. By these means low power factor conditions may be produced on instruments without the necessity of troublesome adjustments of reactances, condensers, etc.

For a given instrument is known with certainty to give no sensible error on measuring current due to structural defects, it is usually more convenient to make subsequent checks to detect any change in the instrument by using direct current. The current and voltage are in this case determined by means of

suitable standard ammeter and voltmeter or by direct reference to potentiometer and standard cells; see *Potentiometers*.

**MEASUREMENT OF THREE-PHASE POWER.** — (See also article by L. T. Robinson in *General Electric Review*, 1912, Vol. 15, p. 350.) The measurement of the power supplied to a three-phase load may be effected in one or more of the following ways. The connections in each case may be made directly or through proper instrument transformers, the latter being used for heavy currents or high voltages, or both.

**Single (One-element) Wattmeter on Three-wire System.** — The current circuit of the wattmeter is connected in series with one of the mains supplying the load and the potential circuit of the wattmeter is connected between the corresponding terminal of the load and the neutral. If the neutral point of the load, or of the transformers supplying the load, is not available, a "Y-box" (see below) can be used to establish an artificial neutral. If the load is perfectly balanced (see *Alternating Currents*) the power input is then three times the wattmeter reading. However, a three-phase load is seldom sufficiently well balanced even in the case of a three-phase motor load, to render this method of measurement an accurate one. In most practical cases it gives merely a rough approximation to the true power.

**Y-Box.** — The simplest form of Y-box consists of two equal non-inductive resistors connected in series, each of the free ends and the junction point being connected to a binding post. Each resistor has a resistance equal to that of the potential circuit of the wattmeter. One terminal of the potential circuit of the wattmeter is connected to the junction terminal of the Y-box and the other terminal of the potential circuit to the line wire in which the current circuit of the wattmeter is connected. The other two terminals of the Y-box are connected to the other two line wires respectively.

In the case of wattmeters designed especially for use with a Y-box, part of the resistance of the potential circuit of the wattmeter is placed in the Y-box, being connected permanently to the junction point between the other two resistors. A similar arrangement may be used as a multiplier. The connections of such a Y-box, wattmeter and instrument transformers are shown diagrammatically in Fig. 3.

**Two-wattmeter Method for a Three-wire System.** — The simple arrangement of two wattmeters shown in Fig. 4 will give exactly the total power in any three-wire circuit, provided each wattmeter by itself gives accurate indications. Aside from the sources of error, as noted above, which may affect the accuracy of a wattmeter on a single-phase circuit, the arrangement

Fig. 3. Single-phase Wattmeter and Y-box for Three-phase Circuit

Fig. 4. Two Single-phase Wattmeters for Three-phase Circuit

as shown in Fig. 4 will give the true power for any condition of unbalance, wave-form, frequency, etc. It is also immaterial whether the load be  $Y$  or  $\Delta$  connected. The connections may be made directly as shown or through current transformers and two potential transformers, the connections being the same as in Fig. 5, except that two separate wattmeters instead of a poly-phase wattmeter are used.

**Rule for Adding or Subtracting Readings.** — With the arrangement shown in Fig. 4 the total power is always the algebraic sum of the readings of two wattmeters. Since a wattmeter reads only in one direction, usually the right, the two instruments must be so connected to the line that the needle of each instrument is deflected over the scale. For a balanced three-phase load having a power factor greater than 50 per cent, the sum of the two wattmeter readings, when the connections are thus made, gives the total power; for a power factor less than 50 per cent the difference of the two readings must be taken. When the power factor is not known, one can determine whether the sum or the difference of the readings should be taken by interchanging the two wattmeters, leaving unaltered the potential connections to the third wire (see Fig. 4); if the pointers of the two wattmeters deflect in the same direction before and after the two readings, if the pointers deflect in the opposite direction (i.e., against the stop) take the difference. In making this test, care must be taken to connect the source side of each of the two lines (in which the current coil of each wattmeter is connected in succession) to the same binding post of the given wattmeter in each of the two positions.

When the load is balanced, and the two wattmeters are connected, as in Fig. 4, so that each gives a positive reading, the question as to whether the power factor is above or below 50 per cent can be determined by changing the potential lead of the lower reading meter from the common connection  $C$  to the line which the current coil of the other wattmeter is connected. If the reading is obtained is positive, the power factor is more than 50 per cent and the readings should be added; if the reading is negative the power factor is less than 50 per cent and the readings should be subtracted.

**Phase Difference between Voltage and Current in the Wattmeter Readings.** — In case the load is balanced it can be shown that if  $\theta$  is the power-factor angle of the load,  $I$  the line current (current per wire) and  $E$  the line voltage (voltage between wires), then the power read by one wattmeter is  $P_1 = EI \cos(\theta - 30^\circ)$ , and the power read by the other is  $P_2 = EI \cos(\theta + 30^\circ)$ . The performance of the first wattmeter is the same as it would be on a single-phase load having a power factor of  $\cos(\theta - 30^\circ)$  and the performance of the second is the same as it would be on a single-phase load having a power factor of  $\cos(\theta + 30^\circ)$ . These relations should be borne in mind when making any corrections for errors due to low power factor (see above).

**Measurement of Power Factor by Two-wattmeter Method.** — From the above relations it can be shown that the power factor of the load, when the load is balanced, may be calculated from the two wattmeter readings  $P_1$  and  $P_2$  by the formula

$$\text{Power factor} = 100 \cos \left[ \tan^{-1} \left( \sqrt{3} \frac{P_1 - P_2}{P_1 + P_2} \right) \right] \quad \text{per cent,}$$

when the power factor is greater than 50%; and by the formula

$$\text{Power factor} = 100 \cos \left[ \tan^{-1} \left( \sqrt{3} \frac{P_1 + P_2}{P_1 - P_2} \right) \right] \quad \text{per cent,}$$

when the power factor is less than 50%,  $P_1$  and  $P_2$  both being taken as positive in both cases and  $P_2$  being the smaller reading.

**Two-element Polyphase Wattmeter on Three-wire System.** — Instead of using two separate wattmeters, as shown in Fig. 4, the two wattmeters may be combined into a single instrument with but one shaft and pointer. The connections for such a two-element wattmeter, when instrument transformers are used, are shown in Fig. 5. For measurements where the power is badly fluctuating and especially when accompanied by low power factor, polyphase wattmeters may be more accurate and convenient. For ordinary polyphase service a polyphase wattmeter is not capable of as high accuracy as two single-phase wattmeters.

Fig. 5. Two-element Polyphase Wattmeter with Instrument Transformers

**Determination of Power Factor with Two-element Wattmeter.** — The two-element wattmeter reads directly the sum  $P_1 + P_2$ , using the notation in the previous paragraph. By reversing the connections of one set of potential terminals to the corresponding potential transformer the meter may be made to read  $P_1 - P_2$ . Hence by the use of a suitable reversing switch the power factor of the load may be readily determined by taking two readings; see preceding paragraph.

**Three Wattmeters for Three-wire System.** — As noted above, where two wattmeters, or a two-element polyphase wattmeter, is used on a three-wire system, the phase difference between the voltage and current in each wattmeter or element may differ greatly from the power-factor angle of the load. For example, in the case of a balanced load having a 50 per cent power factor, the current in one wattmeter differs by  $90^\circ$  from the voltage on the potential circuit of this wattmeter, and it should read zero watts, i.e., this wattmeter operates under the worst possible conditions as regards power factor, and consequently the phase-angle error (see above), particularly when instrument transformers are used, may be quite large when expressed as a percentage. It should be noted, however, that the reading of the wattmeter or element in which the large phase difference occurs contributes proportionally less to the total reading as this phase difference approaches  $90^\circ$ , and consequently the percentage error of the total reading will be only a correspondingly small part of the error in this wattmeter or element.

Fig. 6. Y-Δ Connections for Three Wattmeters on Three-wire System

Where the highest accuracy is demanded, it is therefore theoretically advisable to use three wattmeters connected as shown in Fig. 6. It should be noted, however, that for most practical purposes the very slight gain in accuracy by such as

ment over the two-element wattmeter does not justify the expense of the dual wattmeter and instrument transformers. Again, a precision measurement of power with the three-wattmeter arrangement requires the accurate calibration and the accurate reading of three wattmeters instead of one.

**Measurement of Power in Four-wire Circuits.** — When part of the load returns through a fourth wire, e.g., in an unbalanced three-phase system a neutral wire, at least three wattmeters or wattmeter elements are required to obtain a theoretically accurate measurement of the power. A two-wattmeter having three current circuits may be used for the measurement of power on a four-wire system, and if the vectors representing the three currents to neutral form a triangle will give results having as high an accuracy as can be obtained with a two-element wattmeter on a three-wire system.

If three wattmeters are used, they should be connected in a manner similar to that used for two wattmeters on a three-wire system, i.e., each of the potential circuits should be connected between a main wire and the neutral wire and each of the three current circuits should be connected in series with the corresponding main wire. When instrument transformers are used the primaries of the potential transformers are connected in Y, with the neutral wire connected to the neutral wire, the three branches being connected to the lines; the secondaries and the potential circuits of the wattmeters are also connected in Y, with the wattmeters Y-connected to the Y made by the second-

**Two-element Wattmeter on Four-wire System.** — When used on a four-wire system the current coil of each element is divided into two like sections,

one section of each coil is connected with one section of the other coil, thus forming three groups of coils. Each group is connected to a current transformer as shown in Fig. 7, which also shows connections of the potential transformers, two of which are

used. With this arrangement the instrument measures correctly the power supplied by any two branches of the system for the third branch the power measured that corresponds

Fig. 7. Connections for Two-element Wattmeter on Four-wire System

to the current in this branch and the resultant (vector sum) of the voltages across the other two branches. Voltage unbalance or badly distorted and voltage waves will cause this resultant voltage to differ from the voltage to neutral in the third branch, producing an error in the measurement of this third of the total power. Under ordinary conditions, however, the error is not objectionably large for commercial measurements.

**GRAPHIC WATTMETERS.** — These instruments are designed to draw and plot a curve of power against time, without any appreciable time lag. Instruments of this type consist of a wattmeter element and of a time element. The curve-drawing pointer is actuated either directly by the motion of

the moving part of the wattmeter element, or indirectly by a system of solenoids or a small motor, energized through relay contacts on the wattmeter moving part. The purpose of the time element is to produce a steady motion of the paper at the point where the curve-drawing pointer (pen) is in contact with it. The clock, which turns the paper rolls, is either of the hand-wound type or of the electric self-winding type. In several types the rate of the paper feed may be varied from  $\frac{3}{4}$  inch per hour to as high as 6 inches per minute.

Semi-portable forms of graphic wattmeters are on the market, but the most accurate instruments are for switchboard use only. Large errors due to friction between paper and curve-tracing pen or pointer, or due to change in level of the instrument, are not uncommon with certain types of graphic wattmeters.

**PRECAUTIONS IN USE OF WATTMETERS.** — In addition to the general precautions given under *Ammeters* (p. 37), the following special precautions must be noted. A wattmeter has three distinct limits, namely, current, voltage, and power, no one of which should be exceeded. The potential of the moving coil must not be greatly different from that of the fixed coil, and the connections must always be such as to ensure this condition, both in the use and in the checking of a wattmeter. This precaution is especially necessary when an external multiplier is used for high voltages.

**COSTS, WEIGHTS AND DIMENSIONS OF WATTMETERS.** — (Data for 1920). — The following figures give a rough idea of the cost of wattmeters:

Indicating wattmeters	Portable	Switchboard
Single-phase:	\$	\$
Small size, unshielded or partially shielded.....	45-72	32-55
Regular size, shielded, high grade.....	72-141	.....
Round pattern, 7-inch diameter.....	.....	52-100
Round pattern, 9-inch diameter.....	.....	69-101
Horizontal edgewise.....	.....	54-77
Polyphase (two-element):		
Regular size, shielded, high grade.....	132-197	.....
Round pattern, 7-inch diameter.....	.....	75-115
Round pattern, 9-inch diameter.....	.....	96-124
Horizontal edgewise.....	.....	75-87

Current transformers are required for single-phase switchboard wattmeters of the electrodynamic type when the current exceeds 200 amperes or the voltage exceeds 600 to 750 volts. The upper limit of current for polyphase switchboard wattmeters of the electrodynamic type ranges from 60 to 200 amperes. For induction wattmeters as now made, both single-phase and polyphase, the current limit is 10 amperes. Potential transformers are required for all current ratings when the voltage exceeds 600 to 750 volts.

Switchboard wattmeters are made in 4-inch, 7-inch, and 9-inch round patterns and in horizontal edgewise pattern occupying a space on the panel 6 by 11 inches and projecting 7.6 inches from the panel.

High-grade shielded portable single-phase wattmeters measure about 5 by 9 by 6 inches high, and weigh from 9 to 12 pounds; polyphase wattmeters of the same grade measure from 8 by 8 by 10 inches high to 9.5 by 10.5 by 8 inches high, and weigh from 14 to 17.5 pounds.

**BIBLIOGRAPHY.** — See the Bibliographies in the articles on *Ammeters* and *Watt-hour Meters*; also Robinson, L. T., *Metering on Three-phase Systems*, Gen. Elec. Rev., 1912, Vol. 15, p. 350.

**WAVE ANALYSIS.** — (See also *Alternating Currents.*) Any sine function of a variable  $t$ , that is, any function of the form  $y = Y \sin(\omega t + \phi)$ , be plotted as a wave, as shown in Fig. 1. The constant  $Y$  is called the

Fig. 1.

Fig. 2.

maximum value" of the wave, the constant  $\phi$  the "phase" of the wave, and constant  $\omega$  is called the "periodicity" of the wave. The distance between successive positive maxima (or between successive negative maxima) of such a wave is called the "period" of the wave, and is usually represented by the symbol  $T$ . The reciprocal of the period is called the "frequency," and is usually represented by the symbol  $\frac{1}{T}$ .

Period, frequency and periodicity are related as follows:

$$\omega = 2\pi f = \frac{2\pi}{T}.$$

The phase ( $\phi$ ) of the wave is also equal to the product of the periodicity by distance to the left of the origin at which the wave first crosses the  $t$  axis in the rising direction; see Fig. 1.

In plotting a wave it is usually more convenient to take as the distance along the horizontal axis, not the value of the variable  $t$ , but the value of  $\omega t$ . That is, plotting  $x = \omega t$ , the equation for the wave may be written  $y = Y \sin(x + \phi)$ .

Fig. 1 then reduces to Fig. 2. When the wave is thus plotted the distance between successive positive maxima (or between successive negative maxima) is equal to  $2\pi$  radians or  $360^\circ$ , and the phase is the distance to the left of the origin at which the wave first crosses the axis of  $x$  in the rising direction.

**FOURIER'S SERIES.** — Any periodic function  $y$  of a variable  $t$  may be plotted as a wave as shown in Fig. 3. If the function  $y$  and its first derivative with respect to  $t$  (that is,  $dy/dt$ ) are finite and continuous for all values of  $t$ , then the function  $y$  may be represented by a series of sines of the form

$$y = Y_1 \sin(\omega t + \phi_1) + Y_2 \sin 2(\omega t + \phi_2) + Y_3 \sin 3(\omega t + \phi_3) + \text{etc.},$$

in which  $\omega = 2\pi/T$ , where  $T$  is the period of the given wave (i.e., the distance between successive positive, or between successive negative, maxima) and the  $Y$ 's and  $\phi$ 's are constants. That is, the wave, no matter how complex, may be represented by the sum of a number of sine waves whose frequencies are even multiples of the period of the given wave.

This theorem is of great value in the theory of alternating currents (q.v.), since any alternating current or voltage satisfies the above conditions. The series is known as Fourier's Series.

As in the case of simple sine waves, it is usually more convenient in plotting

Fig. 3.

## Wave Analysis

the distance along the horizontal, not the variable  $t$ , but the value of  $x$ . Putting  $x = \omega t$ , the series for  $y$  may be written

$$y = Y_1 \sin(x + \phi_1) + Y_2 \sin 2(x + \phi_2) + Y_3 \sin 3(x + \phi_3) + \text{etc.}$$

**Fundamental and Harmonics.** — The first term of the series, which has  $\omega$  equal to that of the given complex wave, is called the fundamental or the *fundamental term*, having frequencies which are multiples of the fundamental frequency, are called *harmonics*. For example, the third term, or the *third harmonic*, having this term, has a frequency three times that of the fundamental. The term or sine wave is called the *third harmonic*, etc.

A complex wave is such that the successive positive values of  $y$  in one half wave are numerically equal to the successive negative values of  $y$  in the succeeding negative half wave, only the *odd harmonics* occur. Such a wave is called a *symmetrical wave*. Voltage and current waves are usually of this kind, and therefore contain only the odd harmonics.

**DETERMINATION OF MAXIMUM VALUES AND PHASES OF HARMONICS BY INTEGRATION.** — Consider the  $n$ th harmonic of the series

$$y = Y_1 \sin(x + \phi_1) + Y_2 \sin 2(x + \phi_2) + Y_3 \sin 3(x + \phi_3) + \text{etc.}$$

Plot the value of  $u_n = y \sin nx$  between the limits  $x = 0$  and  $x = 2\pi$ , and integrate the resultant curve, by planimeter, between these limits 0 and  $2\pi$ . Call this area  $U_n$ . Similarly, plot the value of  $v_n = y \cos nx$  between the limits  $x = 0$  and  $x = 2\pi$ , and integrate the resultant curve, by planimeter, between the limits 0 and  $2\pi$ . Call this area  $V_n$ . Then

$$Y_n = \frac{1}{\pi} \sqrt{U_n^2 + V_n^2}$$

$$\phi_n = \frac{x}{n} \tan^{-1} \left( \frac{V_n}{U_n} \right)$$

The wave length of the fundamental corresponds to  $360^\circ$ . If the wave contains only the *odd harmonics*, as is usually the case in current and voltage waves (see *preceding paragraph*),  $U_n$  and  $V_n$  need be plotted only between the limits 0 and  $\pi$ . Calling  $U_n'$  and  $V_n'$  the corresponding areas, then

$$Y_n = \frac{2}{\pi} \sqrt{(U_n')^2 + (V_n')^2}$$

$$\phi_n = \frac{x}{n} \tan^{-1} \left( \frac{V_n'}{U_n'} \right)$$

This method, though cumbersome, is applicable to the determination of the maximum value and phase of any harmonic.

**SEER-HINNEN METHOD OF ANALYSIS.** — (*Elec. Journal*, 1901, page 386; *Electrotechnische Zeitschrift*, 1901, Vol. 22, page 306.) This method is quite simple when the wave contains only the fundamental and the third, fifth and seventh harmonics. When even harmonics are present, or when the wave contains higher odd harmonics than the seventh, certain corrections must be made.

Since voltage and current waves usually contain only odd harmonics, and since the maximum value of a wave containing higher harmonics than the seventh, the simple method of analysis with the necessary corrections is usually sufficiently accurate.

**Method for Determining the Maximum Value and Phase of a Harmonic Containing only the Third, Fifth and Seventh Harmonics.** — To determine the  $n$ th harmonic ( $n$  equals 3, 5 or 7) divide the base of a half

into  $2n$  equal parts and measure the ordinates of the wave at the beginning of each of these sections of the base. Call these ordinates  $y_1, y_2, y_3, \dots, y_{2n}$ , taking the  $y$ 's positive if above the base line, negative if below. If the first section begins where the resultant wave crosses the base line.

Then the ordinates of this harmonic at the points 1 and 2 are, respectively,

$$A_n = \frac{1}{2n} [(y_1 + y_2 + \dots + y_{2n-1}) - (y_2 + y_3 + \dots + y_{2n})],$$

$$B_n = \frac{1}{2n} [(y_1 + y_3 + \dots + y_{2n-1}) - (y_2 + y_4 + \dots + y_{2n})].$$

maximum value of this harmonic is

$$Y_n = \sqrt{A_n^2 + B_n^2},$$

the phase angle, calling the wave length of the fundamental  $360^\circ$ , is

$$\phi_n = \frac{1}{n} \tan^{-1} \frac{A_n}{B_n}.$$

These formulas give the third, fifth and seventh harmonics ( $n = 3, 5$  and  $7$  respectively). The fundamental is found by calculating

$$A_1 = -(A_3 + A_5 + A_7),$$

$$B_1 = y_0 + B_3 - B_5 + B_7,$$

where  $y_0$  is the mid-ordinate of the half wave. Then

$$Y_1 = \sqrt{A_1^2 + B_1^2},$$

$$\phi_1 = \tan^{-1} \frac{A_1}{B_1}.$$

The equation of the given wave is then

$$Y_1 \sin(x + \phi_1) + Y_3 \sin 3(x + \phi_3) + Y_5 \sin 5(x + \phi_5) + Y_7 \sin 7(x + \phi_7).$$

The effective value of the given wave is

$$Y = \sqrt{\frac{Y_1^2 + Y_3^2 + Y_5^2 + Y_7^2}{2}},$$

and the average value is

$$Y_{\text{av'ge}} = \frac{2}{\pi} \left[ Y_1 \cos \phi_1 + \frac{1}{3} Y_3 \cos 3\phi_3 + \frac{1}{5} Y_5 \cos 5\phi_5 + \frac{1}{7} Y_7 \cos 7\phi_7 \right].$$

In using the above formulas strict attention must be paid to algebraic signs.

Fig. 6

**Example.**—Find the third harmonic in the wave shown in Fig. The values of the six ordinates are found by measurement to be 0, 676, 940, 1004 and 554 respectively. Then

$$A_3 = \frac{1}{2}(1004 - 660) = 114.7,$$

$$B_3 = \frac{1}{2}(676 + 554 - 940) = 96.7,$$

$$Y_3 = \sqrt{(114.7)^2 + (96.7)^2} = 150,$$

$$\phi_3 = \frac{1}{2} \tan^{-1} \frac{114.7}{96.7} = 16.6^\circ.$$

Similarly, for the fifth harmonic,

$$A_5 = -92.8 \text{ and } B_5 = 37.4,$$

$$Y_5 = 100 \text{ and } \phi_5 = -13.6^\circ.$$

For the fundamental,

$$A_1 = -114.7 + 92.8 = -21.9,$$

$$B_1 = 940 + 96.7 - 37.4 = 999.3,$$

$$Y_1 = \sqrt{(21.9)^2 + (999.3)^2} = 1000,$$

$$\phi_1 = \tan^{-1} \frac{-21.9}{999.3} = -1.25^\circ.$$

Hence the complete expression for the given wave, taking as the origin point at which the resultant wave crosses the base line in the rising direction

$$y = 1000 \sin(x - 1.25^\circ) + 150 \sin 3(x + 16.6^\circ) + 100 \sin 5(x - 13.6^\circ).$$

The *effective* value is then 718 and average value 673.

**Waves Containing Any Number of Harmonics, Odd or Even.**—*Electric Journal*, 1908, Vol. 5, p. 386; and *Elektrotechn. Zeit.*, 1913, Vol. 34, p.

**WEIGHTS (MASSES) OF MATERIALS.** — (See also *Mechanics, Examples of*.) The density of any substance is the mass of that substance per unit volume. Or, using weight in the ordinary sense as equivalent to mass, the density may also be defined as the weight per unit volume. The numerical value of the density of any substance depends upon the unit in which the mass or weight is expressed and also upon the unit of volume used; *Units and Conversion Factors.* However, it is quite common to state the density of a substance in grams per cubic centimeter, without naming the units, when so expressed the density is numerically equal (practically) to the specific gravity.

The "specific gravity" of a substance is defined as the ratio of the weight (mass) per unit volume of that substance to the weight (mass), expressed in the same unit of an equal volume of water. To make such a statement exact the temperature of the water should be specified. There is no general agreement as to the temperature of reference, though water at 0° C. is commonly taken as the reference temperature. For gases, air at 0° C. and 760 mm. mercury pressure is frequently taken as the reference substance instead of water.

**Variation of Density of Water with Temperature.** — The following table gives the results of measurements by Thiesen, Scheel and Diesselhorst and Doll, Börnstein and Roth, *Physikalisch-chemische Tabellen*, 1913).

DENSITY OF WATER; GRAMS PER CU. CM.

\* Example: The density of water at 33° C. is 0.99473.

**Weights per Cubic Foot and Specific Gravity.** — In the following table are given the values of the density in pounds per cubic foot of the more commonly used substances. The specific gravity, or density in grams per cubic centimeter, corresponding to any weight per cubic foot  $w$  is equal to  $w/62.43$ ; for the conversion factors necessary to convert these figures into densities for other units of mass and volume, see *Units and Conversion Factors*.

## Welding, Electric

**G, ELECTRIC.** — The heat of the electric current is used in processes for welding metals, both ferrous and nonferrous. These may be tabulated as follows:

Designation	Varieties	Kind of current at weld	
Resistance welding	Butt welding	A-C.	
	Spot welding	A-C.	
	Seam (or line) welding	A-C.	
Capacitor welding	Using discharge from static condenser	D-C.	
	Using electro-magnetic discharge	D-C.	
Arc welding	Carbon arc	D-C. (though A-C. may be developed)	
	Metal arc	With bare electrodes	Usually D-C. but occasionally A-C.
		With flux covered electrodes	Either D-C. or A-C.

**APPLICATIONS OF ELECTRIC WELDING.** — Arc Welded a good many years ago the Seamless Steel Boat Company of Wakefield built successful all-steel life boats in which the joints in the shell were welded by the carbon arc process before being pressed into the *Dorothea M. Geary*, a boat with a length of 42 feet and a width and driven by a 50 horsepower gasoline engine, was built with most fitting done by arc welding using bare metal electrodes. It was on Lake Erie in 1915.

The British Admiralty, using flux-covered electrodes, built an arc ton Cross Channel barge. It is 125 feet in length and 16 feet wide. It was built in France an arc-welded barge 65 feet long by 15 feet wide. All the welding work was all done by women. In 1920 the *Fullagar*, a motor built by Messrs. Cammell Laird and Company, and entirely was launched at Birkenhead. The *Fullagar*, which is driven by an internal combustion engine of the type designed by the late Mr. H. F. Fullagar, has a speed of 10 knots and a length of 150 feet.

Other cases are mentioned as being of interest because the displacement of arc-welding for making the joints in the shell plating, foreshadows a very immense field for arc welding.

As yet there is a very large amount of arc welding in ship construction. In the space of this article their mere enumeration would be impossible. The following may be mentioned: repairs of boilers, stern frames, stems, masts, windlasses, shaft-brackets, rudder gudgeons, and fuel tanks. Also, anti-submarine bulges have been attached to hulls and their

shell plates have been arc welded, such undertakings exceeding in magnitude welding of complete vessels of moderate tonnage.

The *Times Engineering Supplement*, for April, 1920, Caldwell enumerates the advantages of arc welding in ship construction:

With the elimination of marking off, drilling or punching, countersinking and caulking, a considerable economy in time and labor can be effected.

By the reduction in width of laps and size of butt straps a saving of from 10 to 25 per cent of material can be effected.

Welded joints can be made to withstand greater stresses than similar riveted joints, and can be made equal in strength to the ship plating.

Once the practice is standard a reduction in the weight of the shell plating is possible without reducing the safety factor.

A welded joint is oil and water tight up to its breaking point, whereas riveted and caulked joints are liable to leak badly at as low as 25 per cent of ultimate strength.

While these may be described as general advantages, there are specific ones here electric arc welding possesses even greater attractions. For example, the most expensive smith-work involved in making complicated knees, angle irons, frames, etc., can be replaced by notching, bending up, and welding them at a fraction of the present cost, and it provides an ideal method of securing water-tight bulkheads without piercing them, and of making tight joints round pipes, etc., where these have to pass through bulkheads.

**Welding in Railway and Other Shops.** — Several of America's great shops each employ many dozens of arc welding operators in repair work on locomotives and are thereby effecting great economies. In street railway shops great economies are obtained; as also in boiler shops, foundries, blast furnaces, machine shops and mines.

**Welding in Manufacturing.** — Not alone arc welding, but also (already on a large scale) resistance welding, are being applied in the manufacturing of a wide variety of products of steel and other metals. The use of such methods is increasing at an enormous rate.

**Welding Steel Buildings.** — In England the steel work of the roofs of several large buildings has been joined entirely by arc welding and the saving of time and money as compared with riveting has been shown to be very great. This is likely to be a very important field for electric welding, both arc welding and resistance welding.

**RESISTANCE WELDING.** — The art of welding metals by passing a large alternating current across the surface of contact of the metals to be joined was worked out and made a commercial success by Professor Elihu Thomson in the 60's. This process, which is known as resistance welding, is in general use and is so familiar to all engineers that there is no occasion for more than the briefest review.

In any given application of resistance welding, the engineering problems that relate chiefly to the design of machines for holding the parts, bringing them into suitable juxtaposition, regulating the mechanical pressure and rate of approach of the parts toward one another at various stages of the process of welding; the metal at the surfaces of contact, arresting the process at the proper time, and the regulation of the current to the most suitable amount at all stages of the process. Careful consideration requires also to be given to the proper shapes of the two surfaces to be brought together and of the proportions of the parts in the neighborhood of these surfaces. For some applications the best results are obtained by welding a third (and otherwise superfluous) piece of metal to each of the two parts to be joined.

Most metals in reasonable states of purity can be joined to one another by the resistance process. Welds can also be made between some alloys. Practically all grades of steel are readily welded. Different metals can also, in some instances, be welded to one another. The current, for resistance welding, is usually supplied from the low-voltage secondary of an alternating current transformer, but direct current might under certain circumstances be used to advantage.

**Butt Welding.** — When, in the resistance process, the parts to be welded to one another are "butted" together, the current passing through the entire section of metal near the weld, the term butt welding is often employed. In resistance welding the heat is generated within the metal and not brought in from the outside as in other processes.

**Spot Welding.** — When, in resistance welding, the current is passed transversely across two plates which it is desired to joint at many places (or spots) the term spot welding is employed. Spot welding has been employed for many years for thin plates of metal. It has recently been applied to the welding of steel plates of thicknesses up to one inch. This latter development is described more fully in a later paragraph.

**Seam Welding.** — When, in resistance welding, the point of introducing and carrying away the current moves along a line so as to make a continuous weld along that line, the term seam welding, or line welding, is employed.

**SPOT WELDING OF THICK PLATES.** — Spot welding of thick plates is an alternative to the long established process of riveting and bids fair to be very extensively employed in most kinds of work now using rivets. As important examples may be mentioned the construction of steel ships, steel buildings, and, in general, in many uses of structural steel. Where the parts can be brought to the welding machine, the process is especially attractive. But portable spot welders have been developed and have been used with success in ship construction.

**Duplex Spot Welder.** — (Fig. 1). — The usual construction of commercial spot welders for use in shipbuilding is similar in general appearance to so-called bull-riveters. The largest spot welder yet built for actual use in ship fabrication has a six-foot gap and operates from a 60-cycle circuit. This outfit is a stationary machine in the frame of which two transformers are incorporated and to which the steel plates and shapes are brought. Bulkheads, frames, floors and other parts are constructed with it, and are then transported by cranes to their places in the ship. This six-foot-gap machine has the capacity to weld two three-quarter-inch-thick plates. It provides a pneumatic pressure of 60,000 pounds and a current of 50,000 amperes. It is called a duplex welder and welds simultaneously two spots, each of some 1.5 inch diameter, in about 30 seconds.

The arrangement is shown diagrammatically in Fig. 1. The outfit comprises two transformers, one located on each side of the plates to be welded. The current crosses the plates in one direction between two electrodes and then back again between two other electrodes. Thus the two secondaries and the two joints make four elements connected in series.

Fig. 1. Duplex Spot Welder

represent the two primaries.

represent the two secondaries (which, in the actual construction, have only one turn each).

and *DD* represent water-cooled, copper electrodes.

represent the two plates to be joined.

above-described duplex feature was introduced in this spot-welder to decrease the inductance of the long loop of conductor which otherwise would have been necessary and which would have involved proportioning the transformer secondary for a higher voltage to overcome the inductive drop.

**Table Spot Welder.**— Fig. 2 is a diagram of the circuits of an ordinary (x) spot welder which welds only one spot at a time. In this figure:

represents the primary of the transformer.

represents its secondary.

and *D* represent water-cooled copper electrodes.

and *F* represent the two plates to be welded.

A typical 60-cycle portable welder of this type having a 27-inch gap weighs only 2800 pounds, including the transformer (which is embodied in the handle), and welds plates of a thickness of half inch with a current of about 30,000 amperes. The required pressure for such work is some 25,000

pounds. For experimental work, currents up to 100,000 amperes have been employed in improvised spot welding machines, and pairs of one-inch-thick steel plates have been welded.

**Light Car.**— Although until very recently spot welding has generally been employed only for

joining thin plates, mention should be made of the 50-ton gondola freight car which was completely spot welded in 1911 by Mr. J. A. Osborne, Chief Engineer of the American Car and Foundry Company of St. Louis, Mo. Since that time, this car has been in regular service on the C. B. & Q. R. In 1918, Mr. Osborne reported that the welded joints have successfully withstood the severe stresses of continuous hard use. The spot welder built by Mr. Osborne in 1911 for this undertaking was demonstrated as capable of making sound welds with plates of  $\frac{3}{4}$ -inch thickness. It had a throat and housed an 85-kw. transformer with a secondary giving 1000 volts on open circuit. The welding points of the copper electrodes had a diameter of  $\frac{3}{4}$  inch.

**Welding Versus Riveting.**— Spot welding would appear to have many advantages over riveting for a great variety of important work now done by riveting. By employing spot-welding great savings are realized through eliminating the laying out and punching of the rivet holes, the subsequent reaming when the holes do not match up. Furthermore, it is avoided the reduction in cross-section and strength occasioned by the stretching of the metal for the rivet holes. With spot welding there is a great saving in weight through the reduction in overlap made practicable as compared with two or three rows of rivets which often have to be employed. Tests show that greater strength can be obtained with a single row of spot welds than with a triple riveting.

**Record of Spot Welding.**— At p. 175 of Vol. 38 (1919) of the Trans. A.I.E.E., John Martin of the American Bureau of Shipping reports as follows: One test performed in the writer's presence, 32,000 amperes with a volt-

Fig. 2. Simplex Spot Welder

age of 4, successfully spot-welded pairs of  $\frac{3}{8}$  inch to 2.5 inches ship steel plates together, the diameter of the spots being 1 inch, the pitch 3 inches, and the hydraulic pressure  $7\frac{1}{2}$  tons. The time of the current was 15 seconds. 15 feet was welded in 30 minutes. The spots sheared at 56,000 pounds, or partly pulled and sheared at 60,000 pounds. Water and oil-tight joints resulted without caulking. For plates of the same pitch, caulking or arc fillet welds would be required for water-tight joints; though by lessening the pitch and decreasing the diameters of the spots, practically the same water-tight results could be had."

**Power Required for Spot Welding.**—In a paper entitled *Practical Applications of Electric Welding*, read by F. P. Vaughan on October 15, 1920, before the Engineering Institute of Canada, the following table of data applying to the spot welding of mild steel plates is given:

Thickness of plates, S.W. gage	Total welded thickness, inch	Power, kw.	Time, seconds
24	0.044	4.3	0.6
22	0.056	4.6	0.8
20	0.072	4.7	1.0
18	0.096	5.3	1.2
16	0.128	6.3	1.8
14	0.160	6.6	1.8
12	0.208	8.0	2.5
10	0.256	9.0	3.0

**Spot Welding Combined with Arc Welding.**—Arc welding (described later) may be used in combination with spot welding, the former being relied upon not only for caulking but to contribute to the total strength of the weld. Some tests comparing ordinary riveted joints with this method of spot and arc jointing are described at page 95 of Vol. 38 (1919) of the *Trans. A.I.E.E.* as follows:

The specimens were made up of the following combination:

1. Spot and fillet welded, Fig. 3 (two samples made).
2. Fillet welded—made by welding fillets about two inches in length at the ends of the plates, Fig. 4 (two samples made).
3. Riveted and fillet welded, Fig. 5 (one sample made).
4. Spot welded—made by welding two spots approximately one inch in diameter, on the plates, Fig. 6 (two samples made).
5. Riveted joint, made by riveting a 0.5-inch by 4-inch by 12-inch plate with two plates 0.5-inch by 4-inch by 16-inch with two  $\frac{3}{4}$ -inch rivets and a 4-inch lap. Fig. 7 (one sample made).

FIG. 3 FILLET AND SPOT WELDED

FIG. 4 FILLET WELDED

FIG. 5 RIVETED AND FILLET WELDED

FIG. 6 SPOT WELDED

FIG. 7 RIVETED JOINT

Fig. 7 (one sample made).

results of the test show the comparative strength of the joints as follows:

	Ultimate load, Pounds
End fillet welded (average of tests on two samples).....	50,350
Butt welded (average of tests on two samples).....	37,500
End fillet welded (only one sample made).....	35,000
Butt welded (average of tests on two samples).....	28,000
Butt joint (only one sample made).....	13,000

**Use of Resistance Welding.** — At p. 146 of Vol. 38 (1919) of the *I.E.E.*, Mr. Hermann Lemp, a pioneer in resistance welding, in comparison welding with arc welding (described later), writes as follows:

"One considers the vast quantities of mild steel products daily welded in the United States alone (by the resistance process of Professor Elihu Thomson) and, with unskilled persons operating automatic and semi-automatic machinery, with a speed unexcelled by the arc-welding process, the writer may be pardoned for drawing attention to one characteristic feature of the process; that parts to be welded are substantially protected against contact with oxygen of the air, and what few oxides may be formed near the edges are actively squeezed out of the joint by the pressure exerted on completing the weld."

In addition, all kinds of metals and alloys, some of which are termed "difficult," are successfully welded thereby. Crane chains, harness rings, bicycle rims, bicycle tubing, wire fences, carriage tires, metal wheels, etc., are welded daily in such quantities as would astonish any one when confronted with the actual figures. In the welding of valve flanges to cylinders of Liberty motors at Detroit, the Thomson Process (of resistance welding) easily outclasses the gas and electric-arc processes, as regards both speed and excellence of product."

#### **D OF BUTT WELDING BY RESISTANCE PROCESS AND T OF ELECTRICITY CONSUMED.** — Mr. Vaughan gives the following table as applying to the butt welding of "ordinary bar iron, wheel rims, cycle rims, shafting and piping and various forms of rods, etc." by the Thomson process.

ing table as applying to the butt welding of "ordinary bar iron, wheel rims, cycle rims, shafting and piping and various forms of rods, etc." by the Thomson process.

Section of metal at the weld, square inches	Approximate power consumption		
	Maximum kw. per weld	Duration of weld, seconds	Kw.-hr. per weld
0.25	10	15	0.075
0.50	15	20	0.13
0.70	20	30	0.2
1.0	25	35	0.3
2.0	40	60	0.7
3.0	50	90	1.25
5.0	65	208	3.75
7.0	80	315	7.0
9.0	95	400	10.5
10.	105	428	12.5
11	115	453	14.5
12	125	475	16.5

For butt welding round copper rods by the resistance process, Mr. Vaughn's values are:

Size		Power, kw.	Time, seconds
Diameter, inches	Area, square inches		
$\frac{1}{8}$	0.05	5	4
$\frac{3}{16}$	0.11	7	5
$\frac{1}{4}$	0.20	14	7
$\frac{5}{16}$	0.31	19.5	9
$\frac{3}{8}$	0.44	28	12
$\frac{1}{2}$	0.60	35	14
1	0.79	48	17
$1\frac{1}{8}$	0.99	63	21

**SEAM (OR LINE) WELDING.**—A seam welder may be so designed as to have the weld made between a wheel rolling on a bar, or between two wheels rolling together. For thick plates, the design with two wheels rolling together is probably the most suitable. Mr. R. E. Wagner, who has had wide experience in the design and use of seam welders, has given the writer the following tabulated data applying to the seam welding of mild steel plates:

Thickness of each plate, inch	Speed making line weld, in feet, per minute	Correspond- ing current, amperes	Pressure in pounds per square inch
0.0140	5	3500	2,200
0.0625	2.5	7000	11,000
0.0938	2.5	8000	22,500

In the above table the pressure is calculated on the basis of having a contact area in each case of  $\frac{1}{16}$  square inch.

The voltage of the welding circuit on open circuit may vary from 2 to 10 volts depending upon the impedance introduced into the welding circuit by its design. The actual drop across the weld will vary between  $\frac{1}{4}$  and 1 volt. The plates at the line of welding must be free from scale and rust. A properly made seam weld has a strength at least equal to that of the plates which are welded together.

**PERCUSSIVE WELDING.**—Mr. L. W. Chubb invented the process of percussive welding in 1905.

**Percussive Welding with Static Condenser.**—At that time the method consisted in discharging a static condenser simultaneously with the delivering of a percussive blow in a direction to force together the two metal parts to be welded. The process was applied chiefly to welding together relatively small wires, the largest being No. 12 B. & S. gauge. The ends of the wires are cut with suitable

ters and the resulting chisel edges arranged to make a right-angle inter- thus starting the discharge of energy at a central point of contact.

urrent density is stated to be about 400,000 amperes per square inch. cess is suitable for welding together wires of utterly different material platinum to lead, tungsten to aluminum, and aluminum to copper.

**Electromagnetic Percussive Welding.** — More recently an electromagnetic of percussive welding has been developed by Mr. Chubb and is adapted of heavy work. Stored up electromagnetic energy is released under such as to establish a short arc between the surfaces to be welded. This is reversed by a very heavy current for less than a tenth of a second and in that time to melt these surfaces. They are immediately forged by a hammer blow. The secondary current approximates 30,000 per square inch at an arc drop of from 20 to 40 volts, and it only flows a fraction of a second. The heat is so localized that the weld is effected with expenditure of a minimum of energy. It is claimed that the energy per weld is only a very small part of that required in resistance welding. With the electromagnetic process of percussive welding parts up to  $\frac{1}{4}$  meter are readily welded and it is anticipated that the method will soon be applied to be applicable to much larger welds.

**Field of Application for Percussive Welding.** — It is claimed that percussive welding permits of readily welding together very unequal sections, since the duration of the process precludes difficulties due to unequal heating or difference in melting points. For example, small rods may be welded to heavy plates. In tool manufacture, steel alloys may be welded to steel. Brass and copper parts may, by the percussive process, be welded to steel parts. Percussive welding has been described in more detail or presented by Mr. Chubb before the American Electrochemical Society, October, 1912 and more recent developments have been described by F. Miner before the A.I.E.E., in June, 1920.

**ELECTRIC ARC WELDING.** — The technique of electric arc welding is usually nothing in common with that of butt and spot welding, although usually identical objects are in some cases obtained by both methods. However, the associated circumstances will indicate which of the two electric welding should be employed. While butt welding and spot welding are applicable to almost all kinds of metals, electric arc welding is confined to the welding of steel.

Entering upon the consideration of electric arc welding, it should be stated that it is one of the two main subdivisions of an art which is often designated **autogenous welding**, but which will here be designated **fusion**

**Welding.** — The term fusion welding is employed to comprise gas and electric arc welding. Gas welding does not come within the scope of this article, and it must suffice to state that the process in its simplest form consists of simultaneously fusing with an oxyacetylene flame (1) the material to be joined, and (2) some material (which is similar in composition) in the form of a rod, the tip of which is subjected to the heat of the flame. The oxyacetylene flame is directed with one hand and the welding rod is manipulated with the other hand.

**Classification of Electric Arc Welding.** — Electric arc welding may be subdivided into several classes. The two broadest classes are:

- a. Carbon arc welding.
- b. Metal arc welding.

In carbon arc welding, an arc (usually several tenths of an inch in length) is established between a carbon or graphite electrode (usually a carbon electrode) and the two pieces of steel which it is desired to join. This carbon electrode is manipulated with one hand and a welding rod is fed into the weld by the other hand. The manual activities in carbon arc welding are seen to be quite similar to those in gas welding. In neither case is it necessary for the material of the welding rod to traverse the arc.

In metal arc welding, there is a fundamental difference in this latter respect since in metal arc welding of mild steel, instead of having a carbon electrode for one terminal of the circuit, the arc is established between a steel welding rod (or welding electrode) and the two steel parts requiring to be joined. There is always a distance of preferably not over one-tenth of an inch between the tip of the welding rod and the work. This distance is bridged by an electric arc.

**Kinds of Work Not Requiring Welding Rod.** — Both for carbon arc welding and gas welding, the edges of the parts to be joined sometimes may be so designed as to obviate the need for any additional material; in other cases no welding rod is necessary in such cases. In Fig. 8 is shown a case where it is not necessary to use a welding rod, since it suffices to simply melt the adjacent flanges with an arc.

**Comparison of Cost of Gas Welding with Cost of Arc Welding.** — Quite a thorough comparison of gas welding with metal arc welding was made in 1917 by Major James Caldwell, then of the Controller's Department of the British Admiralty. This comparison is reproduced at p. 85 of Vol. 38 (1919) of the *Trans. A.I.E.E.* Since that date there has been a great deal of careful work given to the subject. For thoroughly first class welds, the speeds formerly credited to gas and arc welding are not obtained even by the most skillful operators. The author has made every effort to arrive at reasonable values for the various data involved and has compiled the results in the following table which is representative of his opinion. The table indicates that gas welding has an advantage over metal arc welding for plates of  $\frac{1}{16}$  inch thickness, both as regards speed and cost. From  $\frac{1}{8}$  inch to  $\frac{3}{8}$  inch thickness, the author found both methods with the same speed, but the advantage as regards lower cost increases rapidly for the metal arc method with increasing thickness of plate. For thicknesses of  $\frac{1}{16}$  inch and  $\frac{1}{8}$  inch both speed and cost are very decidedly in favor of metal arc welding. The costs (1921 basis) by the two methods are plotted in the curves in Fig. 9. Plenty of authority can be found for disagreement with the present author's results, since speeds over twice as great as those in the table have often been claimed by welding specialists as being representative. The speeds in the table are such as can be maintained by a fairly skilled welder during an eight-hour day and under thoroughly favorable conditions. The plates to be welded are assumed to be laid flat and at a convenient height for the operator to work. It is also assumed that the edges have been prepared and that the plates are clamped and all ready for welding. As regards the consumption of electricity it is assumed that the welding is done from a 110-volt circuit with a rheostat in series with the electrode. With a motor-generator set the consumption would not be enough different to much affect the aggregate cost of (1) electricity, (2) electrodes, and (3) labor.

**Welding Machinery.** — The voltage at the arc is only some 15 to 20 volts, consequently while welding, some 85 per cent of the electricity consumed is wasted in the rheostat when operating from a 110-volt circuit. By interposing a motor-generator set transforming to lower voltage, the efficiency while welding may be considerably increased notwithstanding the losses in the motor

Fig. 8.

			Oxy-Acetylene					Metal arc (bare electrodes)

generator set. But in the intervals between welds there are no losses with the former outfit, while with the latter outfit the running light losses in the generator set detract from the "all-day" efficiency. It will be readily

Fig. 9.

that all the attendant circumstances must be taken into consideration in determining upon the most suitable plant to install for arc welding.

Each of several manufacturers has placed on the market types of welding apparatus with characteristics for which advantages are claimed and realized. Even brief descriptions would occupy too much space for this article. Farther more it is the author's opinion that substantially equally good arc welding can be done with any of the best known types of machines, and it resolves itself down to a question of relative costs and economy of operation. These factors should be given careful comparative study before purchasing a welding plant but it is much more a question of economics than of obtaining the best weld. This latter object depends chiefly on having good operators and good material.

With a-c. welding a transformer is employed, but while the efficiency is good the power factor is very bad. This does not disqualify a-c. arc welding, but should be taken into account in balancing the advantages and disadvantages.

**Speed of Arc Welding and Energy Consumption.** — The speeds of making butt welds by the arc process with various thicknesses of steel set forth in the preceding table are not necessarily applicable to other than the material there employed and all the attendant circumstances. The attainable speed for first class arc welds is a function of (1) the skill and disposition of the operator, (2) the kind of circuit from which he welds and the characteristics of the intermediary welding apparatus and the voltage, (3) the length of the arc which the operator

solds (the shorter the arc, the better the work, but the slower the speed), (2) the kind and quality of the electrodes employed, (3) the positions of the plates to be joined (whether flat on a bench at a convenient height as the one shown, or overhead or inaccessible as the other extreme), (4) the kind and quality of the steel to be welded, (5) the thickness or size of the material to be welded, (6) the preparation of the edges of the surfaces.

In an article by Mr. William Spraragen titled *Speed of Metal Arc Welding*, published at p. 44 of the *Welding Engineer* for June, 1920, the author refers to Figs. 10, 11, 12 and 13 as typical designs for

welded joints and, based on some extensive tests which he has made, suggests as

safe speeds capable of being sustained for long hours when welding half-inch thick ship plates, and allowing reasonable time for changing electrodes and making minor adjustments.

## Number of figure

## Speed of welding

10.....	1.7 feet per hour
11.....	1.5 feet per hour
12.....	2.3 feet per hour
13.....	2.5 feet per hour

**Speed of Arc Welding in Pounds of Electrode Material Deposited per Hour.** — Spraragen states that the average results of a vast amount of tests show that an operator can deposit about 1.2 pounds of metal per hour when working out in the open (as on ships), with the usually attendant general inconvenience and also the disadvantage of liability of air currents; as against about 1.8 pounds of metal per hour in the shop. Both these figures are based on the assumption that the work has been lined up and is ready for welding.

#### TIME, METAL AND CURRENT USED WITH WELDS OF DIFFERENT BEVELS

Total opening of bevel in degrees.....	30	60	90	120
Ultimate strength in pounds per sq. in.	44,000	51,000	45,300	48,800
Angle of bend in degrees at which cracks first start.....	9	15	13	14
Amps.....	160	145	118	125
Weight of electrode used up (pound).....	2.56	3.83	4.63	6.63
Weight of metal deposited (pound).....	1.70	2.53	3.63	5.08
Weight of metal wasted (pound).....	0.86	1.28	0.98	1.55

Feet welded per hour.....	3.22	1.90	1.50	1.07
Circuit kilowatts.....	9.91	9.00	7.68	8.25
Kilowatt-hours per foot of weld.....	3.10	4.70	5.10	7.70
Pounds deposited per foot of weld.....	0.57	0.85	1.21	1.69
Pounds deposited per kw. hour.....	0.18	0.18	0.34	0.22
Pounds of electrode used up per kw. hour.....	0.27	0.27	0.30	0.29

**Allowance for Waste of Electrode Material.**—Based on research involving the welding of ten tons of half-inch-thick ship plate, Spraragen has concluded that out of 100 per cent weight of electrode,

- 70 per cent is deposited in the weld,
- 12 per cent is burned or vaporized,
- 18 per cent is wasted as short ends.

**Angle of Bevel of Welding Edges.**—As to the effect of the preparation of the welding edges on the speed of welding and the quality of the weld, tests were made by Spraragen at the author's request. In each case  $\frac{1}{2}$ -inch thick ship plate was used, and a weld 3 feet long was made in a flat position with  $\frac{5}{16}$ -inch diameter bare electrode and a "free distance" of  $\frac{1}{4}$  inch. The weld plates were cut up and subjected to standard tensile and bending tests. The results are shown in the table at bottom of page 1955.

Fig. 14

Fig. 15

**Preparation of Bottom Edges.**

—In Figs. 14 and 15, Spraragen shows two specimens of half-inch plate both prepared with 60-degree edges, and with the same "free distance" of  $\frac{1}{4}$  inch. In Fig. 14 the bottom edges are sharp, while in Fig. 15 shoulders are provided. The results were:

Fig. No.	Speed of welding, feet per hour	Pounds of electrode wire needed per foot of weld	Pounds of electrode wire used up per hour
14	2.3	1.1	2.3
15	2.8	0.9	2.5

**Wagner's Tests of Relation of Speed to Current.**—With skilled welders the speed of arc welding may be increased considerably when larger currents are employed. Also, up to a certain value, the strength of the weld is greater the greater the current. This is brought out by Mr. R. E. Wagner in a series of tests on  $\frac{1}{2}$ -inch tank-steel plates. The plate edges were prepared with

Current in amperes	Size of electrode, inch	Tensile strength in pounds per sq. in. after grinding off the raised parts of the welds
80	$\frac{5}{16}$	37,000
125	$\frac{5}{16}$	50,000
150	$\frac{5}{16}$	57,000
180	$\frac{5}{16}$ and $\frac{9}{16}$	53,000
220	$\frac{5}{16}$ and $\frac{9}{16}$	66,000
275	$\frac{9}{16}$	62,000
300	$\frac{9}{16}$	58,000

## Welding, Electric

ic V. Two sizes of Roebbing electrodes were used,  $\frac{3}{16}$ -inch and  $\frac{1}{4}$ -inch; pressure was maintained constant and the d-c. current was varied from 50 amperes up to 300 amperes. The results are shown in the following table.

The type of joint is illustrated in Fig. 16 under the heading "Type of Joint." The results are plotted with currents as abscissas and tensile strength ordinates. Wagner stated that "reduction in tensile strength beyond 220 amperes is apparently due to the increased porosity of the deposited metal and difficulty of manipulation." For a complete record of Mr. Roebbing's investigations refer to pages 157 to 160 of Vol. 38 (1919) of *E.E.*

Fig. 16. Tensile Strength versus Current in Electric Arc Welding.

For further Data of Speed and Cost of Arc Welding with Bare Electrodes, see a 1920 General Electric Company bulletin the following data are given for the speed and cost of metal arc welding with bare electrodes and of gas

Metal arc welding			Comparative cost per foot for acetylene welding
Thickness of plate, inch	Speed, in feet per hour	Cost per foot, cents	
$\frac{1}{16}$	20	2.1	1.8
$\frac{1}{8}$	16	3.1	4.7
$\frac{3}{16}$	10	7.1	13
$\frac{1}{2}$	6.5	13	36
$\frac{3}{4}$	4.3	20	Much higher
$\frac{7}{8}$	2.0	42	Much higher
1	1.4	61	Much higher

**Suitable Size of Electrode and Current for Various Thicknesses of Plate.** — In the following table Spraragen gives representative values for the size of electrode and the current to be employed in welding mild steel plates.

Electrode diameter, inch	Plate thickness, inch	Amperes
$\frac{3}{16}$	up to $\frac{1}{8}$	25 to 40
$\frac{1}{8}$	up to $\frac{1}{4}$	50 to 90
$\frac{3}{16}$	$\frac{3}{16}$ to $\frac{1}{2}$	75 to 160
$\frac{1}{4}$	$\frac{1}{4}$ up	125 to 200
$\frac{5}{16}$	$\frac{1}{2}$ up	175 to 250

**Data of Speed and Cost of Welding a Large Steel Tank with Bare Electrodes.**— In 1918, Wagner welded a 12-foot-cube tank of half inch steel and purposely employed a great variety of types of joint including those already shown in Figs. 10 to 13 and also those shown below in Figs. 17 to 20, and a number of other types. The speed of welding was 3.0 feet per hour. The weight of the steel in the tank was 16,000 pounds, and the weight of electrode used up was 334 pounds, of which 299 pounds was deposited in the welds. The total welding time was 165 hours, corresponding to using up electrodes at the rate of just 2 pounds per hour. The total length of weld was 501 feet, the weight of electrode used up per foot of weld thus being 0.60 pound. 0.29 pound of welding wire was deposited and 0.33 pound was used up per kilowatt hour of electricity. The diameter of the welding wire was  $\frac{3}{16}$  inch. Six different operators worked on the job and the average current per operator (when actually welding), was 13 amperes. The per cent of time welder was welding was ascertained to be 65 per cent.

Fig. 17

Fig. 18

Fig. 19

Fig. 20

**Automatic Arc Welding.**— Machinery has been developed permitting automatically feeding the welding wire at such a rate as to maintain a steady and very short arc. A direct current type has recently (1920) been developed for the General Electric Company by Mr. P. O. Noble. Any variation in the length of the arc is immediately corrected by an automatic alteration in the speed of the motor controlling the rate of feed of the welding wire. With this machine the speed of welding is from two to five times as fast as with the best hand operators. Time lost in changing electrodes is eliminated by the use of reel welding wire. This also eliminates the waste of short ends which occurs in hand welding with the usual 18-inch straight welding rods. As further advantages may be mentioned the even deposit of the electrode metal which minimizes defects and produces uniform welds which are stronger and more effective than with the hand process. The uniform arc and uninterrupted feed reduce the power consumption.

At pages 150 to 157 of Vol. 38 (1919) of the Trans. A.I.E.E., Mr. H. D. Morse describes his work in the development of automatic and semi-automatic arc welding machinery and gives illustrations of a semi-automatic machine and some work done with it.

**Flux-covered Electrodes.**— In America practically all metal arc welding is done with bare-wire electrodes. In England, on the contrary, flux-covered electrodes are much the most extensively employed. The limits of space will not permit describing the nature and variety of the flux coverings employed.

From the lack of interest displayed in America on the subject of flux-covered electrodes, it may be inferred that for the great bulk of electric arc welding entirely adequate results are obtained by the much cheaper bare electrode. The author's opinion is, however, that a higher grade of work can be obtained by the use of suitable flux-covered electrodes in the hands of operators skilled in their use. Especially with respect to ability to withstand tests of their ductility and to withstand fatigue tests he believes that welds can be made with flux covered electrodes which can probably not be equalled with bare wire electrodes. It would not appear that this justifies the greater outlay, for ordinary

c. The use of electrodes with other than the very best flux-coverings may lead to welds much inferior to those obtained with bare electrodes of good quality.

The present (1921) cost of flux-covered electrodes ranges from 60 cents per pound for electrodes with steel cores of  $\frac{1}{16}$ -inch diameter down to 40 cents per pound for those of 0.16-inch diameter. Taking a mean value of 50 cents per pound of steel in the electrodes, and assuming for the speed of welding, quantity of electrodes and amount of electricity per foot of weld, the values taken in the table previously given for bare electrodes, there results for the cost per foot in the two cases the following values:

COMPARATIVE COSTS OF MANUAL BUTT WELDING FOR  
VARIOUS THICKNESSES OF MILD STEEL

Thickness of metal, inches	Speed of welding, feet per hour	Outlay in cents per foot of weld, for (1) electricity, (2) electrodes, and (3) labor	
		Using bare electrodes	Using flux-covered electrodes
$\frac{3}{16}$	16	6.0	7.3
$\frac{1}{4}$	13	8.0	10.2
$\frac{5}{16}$	10	11.0	14.8
$\frac{3}{8}$	8	14.0	19.0
$\frac{7}{16}$	6	18.8	25.7
$\frac{1}{2}$	4 $\frac{1}{2}$	25.1	34.2
$\frac{5}{8}$	3 $\frac{1}{2}$	32.9	45.5
$\frac{3}{4}$	3	41.7	60.7

**D-C. and A-C. Electricity for Arc Welding.** — Arc welding is, in America, usually done with d-c. electricity. In England a-c. electricity is in much greater use than in America for arc welding. It is more difficult for the welder when a-c. is used, especially when he employs bare electrodes. But with some kinds of flux-covered electrodes, a-c. may be used without any notable difficulty in manipulation as compared with direct-current. When a-c. is used, every precaution should be taken to guard the operator from shock, notwithstanding the low voltage employed.

**Comparison of Strengths of Riveted and Arc Welded Joints.** — p. 870 of the *General Electric Review*, for December, 1918, Mr. H. Jasper Cox of Lloyd's Register of Shipping, published the following tabular comparison of the tensile strengths of riveted and arc welded joints of ship plates of half-inch and three-quarter inch thickness.

Thickness, inches	Diameter of rivet, inches	Total sectional area, square inches	Breaking stress, pounds per square inch	Strength of plain plate, pounds per square inch	Percent strength of joint
<b>Triple-riveted lap joints</b>					
0.49	$\frac{3}{8}$	.....	42,400	61,400	69.0
0.53	$\frac{3}{8}$	.....	58,900	54,700	62.5
<b>Lap weld with full fillet at both edges</b>					
0.514	.....	10.02	45,300	63,600	71.0
0.73	.....	8.76	40,330	59,600	68.0
<b>Butt weld (not strapped)</b>					
0.505	.....	10.66	51,000	63,600	80.0
0.76	.....	9.88	54,680	59,600	91.5

**Comparative Costs of Joining Ship Plates by Riveting and Welding**  
 The following are British figures and would not necessarily apply in America but they give a good illustration of tendencies. They are taken from an article by Caldwell in *The Times Engineering Supplement* for April, 1920.

Thickness of plate in inches	Description of joint	Diameter of rivets, inches	Cents per foot *
$\frac{3}{16}$	Single riveted lap	$\frac{3}{8}$	43
	Light welded lap	.....	30
	Double riveted lap	$\frac{3}{8}$	81
	Heavy welded lap	.....	40
$\frac{1}{2}$	Single riveted lap	$\frac{3}{8}$	51
	Light welded lap	.....	38
	Double riveted lap	$\frac{3}{8}$	91
	Heavy welded lap	.....	47
	Double butt strap	$\frac{3}{8}$	120
Heavy butt weld	.....	47	

\* On the basis of one pound sterling = \$4.

**CARBON ARC WELDING.**—Where carbon electrodes are used, the electrode is connected to the negative terminal of the circuit. The process is especially suitable for quick work requiring the making of large quantities of material, such as in filling blow holes and in salvaging defective castings and forgings. It is also used for much other work, such as welding long seams which may be so designed with abutting edges as to permit of effecting the weld simply fusing these edges without adding electrode material. An example of such a joint has already been given in Fig. 8.

carbon arc welding the arc is very long (of the order of an inch or so), and considered that this entails the disadvantage that the weld may be badly sed.

**Current Employed in Carbon Welding and Size of Electrodes.** — A reliable trade bulletin gives the accompanying data as reliable values for the current for carbon arc welding.

Class of work	Amperes
Light welding	150 to 250
Medium welding	250 to 350
Heavy welding	400 to 600
Very heavy welding	600 to 1000

The same bulletin gives the accompanying data for the maximum current for carbon electrodes of various sizes.

Diameter of carbon electrode, inch	Maximum current, amperes
$\frac{1}{8}$	100
$\frac{1}{4}$	300
$\frac{3}{8}$	500
1	1000

Higher currents can be used by employing graphite electrodes, but their higher cost usually disqualifies them for use as welding electrodes.

**Speed of Carbon Arc Welding.** — It is found that for depositing or building up metal on flat surfaces where the work is accessible and under otherwise favorable conditions the following data hold:

Current in amperes	Pounds of metal deposited per hour	
	For continuous work	For short jobs of 10 minutes or less
200	1.5	3
300	3.0	6
400	4.5	9
500	6	12

Carbon arc welding, in virtue of the higher current customarily employed, is a much faster process than metal arc welding.

**Automatic Welding with the Carbon Arc.** — Automatic machinery has been in use for several years for welding together abutting flanges with the carbon arc.

With the kinds of joint shown in Fig. 8 it is not necessary to supply any additional metal. The carbon simply travels along parallel to the abutting flanges and the arc raises their temperature to the point where they flow together. Carbon arc welding is usually performed with direct current but sufficient success will probably lead to the development of successful welding with carbon electrodes and an a-c. arc.

In the *Journal of the American Welding Society*, first published in 1922, will be found recorded the most recent developments in Electric Welding.

**WIND PRESSURE.**—(See also *Structures, Simple; Transmission Lines.*) Wind pressure is a subject upon which little exact information exists, although many experiments have been made and much study given to the subject by engineers and scientists. Among the unsettled questions are:

The relation between pressure and velocity.

The variation of pressure with size and shape of exposed plane surfaces.

The direction and intensity of pressure upon non-vertical surfaces.

The intensity of pressure upon non-planar surfaces.

The total pressure upon a number of parallel bars or other members placed by side.

The decrease of pressure upon leeward surfaces.

The lifting power of the wind.

**RELATION BETWEEN INDICATED (U. S. WEATHER BUREAU) WIND VELOCITY AND ACTUAL VELOCITY.**—The indications of the anemometers used by the U. S. Weather Bureau do not give the *actual* wind velocity, but give values considerably higher than the actual velocities, as shown in the following table:

**RELATION BETWEEN INDICATED AND ACTUAL WIND VELOCITY**

Indicated Velocity, mi. per hr.	Actual Velocity, mi. per hr.	Indicated Velocity, mi. per hr.	Actual Velocity, mi. per hr.
10	9.6	60	48.0
20	17.8	70	55.2
30	25.7	80	62.8
40	33.3	90	69.3
50	40.8	100	76.2

As the U. S. Weather Bureau reports the indicated and not the actual wind velocities are given. However, as the anemometers used give the *average* velocity over several minutes, the instantaneous velocities due to sudden gusts may be considerably greater than the indicated velocities; the indicated velocity probably more nearly represents the "gust" velocity than the actual average velocity. In all calculations of maximum wind pressure it is therefore recommended that *indicated* velocity be used.

**RELATION BETWEEN PRESSURE AND VELOCITY.**—The pressure varies about as the square of the velocity, the results given by different experimenters for the pressure due to a *normal wind on a plane surface* range from

$$P = 0.005V^2 \text{ to } P = 0.0032V^2,$$

where  $P$  = pressure in pounds per square foot,

$V$  = actual wind velocity in miles per hour.

The latter of these values represents the results of unusually careful experiments by Stanton (see *Minutes of Proceedings of the Institute of Civil Engineers*, *ts. 156 and 171*) upon the intensity of pressure on plates varying in size from 1 to 100 square feet and is probably more nearly correct than the higher value. In the Stanton formula the values are reduced to correspond to a temperature 60° F. and an atmospheric pressure of 14.7 pounds per square inch.

The influence of size and shape of exposed surface is an important question and is not well understood, although it is known that the resultant pressure on a large surface may be taken as less per square foot than that on a small

surface, since the maximum intensity of the wind is due to gusts of comparatively small cross-section.

**Formulas for Pressure on Plane Surfaces when Wind is not Normal.** — The pressure upon vertical plane surfaces may be taken as normal to the surface and equal in intensity to the assumed wind pressure. Upon surfaces which are not vertical, the pressure is usually considered to be normal to the surface but lower in intensity than upon vertical surfaces. The variation in pressure with respect to the slope is not well understood and a number of empirical formulas are in use, among which are the Duchemin formula

$$P_n = P \frac{2 \sin i}{1 + \sin^2 i},$$

and the Hutton formula

$$P_n = P (\sin i)^{0.81 \cos i - 1},$$

where  $P$  = intensity of normal pressure upon the vertical surface,  
 $P_n$  = intensity of normal pressure upon the given surface,  
 $i$  = angle made by surface with the horizontal.

The following theoretical formula results from the assumption that the wind always blows in horizontal lines, and that if the pressure be resolved into normal and tangential components, the tangential component may be neglected:

$$P_n = P \sin^2 i.$$

This formula gives lower values than the empirical formulas and probably give too low results since it makes no allowance for the reduction in pressure on the leeward side which is known to occur, and which may in part be attributed to the influence of the tangential component. It should also be noted that the wind does not blow uniformly in horizontal lines but may deviate considerably from the horizontal.

The values given by these three formulas are tabulated for comparison, with an assumed value of 30 pounds per square foot for  $P$ . In the absence of further experience upon this phase of wind pressure it would seem wise to use one of the empirical formulas instead of the theoretical one. The Hutton formula is used quite generally by structural engineers in England and the United States.

**Pressure on Non-Planar Surfaces.** — The pressure upon non-planar surfaces is important in the case of chimneys, standpipes, and other similar objects.

Upon the same assumptions as made in the preceding paragraph it may be demonstrated that theoretically the pressure on a cylinder is two-thirds of the total pressure on a plane diametrical section. This value is quite generally used. The pressures thus obtained lack experimental proof but are probably more nearly correct than the pressures obtained by the same method upon plane surfaces.

**Effect of Reduction of Pressure on Leeward Side.** — The pressure upon the windward side of an exposed surface is a function of the density and velocity of the air currents. The pressure on the leeward side is also a function of the shape of the surface, and has been shown by numerous experiments to be less than the static pressure of the air current. The resultant total pressure upon a surface is in consequence not only a function of the direct pressure on the windward side, but also of the pressure on the leeward side, which in turn is a function of the form of the surface. No algebraic formula can be given which will give the pressure on surfaces of varying shape with any considerable degree of precision.

**Wind Pressure on Wires.** — H. W. Buck (*Trans. Inst. Elec. Eng. St. Louis, 1904, Vol. 2, p. 318*) gives the following formula for the pressure due to a normal wind on a stranded wire:

$$P = 0.0025V^2,$$

## WIND PRESSURE IN POUNDS PER SQUARE FOOT

 $P = 30$  pounds per square foot

Angle $\theta$ , degrees	Theoretical	Dachstein	Hutton
	$P \sin^2 \theta$	$\frac{P \sin \theta}{1 + \sin^2 \theta}$	$P(\sin \theta)^{1.84 \cos \theta - 1}$
5	0.0	5.2	3.9
10	0.9	10.1	7.3
15	2.0	14.6	10.5
20	3.5	18.4	13.7
25	5.3	21.5	16.9
30	7.5	24.0	19.9
35	9.9	25.8	22.6
40	12.4	27.3	25.1
45	15.0	28.3	27.0
50	17.6	29.0	28.6
55	20.2	29.4	29.7
60	22.5	....	....
65	24.6	Above 60 deg. use 30 lb.	Above 60 deg. use 30 lb.
70	26.4		
75	28.0		
80	29.1		
85	29.7		
90	30.0		

where  $P$  is the pressure in pounds per square foot of projected area of wire (length times diameter) and  $V$  is the velocity in miles per hour. This formula based upon tests made on a 950-foot span at Niagara Falls; the wind velocities were measured by a U. S. Weather Bureau anemometer corrected to give actual average velocities.

**PRACTICAL RULES FOR WIND PRESSURE ALLOWANCE.**—The many uncertainties connected with wind pressure make worthless the attempts to specify with precision its magnitude and direction. In the lack of additional information and further theoretical studies there seems to be no reason for deviating from the common rules which have been used for many years with satisfactory results.

**Bridges.**—The portal, vertical and horizontal bracing are usually proportioned for a wind pressure of 30 lb. per sq. ft. on the surface of the applied load, and on the exposed surfaces of the floor system and both trusses. The pressure on the applied load is considered as a moving live load, and the other pressure is a dead load. For structures of ordinary spans the wind stresses are computed upon the unloaded structure for a pressure of 50 lb. per sq. ft. In the design the maximum stress computed by either of the above methods is used.

**Buildings.**—For wind pressure on roofs and buildings it is common practice to allow 30 lb. per sq. ft. acting horizontally upon the sides and ends of buildings, or on the vertical projection of roofs. It is also very important to figure the wind stresses on the steel frame considering it as an independent structure without walls, floors or partitions, since failures often occur in erection.

**Transmission Poles and Towers.**—For transmission towers a pressure as low as 13 lb. per sq. ft. has been used. This is perhaps warranted by the

fact that such towers are comparatively low and not exposed to the highest wind pressure. In the report of the Joint Committee on Overhead Line Construction (*Trans. N.E.L.A.*, 1911, Vol. 2, p. 521) the following is recommended: "The wind pressure on the poles, or towers, shall be assumed at 13 lb. per sq. ft. of the projected area of solid or closed structures and  $1\frac{1}{2}$  times the projected area of latticed structures."

**Wire Spans.**—In the report of the Joint Committee just referred to it is recommended that the spans be designed for "a wind pressure of 8.0 lb. per sq. ft. on the ice-covered diameter (ice coating  $\frac{1}{8}$  inch in thickness), at a temperature of 0° F."

**LIFTING POWER OF WIND.**—In the case of a very rapid reduction of atmospheric pressure, as in a tornado, it is often observed that building roofs are lifted and walls blown outward. This phenomenon is due to the air in the building which is under more or less restraint, changing pressure less rapidly than the outside air and thereby producing a difference in pressure. This lifting action doubtless occurs to a greater or less degree whenever the external pressure is reduced, and should be guarded against by anchoring roofs securely to the walls.

A wire may be either solid or stranded, i. e., made up of a number of smaller wires twisted or braided together. A large bare stranded wire is usually called a cable. Data on the insulation and protection of wires and cables will be found in the article on *Wires and Cables, Insulated*. Data on resistance will be found in the article on *Wires, Resistance*, and data on the properties of the various metals will be found in the articles on *Aluminum, Copper, and Steel*.

**PER CENT CONDUCTIVITY.** — The definitions, constants and tables in this article are all in accord with the 1920 edition of the *Standards of the A.I.E.E.* Per cent conductivity refers to the "International Annealed Copper Standard." The assumption of a resistivity temperature coefficient of 0.00393 at 20° C. means that per cent conductivity is only 0.283 per cent higher than the conductivity referred to Matthiessen's Standard (see *Resistance and Conductance*). If the length of a given wire is  $L$  cm., its cross-section  $A$  sq. cm. and its resistance at 20° C. is  $R_{20}$  ohms then the per cent conductivity of this wire is

$$C = \frac{15.328 L}{88,900 A R_{20}} \quad \text{per cent.}$$

Annealed or soft-drawn copper usually has a conductivity of 100 per cent, hard-drawn copper a conductivity of about 97 per cent. Ordinarily hard-drawn aluminum has a conductivity of 61 per cent. The conductivity of iron and steel wire ranges from 8 to 16 per cent.

**DIMENSIONS, RESISTANCE AND WEIGHT.** — The following tables for copper and aluminum are compiled from the tables in *Circular 14, 31 of the Bureau of Standards*, except that for stranded aluminum on p. 1977. The table for steel wire is compiled from that published by the American Steel and Wire Co.

## SOLID COPPER WIRE

\*Let  $C$  = per cent conductivity,  $R_m$  = resistance of 61 per cent conductivity wire at 20° C. (from table),  $R_c$  = resistance of wire of conductivity  $C$  at any temperature  $T$  C. then

$$R_c = \frac{61 R_m}{C} (1 + 0.004 (T - 20))$$

## ALUMINUM CABLES

commercial sizes of stranded aluminum cables, made by the Aluminum Company of America, are not circular mil or A. W. G. sizes, but are of such sections as to give the same conductivity as even circular mil and A. W. G. of copper cables of 97 per cent conductivity. In the following table the diameters and the seventh columns are taken from a pamphlet entitled "Instructions for Installation and Maintenance of Aluminum Electrical Conductors" by the Aluminum Company of America, in 1914.

W. G. gage or circular mils		Usual number of strands	Diameter of bare cable, inches	Resistance at 35° C. or 97° F.*		Weight in pounds	
per (97 cent) valent	Aluminum 61 per cent			Ohms per 1000 feet	Ohms per mile	per 1000 feet	per mile

\*Let C = per cent conductivity.

$R_{12.5}$  = resistance of 12.5 per cent conductivity wire at 20° C. (from table).

$R_t$  = resistance of wire of any conductivity C at any temperature  $t^{\circ}$  C.

then

$$R_t = \frac{12.5 R_{12.5}}{C} (1 + 0.006 (t - 20)).$$

The temperature coefficient is approximate only.

per-clad Steel Wire. — This wire consists of a steel core and a coating of copper permanently welded thereto. It is used chiefly for long transmission and telephone wire. It is made in several grades, which vary in the relative amounts of steel and copper. The grades are designated by corresponding conductivity expressed as per cents of Matthiessen's standard; e.g., 40 per cent grade has a conductivity of 40 per cent.

C = per cent conductivity.

 $R_{40}$  = resistance of 40 per cent conductivity wire at 23.9° C. (from table). $R_t$  = resistance of wire of conductivity C at temperature  $t^{\circ}$  C.,

$$R_t = \frac{40 R_{40}}{C} (1 + 0.00433 (t - 23.9)).$$

temperature coefficient is approximate only.

by Wires of High Tensile Strength. — Copper alloys having a low conductivity, but having a tensile strength from 50 per cent to 100 per cent higher than that of copper are sometimes used where strength or hardness is a primary requisite, as in long spans of small wires or for trolley wires. The Ingersoll Brass Co. make a wire known as "phono-electric wire" which has a conductivity of 25 per cent and a tensile strength ranging from 66,000 lbs per square inch for No. 0000 B. & S. gauge to 85,000 pounds per square inch for No. 18 B. & S. gauge.

**Trolley Wire.** — Trolley wires of two different sections are in use in the United States. The sections shown in Fig. 1 are known as the "American Standard" and the sections shown in Fig. 2 as the "Figure 8" sections.

Fig. 1. American Standard Trolley-wire Sections

American Society for Testing Materials recommend that the sizes be specified in circular mils, and not as gage numbers; the sizes shown in the figure are in the area of the cross-section from the gage numbers given in parentheses less than 5 parts in 1000.

Fig. 2. "Figure 8" Trolley-wire Sections

Trolley wires are usually of hard-drawn copper; the electrical and mechanical properties are the same as for round hard-drawn wire of the same cross-section. Copper alloys, such as phono-electric wire (see above), are sometimes used for trolley wires.

**FACTORS AFFECTING DIMENSIONS, WEIGHT AND RESISTANCE OF STRANDED WIRES.** — Individual stranded wires or cables are of four different types, namely: (a) bunched wire; (b) wire braids; (c) concentric-lay cables and (d) rope-lay cables.

**Bunched Wires.** — Bunched wires are used especially for those extra small cables known as cords, wherein the individual wires are so small that concentric stranding is not necessary to keep them together. The wires are assembled parallel and then generally given a slight twist. Sometimes they are kept together by being wound with soft cotton thread which also serves to prevent adhesion between the insulation and wires.

**Wire Braids.** — In the flat form, wire braids are used for potential leads, and in lighting cables, where a flexible flat conductor is necessary. Tubular wire braids are also frequently formed over the insulation of cables in order to afford mechanical protection. Cables for naval or military purposes and for automobile work are frequently thus protected.

**Concentric-lay Cables.** — A concentric-lay cable is a stranded conductor composed of a central core surrounded by one or more layers of helically laid

A rope-lay cable is a stranded wire made up in the same manner by stranded wires instead of individual solid wires for the core and layers. Cores of concentric-lay cables may be composed of one, two, three or four of equal diameter. A five or six wire core would not be symmetrical seven wires would themselves constitute a core and a layer.

**Number of Wires in Concentric-lay Cables.** — The following table lists all the possible concentric-lay cables with eight or less layers of equal wires and formulae for calculating the number of wires with any number layers.

### NUMBER OF WIRES IN CONCENTRIC-LAY CABLES

(All wires of same diameter)

Number of layers over core	Number of wires in core			
	1	2	3	4
0	1	3	3	4
1	7	10	12	14
2	19	24	27	30
3	37	44	48	52
4	61	70	75	80
5	91	102	108	114
6	127	140	147	154
7	169	184	192	200
8	217	234	243	252
<i>n</i>	$3n^2 + 3n + 1$	$3n^2 + 5n + 3$	$3n^2 + 6n + 3$	$3n^2 + 7n + 4$

As the number of wires per layer increases by six for each successive layer when the core has one wire, the first layer over the core having six. With cores having more than one wire, the increment per layer is not constant.

Fig. 2.

**Diameter of Concentric-lay Cables.** — The diameter of the circumference of any of the above cables is equal to  $(2n + b)$  times the diameter of the wire, where  $n$  is the number of layers over the core and  $b$  has the following values: 1 wire in core,  $b = 1$ ; 2 wires in core,  $b = 2$ ; 3 wires in core,  $b = 2.155$ ; 4 wires in core,  $b = 2.414$ .

The relation between the number of component wires and the diameter of the cable is shown in Fig. 3.

## COMMERCIAL STRANDED CONDUCTORS

Weights in lb. per 1000 ft. of all bare copper cables are computed by multiplying the circular mils by 0.00359.

**rope-lay Cables.**—As already noted, a rope-lay cable is made up in the lay as a concentric-lay cable except that stranded wires are used for the strands instead of individual solid wires. Rope strands are used as conductors which would be too stiff if stranded concentrically. The tables for regular concentric-lay cables may be readily modified to apply to rope-lay cables, as each stranded wire bears the same relation to the rope as an individual solid wire does to the concentric-lay cable. The following table shows the principal forms of rope-lay cables.

WIRES IN ROPE-LAY CABLES

Number of strands*	Total number of wires				
	Wires per strand*				
	7	19	37	61	91
1	7	19	37	61	91
7	49	133	259	427	637
19	133	361	703	1159	1,729
37	259	703	1,369	2,257	3,367
61	427	1,159	2,257	3,721	5,551
91	637	1,729	3,367	5,551	8,281
127	889	2,413	4,699	7,747	11,557
$(n^2+n)+1$	$21(n^2+n)+7$	$57(n^2+n)+19$	$111(n^2+n)+37$	$183(n^2+n)+61$	$273(n^2+n)+91$

\*By "strand" is here meant the stranded wires of which the rope is built up. The number of wires in a rope-lay cable is frequently designated by a product; 7X19 indicates a conductor made up of 7 strands, each strand containing 19

**non-core Cables.**—Cables with hemp centers have caused serious trouble and are not being recommended. (D. B. Kummert, *G. E. Review*, 1912.)

**Dimensions of Component Wires in Commercial Stranded Conductors.**—The table on p. 1875 gives the diameters of the component wires in the types of stranded conductors ordinarily used.

**Effect of Lay on Resistance and Weight.**—In the tables given on pp. 1969, 1970, and 1978, for stranded cables, the values given for "ohms per unit length" and "weight per unit length" are 2 per cent greater than for a solid rod of section equal to the total cross-section of the wires of the cable. This amount of 2 per cent means that the values are correct for cables having a lay of 15.7. For any other lay, equal to 1 in  $n$ , resistance or mass may be calculated by increasing the above tabulated values by

$$\left( \frac{484}{n^2} - 2 \right) \text{ per cent.}$$

**General Formulas for Properties of Cables in Terms of the Properties of the Constituent Wires.**—The following table gives the principal formulas for a concentric-lay cable having a core of one wire.

- = total area in circular mils of the component wires measured at right angles to their axes, when laid out straight.
- = diameter of cable over-all, in inches.
- = diameter of each of the component wires, in inches.
- = diameter of core, in inches.

$d_p$  = pitch diameter, in inches, of any layer (= mean diameter of the wires made by any layer).

$e$  = elongation, per cent, at which the wires (other than the core) break.

$l$  = number of wires in any layer having pitch diameter  $d_p$ .

$N$  = total number of wires except where the core is of special size, in which case  $N$  is the number of wires exclusive of the core.

$n$  = number of layers of wire over the core.

$P$  = pitch of any layer of wires = distance in inches measured along axis of the cable for one complete turn of the helix formed by any one of this layer.

$p$  = pitch-factor of any layer of wires = ratio of the actual length of any layer to the corresponding axial length of the cable.

$R$  = ratio of wire area to the total area of the circle circumscribing the outside of the conductor.

$s$  = stress in pounds per square inch in the core when the elongation is  $e$ .

$t$  = tensile strength of each outer wire, in pounds per square inch.

$T$  = tensile strength of conductor, in pounds.

$W$  = weight of conductor, in pounds per foot.

$w$  = weight of each wire of the cable, in pounds per foot.

$w_c$  = weight of the core of the cable, in pounds per foot.

#### PROPERTIES OF CONCENTRIC-LAY CABLES

	Regular; $d_c = d$	Special; $d_c \neq d$
I. Number of wires in terms of number of layers (and core diameter).	$N = 3(n^2 + n) + 1$ (including core)	$N = 3 \left( n \frac{d_c}{d} + n \right)$ (excluding core)
II. Diameter of cable in terms of diameter of wires and number of layers.	$D = d(1 + 2n)$	$D = d_c + 2nd$
III. Diameter of cable in terms of total area and number of wires.	$D = 10^{-3} \sqrt{\frac{1}{3} \left( 4 - \frac{1}{N} \right) \cdot \sqrt{A}}$	
IV. Ratio of wire area to area of circle circumscribing the outside of cable.	$R = \frac{3(n^2 + n) + 1}{(2n + 1)^2}$	
V. Weight of cable in terms of weight of wire, number of layers and pitch factors.	$W = w$ ( $1 + 6p_1 + 12p_2 + \text{etc.}$ )	$W = w_c + w$ ( $1 + 6p_1 + 12p_2 + \text{etc.}$ )
VI. Strength of cable in terms of strength of the component wires and the pitch factors.	$T = \frac{\pi}{4} s^2$ $\left[ s + 1 \left( \frac{6}{p_1} + \frac{12}{p_2} + \text{etc.} \right) \right]$	$T = \frac{\pi}{4} \left[ s_c^2 + \left( \frac{6}{p_1} + \frac{12}{p_2} + \text{etc.} \right) \right]$

PROPERTIES OF CONCENTRIC-LAY CABLES — *Continued*

	Regular; $d_0 = d$	Special; $d_0 \neq d$
Minimum pitch in terms of wire diameter and core diameter.	$\frac{3 \pi d_p}{\sqrt{(\pi+3)(\pi-3)}} = 10.1$ times pitch diameter	$\frac{\pi d_0 d}{\sqrt{(\pi d_p)^2 - (d)^2}}$
Diameter of wires in terms of total conductor area and number of wires.	$d = \frac{1}{1000} \sqrt{\frac{A}{N}}$	

## STRENGTH, ELASTICITY AND EXPANSION COEFFICIENT OF

— The strength and elasticity of a wire of any material depends to a considerable extent upon the method of manufacture, heat treatment, etc. The tensile strength of soft copper is between 25,000 and 35,000 pounds per square inch, as against 60,000 pounds per square inch for hard-drawn copper. Due to the greater relative thickness of the hard "skin" and comparatively soft "core" of small hard-drawn copper wires as compared with large wires, the tensile strength, in pounds per square inch, of a small hard-drawn wire is greater than the tensile strength of a large hard-drawn wire. For example, a No. 0000 B. & S. hard-drawn copper wire has a tensile strength of about 50,000 pounds per square inch as against approximately 25,000 pounds per square inch for a No. 18. A similar but smaller variation exists for soft-drawn wires. The tensile strength of steel wire depends to a very great extent upon the composition of the steel.

The following table gives, for a No. 0 A. W. G. wire, representative values for the various quantities stated. These values do not hold, except to a rough approximation, for other sizes of wire. For further information see articles on *Aluminum*, etc., and the section on *Specifications* below.

## STRENGTH, ELASTICITY AND COEFFICIENT OF EXPANSION

Of a No. 0 A. W. G. or B. &amp; S. Wire

Kind of wire	Tensile strength, lb. per sq. in.	Elastic limit, lb. per sq. in.*	Modulus of elasticity, lb.-in. units	Coefficient of linear expansion	
				per ° F.	per ° C.
Soft-drawn.....	36,000	.....	.....	$9.6 \times 10^{-6}$	$17 \times 10^{-6}$
Hard-drawn.....	54,500	30,000	$16 \times 10^6$	$9.6 \times 10^{-6}$	$17 \times 10^{-6}$
Aluminum, soft-drawn.....	16,000	.....	.....	$12.8 \times 10^{-6}$	$23 \times 10^{-6}$
Aluminum, hard-drawn.....	25,000	25,000	$9 \times 10^6$	$12.8 \times 10^{-6}$	$23 \times 10^{-6}$
Low-carbon steel, 40% grade.....	60,000	51,000	$22 \times 10^6$	$6.7 \times 10^{-6}$	$12 \times 10^{-6}$
Aluminum concentric.....	75,800	55,000	$18 \times 10^6$	$8.3 \times 10^{-6}$	$14.9 \times 10^{-6}$
Aluminum primary.....	68,000	40,000	$\left. \begin{array}{l} 24 \times 10^6 \\ \text{to} \\ 30 \times 10^6 \end{array} \right\}$	$7.0 \times 10^{-6}$	$12.6 \times 10^{-6}$
Aluminum Wrensch-Martin.....	90,000	45,000		$7.0 \times 10^{-6}$	$12.6 \times 10^{-6}$
Aluminum high strength.....	150,000	82,000		$7.0 \times 10^{-6}$	$12.6 \times 10^{-6}$
Aluminum high strength.....	225,000	135,000		$7.0 \times 10^{-6}$	$12.6 \times 10^{-6}$

\* There is no elastic limit for soft annealed copper and the elastic limits of hard-drawn copper and aluminum are doubtful.

The tensile strength in pounds for solid wires from  $\frac{1}{16}$  inch to  $\frac{1}{2}$  inch diameter are given in the following table.

BREAKING LOAD FOR SOLID WIRES IN POUNDS PER WIRE

Gage No. A. W. G. or B. & S.	Diameter		Hard-drawn copper (Am. Soc. for Test. Mat.)*	Hard-drawn aluminum (23,000 to 33,300 lb. per sq. in.)	Copper-clad steel, 40 per cent grade	Steel (100,000 lb. per sq. in.)
	Inches	Mils

\* Tensile strength in pounds per square inch ranging from 49,000 for No. 0000 to 66,200 for No. 14; see below.

† For wires having a tensile strength of 5 pounds per square inch, multiply  $S/100,000$ . The tensile strength of steel varies from 60,000 to 225,000 pounds per square inch.

**Strength, Elasticity and Expansion Coefficient of Cables.**—The following is a summary of the results of tests made on stranded copper wires at the Massachusetts Institute of Technology in 1912. Each figure is the average of a number of individual tests. In determining the modulus of elasticity of cable was given a preliminary stretch before readings were taken.

## MECHANICAL PROPERTIES OF BARE COPPER CABLES

Size of cable A. W. G. or cir. mils	Number of wires in cable	Pitch of layers, inches		Modulus, lb.-in. units	Elastic limit, lb. per sq. in.	Tensile strength, lb. per sq. in.
		First layer	Second layer			
0	7	4.5	...	$16.6 \times 10^6$	22,000	53,500
300,000	19	7	5	$16.4 \times 10^6$	21,300	59,800
300,000	19	9	4.5	$16.3 \times 10^6$	25,000	56,000
300,000	19	9	9	$16.5 \times 10^6$	24,000	52,600
300,000	19	4.5	3	$13.6 \times 10^6$	25,300	53,800

## PROPERTIES OF COMPONENT WIRES OF ABOVE CABLES

Size of component wires, mils	Modulus, lb.-in. units	Elastic limit, lb. per sq. in.	Tensile strength, lb. per sq. in.
125	$16.9 \times 10^6$	27,000	62,800
125	$18.9 \times 10^6$	27,000	61,900
125	$16.6 \times 10^6$	26,000	61,800
125	$17.5 \times 10^6$	26,000	59,300

by B. Welbourne (Jour. I.E.E., 1917, Vol. indicate that the elastic modulus of copper varies with the number of strands, as shown accompanying table.

**Cable for Catenary Construction.**—A of  $22 \times 10^6$  pound-inch units is representative steel messenger cable.

Following tables are compiled from tables by the General Electric Co. (*Bulletin High* and "Extra high" strength steel may be used where absolutely necessary, as, in view of its stiffness, it requires special fastenings.

Strands	Modulus, lb.-in. units
7	$20.0 \times 10^6$
19	$17.5 \times 10^6$
37	$15.5 \times 10^6$
61	$14.0 \times 10^6$
91	$12.5 \times 10^6$

## STEEL CABLE FOR CATENARY SUSPENSION\*

Galvanized Siemens-Martin Steel Strand, 90,000 Pounds Per Square Inch.

Tensile strength, pounds	Elastic limit, pounds	Elongation, per cent	Lay, inches
3,060	1,830	6 to 9	3
4,860	2,910	6 to 9	3½
6,800	4,080	5 to 8	4
9,000	5,300	5 to 8	4½
11,000	6,600	5 to 8	4¾
19,000	11,400	4 to 6	5

## STEEL CABLE FOR CATENARY SUSPENSION — (Continued)

Extra-galvanized High-strength Crevice Steel Strand				
Diameter, inches	Tensile strength, pounds	Elastic limit, pounds	Elongation, per cent	Lap, inches
3/8	5,100	3,315	3 to 5	3/8
7/16	8,100	5,265	3 to 5	1/2
1/2	11,500	7,475	3 to 5	5/8
5/8	15,000	9,500	3 to 5	1
3/4	18,000	11,700	3 to 5	1 1/8
7/8	25,000	16,250	2 to 4	1 1/2

Extra-galvanized Extra-high-strength Plow Steel Strand.				
Diameter, inches	Tensile strength, pounds	Elastic limit, pounds	Elongation, per cent	Lap, inches
3/8	7,600	5,700	2 1/2 to 4	1/2
7/16	12,100	9,075	2 1/2 to 4	5/8
1/2	17,250	12,930	2 1/2 to 4	3/4
5/8	22,500	16,800	2 1/2 to 4	7/8
3/4	27,000	20,250	2 1/2 to 4	1
7/8	42,000	31,500	1 1/2 to 3	1 1/8

COMPARISON OF COPPER AND ALUMINUM FOR EQUAL LENGTH AND EQUAL RESISTANCE. — (See *Aluminum*.)

**ALUMINUM-STEEL CABLES.** — Cables made of a central steel, solid or stranded, surrounded by one or more layers of aluminum are now finding great favor for aerial lines. Their great advantage is that they may be erected not only with less sag than aluminum but with from 60 to 75 per cent of that of hard-drawn copper.

The modulus of elasticity and temperature coefficient of expansion depend upon the relative cross-section of aluminum and steel. The anchor does not hold both the aluminum and steel, so that at low temperatures the load is divided between the two metals. As the temperature rises, the aluminum expands faster than the steel and the load gradually shifts over to the steel which in turn stretches more to keep pace with the expanded length of aluminum so that there is no relative motion between the two metals. Eventually the steel carries the total load, and the expansion follows the coefficient for steel only.

Let  $H_a$  = fraction of area covered by aluminum,

$H_s$  = fraction of area covered by steel,

$M_a$  = modulus of elasticity of aluminum (9,000,000),

$M_s$  = modulus of elasticity of steel (30,000,000),

$M$  = modulus of elasticity of aluminum-steel cable,

$G_a$  = coefficient of expansion of aluminum (0.0000128),

$G_s$  = coefficient of expansion of steel (0.0000064),

$G$  = coefficient of expansion of cable.

$$M = M_0 H_a + M_s H_s = (9 \times H_a + 30 H_s) 10^6,$$

$$G = \left\{ \frac{1}{1 + \frac{M_0 H_a}{M_s H_s}} \right\} G_s = \left\{ \frac{1}{1 + \frac{M_0 H_a}{M_s H_s}} \right\}^{-1} G_s$$

$$= 0.0000064 \left\{ \frac{1}{1 + 0.3 \frac{H_a}{H_s}} \right\} = 0.0000128 \left\{ \frac{1}{1 + 0.3 \frac{H_a}{H_s}} \right\}^{-1}.$$

**HEAT-CARRYING CAPACITY OF BARE WIRES.**—(See also *Rheostats; Wires, Resistance.*) Let  $d$  = diameter of conductor in inches,missible temperature rise in °C. above surrounding medium (air, earth, or  $r$  = resistance of conductor in ohms per mil-foot at final temperature,ent per conductor in amperes. Assuming that the rate of heat radi-unit length of wire is proportional to the difference of temperature the conductor and the surrounding medium and also proportional to ice of the conductor, then for solid conductors

$$I = K \sqrt{\frac{T \phi}{r}},$$

tranded conductors

$$1.2 K \sqrt{\frac{T d^4}{r}},$$

is a constant, which depends upon the condition of the surface of the upon the amount of heat convection due to air currents. Values of ant  $K$  for air given by different authorities vary from 800 to 1000, referring to still air and the latter to open air.

**TESTS OF BARE WIRES AND CABLES.**—The usual tests on bare gaging diameter, measuring tensile strength, elongation, modulus, bit and electrical conductivity.

**Diameter.**—(See also section on *Specifications, below.*) The best ge for measuring wire diameters is that shown

The wire is placed between the measuring and the screw adjusted until a click occurs. per of large divisions exposed on the axis is 1 by 100; the number of small divisions ex-the axis is multiplied by 25; and the sum of

Fig. 4.

items added to the number indicated on the revolving scale. The e the diameter of the wire in mils.

**Strength, Elongation, Modulus and Elastic Limit.**—The essen- es of a wire-testing machine are a means of applying a measurable ce to the wire, and a means of taking up the elongation. Accordingly, testing machine consists of two pairs of jaws for gripping the wire, one ; connected to a balance lever and the other pair to a power-driven n which draws it in the direction of the axis of the wire. A typical s shown diagrammatically in Fig. 5, where A the two pairs of jaws between which the wire xt. The machine is operated by setting in e mechanism which makes the jaw A move t the direction indicated. The operator then counterrotate C by hand, in the direction in-

Fig. 5.

so as to keep the beam balanced. This operation is continued until the wire breaks, when the elongation of the sample is measured by the travel of the jaw *A* and its breaking strength by the weight indicated on the beam at the counterpoise *C*.

**Measurement of Strain.**—The amount by which the wire is stretched is measured by means of an extensometer which consists of a pair of clamps to hold the wire at points a definite distance apart, and a magnifying scale for measuring the increase of distance between the clamps as the wire stretches. The strain curve obtained by plotting the elongations thus measured against the stresses measured by the machine described above is not a true one, as there is an abnormal elongation due to the necking of the wire, as shown by *DA* in Fig. 6. The standard method of overcoming this, is described in § 8 of the A.S.T.M. *Specification for Hard-Drawn Copper Wire*.

Fig. 6

**Modulus of Elasticity.**—The modulus of elasticity is obtained from the slope of the straight part of the curve. In Fig. 6 the modulus of elasticity is  $OD/CD$  pound-inch

**Elastic Limit.**—The true elastic limit can be obtained only by applying increasing loads, releasing the load (leaving, however, a sufficient residual elongation to keep the wire straight) and measuring the elongation between successive loads. The load at which a permanent elongation begins is the elastic limit.

**Measurement of Resistance.**—In order to maintain a wire at a uniform and known temperature, it must be short. Unless the wire is very small the test sample will have a very low resistance, and an ordinary Wheatstone bridge will not be sufficiently accurate to measure it. This difficulty is avoided by using a Kelvin, Hoop, Willoughby or Reeves type (see *Bridges for Resistance Measurements; Resistance and Conductance*).

**Specifications for Copper Wire and Cable.**—The following specifications for bare copper wire and cable are those prepared by the American Society for Testing Materials, 1915 (hard-drawn copper), and 1915 (annealed copper), and 1916 (copper cable). See also the article on *Specifications for Wires and Cables*, and the section on *Specifications* in the article on *Wires and Cables, Insulated*.

#### SPECIFICATION FOR SOFT OR ANNEALED COPPER WIRE.

**General.**—The copper shall be of such quality and purity that, when drawn and annealed, it shall have the properties and characteristics required.

This specification covers untinned, drawn and annealed round wire.

(a) The wire must be free from all imperfections not consistent with commercial practice.

(b) Necessary brazes in soft or annealed wire must be made in accordance with the best commercial practice.

**Shipment; Coils, Spools and Reels.**—(a) Wire may be shipped in coils, spools or reels as agreed upon by the purchaser and manufacturer. In Table I are stated the maximum and minimum weights of wire of the stated

sizes which may be shipped in any one package, whether coil, reel or spool. In the case of wire larger than 0.010 inch in diameter, the maximum and minimum package weights are net, and in the case of wire 0.010 inch and less in diameter the maximum package weights are gross, and the minimum package weights are net. The table also states the limiting dimensions of the coils, reels and spools on which wire may be shipped. The length and diameter of coils, reels and spools are to be measured over-all and are maximum sizes; spools smaller than these may be used provided the minimum weights called for are carried by the reel or spool. In the table, there are also stated the diameters of the draw-block on which the final drawing of the wire is to be made, if the wire is shipped in coils; it being understood that the wire is not to be re-drawn after final drawing. This provision is made to insure that coils of wire of a given gage, when supplied by different manufacturers, will be of the same general dimensions.

Wire 0.204 inch in diameter and larger may be shipped in larger packages when agreed upon.

(b) The wire shall be protected against damage in ordinary handling and shipping.

TABLE I

Diameters, inches	Package weights, pounds		Diam. of draw- block, inches	Dimensions of reels and spools, inches		
	Max.	Min.		Max. diam.	Max. length	Diam. of block for drawing
0.360 to 0.360	520	290	24	32	21	1 1/2 to 2
0.359 to 0.258	430	290	24	32	21	1 1/2 to 2
0.257 to 0.179	290	140	22	24	12	1 1/2 to 2
0.128 to 0.102	230	95	22	24	12	1 1/2 to 2
0.101 to 0.083	230	75	22	24	12	1 1/2 to 2
0.082 to 0.081	200	75	16	24	12	1 1/2 to 2
0.080 to 0.064	200	50	16	24	12	1 1/2 to 2
0.063 to 0.051	120	50	16	24	10	1 1/2 to 2
0.050 to 0.041	100	50	16	24	10	1 1/2 to 2
0.040 to 0.032	50	20	8	24	8	1 1/2 to 2
0.031 to 0.020	25	15	8	10	6 1/2	1 1/2 to 2
0.019 to 0.011	10	5	8	5 1/2	4	1 1/2 to 2
0.010 to 0.008	5	2 1/2	8	4	4	1 1/2 to 2
0.007 to 0.0056	2 1/2	1	6	2 1/2	4	1 1/2 to 2
0.005	1 1/2	5/8	6	2 1/2	4	1 1/2 to 2
0.004	1 1/2	5/8	6	2 1/2	4	1 1/2 to 2
0.003	1	1/2	6	2 1/2	4	1 1/2 to 2

5. Specific Gravity. — For the purpose of calculating weights, cross sections, etc., the specific gravity of copper shall be taken as 8.89.

6. Size and Gaging. — (a) Size shall be expressed as the diameter of the wire in decimal fractions of an inch.

(b) Wire shall be accurate in diameter; permissible variations from nominal diameter shall be:

7. **Wire 0.010 inch in diameter and larger, 1 per cent over or under.**  
 8. **Wire less than 0.010 inch in diameter, 0.1 mil (0.0001 inch) over or under.**  
 Each coil shall be gaged at three places, one near each end and one approximately at the middle; from spools, approximately twelve feet shall be reeled. The wire shall be gaged in six places between the second and twelfth foot from the end. The coils or spools will be rejected if the average of the measurements obtained is not within the limits specified in (7).

7. **Tensile Strength and Elongation.** — Wire shall be so drawn and annealed that its tensile strength shall not be greater and its elongation not less than the values stated in Table II. Tensile tests shall be made upon samples, and the elongation shall be determined as the permanent increase in length, due to the breaking of the wire in tension, measured between bench marks placed upon the wire originally 10 inches apart. The fracture shall be between the bench marks and not closer than 1 inch to either bench mark. If, in testing a sample from any coil, reel or spool of wire, the results are found to be below the stated value in elongation or above the stated value in tensile strength, tests upon two additional samples shall be made, and the average of three tests shall determine acceptance or rejection of the coil. For wire whose nominal diameter is between listed sizes, the requirements shall be those of the next larger size included in the table.

TABLE II. — ANNEALED COPPER WIRE

Diameter, inches	Tensile strength, lb. per sq. in.	Elongation in 10 in., per cent
0.460-0.290	36,000	35
0.389-0.103	37,000	30
0.103-0.091	38,500	25
0.090-0.003	40,000	20

8. **Resistivity.** — Electric resistivity shall be determined upon fair samples by resistance measurements at a temperature of 20° C. (68° F.) and it shall not exceed 891.58 pounds per mile-ohm (0.15614 ohm per meter-gram).

9. **Testing and Inspection.** — All testing and inspection shall be made at the place of manufacture. The manufacturer shall afford the inspector representing the purchaser all reasonable facilities to satisfy him that the material conforms to the requirements of these specifications.

### SPECIFICATION FOR HARD-DRAWN COPPER WIRE

1. **General.** — The material shall be copper of such quality and purity that, when drawn hard, it shall have the properties and characteristics herein required.

2. These specifications cover hard-drawn round wire, grooved trolley wire, and figure-eight trolley wire, as hereinafter described.

3. (a) The wire, in all shapes, must be free from all imperfections not consistent with the best commercial practice.

(b) Necessary brazes in hard-drawn wire must be made in accordance with the best commercial practice, and tests upon a section of wire containing a braze must show at least 95 per cent of the tensile strength of the unbrazed wire. Elongation tests are not to be made upon test sections including brazes.

4. **Shipment.** — (a) Package sizes for round wire and for cable shall

be agreed upon in the placing of individual orders; standard packages of grooved trolley wire shall be shipped upon reels holding about 2500 pounds each.

(b) The wire shall be protected against damage in ordinary handling and shipping.

5. **Specific Gravity.** — For the purpose of calculating weights, cross-sections, etc., the specific gravity of copper shall be taken as 8.89 at 20° C.

6. **Testing and Inspection.** — All testing and inspection shall be made at the place of manufacture. The manufacturer shall afford the inspectors representing the purchaser all reasonable facilities to enable him to satisfy himself that the material conforms to the requirements of these specifications.

#### Hard Drawn Round Wire

7. **Dimensions and Permissible Variations.** — (a) Size shall be expressed as the diameter of the wire in decimal fractions of an inch, using not more than three places of decimals; i.e., in mils.

(b) Wire is expected to be accurate in diameter; permissible variations from nominal diameter shall be:

For wire 0.100 inch in diameter and larger, one per cent over or under;

For wire less than 0.100 inch in diameter, one mil over or under.

(c) Each coil is to be gaged at three places, one near each end, and one approximately at the middle; the coil may be rejected if, two points being within the accepted limits, the third point is off gage more than 2 per cent in the case of wire 0.064 inch in diameter and larger, or more than 3 per cent in the case of wire less than 0.064 inch in diameter.

8. **Physical Test.** — Wire shall be so drawn that its tensile strength and elongation shall be at least equal to the value stated in Table I. Tensile tests shall be made upon fair samples, and the elongation of wire larger in diameter than 0.204 inch shall be determined as the permanent increase in length due to the breaking of the wire in tension, measured between bench marks placed upon the wire originally 10 inches apart. The elongation of wire 0.204 inch in diameter and smaller shall be determined by measurements made between the jaws of the testing machine. The zero length shall be the distance between the jaws when a load equal to 10 per cent of the required ultimate breaking strength shall have been applied, and the final length shall be the distance between the jaws at the time of rupture. The zero length shall be as near 60 inches as possible. The fracture shall be between the bench marks in the case of wire larger than 0.204 inch in diameter and between the jaws in the case of smaller wire, and not closer than 1 inch to either bench mark or jaw. If, upon testing a sample from any coil of wire, the results are found to be below the values stated in the table, tests upon two additional samples shall be made, and the average of the three tests shall determine acceptance or rejection of the coil. For wire whose nominal diameter is between listed sizes, the requirements shall be those of the next larger size included in Table I.

9. **Electric Resistivity.** — Electric resistivity shall be determined upon fair samples by resistance measurements at a temperature of 20° C. (68° F).

The wire shall not exceed the following limits:

For diameters 0.460 inch to 0.325 inch, 900.77 pounds per mile-ohm at 20° C.

For diameters 0.324 inch to 0.040 inch, 910.15 pounds per mile-ohm at 20° C.

#### Grooved Trolley Wire

10. **Sections.** — Standard sections shall be known as the "American Standard" grooved trolley-wire sections, the shape and dimensions of which are as shown in Fig. 1, above.

TABLE I.—HARD-DRAWN COPPER WIRE

PROX. Size No., & S.	Diameter, inches	Area, circular mils	Tensile strength, lb. per sq. in.	Elongation, per cent
				in 10 in.
300	0.460	211,600	49,000	3.75
300	0.410	168,100	51,000	3.25
00	0.365	133,225	52,800	2.80
0	0.325	105,625	54,500	2.40
1	0.299	83,520	56,100	2.17
2	0.258	66,565	57,600	1.98
3	0.239	52,440	59,000	1.79
				in 60 in.
4	0.204	41,615	60,100	1.24
5	0.182	33,125	61,200	1.18
	0.165	27,225	62,000	1.14
6	0.162	26,245	62,100	1.14
7	0.144	20,735	63,000	1.09
	0.134	17,955	63,400	1.07
8	0.128	16,385	63,700	1.06
9	0.114	12,995	64,300	1.02
	0.104	10,815	64,800	1.00
10	0.103	10,404	64,900	1.00
	0.092	8,464	65,400	0.97
11	0.091	8,281	65,400	0.97
12	0.081	6,561	65,700	0.95
	0.080	6,400	65,700	0.94
13	0.072	5,184	65,900	0.92
	0.065	4,225	66,200	0.91
14	0.064	4,096	66,200	0.90
15	0.057	3,249	66,400	0.89
	0.051	2,601	66,600	0.87
16	0.045	2,025	66,800	0.86
18	0.040	1,600	67,000	0.85

11. **Dimensions and Permissible Variations.**—(a) Size shall be measured as the area of cross-section in circular mils, the standard sizes being as follows:

211,600 circular mils, weighing 3386 pounds per mile.

168,100 circular mils, weighing 2690 pounds per mile.

133,200 circular mils, weighing 2132 pounds per mile.

(b) Grooved trolley wire may vary 4 per cent over or under in weight per length from standard, as determined from the nominal cross-section.

12. **Physical Tests.**—The physical tests shall be made in the same manner as those upon round wire. The tensile strength of grooved wire shall be at least 95 per cent of that required for round wire of the same sectional area; the elongation shall be the same as that required for round wire of the same sectional area.

13. **Electric Resistivity.**—The requirements for electric resistivity shall be the same as those for round wire of the same sectional area.

## Figure-eight Trolley Wire

14. **Sections.** — Standard sections of figure-eight trolley wire shall be shown in Fig. 2, above.

15. **Requirements.** — The requirements for weight, physical properties and electric resistivity of figure-eight trolley wire shall be the same as for same sizes of grooved trolley wire.

### SPECIFICATION FOR BARE CONCENTRIC-LAY COPPER CABLE: HARD, MEDIUM-HARD, OR SOFT

1. (a) **Products Covered.** — These specifications cover bare concentric-lay cables made from round copper wires laid helically around a central core in one or more layers. The central core shall be made of wire having the same quality and temper as the concentric layers, unless otherwise especially provided for in separate specifications governing the individual case.

(b) **Classes.** — The purpose for which the several classes of concentric-lay cables are generally used are as follows:

Class A, for bare, weatherproof, slow-burning, and slow-burning weatherproof cable for aerial use;

Class B, for various insulated cable, such as rubber, paper, varnished cloth, etc.

Class C, for cable where greater flexibility is required than in Class B.

2. **Requirements of Wires.** — The copper wires entering into the construction of standard concentric-lay cable shall, before stranding, meet all requirements of that one of the Standard Specifications of the American Society for Testing Materials for Hard-Drawn, Medium Hard-Drawn, or Soft or Annealed Copper Wire (Serial Designations: B 1, B 2, or B 3), which apply.

3. **Brazes.** — Brazes may be made in the wire when finished and ready for cabling. Such brazes shall be made in accordance with the best commercial practice. No brazes in cable made from hard, or medium hard drawn copper wire may be closer together than 50 feet.

4. **Pitch and Lay.** — The pitch of standard cable shall not be less than 12 nor more than 16 diameters of the cable, and the lay may be right or left handed, unless one direction of lay is specified by the purchaser.

5. **Testing.** — Tests for the physical and electrical properties of the wire composing the cables may be made before, but not after stranding. Experience indicates that the tensile strength of concentric-lay copper cable of standard pitch is at least 90 per cent of the total strength required of the wires forming the cable.

6. **Weights and Area.** — For the purpose of calculating weights, cross sections, etc., the specific gravity of copper shall be taken as 8.89 at 20° C. The resistance and mass of a stranded conductor are greater than in a solid conductor of the same cross-sectional area, depending on the lay (that is, the pitch of the twist of the wires). Two per cent shall be taken as the standard increment of resistance and of mass. In cases where the lay is definitely known, the increment shall be calculated and not assumed.

7. **Variation in Area.** — The area of cross-section of the completed cable shall not be more than 2 per cent below the area specified, as determined by weight.

8. **Construction.** — The area of cross-section, number and diameter of wires, in standard cable Classes A, B and C, shall be as specified in Table 1.

TABLE I

Tension of conductor regular mils.	Approximate A. W. G. or B. & S. gauge sizes	Class A		Class B		Class C

Note. — Class A cable, sizes 4/0 and 3/0, is usually 7-strand when bare and 19-strand when weatherproof, etc.

9. (a) **Packing and Shipping.** — Packing sizes for cable shall be agreed upon in the placing of individual orders.

(b) The cable shall be protected against damage in ordinary handling and transportation.

10. (a) **Inspection.** — All testing and inspection, both of individual wires entering into the construction of the cable, and of the completed cable shall be made at the place of manufacture. Tests on individual wires shall be made on samples taken before cabling, and not on wires removed from the completed cable.

(b) The manufacturer shall afford the inspector representing the purchaser all reasonable facilities to satisfy him that the material conforms to the requirements of these specifications.

**INSTALLATION OF BARE WIRES AND CABLES.** — For the installation of wires and cables in buildings see article on *Wiring of Buildings in Light and Power*. Below is given a brief description of modern practice in erecting bare wires and cables on pole or tower lines. For the construction of the latter see articles on *Distribution Lines; Transmission Lines*. Catenary construction is described in the article on *Trolley Systems, Overhead*.

**Simple Span Construction with Pin Insulators.** — Starting at an anchored pole, a rope about twice the length of the span is put over the cross arm and the wire pulled up by means of it. The rope is then put over the cross arm of the next pole and the wire drawn up in the same way. This is repeated from pole to pole until the reel, which remains at the starting point, is exhausted. The pulling may be done by men, horses, automobile, or locomotive. Care should be taken to prevent the wire unwinding too rapidly from the reel and the end of the wire must be prevented from slipping away.

The wire is placed on the insulators by means of a block and tackle attached either to the arm above or to a temporary boom. The next step is to draw the wires to the proper tension. Commencing at the first pole after the anchor, the wire is gripped by a clamp attached to a rope which is pulled until the wire is drawn to the sag indicated by a table or curve showing the proper sag at different temperatures and spans (*Spans, Wire*). The sag is gauged by sighting from pole to pole, using a gauge or sight on each pole, and drawing the wire until the bottom of the span is tangential to the sight line.

**Tying to Insulator.** — (See also *Insulators for Overhead Lines*.) The wires are tied to their insulators by small wires, usually of the same metal, as shown in Fig. 7. The two ends of the tie wire (not visible in Fig. 7) are twisted together for three or four turns. The tie wire must be held quite taut while it is being installed.

**Simple Span Construction with Suspension Insulators.** — Where suspension insulators are used, the wire, instead of being initially placed over the cross arms, is temporarily suspended therefrom on snatch blocks provided with wooden rollers.

Prior to running the cables, linemen are sent ahead to attach the snatch blocks to the arms of the towers. The cables are then strung loosely through the snatch blocks, in much the same way as they are strung over the cross arms in the construction described above. The cables are anchored to the first pole and the necessary tension applied to the cable between the first and second towers, a dynamometer being used to indicate when the required stress point has been reached. The cable is then anchored

Fig. 7.

second tower and the operation repeated for the different spans until the length is exhausted. The cable is then transferred to the insulator and the anchorages removed except at the ends.

**Clamping to Insulator.** — The usual type of insulator clamp (Fig. 8) is of a curved, malleable-iron wire seat nine inches long, a saddle which fits over it and a pair of hook bolts to hold the wire between the saddle and wire seat. The clamp is supported from the insulator through a pin joint. Copper wire or cable is laid in the seat, the saddle placed on it and the hook bolts laced in position. In the case of aluminum wire a  $\frac{1}{2}$ -inch aluminum sleeve should be placed around the wire in the clamp. The clamp is then attached to the insulator by a bolt and socket or pin joint.

Fig. 8.

**Joining Conductors.** — The following methods are used:

**Western Union Joint.** — The two ends of the wire are brought together so that they lap from 3 to 8 inches, depending upon the size. Then at half-way between the two ends, each wire is wound around the other in a tight helix. With hard-drawn copper, excessive stress is avoided by making the helix a long pitch for the first turn or two and then gradually reducing it until a tight helix is obtained.

It should appear from tests on galvanized-iron wire by C. T. Rashman (*E. W., vol. 56, p. 1187*), that in order to make the joint as strong as the wire, the joint should have the form shown in Fig. 9 which may be described as consisting of five turns and five end turns at each end.

Fig. 9.

Fig. 10.

Fig. 11.

For the purpose of obtaining five turns in the neck, the following length of neck was necessary:

The form of splice shown in Fig. 10 should be used.

**Dovetailing Strands.** — The cables are for say three or four feet, dovetailed or lapped, and the strands individually wound in the unopened part of the cable. The joint may be soldered or not, as desired.

**Aluminum Tube Joint.** — Aluminum conductors of sizes up to about one-half inch diameter are usually jointed by inserting the two wires side by side into a flat aluminum tube, which is then given 3 or 4 twists as shown in Fig. 11 by means of a special kind of lead connectors.

Size wire, B.W.G.	Length of neck, inches
14	3- $\frac{1}{2}$
12	3- $\frac{3}{4}$
10	4
8	6
6	7

**Pressed Aluminum Joint.** — Aluminum conductors larger than one-half inch diameter are more often jointed by dovetailing the strands, or by special clamps such as the Dossert connector (*see below*), or by inserting the wires into a cast aluminum sleeve which is squeezed hydraulically until the wires and sleeve flow into a solid homogeneous mass.

**Dossert Joint and Connector.**—The Dossert joint, shown in Fig. 12, consists of a compression sleeve which is slipped over the conductor, a screw

Fig. 12.

Fig. 13.

the lug proper and a nut threaded with a taper thread. The sleeve contacting the conductor is thrust into the lug, with the nut over it. The nut is then tightened until the reaction of the tapered surface and the sleeve gives rise to a pressure of several thousand pounds per square inch, thereby making perfect electrical contact.

The Dossert connector or terminal is similar in construction, and is shown in Fig. 13.

**MINOLOGY.** — The terminology employed in referring to wires and cables has been in a very confused state, the same term being used with several different meanings. The following terminology is quoted from the *Standards of the A.I.E.E.*

**Wire.** — A slender rod or filament of drawn metal.

This definition restricts the term to what would ordinarily be understood by the term "wire." In the definition the word "slender" is used in the sense that the length is in comparison with the diameter. If a wire is covered with insulation, it is called an insulated wire. While primarily the term "wire" refers to the metal, less when the context shows that the wire is insulated the term "wire" will be understood to include the insulation.

**Conductor.** — A wire, or combination of wires not insulated from one another, suitable for carrying a single electric current.

The term "conductor" is not to include a combination of conductors insulated from one another, which would be suitable for carrying several different electric currents.

Bus conductors (such as bus-bars) are, of course, conductors, but are not considered under the terminology here given.

**Stranded Conductor.** — A conductor composed of a group of wires or any other combination of groups of wires.

The wires in a stranded conductor are usually twisted or braided together.

**Strand.** — One of the wires or groups of wires of any stranded conductor.

The majority of American copper wire manufacturers have used the word "strand" to designate a group of bare wires twisted together.

**Cable.** — (1) A stranded conductor (single-conductor cable); or (2) a combination of conductors insulated from one another (multiple-conductor cable).

The component conductors of the second kind of cable may be either solid or stranded, and the kind of cable may or may not have a common insulating covering. The first kind of cable is a single conductor, while the second kind is a group of several conductors. The term "cable" is applied by some manufacturers to a solid wire heavily insulated and covered; this usage arises from the manner of the insulation, but such a cable is not included under this definition of "cable." The term "cable" is a general

one and in practice it is usually applied only to the larger sizes. A small cable is called "stranded wire" or a "cord," both of which are defined below. Cables may be insulated, and the latter may be armored with lead or steel wires or bands.

**Stranded Wire.**— A group of small wires, used as a single wire.

A wire has been defined as a slender rod or filament of drawn metal. If such a rod is subdivided into several smaller filaments or strands and is used as a single wire, it is called a "stranded wire." There is no sharp dividing line of size between a "stranded wire" and a "cable." If used as a wire, for example, in winding inductance coil magnets, it is called a stranded wire and not a cable. If it is substantially insulated, it is called a "cord," defined below.

**Cord.**— A small cable, very flexible and substantially insulated to withstand wear.

There is no sharp dividing line in respect to size between a "cord" and a "cable," likewise no sharp dividing line in respect to the character of insulation between a "cord" and a "stranded wire."

**Concentric Strand.**— A strand composed of a central core surrounded by one or more layers of helically laid wires or groups of wires.

**Concentric-lay Cable.**— A single-conductor cable composed of a central core surrounded by one or more layers of helically laid wires.

**Rope-lay Cable.**— A single-conductor cable composed of a central core surrounded by one or more layers of helically laid groups of wires.

This kind of cable differs from the preceding in that the main strands are themselves stranded.

**N-Conductor Cable.**— A combination of N conductors insulated from each other.

It is not intended that the names as here given be actually used. One would not speak of a "3-conductor cable" and a "12-conductor cable," etc. In referring to general case, one may speak of a "multiple-conductor cable" (as in definition 11 above.)

**N-Conductor Concentric Cable.**— A cable composed of an insulating central conducting core with (N-1) tubular stranded conductors laid over concentrically and separated by layers of insulation.

This kind of cable usually has only 2 or 3 conductors. Such cables are used in carrying alternating currents. The remarks on the expression "N-Conductor" given in preceding definition apply here also.

**Duplex Cable.**— Two insulated single-conductor cables twisted together. They may or may not have a common insulating covering.

**Twin Cable.**— Two insulated single-conductor cables laid parallel, having common covering.

**Twin Wire.**— Two small insulated conductors laid parallel, having common covering.

**Triplex Cable.**— Three insulated single-conductor cables twisted together. They may or may not have a common insulating covering.

**Twisted Pair.**— Two small insulated conductors twisted together without common covering.

The two conductors of a "twisted pair" are usually substantially insulated, so that the combination is a special case of a "cord."

**Sector Cable.**— A sector cable is a multiple-conductor cable in which the

section of each conductor is substantially a sector, an ellipse, or a figure intermediate between them.

or cables are used in order to obtain decreased overall diameter and thus permit use of larger conductors in a cable of given diameter.

**Round Conductor.** — A round conductor is either a solid or stranded conductor of which the cross-section is substantially circular.

**Split Conductor.** — A split conductor is a conductor which is divided into two or more parts, separated from one another by insulation which is thin and spread with the insulation around the conductor.

The term split conductor usually designates a conductor in two parts or splits, which are either concentric or external to one another.

**Factor of Assurance.** — The factor of assurance of wire or cable insulation is the ratio of the voltage at which it is tested to that at which it is used.

**Insulation Resistance.** — The insulation resistance of an insulated conductor is the electrical resistance offered by its insulation, to an impressed voltage sufficient to produce a leakage of current through it.

**Circular Mil.** — A circular mil is a unit of area equal to  $\frac{\pi}{4}$  ( $= 0.7854 \dots$ ) square mil. The cross-sectional area of a circle in circular mils is therefore equal to the square of its diameter in mils. A circular inch is equal to a million circular mils.

**Lay.** — The lay of any helical element of a cable is the axial length of a turn of the helix of that element.

The helical elements of a cable may be each strand in a concentric-lay cable, or each insulated conductor in a multiple conductor cable.

**Direction of Lay.** — The direction of lay is the lateral direction in which the strands of a cable run over the top of the cable as they recede from an observer along the axis of the cable.

### INSTRUCTION OF INSULATED WIRES AND CABLES. —

For information on the manufacture and properties of insulating materials will be found in the following articles on *Cambric*, *Varnished*, *Gutta-percha*, *Paper*, *Impregnated*, *Rubber-insulating Materials*, *Miscellaneous*. Data on the conductor itself will be found in the articles on *Copper*, *Aluminum*, *Wires and Cables*, *Bare*.

**Conductors.** — Round copper wire, solid or stranded, is almost invariably used for insulated wires and cables. Aluminum, requiring a larger cross-section for the same conductance per unit length, requires more insulating material for the same thickness of insulation. Aluminum cables, however, are sometimes provided with a weatherproof covering.

**Stranding.** — Conductors are stranded in order to make them more flexible. The cable can then be drawn into a conduit more readily, following the bends of the conduit without injury during installation. In the case of overhead cables, flexibility is required first in order to permit them to be put on the poles; second, to permit easy installation, and third to permit them to be bent around the walls of splicing chambers. Cords, elevator cables, mining machine cables, etc., must have considerable flexibility in order to permit them to be easily shifted from place to place in service.

In conduit work it is found unnecessary to strand conductors smaller than No. 6 A. W. G., although some contractors use stranded conductors as small as No. 12.

**Sector-shaped Conductors.** — Two, three and four conductor cables,

with sector-shaped conductors are in successful use, the three-conductor type being most common. It has been shown experimentally that if the conductors are properly shaped there will be lower dielectric stresses than in a round conductor cable of the same cross-section. The principal advantage of this type of cable, however, is the greater carrying capacity for a given outside diameter.

**Preparation of Conductors for Insulation.**—Where rubber insulation is used it is necessary to cover the conductor with a thin film of tin or with a layer of soft cotton threads.

**Tinning.**—Copper and rubber when brought into contact react upon one another chemically. It was formerly thought that this action was due to the sulphur in the rubber compound combining with the copper and in old days, it was common practice to place a layer of pure rubber next to the copper and the regular vulcanized compound over that. It was found, however, that pure rubber reacted with the copper even more vigorously than vulcanized rubber containing free sulphur. The pure rubber broke down into a sticky mass. It was later found that tinning the copper afforded the necessary protection as tin does not react with rubber.

**Separators.**—Small stranded conductors are usually covered with a winding of soft cotton threads for the following purposes:

1. To protect the copper and rubber from mutual chemical action where coating of tin on the copper cannot be used.
2. To hold together a group of fine wires so that individual wires will stand up and penetrate the insulation during the manufacturing process.
3. To prevent adhesion between the rubber and copper in order that the copper may be easily bared for making connections.

A separator composed of a wind of soft cotton is used on cords of various types for the first and second reasons. A similar cotton wind on small conductors or paper or dry muslin tape on large conductors is used on cables for car wiring for the third reason given above.

**Insulation.**—The materials used for insulation are vulcanized rubber, gutta percha, varnished cloth, impregnated paper, asbestos, cotton and silk threads, enamel, etc.

**Rubber Insulation.**—There are two processes by which rubber compound is put on wire, the strip and the tube or seamless processes. By the former, the compound is first made into long narrow strips and then pressed around the wire; by the latter, the wire is run through a die through which the compound is pressed on to the wire. Insulation made by the former process shows a seam or ridge where the sides of the strip have united, unless a tape is applied before vulcanization, while that made by the tube process is seamless.

Rubber insulating compounds are prepared by mixing rubber gum with sulphur, wax and fillers which may be mineral substances or rubber substitutes. Experience has shown that from 25 per cent to 30 per cent of rubber must be used in order to obtain compounds which will resist oxidation when exposed to the air.

The various grades of rubber insulation on the market may be divided into three classes, known respectively as 30 per cent Hevea, Intermediate and Gutta percha compounds. The majority of commercial 30 per cent Hevea compounds probably fall within the following limits of composition:

Ingredient	Percentage by weight
Rubber.....	30 to 35
Whiting.....	0 to 30
Zinc oxide.....	25 to 67

Ingredient	Percentage by weight
Litharge.....	1 to 12
Ozokerate.....	2 to 4
Sulphur.....	2 to 4

Compounds of intermediate grade usually contain less than 30 per cent of rubber mixed with reclaimed rubber, to make a total of at least 30 per cent per gum. The other ingredients are similar to those used in 30 per cent compounds.

Some compounds contain a mixture of new and reclaimed rubber, mineral or black hydrocarbon, sulphur and mineral fillers.

**Gutta-Percha** is applied to the wire in the same manner as rubber. It is only for deep-sea submarine cables.

**Varnished Cloth.**—The prepared cloth is applied to the conductor in the form of tape wound on helically and reversed every two layers, with overlapping joints staggered in successive layers. A thin layer of a non-hardening filler is applied between layers.

**Impregnated Paper.**—Strips of Manila paper are applied helically, thoroughly dried and impregnated with an oily compound.

**Asbestos.**—Asbestos is used for low-voltage wires to be used in very hot climates.

It is applied in the form of threads or tape, usually in several layers. In some cases more layers of varnished cloth are sometimes used to separate the groups of asbestos tapes, and the whole is covered with a protecting braid.

**Cotton and Silk.**—Cotton or silk insulation consists of one to three layers of threads spun on to the wire.

**Enamel.**—This type of insulation is suitable only for wires under 10 mm diameter. Cellulose acetate is a common form of enamel. A solution of cellulose acetate is applied to revolving coating rolls, which, in turn, deposit the coating on the moving wire. The quantity of solution placed on the wire must be controlled to a nicety. After receiving its coating of solution, the wire passes through an oven at the rate of several hundred feet per minute. The volatile solvent is here driven off and the coating hardened, after which the process is repeated until the required number of coatings have been applied. This method affords an even distribution of the film over the whole surface of the wire (R. S. 1917).

**Fillers.**—Dry jute or paper is used as a filler between the insulated conductors in multiple-conductor cables, being placed directly in contact with the insulation. Bituminous or asphalted jute is used as a filler between the sheath and armor of armored cables.

**Protective Coverings.**—Coverings of treated cotton, hemp, paper, reinforced rubber, and lead are used to protect cables from mechanical injury and corrosion.

**Cotton Braid.**—The most common covering for rubber-insulated conductors is a cotton braid saturated with a compound consisting of asphaltic materials and waxy hydrocarbons (principally paraffine wax). The hydrocarbon compound is used to carry the asphaltic material into the fibers.

The purpose of this saturation is to protect the cotton against natural deterioration.

The melting point of saturating compound is from 118 to 124° F.

The saturated cotton is covered with a finishing wax, the purpose of which is to fill the interstices between threads and to afford a smooth surface which will repel moisture and permit the wire to be drawn into a conduit with the least

friction. Finishing wax is usually composed of asphaltic material and high grade waxes, such as Carnauba and Montan wax, which are used to give it luster.

There are two important grades of finishing wax, one of which has a melting point between 156 and 166° F. and a higher grade which has a melting point between 180 and 190° F.

**Weatherproofing.**—Treated cotton braid is also put on uninsulated hard-drawn copper wire for overhead service, in order to protect the wire from destructive arcing due to accidental contact with tree branches and other foreign bodies.

**Lead Sheath.**—The only thoroughly waterproof cable covering yet devised is a lead sheath. It is put over the insulation by passing the cable through a die while hot lead is pressed hydraulically around it through an anvil die, forming a continuous and close-fitting pipe. Were it not for electrolytic corrosion, it would be practically permanent. Unfortunately lead is subject to electrolytic and even chemical corrosion. It is also rendered brittle and eventually breaks into pieces when exposed to vibration, this effect being due to crystallization. Pure lead is suitable for cables which are hard and compact. Other cables require a small quantity of tin to harden the lead. For a given thickness pure lead is cheaper, but for a given tensile strength a 50 per cent tin alloy is cheaper.

Antimony has been used instead of tin with very satisfactory results and material saving in cost, especially with telephone cable.

**Armor Wire and Tape.**—Submarine cables are usually covered with steel wire armor and cables to be buried direct in the ground are usually covered with galvanized steel tape armor. In either case the armor is covered with asphalted jute.

**APPLICATIONS OF VARIOUS TYPES OF CABLES.**—The type of insulation and protection to employ in any instance depends upon the purpose for which the conductor is to be used and the place in which it is to be installed.

**Power Cables,** that is, cables for the transmission or distribution of electrical energy, may be installed in buildings, in cars, in underground conduits, on poles, or under water.

Wires and cables for buildings are usually rubber insulated and covered with a saturated braid. Varnished cambric is often used for the larger sizes.

Wires and cables for power houses are usually varnished cambric insulated with either a saturated or a flame-proof braid.

Wires and cables for underground conduit lines are almost invariably paper insulated, but rubber or varnished cambric are sometimes used.

Wires for mining machinery and for railway signals are invariably rubber insulated.

**Submarine Power Cables** are usually insulated with rubber, sometimes sheathed in lead and armored with wire or steel bands. In recent years, however, paper-insulated lead-sheathed and armored submarines have come into extensive use.

**Communication Wires and Cables,** that is, wires and cables for telegraph and telegraph service, are rubber insulated where only two or three conductors are required. Cables composed of many pairs are generally insulated with dry paper and are known as dry-core cables.

Submarine telegraph cables are insulated either with gutta-percha or vulcanized rubber, the former being for deep-sea use. Such cables are protected by jute and steel wire armor.

Insulated Conductors for Instrument and Machine Windings. — For wire or wire insulated with cotton or silk is used for the former, while bed cambric, mica and asbestos compounds are used for the latter.

**INSULATION THICKNESS.** — The thickness of insulation required for storage cables is merely that necessitated by inevitable irregularities of nature and roughness in handling. At voltages between 500 and 1000, electric stress begins to have an influence and when 2000 volts are reached, electric stress becomes the dominant factor. If certain assumptions are made the thickness of insulation corresponding to a given dielectric stress can be calculated, but these assumptions are only partially realized in practice. These assumptions are:

1. That the radial depth of the insulation or dielectric is the same at all points, i.e., that the cross-section of the cable is a perfect circle with the conductor section (also a perfect circle) exactly in the center of the insulation. Due, however, to the crinkling of tape, the pressure of the braid, or other accidents in manufacture, this is never the case. The eccentricity of the conductor with respect to the insulation may, however, be allowed for by adding to the theoretical thickness of insulation an additional thickness, known as the "error thickness" or excess thickness.

2. That the dielectric is perfectly homogeneous throughout. This is never true in practice. It is probable that even in the most carefully made cable there is a minute amount of air and moisture, but sufficient to vitiate considerably any conclusions based on absolute homogeneity of the dielectric. In the case of impregnated paper, the lack of homogeneity results in constant departures from the following law.

3. That when the electric stress, or potential gradient at any part of the dielectric exceeds a certain value  $F_2$  known as its dielectric strength, that part of the dielectric becomes a partial conductor even though there is no actual rupture occurring.

4. The above assumption is made only in the case of rubber insulation, and then only when the electric stress is applied for a considerable time. The internal breakdown of the rubber appears to be due to the ionization of the air between the rubber and conductor, the rubber being oxidized, split internally, and showing signs of disintegration. (See C. A. Adams, Trans. A.I.E.E., 1917, pp. 514-517.)

**Theoretical Thickness of Insulation.** — Let

$F$  = potential gradient, in kilovolts per centimeter, at any point  $P$  in the dielectric at a distance  $x$  centimeters from the center of the wire, Fig. 1,

$V$  = kilovolts between wire and sheath (or outside surface of insulation).

$r$  = radius of wire, in centimeters,

$R$  = outside radius of insulation, in centimeters,

$F_2$  = dielectric strength of the insulation, in kilovolts per centimeter.

Fig. 1.

on the assumption of a perfectly homogeneous dielectric and perfect contact between conductor and insulation,

$$F = \frac{E}{x \log_e \left( \frac{R}{r} \right)}$$

∴ the potential gradient is the greatest at the surface of the conductor

and decreases toward the outer surface of the insulation as shown in Fig. 2. The potential gradient at the surface of the conductor is

$$F_{\max} = \frac{E}{r \log_e \left( \frac{R}{r} \right)}$$

For the same outside diameter of the insulation this stress at the surface varies with the radius of the conductor as shown in Fig. 3, and has a minimum value theoretically when  $r = R/2.72$ , but actually when  $R/r$  is somewhat greater than 2.72.

Fig. 2.

Fig. 3.

Consequently, if the breakdown of a cable is a progressive action, i.e., if the insulation breaks down close to the wire and then the breakdown spreads through the insulation, it is evident, from Fig. 3, that if  $r$  is greater than  $R/2.72$  and the impressed voltage  $E$  is such as to produce a stress  $F_r$  at the surface of the conductor in excess of  $F_s$ , then as successive layers of the insulation break down,  $F_r$  at each new conducting surface thus formed will be greater than  $F_s$  and the breakdown will rapidly extend to the sheath. If, however,  $r$  is less than  $R/2.72$ , then a value of  $F_r$  in excess of  $F_s$  will break down only a surface layer of insulation to render the value of  $F_r$  at the new conducting surface formed just equal to  $F_s$ .

Therefore, on the basis of the assumptions noted in the preceding section, the maximum voltage which a cable can withstand is equal to

$$E_m = F_s r \log_e \left( \frac{R}{r} \right),$$

provided  $R/r$  is less than 2.72, but when  $R/r$  is greater than 2.72 the maximum voltage is

$$E_m = F_s r_0 \log_e \left( \frac{R}{r_0} \right) = \frac{RF_s}{2.72},$$

and is independent of the radius of the conductor.

If there are films or globules of air in the insulation the dielectric stress in them will be greater than in the surrounding insulation in the ratio of the dielectric constant of the insulation to that of the air. As the dielectric constants of common insulating materials are between two and five times that of air, the air will be stressed between two and five times as much as the insulation. If the air ionizes at a much lower stress than the dielectric strength of the insulation, the limiting working voltage of a cable may depend upon the effects of air ionization. In the case of rubber insulation the principal effect is oxidation to ozone, but in the case of paper or varnished cambric the energy loss due to ionization is the most serious matter.

**Practical Determination of Insulation Thickness.** — On account of the numerous assumptions which must be made in determining the necessary thickness of insulation from any simple theory, such as outlined above, a theoretical

little value in the generality of cases and reliance must be placed upon  
ence, as embodied in the standards of various associations.

\* The rubber to comply with the rubber specification of the National Board of Underwriters, which assumes the use of 20 per cent of rubber gum.

† The A.I.E.E. Standards for 600 to 7000 volts are identical with the code except that they cover only 30 to 40 per cent hevea insulation and that for multiple conductor cables of any voltage the thickness of insulation on each conductor shall be based on the highest r.m.s. voltage between the conductor and the outside of the insulation.

‡ The rubber insulation to comply with the specifications of the R.S.A., which calls for a very high-grade 30 per cent Para compound.

\* Above working voltages are based on all conductors of the circuit being insulated. For d-c 600-volt railway single-conductor, leaded cables, use 1,000-volt class. For three-phase "Y"-connected circuits with grounded neutral and three-conductor cables, thickness of insulation between conductors and ground shall only be  $\frac{1}{2}$  of that between conductors.

† For three-conductor cables only, use 1,000-volt class for single-conductor from 0 to 1,000 volts.

‡ For three-conductor cables use  $\frac{1}{4}$  in. for No. 6 to No. 0000,  $\frac{3}{16}$  in. for 250,000 to 500,000 cir. mils and  $\frac{1}{4}$  in. for larger sizes.

n, Silk and Enamel. — The thicknesses rated by various manufacturers "single," "double," and "triple" covered differ by several mils; see *Electromagnet Windings*. Enamel insulation will stand a working voltage of about 500 volts alternating per mil of thickness. Silk or cotton insulation will stand about one-quarter as much.

**WEIGHT OF INSULATED WIRES AND CABLES.** — So many cables enter into the weight of an insulated wire or cable, and there are so many forms in use, that it is impossible to give comprehensive tables here. The reader is referred to the catalogues and circulars of the manufacturing companies. When such sources of data are not available the weight may be calculated from the dimensions of the cable by finding the sum of the weights of the conductors and the weights of the insulation, braid, tape, sheath, etc. The weight of a conductor may be found in the wire tables under *Wires and Cables, Rev.* The weight of the insulation, braid, tape or sheath, may be found by calculating the cross-section of each of these materials and multiplying by the length of the cable and a factor proportional to the density of the material; see the accompanying table.

The cross-section of a tube having an internal diameter  $d$  and thickness  $t$  is  $\pi(d+t)t$ . When the diameter and thickness are in inches and the specific gravity of the material forming the tube is  $\delta$ , then the weight in pounds per 1000 feet of tube is

$$W = 1362 \delta t(d+t).$$

The values of the specific gravity  $\delta$ , the product  $1362\delta$ , and the weight per 1000 feet, for the various materials used in the construction of cables are given in the accompanying table. From this relation the weight per 1000 feet of any tube (circular cross-section) layer of insulation, braid, tape or sheath may be readily calculated. The formula is, therefore, directly applicable to single-conductor cables.

The weight of duplex or triplex cables is calculated as for a group of conductor cables, except with regard to the fillers. The cross-section of the filling material is most readily calculated by subtracting from the cross-section of the entire cable the cross-sections of the individual conductors and the insulation, sheath, etc. The weight of twin cables can also be readily calculated by calculating the cross-section of the various parts in inches and multiplying by the length and the proper density factor.

The weight of separators in pounds per 1000 feet is usually between

#### WEIGHTS OF CABLE INSULATION

Material	Specific gravity, $\delta$	Pounds per cubic inch, $0.03613 \delta$	1000 ft.

is the mean diameter, expressed in inches, of the conductor and separa-

weight of saturated braids per 1000 feet is from 12 to 30 times the diameter of insulation expressed in inches.

corresponding multiplier for 12 mil tape with  $\frac{3}{4}$  lap, is 24.

**INSULATION RESISTANCE.** — The insulation resistance of a cable is expressed in megohm-miles, sometimes erroneously called megohms mile. The total insulation resistance of a cable varies inversely as its length, e.g., a cable two miles long has half the resistance between conductor and sheath of a length of one mile of this cable. The formulas for insulation resistance of various types of cables are given below.

**Two-conductor Cable.** — In absolute units the insulation resistance of a cable of length  $l$  centimeters of such a cable is

$$R' = \frac{\rho}{2\pi l} \log_e \frac{D}{d},$$

where  $d$  = diameter of conductor,  $D$  = outside diameter of insulation,  $R$  = insulation resistance,  $l$  = axial length,  $\rho$  = specific resistance. From the above formula megohm-miles are

$$R = k \log_{10} \frac{D}{d},$$

where  $k = 0.43 \times$  (specific resistance in millions of megohms per centimeter cube)

and  $d$  and  $D$  are in either inches or centimeters. The value of  $k$  for various types of insulation at 60° F., is given in the table. The time of electrification of a cable is usually one minute constant  $d-c$  volt-ampere in the accompanying table.  $k$  varies with the time of electrification and with the temperature.

Insulation	k at 60° F.	
	Limits	Usual values
Vulcanized rubber.	780 to 23,000	3000 to 6000
Gutta-percha.....	500 to 4,000	2500
Varnished cloth....	400 to 1,200	700
Impregnated paper.	1000 to 3,000	1500

Tables on the following pages give the value of  $\log_{10} \frac{D}{d}$  for various sizes of cables and thicknesses of insulation.

Insulation resistance measured with alternating current, it will be much less than with direct current because of the dielectric loss.

**Two-conductor Cable in Lead Sheath.** — The insulation resistance between the two conductors of a two-conductor cable is practically the same as between each conductor separately and the sheath.

Insulation resistance of a three-conductor cable between any one conductor and the other two conductors and the sheath is approximately one-half that between each conductor separately and the sheath. Simple formulas for insulation resistances in terms of the dimensions of the cable are not available, as various parts of the coverings (insulation, fillers and braids) have different specific resistivities.

**CAPACITY AND CHARGING CURRENT.** — See article on *Capacity and Charging Current*.

**INDUCTANCE, REACTANCE AND IMPEDANCE.** — The formulas for bare wires and cables (see *Inductance and Inductive Reactance*) are also applicable to lead-sheathed insulated cables, the insulation and sheath producing practically no effect on the self inductance.

**Resistance and Impedance of Three-conductor Cables.** — The following table, published by the G. E. Co., is based upon 100 per cent conducting copper at 75° F., with an allowance of 3 per cent for spiral path of the component wires, 60 cycles per second, and standard thicknesses of varnished cambric insulation.

## RESISTANCE AND IMPEDANCE OF THREE-CONDUCTOR COPPER CABLES

Resistance ohms of each con- ductor per mile <i>R</i>	Impedance of each conductor at 60 cycles, ohms per mile, <i>z</i>

$e$  is  $x = \sqrt{z^2 - r^2}$ ; the inductance is  $L = x + 2\pi f$  where  $f$  is the cycles per second.

**and Reactance of a Pair of Armored Single-conductor**  
J. B. Whitehead (*Trans. A.I.E.E.*, 1909, Vol. 28, p. 737), gives formula for the self inductance of each of two parallel armored cables:

$$L = 0.161 \left\{ 2 \log_4 \frac{D}{r} + \frac{1}{2} \right\} + 0.078 (k - 1),$$

henrys per mile of each conductor,

$D$  = distance between centers of conductors, any unit,

$r$  = radius of each conductor, in same unit as  $D$ ,

$k$  = permeability of the armor wires.

The paper concludes as follows: 1. Theoretically the reactance of single-conductor, iron-armored power cable may be from 1.5 to 2 times that of unarmored cable, depending on the distance to return wire. 2. In cables as manufactured the reactance is about 0.7 of the maximum theoretical value as calculated by the above formula. 3. The effective resistance at 25 and 60 cycles is respectively 1.5 and 1.7 times the d-c. resistance for a current density of 1000 circular mils, and varies little with the distance between conductors. 4. The impedance for distances under 12 inches is about 3 times that at 60 cycles and 1.7 to 2 times the d-c. resistance at 25 cycles. 5. The impedance is and the armor grounded at both ends the impedance is and is largely of the nature of resistance. 6. The impedance of iron-armored cable with conductors located 0.873 inches apart and at the current density given above is about 5 per cent greater at 25 cycles and 3 per cent greater at 60 cycles than the calculated value. 7. The increase in effective resistance, due to eddy currents in the lead

H. W. Fisher (*Trans. A.I.E.E.*, 1909, Vol. 28, p. 747) says that the insulation of armored cables cannot be calculated with any degree of certainty owing to the effect of slight differences in the air gaps between armor wires. He adds that a single-conductor No. 0 B. & S. cable armored with two flat bands of steel ( $0.39 \times 1.1$ ) may have a maximum effective resistance 8 times the resistance when the lead and armor are disconnected, and that under practical conditions of operation the ratio is about 3.5. With larger cables the ratio will be greater.

Unless the armor and lead of single-conductor cables are bonded together, arcs may occur between them and under water they would be injured by alternating-current electrolysis. Single-conductor steel armored cables cannot be used with 60-cycle currents greater than 8 or 10 amperes because of the resistance and losses due to hysteresis and eddy currents.

#### CURRENT-CARRYING CAPACITY OF WIRES AND CABLES

The maximum permissible temperature rise of insulated conductors is limited by the effect of heat upon the insulation. The highest temperatures that may be safely attained continuously are given in the table below.

Insulation	Maximum permissible temperature centigrade	
	Low voltage	At E kv. between conductors
Impregnated paper...	85	85-E
Varnished cambric...	75	75-E
Rubber insulation...	60	60-0.25E

When rubber is heated, the usual order of events is as follows: Oxidation accelerated if air is present, "devulcanization" commences, i.e., the rubber molecule breaks up without, however, liberating any sulphur; vulcanization proceeds until all the free sulphur has combined with the rubber or some other matter. In the case of varnished cambric, both the insulation resistance and dielectric strength fall quite rapidly after the limiting temperature is attained. The same applies to impregnated paper in a less degree. Furthermore, at high voltages, the dielectric loss is often considerable, and if neglected in calculating carrying capacity, is likely to make one overlook possibilities of temperatures far in excess of those to be expected on the basis of  $I^2R$  losses alone. The A.I.E.E. rule for high voltage cables may be assumed to refer to temperatures calculated on the assumption that the only losses are ohmic losses in the conductor. Hence, if the A.I.E.E. temperatures are used, dielectric losses may be neglected and the carrying capacities derived from these temperatures may be used with safety. The A.I.E.E. rule is equivalent to assuming that the dielectric

loss in watts per foot are equal to  $12 \frac{E}{R}$  (see below).

Where, however, cables of either very low or very high dielectric loss are used, it may be advisable to calculate the carrying capacity, taking the dielectric loss into account, as in the former case a higher, and in the latter case, a lower carrying capacity will be obtained than when the A.I.E.E. rule is followed.

formula for Carrying Capacity, Using A.I.E.E. Rule. — Where the cable traction or operating conditions are unusual, the carrying capacity may be stated from the following formula.

$$I = 110 \sqrt{\frac{T}{rR}}$$

where  $I$  = amperes,

$T$  = permissible temperature rise, degrees centigrade,

$r$  = electrical resistance per 1000 feet of each conductor in ohms (the factor 110 would become unity if  $r$  were expressed in ohms per inch),

$R$  = heat resistance, from conductor to air, in degrees, centigrade rise per watt lost in each inch of conductor (see below).

formula for Carrying Capacity, Using Actual Dielectric Loss. — When desired to take into account the dielectric loss, an approximation may be made by assuming the entire dielectric loss to occur at the surfaces of the conductors. Then:

$$I = 110 \sqrt{\frac{1}{r} \left( \frac{T}{R} - W \right)}$$

where  $W$  = dielectric loss per inch of cable for each phase at the ultimate temperature. This is 1/30 of the dielectric loss in watts per foot of cable,

example. — In the case of a No. 0000 paper insulated cable for 12,000 volt use, with a dielectric loss of one watt per foot at 85° C., the carrying capacity will be about 5 per cent less than if the dielectric loss were zero.

formulas for Heat Resistance of Cables. — The heat resistance of single conductor cables may be calculated from the formula given below.

where  $D$  = overall diameter of cable, inches,

$Q$  = ratio of the outer to the inner diameter of each layer of heat insulation,

$K$  = heat resistivity of the material of each layer of heat insulation in degrees centigrade rise per watt per inch cube.

= 285 for rubber,

= 300 for varnished cambric,

= 300 for impregnated cotton,

= 465-485 for impregnated paper,

= 100 for asphalted jute,

= 300 for impregnated cotton braid.

$H$  = heat resistivity from cable surface to room, in degrees centigrade per watt dissipated from each square inch of surface.

= 120 for impregnated braid,

= 120 for painted steel braid,

= 180 for lead bright,

= 155 for lead dull.

then,

$$R = 0.318 \frac{H}{D} + 0.367 \sum K \log_{10} Q.$$

A corresponding formula for multiple conductor cables has been developed by and is quoted by Powell, *Trans. A.I.E.E.*, 1916, Vol. 35-2, p. 1035. The resistances of triplex paper, lead cables are given below, based upon Mie's formula and the following heat resistivities,

$$K = 475 \text{ and } H = 155.$$

These tables give the heat resistance from each conductor to air and are used with values of  $r$  for one conductor to get the carrying capacity of each conductor.

## HEAT RESISTANCE OF THREE-CONDUCTOR CABLES

When a cable is in a duct, the heat resistance of the duct should be taken into account. For a single duct, this is usually from 1 to 20 degrees C. per watt lost in each inch of duct. Clark and Shanklin, *Trans. A.I.E.E.*, 1920, give the heat resistance from the conductors in a cable, to the earth, as 69° C. lost in each inch of duct, or 207° C. per watt lost in each inch of each conductor of a triplex cable. R.W. Atkinson, *Jour. A.I.E.E.*, Sept., 1920, gives 100 per watt-inch as a safe average figure for a conduit containing up to 16 surrounded by earth with a normal amount of moisture.

**TABLE "A" TO REDUCE CARRYING CAPACITY PER CABLE WHEN SEVERAL EQUALLY LOADED CABLES FILL A DUCT LINE**

This table is based on the following heat resistivities:

Material	C° per watt per inch cube
Rubber.....	285
Varnished cambric.....	300
Impregnated paper.....	475
Saturated braid.....	300
	C° per watt per square inch
Lead (to air).....	155
Braid (to air).....	120

**Cables Buried Underground, Under Water, etc.** — A cable buried in earth will carry 25 per cent more current with a given rise in temperature than it will when run in a dry duct, depending upon the character of the soil. Immersed in water it will carry about 50 per cent more.

**Current-carrying Capacity of Lead Sheath.** — The carrying capacity of a lead sheath is given approximately by the following formula:

$$C = 128 \sqrt{d^2 - p^2} T,$$

where

$d$  = outside diameter of sheath in inches,

$p$  = thickness of sheath in inches,

$T$  = temperature rise, ° C.

**Rise of Temperature with Time.** — Fig. 5 shows the rise of temperature with time for a single conductor, 0.5 square inch in cross-section, carrying 750 amperes. Curves I to VI are from a paper by C. Beaver (*Jour. I.E.E., 1911*) and curve VII from Del Mar's *Electric Power Conductors*.

### TESTS AND INSPECTION OF INSULATED WIRES AND CABLES.

(See also section on Specifications, below.) Wires and cables are submitted to factory tests to ascertain whether they meet specified requirements. For the tests on the conductors themselves, see the article on *Wires and Cables, Bare*. The usual factory tests of insulation are the high-potential test and the measurement of insulation resistance and capacity. In the case of rubber insulation, the tensile strength and elasticity of the insulation are also measured. Insulated wires and cables are also tested after installation to discover incipient faults and to locate existing faults.

The tests described below in greatest detail are those employed by the majority of American cable manufacturers and operating engineers. Methods of measuring insulation resistance are described in the article on *Resistance and Conductance*, and methods of measuring capacity and inductance in articles on *Capacity and Inductance*.

**A.I.E.E. Rules for Tests.** — Electrical tests of insulation on wires and cables shall be made on the entire lengths to be shipped.

The outer surface of the insulation of complete insulated wires and cables shall be grounded while being electrically tested. If the insulation is not protected with a conducting covering and if the covering is not liable to injury by contact with the ground, shall be obtained by immersing the insulated wire or cable in water for at least twelve hours and testing at the end of that period while immersed. If the outer covering is susceptible to injury by immersion, the insulated conductor shall be tested before the application of such covering.

Dry core paper-insulated lead-covered cables, such as telephone and telegraph cables, for use in water, shall be tested after at least twelve hours' immersion.

In the case of multiple-conductor cables, without waterproof overall protection of insulation, no immersion test should be made on finished cables, but only the individual conductors before assembling.

**High-voltage Tests.** — High-voltage tests are intended to detect weak spots in the insulation and to determine whether its dielectric strength is sufficient

Fig. 5.

enabling it to withstand the voltage to which it is likely to be subjected  
 ice, with a suitable factor of assurance.

voltage tests shall be made at the factory by applying an alternating  
 between the conductor and sheath or water. The initially applied  
 must not be greater than the working  
 and the rate of increase shall be ap-  
 ply uniform and not over 100 per cent  
 nds.

in the case of communication cables  
 s insulated with code rubber come  
 e duration of the test voltage shall  
 onsecutive minutes. Code wires are  
 one minute.

ultiple-conductor cable is designed  
 ne operating voltage between cond-  
 d sheath or water as between cond-  
 h conductor shall be tested against  
 onductors connected together and  
 h or water. If the cable is designed  
 ating voltage between conductors  
 different from that between con-  
 test between conductors and the  
 ter shall be made separately and  
 l on the normal operating voltage  
 ductors and sheath or water as  
 the accompanying table.

s based upon the minimum thick-  
 tion specified by engineers and  
 anpanies. The following tables

Tests on three-phase cables for grounded neutral in proportion to thickness of insulation: Example, three-phase 13,000-volt circuit "Y," neutral grounded, insulation on each conductor  $\frac{3}{16}$  inch (total between conductors  $\frac{1}{2}$  inch), outer belt  $\frac{3}{16}$  inch (total  $\frac{3}{8}$  inch); test pressure at factory for five minutes, between conductors 32,500 volts, each conductor to earth 17,500 volts.

## HIGH-VOLTAGE TESTS FOR RUBBER COVERED WIRES AND CABLES

(a) National Electric Code, One Minute Test

Size	Working voltage					
	600	1500	2500	3500	5000	7000
14 to 8 A. W. G.	1500	6000	8000	10,000	12,500	17.5
6 to 2	2000	7000	9000	10,000	12,500	17.5
1 to 0000	2500	8000	10000	10,000	12,500	17.5
225,000 to 500,000 cir. mils	3000	9000	10000	11,250	12,500	17.5
600,000 and over cir. mils	3500	10000	10000	12,500	12,500	17.5

(b) A.I.E.E. Standards, Five Minutes Test

One kilovolt per 64th inch insulation thickness up to  $1/64$  in. Above  $1/64$  to kilovolts plus 1.5 kv. per 64th inch up to  $3/64$ . Where thickness is  $1/64$  or over, rule applies only to conductors as big as No. 6 A.W.G. The A.I.E.E. allows lower test voltage for working voltages up to 600 v. a-c. In this case the rule is as follows:

14-8 A.W.G.	3.0 kv.
7-0000	3.5
250,000 and larger	4.0

stripped from stranded conductors are neglected in computing the cross-sectional area.

In order to measure its tensile strength the sample of rubber is held in a sort of grip and stretched in a machine similar to that used for wire (see *Bulletin of Standards Bulletin No. 37*). It is usual to reduce the results thus obtained to pounds per square inch.

**Tests after Installation.**—A high-potential-test with the voltages given above in the tables is usually applied to the full length of cable immediately after installation and at regular intervals to detect incipient faults. The line voltage is frequently used for the periodic tests. Grounds or crosses of relatively low resistance may be detected by bridge methods or by explosion as described below.

Fig. 6.

Fig. 7.

Some engineers make periodic insulation-resistance tests and plot the results as a curve. If the curve manifests any decided downward tendencies the cause is immediately sought for. The methods of making these tests are given below.

**Testing for Faults by Murray Bridge Methods.**—The bridge used in the Murray loop tests is shown diagrammatically in Fig. 6. It consists essentially of a resistance wire graduated into two equal scales each reading from 0 to 100, the zero points being at the ends of the wire. A galvanometer

connected across the zero points and a flexible lead connected to the positive terminal of a source of direct current is put in sliding contact with the bridge. The negative terminal of the direct-current source is grounded.

**One Conductor Grounded.**—When one conductor of a multiple-conductor cable is grounded, the bridge is connected as shown in Fig. 7, a jumper being placed between the faulty conductor and one of the others. The sliding contact is moved along the bridge wire until the galvanometer deflection becomes zero. Let  $a$  = distance of sliding contact, on bridge scale, to the terminal of bridge connected to faulty wire, as a percentage of the length of half the bridge wire, and  $L$  = length of cable; then if  $x$  is the distance from the bridge to fault,

$$x = \frac{aL}{100}.$$

**Two Conductors Crossed.**—When one conductor of a three-conductor cable is crossed with another, the bridge is connected as shown in Fig. 8, a jumper

Fig. 8.

Fig. 9.

is again used, although connected differently. Zero reading is obtained on galvanometer as before, and, using the same notation,

$$x = \frac{aL}{100}.$$

**One Conductor Open.**—When one conductor is open, the bridge is connected as shown in Fig. 9, a telephone receiver being substituted for the galvanometer, alternating current for the direct current. The sliding contact is moved along the bridge until silence is obtained in the telephone.

Let  $a$  = distance from sliding contact to the terminal of bridge connected to the conductor,

$b$  = distance from sliding contact to the terminal of bridge connected to whole conductor: then,

$$x = \frac{b}{a} L.$$

**Ayrton's Method to Detect Crosses.**—In Fig. 10,  $a$ ,  $b$  and  $r$  represent three arms of a Wheatstone bridge, the fourth arm being the conductor  $N$ , which is in contact with a second conductor  $M$  of the same cable at the point  $P$ . Ground the conductor  $N$  at the far end and let  $x$  and  $y$  be the resistances

Fig. 10.

Fig. 11.

of the grounded conductor from the bridge to  $P$  and from  $P$  to the ground and respectively. Let  $a$ ,  $b$  and  $r$  be the resistances of the other three arms of the bridge. Make  $a = b$ , and adjust the variable resistance  $r$  until the galvanometer shows no deflection; then

$$x + y = r,$$

neglecting the resistance of the ground.

Then connect battery to  $M$  instead of to earth as shown in Fig. 11, and adjust  $a$  to a value  $a_1$  such that the galvanometer shows no deflection. Then  $ax = a_1r$

$$\frac{x}{x+y} = \frac{b}{b+a_1}.$$

But from first arrangement  $x + y = r$ , whence

$$x = \frac{br}{b+a_1}.$$

From the resistance of the conductor per foot, the distance to the point  $P$  is then immediately determined.

**Varley Loop Test for Grounds.** — Grounds may be located by the arrangement shown in Fig. 12. Loop the bad wire at the distant end with a good one of equal resistance. Call the resistance of the good wire  $c$  and the resistance to the fault on the bad wire  $x$ . Adjust the rheostat until the galvanometer balances. Then

$$x = \frac{2bc + ar}{a + b},$$

Fig. 12.

$a$ ,  $b$  and  $r$  being the values of the bridge arms and rheostat respectively when the galvanometer shows no deflection. (*S. G. McMoran.*)

**Varley Loop Test for Crosses.** — This is made by substituting one of the crossed wires for the earth path of Fig. 12, using one good wire as before.

**Cable Tests by Exploring Coil.** — Grounds on wires in cables can be located by the use of a telephone receiver connected to an exploring coil. To do this, connect a source of interrupted current to one end of the wire in trouble, the other terminal of the source being grounded. Remove from the wire in trouble all the grounds other than the fault. Then move along the cable a coil such as one spool of an 80-ohm telephone ringer (see *Telephone*) across whose terminals a receiver is connected. Hold the exploring coil with an iron core at right angles to the cable. A tone from the interrupter should be heard when the exploring coil is between the fault and the source of sound but not when it is beyond the fault. (*S. G. McMoran.*)

**Listening Tests on Telephone Lines.** — A long telephone line will usually show a fault if one of its wires is grounded, open or crossed with a third wire, which the latter be grounded or clear. To determine where the fault is, listen on the line while assistants short-circuit it at different places. The fault is beyond the short-circuit if the short-circuit makes the line quiet. (*S. G. McMoran.*)

**SPECIFICATIONS.** — (See also articles on *Wires and Cables, Bare.*) The following forms are recommended for insulated wire and cable specifications. The general idea is for the purchaser to have printed or mimeographed forms and to fill them in according to specific requirements. These tabular specifications are supplemented by general specifications for workmanship and material which should be included when bids are sought or orders given. This arrange-

It minimizes the chance of accidental omission on the part of the purchaser manufacturer and saves the bidder time in reading long specifications.

**Items to be Covered in Detail Specification. —**

Specification No.,

State briefly the service for which the conductor is intended,

Number of separately insulated conductors,

Material of conductors,

Kind of stranding (parallel, concentric or rope),

Number of strands per conductor,

Number of wires per strand (if rope strand),

Minimum area of conductor or A.W.G. No.,

Conductor shall *not* be tinned (omit the word "not" as required),

Kind of separator, if any,

Insulation material, each conductor,

Kind of belt,

Minimum thickness of insulation, each conductor,

Kind of belt,

Kind of material,

Number of tapes, each conductor,

Kind of tapes, over each layer,

Kind of over-all,

Kind of core wire (if any), size,

Kind of insulation,

Location,

Kind of armor, material,

Number,

Thickness, inches,

Kind of material,

Number on each conductor,

Number over-all,

Kind of armor (if required), material,

Number,

Arrangement,

Kind of armor (if required), material,

Kind of material under sheath,

Kind of material,

Kind of material, thickness of sheath,

Kind of material between sheath and armor, material,

Thickness, measured after armoring,

Kind of material, wire or band,

Kind of material over armor,

Minimum over-all diameter (if limit is necessary),

Kind of material, maximum,

Kind of material, minimum,

Number to be supplied in coils or on reels,

Workmanship and materials shall conform with stated general specifications as the following:

**GENERAL WIRE AND CABLE SPECIFICATIONS. —** Purchasers are desirous of obtaining wires or cables of adequate design and good condition, use specifications which describe the major details of construction to be followed and tests to be applied.

Formerly every customer who purchased on specification wrote his own specifications, but this led to endless difficulty with the manufacturers who had to make special compounds or follow special rules for each customer. In recent

years various engineering societies have adopted standard specifications which are now largely used.

*American Institute of Electrical Engineers.* — (a) *Standards of the A.I.E.E.* which cover definitions of terms, methods of test, insulation thickness for all grade rubber insulation, test voltages, etc.

(b) *Marine Code*, which covers merchant ship wiring.

*American Railway Association.* — Signal wire specifications.

*American Railway Engineering Association.* — General wire specifications

*American Society for Testing Materials.* — Specifications for bare copper wire and cables. Tentative specifications for rubber-insulated conductors.

*Association of Railway Electrical Engineers.* — Specifications for practical all types of wires and cables used by railways. (Now becoming obsolete.)

*Joint Rubber Insulation Committee* (superseded in 1921 by A.S.T.M.). — Specification for 30 per cent hevea rubber insulation.

*National Board of Fire Underwriters.* — Specification for wires and cables to be used in buildings.

*National Electric Light Association.* — Specifications for paper-insulated lead-covered underground cable.

**Rubber-insulated Wire and Cable.** — Most of the characteristics of rubber compounds are so good from the point of view of electrical insulation that the efforts of purchasers are mostly concentrated on obtaining life, or permanency.

There are three recognized standard specifications for rubber insulation: the National Electrical Code specification which is the least severe, the Joint Rubber Insulation Committee specification which has severe chemical requirements and the American Railway Engineering Association (Signal Division) specification which specifies a formula and requires rigid inspection during manufacture. The idea of chemical clauses is that by specifying close limits upon the following analytical results (obtained by a standard method of analysis), the use of inferior permanent substances will be prevented.

Analytical results upon which limits are placed	Deleterious substances whose use is prevented by limits upon analytical results
Total sulphur	Reclaimed rubber
Alcoholic potash extract	Rubber substitutes
Chloroform extract	Tars
Mineral matter	Carbon, cellulose, etc.
Saponifiable acetone extract	Unextracted high resin rubbers
Unsaponifiable acetone extract	Deresinated rubber

The chemical requirements are supplemented by mechanical and electrical requirements, the former for the purpose of checking vulcanization and the latter to ensure proper insulating qualities.

**Paper Cable.** — The principal characteristic which is insisted upon for low voltage paper insulated cables is good condition of the paper in regard to mechanical strength, in order that the cable may not be injured during installation. When cables are installed they often have to be bent to a very short radius, and unless the paper is in very good condition, it will crack, usually on the outside of the bend. If the paper is wrinkled, scorched or improperly lapped, it will break open when it is installed.

chairs, therefore, require that a high grade of manila rope paper be used that it be free from wrinkles, tears and scorches.

In the case of high-voltage cables, in addition to the requirements for low-voltage cable, it is usual to put a limit upon the dielectric losses in order to insure the cable having ample carrying capacity.

Where bending tests, followed by high voltage tests, are often specified to detect defects in the paper, and lack of uniformity in drying or impregnating caused by the megohms test.

**Varnished Cambric Cable.**—Most of the specifications for varnished cambric cables are not very severe, except in requiring a smooth application of varnish and proper overlap.

Dielectric loss requirements are not applied to varnished cambric cables, and the recent specifications call for certain characteristics of the varnish itself, which make it necessary to use only the highest grade of cloth.

The specifications call for soaking the cambric in petroleum at a high temperature to make sure that it does not become tacky as a result of reaction with the "mer" compound.

**INSTALLATION OF INSULATED WIRES AND CABLES.**—For the installation of wires and cables in buildings see articles on *Wiring of Buildings*, *Light and Power*; *Wiring of Buildings for Miscellaneous Devices*. Below is a brief description of modern practice in installing insulated wires and cables on messenger wires and in underground conduit systems. For the construction of the pole lines carrying the messenger wire see articles on *Poles and Pole Lines*; *Towers, Transmission*. For the construction of conduit systems see article on *Conduits and Conduit Lines*. See also the articles on *Distribution Lines* and *Transmission Lines*.

**Messenger Construction.**—The messenger wire is erected in the same manner as an ordinary line wire; see article on *Transmission Lines*. A "leading wire" is stretched from the bottom of one pole to the messenger wire on the next pole, forming an incline on which to pull up the cable. A pulling rope is fastened to the end of the cable by means of a cable grip and carried over the side of the messenger to the point where the cable is to reach, thence through a ch-block down to the terminal pole to a second block at the bottom and up to a capstan, winch, locomotive or whatever is to be used for pulling. Temporary rollers should be provided on the poles over which the rope runs and the rope should be suspended from the messenger by wire hooks. The cable is then slowly drawn up the inclined wire and along the messenger, attaching temporary carriers to the cable as it is paid out and hooking them over the messenger to carry the weight of the cable. Linemen must be stationed on each span to pass these carriers around the messenger clamp or insulator. The final tensioning of the cable may be accomplished in either of the following ways: (1) When the end of the cable arrives at the beginning of the last span, the men on each pole replace the temporary carriers by permanent hangers, and pass them regularly along the cable, so that when the last span is pulled, all hangers will be in place. (2) When the cable has been pulled all the way, a man rides along the messenger wire in a carriage replacing each temporary carrier by a hanger. This plan is preferable as the hangers may be attached directly to the messenger wire, and are less likely to slip on the cable.

**Installation of Cables in Ducts.**—The conduit system having been completed, it must be prepared for the reception of the cable by being cleaned and rodded as described in the article on *Conduits and Conduit Lines*.

Where there are several ducts available, the choice of the particular duct to be used should be governed by the following considerations: 1. Avoiding un-

necessary crossings of cable in the splicing chambers, substations, etc.; 2. Avoiding the obstructing of empty ducts; 3. Keeping the cables cool; and 4. Keeping d-c. cables away from others. The following statement in the catalogue of the A. S. & W. Co. is pertinent with regard to keeping the cables cool. "Usually the coolest and best heat-radiating ducts are those located at the lower corners of the system, next are those nearest to the outside of the system and lastly the middle and top ducts which not only take up heat from the lower cables, but must dissipate heat through adjoining ducts. Attention to these points when planning a new system may prove very profitable in the end."

Fig. 13.

The next step is to set the cable reel on the shaft of a pair of wheels of slightly greater diameter than the reel itself or on jacks and raise it slightly above the ground, taking care to locate it as shown in Fig. 13, so that the cable will unreeled into the manhole without making a reverse bend.

The pulling rope having been left in the duct after rod-ding, the cable is unreeled sufficiently to bring its end close to the mouth of the latter and a wire pulling grip (Fig. 14) is drawn over its end. The end of the grip is hooked to the rope and the rope pulled from the other end. Fig. 15 shows an arrangement of pulleys for guiding the pulling rope. The pulling may be done by capstan, winch, motor truck, horse or by hand, depending upon the size and amount of cable to be pulled, and upon local conditions. The cable should be carefully guided into the duct so as to avoid sharp bends and abrasions, and a small quantity of grease may with advantage be spread over the cable as it enters the duct. R. J. Robb (*Journ. I.E.E.*, 1911, Vol. 47, p. 350) says that 112 pounds of petroleum jelly is required per mile of cable. It is also necessary to cover the edges of the duct with pieces of lead to prevent abrasion of the cable as it passes into the mouth of the duct.

Fig. 14.

Fig. 15.

**Protection of Cables in Splicing Chambers.** — (See also article on *Conduits and Conduit Lines*.) Wherever there are several large cables in a splicing chamber, there is always danger that a burn-out of one cable will involve some or all of the remainder. Hence it is usual to protect such cables by means of one or more of the following methods:

1. Concrete shelves,
2. Open-face conduits,
3. Cement coating with  $\frac{1}{4}$ -inch rope bond,
4. Asbestos tape saturated with silicate of soda,
5. Asbestos tape covered with soft steel-tape armor,
6. Asbestos rope,
7. Split tile duct.

Methods Nos. 1 and 2 are applicable only to chambers containing few cables

3 has given good results in many cases, but the cement is liable to crack fall away from the cable unless carefully bonded. On the other hand, the ion of a burn-out is plainly indicated by the cement covering being blown. No. 4 combined with No. 5 is very generally used and gives very satisfactory results. No. 6 is but little used. No. 7 is very satisfactory, but is clumsy, and cannot be used where there are many cables in the chambers. The necessity for such protection (according to the Committee on Under-construction of the N. E. L. A., 1911) is equally great with low-tension cables as with high-tension cables, for, while a breakdown of the insulation of a high-tension cable is often attended with a violent explosion and the generation of a very high temperature, the duration of the trouble is limited to one or two seconds; whereas in the case of a short circuit on a low-tension cable, it continues to burn with a considerable flame for several minutes, which may be quite long enough to damage adjacent unprotected cables.

In the case of direct-current feeders for electric railways, where the return is grounded, the danger of burn-outs spreading is much greater than with the usual lighting systems referred to in the N. E. L. A. report. This subject is treated at greater length in the author's *Electric Power Conductors*, in which the following is quoted: "If it is necessary to put direct- and alternating-current cables in the same duct line, it is well to isolate the direct-current cables as much as possible in the splicing chambers. The racks on which direct-current cables are supported should not be in metallic contact with other racks. However, this is unavoidable, the cables should not lay directly on the racks, but on insulating pads or blocks."

**Inspecting Insulated Conductors.** — (See also article on *Wires and Cables*, p. 2035.) Having selected the corresponding cable ends, they should be inspected for mechanical defects along the entire exposed length and bushings placed over them at the ducts so that the sheath will not be cut by the edges of the bushings. The cables should then be bent until the ends overlap, the bends being of ample radius throughout, and the position of the cable such that the ends, when completed, will not have to bear any elastic stress or weight.

**Drying Out Cable Ends.** — In the case of paper- or cambric-insulated cables, the ends should be examined for moisture before they are finally cut and if any exists or is suspected, heat should be applied to the sheath, starting at the duct end and slowly working to the open end. This is usually done with a gasoline torch but sometimes by pouring on hot insulating compound.

**Overlap.** — This operation having been completed, the cable ends are prepared so as to leave an overlap, depending upon the method of joining the conductors (see below) and upon the number of separately insulated conductors in the cable. If the cable has but a single conductor, and a butt joint is to be used, the overlap should be merely sufficient to allow for cutting off the ends, whereas if an interlaced joint is contemplated, the overlap should be greater by about 4 times the diameter of the conductor.

**Removal of Sheath.** — The next operation is to cut off a sufficient length of lead sheath to permit the joint to be made. This length may be determined from the size of the sleeve to be used (see below). The operation is performed with a chipping knife and hammer, or with a special tool designed for the purpose, and the greatest care should be exercised to avoid cutting the insulation to the slightest degree. It is usual to make a cut around the sheath and gradually increase its depth until the lead is cut through. The lead must not be cut lengthwise from the circular cut to the end, injury to the insulation being avoided by holding the knife tangent thereto. The lead may then be led off with a pair of pliers and loose particles carefully removed. In the

case of high-tension cables the ends of the lead should then be turned up slightly to a bell-mouth shape by means of a fibre wedge.

**Putting on Lead Sheath.** — Before jointing the conductors, the lead sleeve should be slipped over one of the cable ends and pushed out of the way. The ends of the sleeve and the corresponding surfaces of the sheath should have been previously scraped for a length of about a couple of inches along the outside and the cleaned surfaces smeared with stearine.

**Removal of Insulation.** — The next step is to cut back the insulation for a length between  $\frac{1}{4}$  and  $\frac{1}{2}$  inch greater than half the length of the connector to be used, and taper the remainder uniformly for a distance of 1 to  $1\frac{1}{2}$  inch using a small sharp knife. In the case of multiple-conductor cables having a belt, the belt must be cut back sufficiently to expose all the joints, the greatest care being exercised to avoid cutting the inner insulation in doing so. The paper tapes should be tied with string to prevent unwrapping. The surface of each taper should be covered temporarily with a strip of dry cloth.

**Jointing the Conductors.** — The next process is to prepare the conductor or conductors for jointing. The most usual type of joint is made by butting the ends of the conductors and enclosing them in a cylindrical copper connector. The conductors are first cleaned with gasoline and then tinned by pouring molten solder over them, using stearine for flux. All burrs should be removed with a file and the ends smoothed so that they will butt together perfectly. The connector is then put over one conductor end and the other end slipped in until the two ends butt. Solder is then poured over the joint until it is thoroughly saturated, when the surplus is wiped off so as to leave no sharp projections.

**Connectors.** — The connector should have a cross-section not less than that of the conductor and a length about four times the diameter of the conductor.

From points  $\frac{1}{4}$  inch back from each end, it should be pencilled down to the rounded edges at the ends, and it should be split the entire length.

It should be finished so as to eliminate all sharp points and edges. The opening should not be over  $\frac{3}{16}$  inch in width.

**Jointing Stranded Conductors.** — While the connector joint is by far the most common, stranded conductors may be joined by cutting the wires alternately long and short, and fitting the two conductor ends into one another. The joint is then bound with small wire. Stranded conductors are sometimes joined by cutting the wires of successive layers alternately long and short, and telescoping the ends into one another.

**Insulation of Joint.** — The next step is to insulate the joint. The depression at each end of the copper sleeve should be filled flush with impregnated 4-strand cotton twine, which should be thoroughly impregnated with compound. The usual process is to cover the joint with a tape of similar material to the remainder of the cable insulation, although this method is not universal. If oiled paper or varnished cambric, the tape should be cut on the bias. Narrow strips of impregnated tape should first be wrapped back and forth in the space between the two ends of the original paper insulation until it is built up to the level of this insulation. Compound should be applied on each layer. Wider tape is then wound on until a thickness about 40 per cent greater than that of the cable insulation is reached.

In the case of three-conductor high-tension cables the wrapping should commence at a point on the covered conductor 3 inches from the outer belt and extend to a corresponding point at the other end. The wrapping is then continued back and forth, stopping each successive layer  $\frac{1}{4}$  inch short of the end of the preceding layer. In applying the tape, each turn should be drawn tight

ould overlap the preceding turn by two-thirds of its width. the tape should be applied tightly and evenly. In the case nsion should be such as to stretch it to about half its width. must be taken to have everything perfectly clean and dry.

t." — Where cotton or linen tape is used, each layer must uring hot compound over it until all the moisture is expelled ing is thoroughly saturated. Before applying the com- ould assure himself that it is *not* hot enough to ignite a d in it; otherwise the tape is likely to be charred. This e entering the splicing chamber, as the accidental ignition d is dangerous in such a confined space.

— Where rubber tape containing sulphur is used, it should ed by the application of heat from a spirit lamp, care being heat evenly and to avoid burning the insulation. This mplete in about one minute with conductors up to one-half

or **Three-conductor Cables.** — In the case of three-con- all the conductors are joined and insulated as described, a diameter is inserted between them at the center of the joint cr. A band of tape is then wrapped around all three con- ameter that the whole will slide nicely into the lead sleeve. Instead of this, a band of tape may be built around each iter of the splice.

#### uting Tubes.

f insulating n insulating ductors be- bring it over after is com- to get the y during sol- large enough

Fig. 16.

the insulation. Such tubes are made of prepared paper, micranite. The jointed conductor should first be wound to the level of the original insulation, "boiled out" as de- then the sleeve slipped on. A further "boiling out" with mpletes the job. In the case of belted multiple-conductor to the insulating tube over each conductor a large tube er the belt before splicing the conductors.

**Baffles.** — Baffles of micranite, bakelite, etc., are now com- en conductors of triplex cables. They replace part of the around each conductor and the whole of the belt. The monwealth Edison Co. splices are of this type.

**ves.** — The joint having been insulated, the lead sleeve t symmetrically over it, and the ends beaten down into sheath, taking care to make the sleeve concentric with the

sheath are then joined by pouring solder over the ends from e the joint with a cloth. This process should be continued tight joints are obtained, the under side being examined for if a hand mirror.

is well wiped on, two small holes should be made in the top pound poured in one hole until it appears at the other. If are the compound should be poured in one hole and allowed

to escape from the other until this defect ceases. The joint should be allowed to cool for about an hour, and if then the compound has settled should be added until the sleeve is full. The sleeve is then closed by small patches of lead over the holes. When the joint has thoroughly set and solidified, it may be pushed gently into its permanent place.

The following data on lead sleeves are given by the Standard Underground Cable Co.

DATA ON LEAD SLEEVES

	Outside diam. of cable, mls	Inside diam. of sleeve, inches	Length of sleeve, inches	Gals. of compound per joint
Single-conductor, light and power, up to 6600 volts.	Up to 550	1	8	0.05
	551-850	1½	10	0.1
	951-1350	2	12	0.2
	1351-1750	2½	12	0.3
	1751-2150	3	14	0.5
	2151-2550	3½	14	0.6
Single conductor, light and power, above 6600 volts.	Up to 550	1	10	0.05
	551-950	1½	12	0.1
	951-1350	2	14	0.2
	1351-1750	2½	16	0.4
	1751-2150	3	18	0.6
	2151-2550	3½	18	0.8
Multi-conductor, light and power, all voltages.	Up to 800	1½	14	0.2
	801-1200	2	16	0.25
	1201-1600	2½	16	0.35
	1601-2000	3	18	0.6
	2001-2400	3½	18	0.8
	2401-2800	4	18	1.0
	2801-3200	4½	20	1.4

**Compounds for Filling Lead Sleeves.**—Various compounds have been used for filling the sleeves, such as conduline, G. E. No. 227 compound, E. P. Trotter's "B-7," ozite, etc. The Commonwealth Edison Co. of Chicago uses a compound developed by the engineers of the company. It is poured at a temperature of 150° C.

A good compound should have a high melting point, adhesiveness, high electric strength, low coefficient of contraction and should not be brittle at ordinary temperatures.

**Stamping the Joint.**—After the joint is completed the joiner should stamp his initials at each end of the sleeve.

**Taped Joints.**—Where the cable has no lead sheath, but is unbraided, it is usual to finish the joint with friction tape.

**Shielded Splice.**—A joint used for 25,000-volt cables is described by Torchio, Elec. W., 1916, Vol. 67, p. 873. The conductors are wrapped with saturated paper-tape, and over the three conductors is provided an outer jacket pierced with holes to allow a free circulation of oil. Over the jacket is

gum sleeve and around it a heavy lamp wick. The gum protects the sharp potential gradients and the wick retains the insulating oil within place. When the joint is completed, it is subjected to a vacuum of 27-29 and then filled with liquid petrolatum.

**minerals.** — Conductors may be soldered to lugs or terminals or they may be joined mechanically by means of a Dossert or similar connector.

In the former case the insulation is cut from the end of the conductor, which is then brightened by scraping or sandpapering and smeared with soldering flux.

The conductor is then tinned by plunging into molten solder. The lug also may be tinned internally and heated so that it will hold some solder in the molten state. The conductor, also heated above the melting point of solder, is then pushed into the lug and the latter cooled by the application of wet waste.

The shreds and globules of solder are filed off and the surfaces are smoothed with sandpaper. Some jointers prefer to hold the lug in the molten solder until it attains the same temperature as the latter. In this case, if the lug has been previously treated with flux, its outside as well as its inside surface may be tinned and it will make better contact with its accompanying lug or terminal. If, however, the copper or brass surface is desired for appearance, it may be preserved by coating the outside of the lug in a light oil of high flash point before dipping it into the solder.

In either case it is advisable to wrap the end insulation in a rag previously soaked in cold water to prevent it being melted or charred.

**Leaking Sheaths.** — The conductors of high-tension cables induce electrostatic charges on the sheaths, often raising the latter to dangerously high potentials.

It is, therefore, customary to ground the sheaths of cables at suitable intervals in order to carry off the "static," as these induced charges are called. The sheaths of low-tension cables do not have to be grounded to drain off static electricity. The sheaths of direct-current railway feeders which are used in conjunction with a grounded return system should, however, be grounded to the negative return system, except when the tracks have insulated sections for electric block signals, in order to afford a low-resistance path for a short-circuit current. Unless this is done, the escaping current will return through the earth paths, inflicting damage without attaining sufficient strength to trip the protection circuit breakers.

**BURN-OUTS OR PUNCTURING OF INSULATION.** — Cable burn-outs may be caused by mechanical injury, exposure to excessive heat or cold, cumulative heating, by chemical deterioration, or by transient high-voltage phenomena.

**Burn-outs Due to Mechanical Injury.** — Paper insulation differs from varnished cambric in depending upon the integrity of the lead sheath which encloses it. Hence in the case of paper-insulated conductors, a puncture of the lead sheath will sooner or later result in a burn-out even though it may take a week or longer for the moisture to penetrate the insulation sufficiently to accomplish this. (*Burch, Trans. A.I.E.E., 1903, Vol. 22, p. 433.*)

Mechanical injury often occurs in the process of installing underground cables. A sharp projection in a duct will cut a groove in the lead sheath, thereby reducing its effective thickness and rendering it liable to crack open. The bending of cables in splicing chambers may crack the insulation, especially if tightly packed paper insulation is used. A loosely insulated cable is also liable to injury by bending will flatten the cable, compress the insulation in one direction and flare it out in the other, causing voids or air spaces between the layers, which under the influence of high voltages will cause electric discharges, heating and consequent chemical action. Mechanical injury after installation

may be due to settlement of the conduit line, to careless stepping upon the cable to vibration setting up crystallization of the lead sheath, etc.

Exposure to alternate heat and cold leads to expansion and contraction which may introduce mechanical stresses into the insulation and thereby injure it. Excessive heat (120 to 150° F.), such as would result from direct exposure to summer sunlight, is likely to dangerously reduce the insulating qualities of varnished cambric and to a less extent that of impregnated paper. A higher degree of heat (200° F.), such as would occur in the proximity of steam pipes has the effect of making rubber insulation become brittle.

Chemical deterioration may be due to electrolysis (q.v.) or merely to ordinary chemical reaction between the sheath and the material in contact with it, the former cause being the more common.

**Burn-outs Due to Static Discharges.** — Failure of high-tension rubber insulated conductors is sometimes due to electrostatic discharges from a charged conductor to its supports, the irregular potential gradient giving rise to local static discharges with consequent formation of ozone and oxidation of the rubber.

**Burn-outs Due to Imperfect Manufacture or Splicing.** — Insulated conductors also burn out because of defects of manufacture or of splicing. The former class of defects is happily rare, but dirt, moisture and jagged edges of metal are frequently responsible for the failure of joints, especially on high-tension cables.

**Transient High Voltage and Currents.** — "Surges," i.e., transient high voltages and heavy currents, are sometimes responsible for very serious cable failures, such as described in *Trans. A.I.E.E.*, Vol. 24, p. 297. To determine the origin and cause of high-voltage disturbances, so as to be able to guard against their recurrence, the most important thing seems to be to very carefully observe and record all the details of the phenomena, even those which appear unessential. The existence of static (i.e., high-voltage discharges of small currents) on switchboards, lines, etc., and the existence of voltages and currents different from those which may be expected require special attention. Either of these is sufficient to raise the suspicion of some dangerous fault in the system or some dangerous arrangement of apparatus, which requires consideration. The severity of the phenomena depends almost entirely upon the power momentarily available in the system and very rapidly increases with the size of the generating stations (*C. P. Steinmetz*).

After considering the likelihood and severity of such potential disturbances P. Junkersfeld and E. Schweitzer reached the following conclusions with respect to their influence upon the use of high-tension cables.

1. Where local and commercial conditions justify, pressures as high as 2500 volts can be satisfactorily used even for systems aggregating as much as a hundred miles of cable. No single line of such a system would be much longer than twenty miles. If higher voltages are needed to meet operating requirements and can be justified commercially, special construction will be necessary to overcome limitations in paper, rubber or varnished-cambric insulation, and also in the standard forms of underground conduit or subways used in this country.

2. On comparatively short lengths, underground or under water, as a part of a long overhead transmission line, cables operating at 40,000 volts can be used.

3. Potential rises of 50 per cent and 100 per cent are not uncommon in large underground cable systems, although this fact may not always be manifested due to the high factor of safety in the insulation.

**Occurrence of Cable Burn-outs.** — The following table gives the number of cable burn-outs reported to the Underground Systems Committee of the N.E.L.A. in 1921.

CLASSIFICATION OF CABLE FAILURES ACCORDING TO VOLTAGE  
FOR YEAR 1920

	Voltages						
	6,000 to 9,000	9,000 to 12,000	12,000 to 15,000	15,000 to 18,000	18,000 to 21,000	21,000 to 24,000	24,000 to 27,000
Number of companies reporting	6	5	7	1	1	5	3
Miles of cable	1151.4	1207.3	1093.1	5.7	80	408.7	37.1
Number of failures	48	98	108	0	8	17	5
Number of failures	11	32	90	0	6	28	0
Number of failures	59	130	198	0	14	45	5
Failures per 100 miles of cable	5.1	10.8	18.1	0	17.5	11.0	13.5
Failures per 100 miles of cable	2.6	7.9	10.5	0	17.7	19.3	24.2

— The life of cables depends so much upon the type, excellence of manufacture and conditions of service, that specific figures are of little use. Furthermore, many of the earliest cables made are yet in satisfactory operation. For example, there are at Buffalo, rubber-covered 11,000-volt cables that were installed in 1897, and in 1921 they were in perfect condition.

DISCUSSION.— There are so many types of wires and cables and the prices vary so greatly that it is impossible to give adequate cost data. The following examples will give a general idea of the cost of a few common types of cables:

Kind of wire or cable	Cost per 1000 ft.
14 code wire	\$6.00 to \$ 12.00
1 conductor, 2500 volt, rubber ins., Park cable	\$85.00 to \$115.00
1 conductor, 1 circ. inch, $\frac{3}{32}$ " paper and $\frac{1}{8}$ " lead	\$725.00 to \$1350.00
1 conductor, 0.35 circ. inch, $\frac{3}{32}$ by $\frac{3}{32}$ , $\frac{1}{8}$ " lead	\$1070.00 to \$1710.00

**WIRES, RESISTANCE.** — (See also *Electromagnet Windings; Resistors and Conductance, Electric; Rheostats and Resistors; Wires and Cable, Insulated; Wires and Cables, Insulated.*) Metals and alloys having high specific resistance or low temperature coefficient of resistance are largely used for resistors. Some of the principal metals used for this purpose are listed below. They are usually obtained in the form of wires, ribbon or sheets. The data given are for Nichrome, Climax, Advance, Therlo, Yankee Silver, Ferro-nickel, Mond Metal, Kromore, No. 193 Alloy, and Nickel Silver were supplied by the Driver-Hill Co., those on Calido, Ideal, Akbar, Comet, Karma, Lucero, Nickel, Phenix and Rayo were supplied by the Electrical Alloys Co., those on Excello, la la and Superior resistance metals were taken from the catalogue of H. Baker & Co. those on Acme, Electric, Excelsior, Eureka, Peerless, Premier Nickel Chrom, Sichrome, Superior Nickel Chrome and Tarnac were supplied by the All Metal Wire Co., those on Chromel were supplied by the Hoskins Manufacturing Co., and those on Manganin by Baker & Co.

Acme is a nickel-steel-chromium alloy and is used in heat radiating devices. It is similar to No. 193 Alloy and Comet.

Advance is a copper-nickel alloy, containing no zinc. It is uniform in composition and constant in its resistance under all conditions of service. Because of its high thermal e.m.f. against copper, it cannot be used in detecting apparatus in which the generation of an electromotive force would cause errors, as for example, in a wheatstone bridge where a few microvolts would cause an error in the galvanometer deflection. It is used in switchboard meters, street car heaters, and other forms of heating devices provided its operating temperature is not exceeded. For ordinary temperature measurements commercial grade may be used as a thermo-couple element. For accurate temperature measurements, it should be purchased on specification.

It is similar to Excelsior and Ideal.

Akbar is an alloy of copper, nickel and manganese. It is used for heat purposes.

Calido is a high percentage nickel-chromium alloy. The melting point is about 1530° C. It is recommended for electrically heated devices at temperatures up to 1000° C.

Chromel is furnished in three grades: Chromel "A" is an alloy containing about 80 per cent nickel and 20 per cent chromium. It is used in heating devices such as hot plates at temperatures from 875° C. to 1100° C. Chromel "B" contains about 85 per cent nickel and 15 per cent chromium. It is more durable than Chromel "A" but is suitable for the same class of work where conditions are less severe. Chromel "C" is a nickel-chromium-iron alloy containing about 25 per cent iron and 11 per cent chromium. Its iron content somewhat lowers its durability at high temperatures. It is used extensively in flatirons where it is enclosed and thus protected to a certain degree against oxidation.

Climax is a high-resistance nickel-steel alloy. It is especially well suited for use in rheostats. It is one of the cheapest resistance metals, but has a tendency to rust and scale and should therefore not be used in smaller sizes than No. 20 A.W.G. It is similar to Electric and Phenix.

Comet is an alloy of nickel, chromium and steel. It is low in cost and is used extensively in heating devices, at temperatures below red heat. This alloy with Ideal wire produces a thermocouple of high e.m.f. and as such is more durable than iron or copper. It is similar to Acme and No. 193 Alloy.

Constantan is a copper-nickel alloy. It is used primarily as an element.

**couples.** Constantan, Advance and Ideal are very similar and used for purposes. When thermocouples are to be made up for use with calli- apparatus, the thermoelements should be purchased on specification urities in very small quantities affect the thermal e.m.f. (see article on ers).

**rtis** is used as resistance element at medium low temperatures in such as controlling devices and rheostats. It can be soldered with any stand- x and is similar to Climax and Phenix.

**eka** is a nickel-copper alloy and is claimed to be superior to German because it is free of zinc, which produces brittleness when the alloy is ated. It is used for general heating purposes such as car heating. In it is similar to Lucero.

**stior** is an alloy of nickel and copper. It has characteristics similar to ce, Ideal and Constantan and is used for similar purposes. The manu- r recommends it for use in heating pads and other light duty service.

**lle** is adapted for use in electric heating devices.

**o-nickel** has a high current-carrying capacity, on account of its low resistance. As it will rust, it can only be used where it is not attacked ture.

**man Silver** is an alloy of copper, nickel and zinc. The "grade" of e designates the percentage of nickel. The 18 per cent grade is the ommon. The resistance of any particular grade depends upon the of annealing; hard wire is slightly higher in resistance than soft. Ger- her was for many years the only resistance alloy obtainable, but it is ing generally displaced by materials of the same specific resistance but rior qualities. (See article on *Alloys*.)

**is** is recommended for use in instruments and electrical devices where a perature coefficient is desired.

**l** is an alloy of nickel and copper, and contains no zinc. The manu- s state that its temperature coefficient is "nil." It may be used cipient red heat of 520° C. Its use in general is the same as that of e. When used with Comet wire it forms a very durable and desirable couple. In general it is similar to Advance and Excelsior.

**na** is a nickel-chromium alloy used for heating purposes at temperatures 100° C.

**ore** is a nickel-chromium alloy. It is used at temperatures up to in heat radiating elements. It is similar to Peerless and Rayo.

**ro** is a nickel-copper alloy and is intended for use in place of German It is used in car heaters and other similar heating devices. In general ilar to Eureka.

**ganin** is a material developed by the Reichsanstalt, for use in ents and standards. The alloy which was shown to be the best for purposes is one containing 85 per cent of copper, 12 per cent of man- and 3 per cent of nickel. Prior to 1918 it was imported but now it is anufactured in the United States and is known as Baker manganin. cer manganin contains a small amount of iron and is claimed to be an ment over that formerly obtainable.

**anin** should be used with a double silk covering saturated with shellac ) baked in an oven at 140° C. for at least 24 hours. The baking process the wire and sets the shellac so as to exclude air from the wire which otherwise become slightly oxidized in use. Oxidation increases the ure coefficient of resistance. When used in resistance standards and

precision apparatus the shellacked coils of wire should be sealed to exclude from the shellac, otherwise the shellac will absorb varying amounts of moisture from the air under a variation of humidity. When the shellac absorbs moisture it expands and changes the tension of the wire and thus changes its resistance. The resistance element should be adjusted to its desired value after the annealing process, as the resistance of the wire decreases by a few tenths of one per cent upon annealing.

The change of resistance with temperature is not a straight line but is represented by the formula:

$$R_t = R_{20}[1 + \alpha(t - 20) - \beta(t - 20)^2],$$

in which  $R_{20}$  is the resistance at  $20^\circ \text{C.}$ ,  $R_t$  is the desired resistance at the temperature  $t$  in degrees centigrade,  $\alpha$  is a constant given in Table I,  $\beta$  is a constant usually equal to  $4 \times 10^{-7}$ .

**Monel Metal** contains approximately three parts nickel to one of copper. In smelting and refining the ore from which monel metal is made, nickel and copper are not separated, and, therefore, appear in the final alloy in the same relative proportions. The treatment of this ore consists merely in eliminating the impurities, excepting a small percentage of reduced iron. As a result the metal is tough, strong, as non-corrosive as nickel, and is the same in appearance; whereas nickel, as a pure metal, is relatively expensive, owing to the difficulty of isolating it. This alloy is produced at a cost which permits favorable competition with German silver, etc. Its resistance varies somewhat in different lots, and according to temperature variation is, however, no greater than that of 18 per cent German silver.

**Nichrome** is practically non-corrosive, has an extremely high melting point (about  $1550^\circ \text{C.}$ ) and is far superior to nickel in its ability to withstand high temperatures. It is especially recommended for use in electrically heated appliances and resistance elements generally where extreme conditions are encountered.

**Nichrome II** is strongly resistant to oxidation. It has been especially developed for use in carbon combustion furnaces, and other high-temperature furnaces where the more extreme temperatures are to be met.

**Nickel**, due to its high temperature coefficient, is very efficient for use in resistance thermometers and owing to its non-corrosive qualities it is commonly employed for rheostats where acid fumes are to be met with.

**Nickel Silver**, as commonly known, contains 18 per cent of nickel. Its resistance varies somewhat in different lots and according to temperature.

**Peerless** is an alloy of nickel and chromium used in such service as electric ovens and furnaces. It does not deteriorate when operating continuously at  $1100^\circ \text{C.}$  with exposure to air. It is similar to Kromore and Rayo.

**Phenix** is a nickel-steel material suitable for resistances at comparatively low temperatures. It is readily soldered with any standard flux. It is used extensively in arc lamps, rheostats, resistors for controllers and other heavy duty apparatus. It is similar to Electric and Climax.

**Premier Nickel Chrome** has a high resistivity and used in heating appliances at temperatures up to  $1000^\circ \text{C.}$  It is similar to Nichrome and Call.

**Rayo** is an alloy of nickel and chromium in such proportions that it can withstand high temperatures and mechanical rubbing. It can be used continuously at temperatures up to  $1100^\circ \text{C.}$  without deterioration. It is used in electric ranges and ovens. It is similar to Kromore and Peerless.

**Sichrome** is a new alloy consisting of silicon, chromium and iron. It

\* 10 per cent German silver has substantially the same properties as Advance metal.

claimed to have a less tendency to corrode than the nickel chromium alloy. It is intended for use in heating elements at temperatures up to 1100° C. or rather severe conditions. Its specific gravity is lower than that of any resistance wire.

Superior is a nickel-steel alloy recommended for use in rheostats, or in resistances, etc.

Superior Nickel Chrome is an alloy containing approximately 80 per cent nickel and 20 per cent chromium. It is used in heating devices at temperatures up to 1100° C.

Tarnac is an English product which is very similar to manganin and is used for the same purposes. For precision purposes it should be treated in the same manner as manganin. The variation of its resistance with temperature is similar to that of manganin. The value of  $\beta$  in this case is usually  $2.5 \times 10^{-5}$ . It has a maximum resistance at 70° C.

There is an alloy of copper, manganese and aluminum for work where a low thermo-electric effect against copper is demanded. Compared with manganin, this alloy gives a higher specific resistance, does not oxidize so fast, is more stable in its electrical and mechanical behavior. This material is especially suitable for shunts. Temperature coefficient is  $+0.0000031$  per cent. It cannot be soldered but has to be brazed. This characteristic is favorable for its proper use. It should be treated in the same way as manganin to produce accurate resistance coils.

Yankee Silver. — This is a new alloy with most of the qualities of "88 per cent German Silver." It will withstand repeated heating and cooling and gives satisfactory service where German silver fails.

No. 193 Alloy consists of nickel, iron and chromium. It serves as resistance elements for elevator controllers and rheostats at temperatures up to 640° C. It is similar to Acme and Comet.

TABLE II. — RESISTANCE, WEIGHT AND CURRENT-CARRYING CAPACITY OF WIRES

$$\text{Resistance, ohms per foot at } 20^\circ \text{ C.} = \frac{K\rho}{1000}$$

where  $\rho$  is the resistivity of the metal in microhms per centimeter cube, taken from Table I, and  $K$  is given in the table below.

$$\text{Weight, pounds per foot} = \frac{H\delta}{1000}$$

where  $\delta$  is the specific gravity of the metal, taken from Table I, and  $H$  is given in the table below.

$$\text{Current for given temperature rise, amperes} = \frac{10 I_0}{\sqrt{\rho}}$$

where  $\rho$  is the resistivity of the metal in ohms per centimeter cube, taken from Table I, and  $I_0$  is given in the table below. This formula is based upon the following method to convert the resistivity at 20° C. to that at the temperatures stated:

100° C. ....	1.031
200° C. ....	1.052
500° C. ....	1.085
1000° C. ....	1.118

These are correct for Calido wire. For any other wire, the current derived from the above formula must be multiplied by the factor  $\sqrt{\frac{m_1}{m_2}}$ , where  $m_1$  is a multiplier from the above table and  $m_2$  the corresponding multiplier for the wire in question.

Resistance factor (a)	Weight factor (b)	Current-carrying Cap. $I_0$ for $\rho = 100$ (c)			
		100° C.	200° C.	500° C.	1000° C.

**General Requirements.**—Wires and fittings designed to conduct electricity in a building should be selected as to size and insulation and installed in such a manner that: (1) the attending fire risk and the possibility of electric shock to the inhabitants shall be a minimum; (2) the delivery power efficiency of the system shall be reasonable; (3) the voltage at the receiver shall approximate the rated voltage of the receivers and shall remain sensibly constant; (4) the mechanical arrangement of the system shall be simple and convenient for inspection and use; (5) the conductors shall be mechanically protected from external injury; (6) the service shall not be interrupted under normal load; (7) the cost of the materials, labor of installation and replacement due to depreciation shall not be excessive, and (8) the wiring system shall conform to the rules and regulations of any authority having jurisdiction over the building in question.

**SYSTEMS OF WIRING.**—For direct-current and single-phase distribution the two-wire system (Fig. 1) and the three-wire system (Fig. 2)

Fig. 1.

Fig. 2.

employed. For two-phase distribution either three or four wires are used. In three-phase distribution three wires are usually employed, although a fourth or neutral wire is sometimes installed. Fig. 3 shows typical methods of controlling a group of lamps from two or more switches.

**Direct-current and Single-phase Distribution.**—In direct-current single-phase alternating-current circuits, the two-wire or the three-wire system is used. The two-wire system is used for the greater part of interior wiring, the three-wire system being used chiefly for feeders and mains. The three-wire system possesses the advantage over the two-wire system that for

e power transmitted at the same efficiency to receivers of the same voltage, three-wire system requires less weight of conductor. The neutral wire of a e-wire system is usually of the same size as either outside wire, the saving pper over the two-wire system then g % or 62.5 per cent (see *Distribution of ric Energy*). In some cases, buildings wired with the three-wire system in h the neutral wire is made twice the of either outside wire so that if neces- , the system may be operated either as o-wire or a three-wire system; in the r case the two outside wires are con- ed in parallel. Power may then be lied to the building from a local two- : source of supply (isolated plant in the ing) or from an emergency three-wire t service.

his case wires of such size would be as would give normal efficiency and lation when used as a two-wire system; loss when used as a three-wire system d then be only half as great.

he first cost of a three-wire system may not be less than that of a two-wire m because of the increased cost of the fittings, insulation and the labor of lation. The three-wire system is not as simple as the two-wire system, is subject to more disturbances unless the load is kept balanced. Some ric power companies limit the power which they will supply to a two-wire m and in such cases in new installations buildings taking power above the ire limit must be wired with the three-wire system. The two-wire system ed for either lighting or power loads while the three-wire system is used ither lighting or mixed lighting and power loads, motors in the latter case g connected between the outside wires.

o-phase and Three-phase Distribution. — For distributing two-phase ating currents, either three or four wires are employed. A four-wire phase system may be treated as two separate two-wire systems, which ot in any case be connected in parallel. A single wire 41 per cent larger i either of the wires it displaces may be substituted for any two of the wires e four-wire two-phase system thus making a three-wire two-phase system. r three or four wires may be used for two-phase lighting or power loads. ree wires are usually employed on three-phase alternating-current circuits ying power to lighting or power loads. If the neutral is accessible, a neutral ay also be used, making a four-wire three-phase system for lighting s, the lamps being connected between any outside wire and the neutral

Fig. 3.

**STANDARD VOLTAGES FOR LIGHTING AND POWER LOADS.** — all standard lighting loads the voltage across the lamps ranges from 100 to 125 volts in accordance with the rating of the lamps. In a few cases, lamps rated between 200 and 250 volts are used with the corresponding voltages. The voltage between the service wires of a constant-current series-arc or series-fluorescent lamp system must not be greater than 5000 volts, the maximum voltage for inside work allowed by the National Electrical Code (see p. 2063). Constant-current systems are used chiefly in lighting large areas as in mills, mines, armories, etc. On power loads standard voltages of approximately 120 or 550 volts are used depending on the magnitude of the load supplied.

**STANDARD FREQUENCIES OF ALTERNATING-CURRENT CIRCUITS.**—Alternating currents are usually supplied to lighting loads at a frequency of 60 cycles and to power loads at 25 cycles. In some cases the frequency of 40 cycles is used when the lighting and power loads are of about the same magnitude.

**PRELIMINARY LAYOUT OF THE WIRING SYSTEM.**—If power is to be supplied to the building from some outside source, the service entrance must first be located from plans or by an inspection of the building itself. In most cases, service entrances are made in the basement, although first-floor entrances may be substituted when basement entrances are impracticable. In overhead-service connections, the service wires are usually run in conduit on the outside of the building from the point where the wires are attached to the building to the service panel-board. In underground-service connections, the service wires are run in conduit from the street mains through the basement walls. In the latter case, the conduit should be tightly closed at the outlet to prevent gases from entering the building. Fig. 4 shows two types of service connections.

**Location of Panel-Board.**—The service panel-board should be placed securely in an accessible location and should contain space for the service cut-outs, service switch and meter. When power is supplied from within the building, the switchboard of the power plant must be located as a starting point in the design of the feeder system.

**Location of Outlets, Switches, etc.**—Outlets, control switches and cut-out cabinets should then be located throughout the building. Great care must be exercised in locating outlets and control switches in such positions as to accommodate the receiving devices planned for the building. Cut-out cabinets, which constitute the local distributing centers, should be located as near as possible to the dependent receiving devices and should at the same time be easily connected by feeders to the main switchboard. Fig. 5 shows a riser diagram and Fig. 6 a diagram of the wiring for one floor of an office building.

**Number of Feeders.**—Having located the outlets, control switches, distribution centers and the main switchboard, a feeder system must be planned to suit the conditions under which the system is to operate. The number of feeder sets required depends upon: (1) the power taken by the receiving devices; (2) the degree of control desired at the main switchboard; (3) the number of receiving devices which may rely upon one set of feeders; (4) the desired uniformity of voltage at the receiving devices, and (5) the character of the receiving devices. If the total current supplied to the building is roughly calculated and is found to exceed 650 amperes (the allowable carrying capacity of a 1,000-cmil circular-mil rubber-insulated conductor), more than one set of feeders should be used, since it is impracticable to install feeders larger than one inch in diameter.

\* Numeral indicates number of standard 16 C. P. incandescent lamps.

† If gas only.

Unless controlled by remote control switches, separate feeders must be led from the switchboard to receiving devices which are controlled at the switchboard.

If a single set of feeders is used on a lighting load, the possible extinction of lights in a building by an open circuit in the main feeders may cause a loss; on a power load an interruption of all the machinery for any length of time may cause a considerable loss of money. To avoid such a discontinuance of service, it is customary to connect separate feeders to sectionalized parts of a load, so that the entire load may not be interrupted at one time.

The voltage at receiving devices may be made more uniform by the use of more than one set of feeders than by the use of one set of feeders, except when a single set of feeders may be run to a distributing panel to which branch feeders of nearly equal length are connected. When the power taken by certain receiving devices varies extensively and rapidly, the voltage at all other devices connected to the same feeder will vary accordingly, and in such cases lamps must be connected to separate feeders to avoid undesirable flickering.

**Wiring Diagram.** — After deciding upon the number of feeders to be used in an installation, a diagram should be made showing the location and length of feeders and branch circuits. When the wiring system is sectionalized, each section should be treated by itself as a complete system. Figs. 5 and 6 are typical wiring diagrams for an office building.

**RING CALCULATIONS.** — The proper size of wire for any feeder is determined by three factors: (1) mechanical strength; (2) current-carrying capacity, and (3) the allowable potential drop in the feeder.

**Minimum Size of Wire.** — The National Electrical Code specifies No. 14 A. W. G. as the minimum allowable size for all classes of rubber-insulated wire, except that in fixture work and for pendant cords wires as small as No. 18 A. W. G. may be used. The minimum allowable size of varnished cloth insulated wire is No. 6 A. W. G., except by special permission.

**Kind of Insulation.** — Rubber insulated wire protected with an outside braided covering and varnished-cloth insulated wire also with an outside braided covering may be used where not exposed to moisture.

**Lead Sheaths.** — Lead-covered wire should be used when installed in tile walls for mechanical protection against abrasion and in underground runs in basements, etc., where condensed moisture may be present.

**Current-carrying Capacity.** — The following table, from the National Electrical Code, gives the allowable carrying capacity of copper wires and aluminum wires of 98 per cent conductivity, and must be followed in placing interior wiring. See also *Wires and Cables, Insulated*.

**CURRENT-CARRYING CAPACITY OF COPPER WIRES**

\* For insulated aluminum wire the maximum allowable current is 84 per cent of that given in the table for the corresponding type of insulation.

† This includes paper, slow-burning insulation, etc.

**Currents Taken by Various Receiving Devices.** — The current taken by each receiving device if not stated in the specifications may be determined roughly from the following tables.

**CURRENT TAKEN BY INCANDESCENT LAMPS AT 112 VOLTS**

Candle power	Amperes per lamp		
	Carbon	Gem	Tungsten
16	0.5	0.35	.....
20	.....	.....	0.25
32	1.0	0.7	.....
48	.....	.....	0.53
50	1.4	1.1	.....
80	.....	.....	0.85
100	2.7	2.2	.....

## CURRENT TAKEN BY ORDINARY ARC LAMPS

*1/8-inch carbons*

Type	Multiple*		Series	
	Volts	Ampere	Volts per lamp	Ampere
net current	110 220	5 to 6.5 3	70	5 to 6.6
starting current	110 220	6 to 8.5 6		

On multiple-arc-lamp circuits, the conductors must be designed to carry 150 per cent of the normal current taken by the lamps.

## CURRENT TAKEN BY DIRECT-CURRENT MOTORS\*

Horse-power	Ampere at		
	110 volts	220 volts	350 volts
1/2	4.5	2.2	1
3/4	6.8	3.4	1.5
1	9.0	4.5	2
1 1/2	13.6	6.8	3
2	16.9	8.5	3.8
3	25.4	12.7	5.6
4	33.8	16.9	7.5
5	42.3	21.1	9.3
7 1/2	56.5	28.2	12.4
10	75.3	37.6	16.6
15	113	56.5	24.9
20	150	75.3	33.1
25	188	94.1	41.6
30	226	113	49.7
40	301	150	66.3
50	376	188	83.8
60	452	226	99.4
70	527	263	116
80	603	301	132
90	678	339	149

\* For single-phase a-c. motors divide current given by power factor of motor.

## CURRENT TAKEN BY THREE-PHASE INDUCTION MOTORS

Power factor taken as 80 per cent

Horse-power	Amperes per wire at line voltages of		
	110 volts*	220 volts*	330 volts*
1	6	3	1.2
2	12	6	2.4
3	18	9	4
4	24	12	5
5	26	14	6
10	56	28	11
15	85	42	17
20	112	56	22
25	140	70	28
30	167	83	33
40	222	110	44
50	278	140	58
60	330	165	66
70	385	192	77
80	440	220	88
90	490	245	98
100	550	275	110
150	790	395	158
200	1050	525	210
250	1320	660	264
300	1580	790	316

\* These are volts between wires; the corresponding volts to neutral are 63.5, 127 and 318, respectively.

## WATTS TAKEN BY HOUSEHOLD APPLIANCES

Device	Watts	Device	Watts
Flatirons.....	350-500	Curling iron.....	90
Immersion heater.....	300-500	Vibrators.....	50
Water heaters.....	600-5000	Vacuum cleaner.....	150
Chafing dishes.....	420	Stove (4 burner and oven).....	5770
Grill.....	660	Bake oven.....	5-5000
Coffee percolators.....	420	Dish washer.....	200
Toasters.....	500	Washing machine.....	600
Heating pads.....	60	Ironing machine.....	2.5-6 kw
Cigar lighters.....	70	Hot plates (2).....	2300
Glue pots.....	440-880	Hot plates (3).....	3100

Sewing machine.....	50	Office fans.....	30-600

— In most installations the potential drop *per conductor* from the service-entrance or switchboard and the farthest receiver is taken as 3 per cent of the *voltage to neutral* at the service-entrance or equivalent to a *total drop* (both wires) of 3 per cent of the *voltage to neutral* in the case of a two-wire direct-current or single-phase wire systems the two outside wires are to be regarded as

for single-phase alternating-current systems the maximum potential drop will then be  $0.015 \times 110 = 1.65$  volts for a 110-volt system, etc. In three-phase systems the potential drop will be  $0.03 \times \frac{110}{\sqrt{3}} = 1.91$  volts for a 110-volt system, etc.

In feeders and branch circuits the drop is usually made two-thirds and the drop in the branch circuits one-third.

In the case of a lamp load the allowable drop of 3 per cent is based on the voltage drop corresponding to the *total connected load*, i.e., this is the maximum load that can be burned. In ordinary buildings the actual maximum load is usually less than one-third the connected load; consequently when the voltage is based on this basis the voltage at the lamps will seldom be more than the voltage at the service connection.

**Size of Wire.** — Let

$I$  = current in amperes,

$e$  = potential drop *per conductor* in volts,

$l$  = length of conductor in feet,\*

$A$  = cross-section of a copper wire in circular mils is

$$A = \frac{KII}{e} \tag{1}$$

depending upon the specific resistance of the wire, the size of the wire, the frequency and the power factor of the receiver. For alternating-current circuits is therefore not a constant but for its value for the sizes of wires and spacings (1 to 6 inches) for interior wiring is approximately as given in the following table. The values for direct-current apply to single-phase, 2-phase 4-wire

System	Power factor	Values of $K$ for copper
Direct current.....	.....	11*
Single phase ac current.....	.....	.....
Lighting load only.....	1.00	11
Lighting and power loads	0.95	12
Lighting and power loads.	0.90	13.5
Power loads.....	0.85	15
Power loads.....	0.80	17

\* This value is practically exact, the others are approximate only.

In the case of systems at any frequency from 25 to 60 cycles per second, for single-phase 3-wire system proceed as for a 2-wire system in the presence of the neutral wire; the neutral wire should be of the same size as each outside wire as thus calculated.

$l$  = length of each conductor; the total length of wire for a two-wire

Commercial sizes of wire differ successively by about 25 per cent in the larger sizes and 60 per cent in the smaller sizes; the odd-numbered sizes smaller than No. 1 are not generally manufactured, although No. 3, 5 and 9 are sometimes made. From the table below \* select the size of wire corresponding to the calculated area. Unless the calculated area in circular mils agrees very closely with the area of one of the conductors given in the table, the next larger size of wire should be selected.

**600-VOLT RUBBER-INSULATED COPPER WIRE**

(Single Braid, N.E.C. Standard; Conductivity of Copper, 98 per cent)

Size, A.W.G.	Cross- section of copper, circular mils	Over-all diam- eter, inches	Ohms per 1000 feet at 77° F.	Pounds per 1000 feet of insu- lated wire	Reactance per 1000 feet of each wire

\* More extended wire tables will be found in the article on *Wires and Cables*

† Two insulated wires side by side, the insulation of the two wires in contact

‡ Measured from insulation to insulation, equals distance between conductors

**Check on Calculation of Size of Wire.** — Calculation of Actual Potential Drop. — (See also *Alternating Currents*.) From the table, corresponding to size of wire selected, take

$r$  = the resistance per 1000 feet of conductor,

$x$  = the reactance per 1000 feet of conductor,

put

$l$  = length of each conductor in feet,

$I$  = amperes per conductor,

$V$  = volts to neutral at receiver,\*

$\cos \phi$  = power factor of receiver,

$R = \frac{rl}{1000}$  = total resistance per conductor,

$X = \frac{xl}{1000}$  = total reactance per conductor.

$v$  the actual volts drop per conductor is

$$v = \sqrt{(V \cos \phi + RI)^2 + (V \sin \phi + XI)^2} - V. \quad (2)$$

A very close approximation in all ordinary cases this is equal to

$$v = RI \cos \phi \left( 1 + \frac{X}{R} \tan \phi \right). \quad (3)$$

If the drop as calculated does not check within a reasonable value with the  $\cos \phi$  assumed in calculating the size of the wire, select another size of wire and recalculate, etc. This refinement will be found necessary, only in the case of power factors and when the size of wire as calculated is either exceptionally large or exceptionally small, in which case the values given for the factor  $K$  in the formula for  $A$ , equation (1), may be in error by a large amount (in limit-cases 50 per cent or more).

In addition to making sure that the drop will be within a reasonable amount, one should also note whether the conductor selected is large enough mechanically and has the proper current-carrying capacity (see above), remembering that the National Electrical Code requires that conductors through which power is supplied to a motor shall have a current-carrying capacity equal to 125 per cent of the full-load current taken by the motor.

**Example of Calculation for a D-C. or Single-phase System.** — Incandescent lamps taking 0.5 ampere each are supplied with power from a 115-volt cycle service through a set of feeders 200 feet in length which terminate at a cut-out cabinet as shown in Fig. 7.

The lamps are grouped in sets of 10 lamps each (only one set is shown) and each is connected to the cut-out cabinet through branch circuit conductors averaging 25 feet in length. Assuming a total

Fig. 7.

potential drop of 3 volts, the drop per conductor will be 1.5 volts. The drop per conductor in the branch circuit should then be one-third of 1.5 or 0.5 volt and the drop per conductor in the feeder circuit should be two-thirds of 1.5 or

\* For d-c. or a-c. single-phase or a-c. 2-phase, 3-wire systems  $V = \frac{1}{2} \times$  (volts between wires); for a 3-phase system  $V = \frac{1}{\sqrt{3}} \times$  (volts between wires); for a 2-phase 3-wire system  $V = \frac{1}{2} \times$  (volts between either outside wire and middle wire). In calculating the normal drop in a single-phase 3-wire system pay no attention to the middle wire, i.e. assume a balanced load.

1 volt. The respective calculations of the areas of the conductors in the feeder and branch circuits may then be carried on independently. In the branch circuit, referring to equation (1),  $I = 10 \times 0.5 = 5$ ,  $l = 25$  and  $v = 0.5$ , which for copper wire

$$A = \frac{11 \times 5 \times 25}{0.5} = 2750 \text{ circular mils.}$$

From the wire table it is found that the next larger commercial size is No. 13 A. W. G., which has a resistance of 2.58 ohms per 1000 feet, and a reactance (assuming a 2.5-inch spacing) of 0.106 ohms per 1000 feet.

Referring to equation (3),  $V = 57.5$ ,  $\cos \phi = 1$ ,  $\tan \phi = 0$ ,  $R = 2.58 \times 25/1000 = 0.0645$ ,  $X = 0.106 \times 25/1000 = 0.00265$ , whence

$$v = 0.0645 \times 5 = 0.323.$$

Equation (2) gives the same value. This voltage is 35.4 per cent less than the assumed voltage of 0.5 volt, but since No. 13 wire is not a commercial size, a closer realization of the assumed voltage is impracticable.

In the same manner, the required area of the conductors used in the feeder circuit is determined by substituting the following values in equation (1):  $I = 100 \times 0.5 = 50$  amperes,  $l = 200$  feet, and  $v = 1$  volt. Hence

$$A = \frac{11 \times 50 \times 200}{1} = 110,000 \text{ circular mils.}$$

From the wire table it is found that a No. 00 A. W. G. wire must be used.

The above calculations although made for a lighting load apply equally well to a motor load, except that in the final selection a wire must be chosen which will carry 125 per cent of the full-load current of the motor.

**Example of Calculation for a Three-phase System.** — Power is to be supplied by three feeders each 400 feet in length to a three-phase, 60-cycle, alternating-current motor (power factor 80 per cent), the voltage between any two line wires at the service entrance being 550 volts. At full load the current taken by the motor is 50 amperes. The voltage to neutral at the service entrance is  $\frac{550}{\sqrt{3}}$  or 318 volts. The wires are to be spaced 6 inches apart.

Allowing a drop in each conductor of 3 per cent of the voltage to neutral, the drop will be 3 per cent of 318 or 10 volts approximately. The following values should then be substituted in equation (1):  $K = 17$ ,  $I = 50$  amperes,  $l = 400$  feet and  $v = 10$  volts, giving

$$A = \frac{17 \times 50 \times 400}{10} = 34,000 \text{ circular mils.}$$

From the wire table it is found that a No. 5 A. W. G. wire might be used considering the potential drop alone but since the carrying capacity of the conductor must be  $1.25 \times 50$  or 62.5 amperes, it would be necessary to use a No. 4 wire.

Adopting a No. 4 wire and referring to equation (3),  $V = 318$ ,  $\cos \phi = 0.8$ ,  $\tan \phi = 0.75$ ,  $R = 0.253 \times 400/1000 = 0.101$ ,  $X = 0.101 \times 400/1000 = 0.0404$ , whence

$$v = 0.101 \times 50 \times 0.8 \left( 1 + \frac{0.04 \times 0.75}{0.101} \right) = 5.3 \text{ volts,}$$

ich is a little more than half the allowable drop of 10 volts. Equation (2) also es 5.3 volts.

**AUTHORITIES GOVERNING THE INSTALLATION OF WIRING BUILDINGS.**—As noted at the beginning of this article all interior ing must be installed in accordance with the regulations of the authorities ing jurisdiction over the building in question. In general, these authorities : (1) the fire underwriters; (2) the municipal authorities; and (3) the power opany supplying the current.

**National Electrical Code.**—This code is a set of instructions published in n years by the National Board of Fire Underwriters. A List of Electrical ings approved by the Underwriters' Laboratories, Inc. is published by the tional Board in April and October of each year. In order that fire insurance any building wired for electric light or power may be obtained from an urance company, the wiring must be installed in accordance with the rules of : National Electrical Code or such modifications of it as are required by law certain municipalities (see *Municipal Regulation, below*). Permission must o be obtained to use any fitting not included in the list of approved fittings. Both the Code and the List of Approved Fittings may be obtained gratis applying to the National Board of Fire Underwriters, 135 William St., New rk City. In view of this fact, and the frequent revisions of the rules and t it is not deemed advisable to give them in detail here. The general require-nts, however, are covered in the section below on *Methods of Installing iring*.

**Municipal Inspection.**—Many state legislatures have passed laws regu-ing the installation of electric wiring and empowering the appointment of icipal inspectors of wiring. In some states fines are imposed by legislative ctment upon those who violate the inspector's rules. Although free to decide on the proper installation of electric wires, municipal inspectors have gener-y adopted the National Electrical Code as a standard with modifications ted to their desires. A copy of these modified rules can usually be obtained stis from the municipal authorities.

**Regulations of the Light and Power Companies.**—The National Elec-cal Code is usually adopted by electric power companies with the addition of ecific requirements pertaining to service connections, placing of meters, type system, etc.

**METHODS OF INSTALLING WIRING.**—The National Electrical ode approves the use of the following methods of wiring: open work, moulding ooden moulding and metallic raceways), concealed knob and tube work, gid conduit, flexible conduit, armored cable and flexible tubing (in short runs). ese methods are described in detail below, but first are given the more impor-nt general requirements regarding joints, protection, cut-outs, switches, etc., ich apply to all classes of wiring for voltages not exceeding 600.

**General Requirements.**—All joints must be mechanically and electrically cure without solder and unless made with some form of approved splicing vice must be soldered and covered with an insulation equal to that on the nductor. Wires must be separated from contact with walls, floors, timbers : partitions through which they may pass by non-combustible, non-absorptive ulating tubes, such as glass or porcelain, except at outlets where flexible tubing required. Unless inclosed in conduit or moulding, wires must be separated om any conducting material or from any other electric wire not more than 6 inches away by some continuous and firmly fixed non-conductor creating permanent separation. In damp places wires must be separated from pipes y an air space and should be run over rather than under pipes upon which

moisture may gather. Wires must be protected from mechanical injury by running-boards or guard-strips on low ceilings and by wooden boxing or metal conduit on side walls. Protection on side walls must extend not less than 6 feet from the floor. No method other than open wiring may be used when the difference of potential between any two wires exceeds 550 volts.

**Automatic Cut-outs** (fuses or circuit breakers) must be placed in the service wires (i.e., the leading-in wires from the street circuit), and at every point where a change is made in the size of wire unless the cut-out in the larger wire will protect the smaller wire. The cut-out in the neutral of a three-wire system may be omitted if the neutral wire is grounded and is of the same size as the outside wires. No set of incandescent lamps requiring more than 660 watts, whether grouped on one fixture or on several fixtures must be dependent upon one cut-out. Cut-outs must in general be inclosed in an approved cabinet although circuit breakers and inclosed fuses may be placed in plain sight in places where there is no danger of igniting any combustible material.

Heating devices, which singly or in groups require more than 660 watts must be protected by a cut-out and the supply conductors should preferably be installed in rigid conduit. Such conductors should be insulated with rubber.

**Switches** which disconnect all wires (i.e., switches having 2, 3 or more poles) must be placed in the service wires as near as possible to the point where they enter the building and in all circuits supplying current to motors, heating devices or lamps; except that in the case of motors of one-fourth horse-power or less in circuits where the voltage does not exceed 300 volts, and in circuits supplying not more than 660 watts of power to heating devices or lamps, single pole switches may be used in two-wire systems or branches. Switches must always be placed in dry, accessible places and must be grouped as far as possible. When used in rooms where combustible flyings are liable to exist, switches must be placed in dust-tight cabinets and when flush switches are used, they must be inclosed in an approved steel box.

**Open Wiring.**—When the appearance of the wiring is not important, exposed surface wiring supported on cleats or insulators furnishes one of the safest and best methods of wiring. The wires must be insulated in dry places with rubber, varnished cloth, slow-burning weatherproof or slow-burning insulation, in damp places with rubber insulation, and in locations where the wires are exposed to corrosive vapors with weather-proof, varnished cloth or rubber insulation.

**Spacing of Wires and Supports.**—Wires must be separated from each other and spaced from the surface wired over as given in the accompanying table.

Wires must be supported under ordinary conditions at least every 4.5 feet, except that in mill construction, wires of not less than No. 8 A. W. G. gage, if separated about six inches, may be run from timber to timber and be supported at each timber only. Open wiring cannot be used in elevator shafts.

**Cleats.**—Cleats are made in a variety of forms. The following are the dimensions of cleats of the form shown in Fig. 8, all dimensions being in inches.

Voltage	Inches from surface to insulation on wire		Inches between wires from insulation to insulation
	Dry	Damp	
0-300	0.5	1	2.5
301-600	1	1	4

\* In the case of 3-wire d-c. or single-phase systems the neutral may be placed between the two outers, these latter being 2.5 inches apart.

Fig. 8

## DIMENSIONS AND COSTS OF CLEATS

Size of wire, circular mills or A. W. G.	1-wire cleats			
	Dimensions, inches			Size of screw, inches
	A	B	C	
14-12	2	1 1/4	3/4	3 x 8
10-8	2	1 3/8	3/4	3 x 8
6-3	2 1/4	1 3/4	1	3 x 10
2	2 3/4	1 3/4	1 1/4	3 1/2 x 12
1-0	2 3/4	2	1 3/8	3 1/2 x 12
00	2 3/4	2 1/4	1 3/4	3 1/2 x 12
000	3	2 3/4	1 3/4	4 x 14

**Wooden Moulding.** — When exposed wiring is not desired, and when it is practicable in old buildings or too expensive in new buildings to install concealed wiring, wooden moulding may be used, provided the difference of potential between any two wires in the same moulding does not exceed 300 volts. Its use is forbidden in elevator shafts and in concealed or damp places. Wooden moulding is manufactured in the following sizes. See table on next page.

Moulding may be made inconspicuous by matching the wood of the moulding to the finish of the room and by using a capping, which will conceal the purpose of the moulding. In this manner, moulding may be made to simulate picture moulding, and on ceilings a panel effect can be obtained by the use of dead moulding. All wires used in wooden moulding must have a rubber insulation and must not be jointed or tapped in the moulding. Branch taps may be made with tap fittings designed for the purpose. Many other moulding fittings are manufactured, which, if used, reduce the labor of installation and improve the general appearance of the work. Wooden moulding is fastened to walls by means of thin screws or toggle-bolts and the capping is nailed on with brads. "Kicking boxes" are usually placed around the end of moulding on floors to protect the wires and porcelain tubes from possible injury.

**Metallic Moulding.** — Metallic moulding may also be used to conceal and protect wires when the difference of potential between any two wires in the moulding is not more than 300 volts and the power transmitted through the wires contained in the moulding does not exceed 1320 watts. Metallic moulding is manufactured in one width only, namely, 1 inch wide by 3/8 to 1/2 inch deep, the depth depending upon the type of moulding. The two types of metal

## STANDARD WOODEN MOULDING

No. of wires	Size of groove, inches	Dimensions, inches		Size of wire	
		Width over all	Depth, cap to base	A. W. G. or circular mils	
				Solid, or braid	Stranded, or braid
2	$\frac{1}{4}$	$1\frac{1}{2}$	$1\frac{1}{16}$	14-12	
2	$\frac{5}{16}$	$1\frac{1}{16}$	$1\frac{1}{16}$	10-8	8
2	$\frac{3}{8}$	2	1	6-4	6-5
2	$\frac{7}{16}$	$2\frac{1}{16}$	$1\frac{1}{8}$	3-2	4-2
2	$\frac{1}{2}$	3	$1\frac{1}{8}$		1-000
2	$\frac{3}{4}$	$3\frac{1}{2}$	$1\frac{3}{8}$		0000-2500
2	1	$4\frac{1}{4}$	$2\frac{1}{8}$		300,000-400,000
3	$\frac{1}{4}$	$2\frac{1}{8}$	$1\frac{1}{16}$	14-12	
3	$\frac{5}{16}$	$2\frac{1}{8}$	$1\frac{1}{16}$	10-8	8
3	$\frac{3}{8}$	$2\frac{1}{8}$	$1\frac{1}{8}$	6-4	6-5
3	$\frac{7}{16}$	$3\frac{1}{8}$	$1\frac{1}{8}$	3-2	4-2
3	$\frac{1}{2}$	$4\frac{1}{8}$	$1\frac{1}{8}$		1-000
3	$\frac{3}{4}$	$5\frac{1}{8}$	$1\frac{3}{8}$		0000-2500
3	1	$6\frac{1}{8}$	$2\frac{1}{8}$		300,000-400,000

moulding in common use differ principally in the method of attaching capping. In the "Lutz" metal moulding the capping consists of a thin metal strip, which is slid into the two grooves that form the upper edge of the moulding. In the "National" metal moulding the capping is snapped over the base. "Lutz" moulding is made in 10-foot lengths while the National moulding is made in 8-foot 4-inch lengths.

Metallic moulding cannot be used in concealed or damp places except in passing through a floor, such moulding may be used if carried through an iron pipe extending from the ceiling below up through the floor to a point 3 feet above the floor or to a point at least 3 inches above the floor where its appearance is an essential feature. Such moulding may be carried through walls and partitions provided it is in one continuous length and that the location is dry. All parts of a metallic moulding system including outlet boxes, junction boxes and cabinets must be electrically connected and grounded. Fittings employed with metallic moulding must be so constructed as to protect the insulation of the wires from abrasion. Wires placed in metallic moulding must be insulated and installed as in wooden moulding with the exception that in alternating-current systems two or more wires of the same circuit must be installed in the same moulding. It is suggested that this also be done for direct-current systems when there is a possibility that an alternating-current system may be used at some future time.

**Concealed Knob and Tube Work.** — This method of wiring is forbidden by the inspectors in many large cities, but when approved, it is employed in buildings of frame construction when it is desired to install the wiring at

The wires when running parallel to beams or studding and when running through beams, studding or floors in plain tubes. When passing through floors at the bottom or through braces, the porcelain tubes insulating the least four inches above the floor or brace. Split knobs in support of conductors smaller than No. 8 A. W. G. wires where a solid knob or strain insulator must be used. In support of wires larger than No. 8 A. W. G., solid knobs may be used. Wires in plain tubes and tie wires when used must have an insulation which will protect the conductors when they are confined.

**Open Wires.** — Wires must be installed in such a manner that the separation between any two wires is at least 5 inches and each wire must be supported by a distance of at least 1 inch. If such separation cannot be maintained, each wire must be supported in a continuous length of approved flexible tubing. The tubing must be protected by flexible tubing extending in each direction from the last porcelain support to at least 1 inch beyond the

**Open Supports.** — Wires must be supported under ordinary conditions at a height of 4.5 feet and if the wires are liable to be disturbed the supports must be shortened.

**Knobs.** — Two types of knobs are used, namely, the solid knob and the split knob. The following table gives the dimensions of one type of knob:

Split knobs *		Tubes	
Height, inches	Diameter, inches	Inside diameter, inches	Outside diameter, inches
1½	1½-1¾	¾	¾
2	2	¾	1¼
		¾	1½
		¾	1¾

\* Holding single wire 1 inch away from wall.

— Although the most expensive method, rigid conduit is the best method of wiring and its use is required by inspectors in many large cities. Two kinds of conduit are manufactured: one with a lining of insulating material, and unlined conduit, having a lining of insulating enamel. Unlined conduit is used more often than lined conduit because unlined conduit is cheaper to buy and to install and wires can be drawn in unlined conduit more easily than in lined conduit. The danger of corrosive action on the conductors due to a possible leak in the lining is avoided by the insulating lining. The conductors used in lined conduit must be smaller in diameter than the conductors used in unlined conduit, because the conductors in unlined conduit must have an additional layer of braid or tape around them in drawing in the wires. Rigid conduit is manufactured

## STANDARD RIGID CONDUIT

Made in 10-foot lengths

Standard size of pipe, inches	Internal diameter, inches	External diameter, inches	Nominal weight per 100 feet, lb.	No. of threads per in. of screw	Maximum size of double-brake wire used in a single conduit A. W. G. or cir. mils		
					1 wire	2 wires	3 wires
1/4	0.62	0.84	85	14	8	14	.....

1 1/2	3.06	3.50	754	8	2,000,000	500,000	400,000
1 3/4	3.54	4.00	900	8	.....	800,000	500,000
2	4.02	4.50	1066	8	.....	1,200,000	850,000

**Bushings, Bends, etc., in Rigid Conduit.** — All parts of the conduit system including outlet or junction boxes must be mechanically secured in place and must be electrically connected and grounded. At outlets or junction boxes rigid conduits must be provided with bushings or nipples to protect the wires from abrasion. The radius of curvature of the inner edge of an elbow bend must not be less than 3.5 inches and there must not be more than one equivalent of 4 quarter bends from outlet to outlet, the bends at the outlet being counted. Bends should be used whenever possible in place of elbows as the wires will pass more easily around a bend than an elbow. The various bending tools that are on the market consist of some form of lever, the end of which may be slipped over the conduit while it is in position. When the number of bends between outlets becomes excessive or when a large number of conduits placed side by side must be deflected, pull boxes are installed so that the direction of the conduit may be changed and the wires may be drawn in more easily. In fireproof buildings conduit is frequently installed just after the steel work has been erected and is then covered up by concrete or tiling.

**Insulation of Wires Used in Rigid Conduits.** — Wires used in rigid conduit must have an approved rubber insulation and must not be spliced or tapped within the conduit. Varnished cloth insulation may be used in permanently dry locations. In alternating-current systems the two or more wires of a circuit must be drawn in the same conduit. It is suggested that this be done for direct-current systems also when there is a possibility that an alternating-current system may be used at some future time. The same conduit must not contain more than four two-wire or three three-wire circuits of the same system and circuits of different systems must be run in separate conduits.

Wires should not be drawn in until all mechanical work on the building is completed. For short runs wires may be pushed in at one opening and they come out at the other opening, but on long runs or where there are many bends, a spring-steel "fish-wire" or "snake" is first pushed through the conduit and a piece of sash cord attached to the "fish-wire" is pulled through. The

ched to the sash cord and pulled through. When the through a conduit easily, powdered soapstone is blown use the friction of the conductors.

Wires. — In vertical runs conductors must be supported dance with the following table:

.. W. G. to 0,	every 100 feet
.. W. G. to 0000,	“ 80 “
W. G. to 350,000 cir. mils,	“ 60 “
ir. mils to 500,000 cir. mils,	“ 50 “
ir. mils to 750,000 cir. mils,	“ 40 “
ir. mils,	“ 35 “

ported by a turn of 90 degrees in the conduit system esigned for the purpose.

above, varnished cambric insulated conductors must be r ends of vertical runs by securely attaching the copper, ion has been removed, to a strain insulator.

2073 for tables, covering number of wires in a conduit.

— In distinction to flexible tubing, a non-metallic tubing, etallic tubing built up of spiral, convex and concave steel : in such a manner as to form a fairly smooth surface, ally. “Flexible conduit,” which is metallic, is usually lexible tubing” (see below), which is non-metallic tubing. esses the advantage over rigid conduit in that it can be and quickly from outlet to outlet and if necessary may be ons or floors. Its chief disadvantages are that it is neither re-proof. Flexible conduit is manufactured in the follow-

TANDARD FLEXIBLE CONDUIT

Weight per 100 feet, pounds	Approx. feet in coil	Maximum size of double-braided wire used in single conduit A. W. G. or cir. mils		
		1 wire	2 wires	3 wires

265	25-50	800,000	300,000	00

s to installation and wires used in rigid conduit apply as

**Armored Cable.**—In place of flexible conduit in which wires must be drawn after the conduit is installed, armored cable consisting of rubber-insulated conductors protected by interlocking spiral steel strips may be used. When installed in damp places, leaded armored cable, which has a lead covering between the insulation and the steel armor, must be used. Armored cable is employed extensively in wiring old buildings where it would be impossible to install rigid conduit without cutting up the walls and floors. Armored cable for interior wiring is manufactured in the following sizes:

## STANDARD ARMORED CONDUCTORS

Size of each conductor A. W. G.	Number of bunched conductors	Approximate outside diameter, inches	Weight per 100 feet, pounds	Approximate feet in coil
14	1	0.37	20	250
12	1	0.40	21.5	250
10	1	0.435	23	250
8	1	0.500	28	250
6	1	0.640	54	250
10*	1	0.435	23	250
8*	1	0.500	28	250
6*	1	0.640	54	250
4*	1	0.690	59	200
2*	1	0.770	71	200
1*	1	0.860	98	100
10*	1	0.555	48	250
8*	1	0.620	54	200
6*	1	0.760	81	200
4*	1	0.820	90	150
2*	1	0.900	120	150
1*	1	0.985	165	100

\* Stranded.

All requirements as to mechanical and electrical connections to outlet boxes, grounding, splicing and tapping of wires, assembling of conductors in alternating-current systems, etc., applying to rigid conduit also pertain to armored cable. Bends in armored cable may be of smaller radius than in rigid conduit, however, the minimum allowable radius of a bend being 1.5 inches for armored cable.

**Flexible Tubing.**—In addition to its use in all places where it is necessary to add to the insulation of the conductors, if the difference of potential between the wires is not over 300 volts, continuous flexible tubing may be used to protect individual wires when fished for short distances in dry places. Although not allowed by some inspectors, flexible tubing is extensively used in this manner in conjunction with moulding or knob and tube work, especially in old buildings where it is necessary to fish the wires to avoid

## GENERAL RULE FOR ANY NUMBER OF WIRES

size of conduit for a given combination of wires may also be estimated as follows: Find the total circular inches\* of area of insulated wire to be put in conduit and divide by the following factor:

1 conductor 0.56

2 conductors 0.33

3 conductors 0.42

4 conductors 0.40

Over 4 conductors 0.37

The result will be the circular inches inside area of conduit required. The diameter of conduit will be the square root of this figure.

example, what size conduit is required for six No. 8 and four No. 2 wires? The overall diameter of a No. 8 is 0.27 in. and of a No. 2 is 0.47 in. Their areas in circular inches are  $0.27 \times 0.27 = 0.073$  and  $0.47 \times 0.47 = 0.22$ , respectively. Six times 0.073 is 0.436 and four times 0.22 is 0.88. The total is  $0.436 + 0.88 = 1.316$  circular inches, which divided by 0.37 gives 3.56 circular inches. The square root of this is 1.89 which is the diameter of pipe required. The next standard size is 2 inches.

\*The area in circular inches of any circle is equal to the square of its diameter divided by 4.

**COST OF WIRING.** — The total cost of wiring a building is made up of three elements: materials, labor and engineering. The labor and engineering charge will depend upon local conditions, and these costs may be estimated accurately only by reference to similar costs in completed work of the same general character. In regard to labor, the local conditions must include the factor of wages paid in the vicinity and the amount of work completed in a given time by the class of labor available. In determining the engineering charge the contractor must estimate the amount for each contract which should be charged to office expense and solicitation of business.

**Office Estimates.** — The cost of the materials is usually determined from a supply catalogue. This may be accomplished by finding (1) the costs of the wiring materials between outlets and (2) the costs of the special devices such as outlet boxes, switches, cut-out cabinets, etc., and adding the two together.

**Cost of Complete Installations.** — According to 1920 prices of materials the cost of wiring various types of buildings per outlet (switches counting as two outlets) is as follows:

Residences wired with armored cables.....	\$5.50-\$7.00
Office buildings, hotels, lofts, factories, etc., with wires installed in rigid conduit.....	8.00-9.00

Knob and tube and cleat wiring is not now much less in cost than conduit work on account of the high labor cost.

**Field Estimates.** — In order to enable its representative to make a rough estimate of the cost of wiring a building while he is interviewing the owner or agent, the contract department of a lighting company usually provides its solicitors with a schedule of wiring costs, based (1) upon the number of lamp sockets and switch outlets to be provided, or (2) upon the total number of outlets (both lamp and switch), or (3) upon the number of lamp sockets and the number of lamp outlets required. Such wiring schedules are usually applicable only to finished buildings; the cost of wiring a building while it is being erected is usually much less than the cost of wiring the same building after it has been completed.

**First Method.** — The buildings to be wired are divided into classes and the cost of wiring a building in any class is based upon the number of lamp sockets, the number of switch outlets, and the type of switches and receptacles installed. The disadvantage of this method is that it does not take into account the number of lamp outlets. In two buildings in which the same number of lamp sockets are installed, the number of lamp outlets may differ widely and as a result the labor and material required for the work will differ in the two buildings although the cost of the wiring may be the same. In most instances, however, this defect is not serious, because of the close relationship between the number of lamp sockets and the number of lamp outlets which are usually installed in the buildings for which the schedule is intended.

**Second Method.** — The various openings for switches, receptacles, drop cords and fixtures are considered as outlets and on the number of these is based the cost of work in houses of different classes of construction. An extra charge is made for hardware and for work installed under double or hardwood floors. With this method the number of lamp sockets installed in two houses for which the cost of wiring is the same may differ considerably. For schedules of cost see *Elec. World*, 1910, Vol. 56, p. 1134.

**Third Method.** — The buildings to be wired are divided into classes and the cost of wiring a building in any class is based upon the number of lamp outlets and lamp sockets and the type of switches installed. This method

improvement on Methods I and II as it does take into account the average number of lamp sockets per lamp outlet, and while the cost of the wiring in two plans requiring the same labor and material may differ slightly, such difference will not be as frequently encountered as in the other two methods. As an example of this type of schedule see article in *Elec. World*, 1912, Vol. 59, p. 548, irrespective of the method used by the Consolidated Gas, Electric Light and Power Company of Baltimore, Md.

**BIBLIOGRAPHY.** — Auerbacher, L. J., *Electrical Contracting*, New York, 1907; Croft, T., *American Electricians' Handbook*, New York; Cushing, *Standard Wiring*; Knox, C. E., *Electric Light Wiring*, New York, 1907; Poppe, T. W., *Wiring*, New York, 1912; Horstmann and Tousley, *Wiring Diagrams and Descriptions*, Chicago, 1904, and *Modern Electrical Construction*, Chicago, 1911; Bursill, A., *Electric Wiring*, London, 1911; articles in *Elec. World*, *Elec. Eng. Rec.*, and *Elec. and Mech.*, *National Electrical Code*.

**WIRING OF BUILDINGS FOR MISCELLANEOUS DEVICES**

— (See also *Wiring of Buildings for Light and Power*.) In addition to the wiring designed to conduct electrical energy to lamps, motors and heating devices in a building, wires may be installed in connection with telephone (q.v.), telegraph (q.v.), district messenger and call-bell circuits, fire and burglar alarm and opening devices, gas lighters, watchman's clocks and electric clocks. Some of these devices are operated at low voltage, it is unnecessary to use the same care in selecting and installing the wires as in the higher voltage systems, except that in all low-voltage systems care must be exercised that the conductors shall not become crossed with light and power circuits.

**Protection of Low-voltage Wiring.** — When the conductors of any low-voltage system are brought into a building from the outside, an approved protective device must be located as near as possible to the entrance of the wires to the building. With the exception of instrument circuits of telegraph systems where cut-outs only are required, protective devices must contain a lightning arrester with a ground connection and a cut-out or heat-coil (see *Telephone Instruments and Circuits*). The conductors beyond the protective device in low-voltage systems need be insulated only sufficiently to prevent short-circuits and the consequent interruption of service. When bunched together in a vault or run the wires must be inclosed in a fire-resisting covering to prevent the wires from carrying fire from floor to floor. Low-voltage circuits may be run in the same shaft with light and power circuits, provided the two classes of wires are separated by at least two inches or one of the classes is run in a non-combustible tubing. Low-voltage wires may not be run in any case in the same tube with lighting or power wires.

**Telephone Wiring.** — (See also *Telephone Instruments and Circuits*.) In large buildings, rubber-insulated twisted pairs of wire are used extensively for telephone work. The twisted wires may be fished between partitions or concealed in moulding and if open wiring is not objectionable, the wires may be carried along the finish of the room and fastened with insulating staples or tacks. In new buildings the wires are frequently installed in conduit and the connections are made at connection boxes designed for the purpose. In large buildings, when the number of telephones in use becomes very great, lead-covered insulated cable containing multiple pairs of conductors is installed in wire-ways provided for the purpose. Distributing connection boxes to which many circuits may be connected are then installed on each floor.

**Bell Wiring.** — In its simplest form a bell-wiring system consists of a battery (usually a Leclanché type or dry battery), a bell-push, a bell or buzzer and the connecting wire. Paraffine-impregnated double-cotton covered wires ranging in size from No. 16 to No. 22 A.W.G. gauge are usually employed, either singly or in the form of twin wires. The wires may be fished, concealed in moulding or run exposed along the finish of the room. When a large number of bell-wires must be run together through a building as in the case of a hotel annunciator system, the wires are frequently inclosed in a cotton braid or in a tube made of zinc or impregnated paper. In many buildings supplied with an alternating current source of power a small step-down transformer is used in place of the batteries, thus effecting a saving in the cost of the installation and eliminating the possibility of run-downs by

Fig. 1.

2. In Fig. 1 are shown several systems of bell wiring; these figures are explanatory.

**Burglar Alarms.** — In place of the bell-push used in bell-wiring systems, the circuit may be closed by some circuit-closing device attached to windows, doors, etc., so that the opening of any window or door in the building will be known by the ringing of a bell. As such a system has the objection that it will not operate if the battery is run down or if the wires are cut, a closed-circuit system is preferable, in which the opening of a window or door opens the circuit

Fig. 2. Open-circuit Burglar Alarm

Fig. 3. Closed-circuit Burglar Alarm

a relay in turn closes the bell circuit. In Fig. 2 is shown a typical open-circuit system and in Fig. 3 a typical closed-circuit system. In Fig. 4 are shown a window spring A and a door spring B.

**Door Alarms.** — In the manually-operated system glass disks are placed at convenient points throughout the building and with each disk is provided a hammer, with which the disk may be broken in case of fire. The breaking of the disk opens or closes an electric circuit by means of which electric gongs are rung throughout the building. In the automatic system the expansion or fusion by heat of elements in door-closing or opening devices usually placed on doors, causes gongs to ring throughout the building and to the watchman's office.

Fig. 4.

**Door-opening Devices and Electric Clocks.** —

Doors may be opened by pressing a button at some convenient point and thereby closing a circuit, through which current flows, energizing a magnet, which releases the nosing in the door lock. In the same manner, a moving disk on a master clock may periodically close a circuit, through which a magnet is energized which operates a pawl attached to the hands of another clock.

**Watchman's Clock.** — Circuit-closing devices are placed at different points throughout a building so that a watchman on his rounds may close the circuit by means of a handle or special key. The closing of the circuit at any station makes a record on a dial in the watchman's clock indicating the time at which the circuit was closed at each particular station, the stations being designated by numbers. To obviate the possibility of run-down batteries, magneto systems are often installed, a small magneto being placed at each station.

**Gas Lighters.** — In the "pull-burner" and "automatic-burner" systems, when the gas is turned on, an electric circuit is made and broken by means of contacts placed at the tip of the burner. To intensify the spark at the burner, an inductance coil is always connected in series with the circuit. In the "pull-burner" system (Fig. 5) the pulling of a chain or the turning of a key on the gas jet opens the gas and at the same instant makes and breaks the circuit by contacts

placed near the burner. In this system one wire connects the battery in series with a spark coil to the contact device, the other terminal of the contact device being grounded to the gas pipe through which connection is made to the other terminal of the battery.

Fig. 6.

In the "automatic-burner" system (Fig. 6) three wires are run from a two-button push to one pole of the battery and one terminal each of the two magnets on the automatic burner, the other terminals of the battery and the two magnets being grounded on the gas pipe. The two push buttons are usually made black and white respectively, the white button being pushed to light the gas and the black one to extinguish it. When the white button is pushed, a circuit is closed connecting the battery, the magnet which turns on the gas, the vibrating contactor and the spark coil in series. When the black button is pushed, a circuit is closed connecting the battery and the magnet, which turns off the gas series.

**RAYS.** — (See also *Generators, Static; Induction Coils.*) X-rays or Röntgen rays are generated when the cathode rays of a vacuum tube impinge on any solid substance. The form of X-ray tube commonly used, known as "focus tube," is shown in Fig. 1. When a high unidirectional e.m.f. is impressed between the anode (A) the cathode (C), the cathode rays emitted from (C) strike upon anti-cathode (B) from which X-rays originate. The anode and cathode are made of osmium because of its low coefficient of disintegration under vacuum discharge. The anti-cathode is made of platinum to withstand the intense heat of ionic bombardment. The anti-cathode must be electrically connected to the anode to prevent the possible emanation of cathode rays from its surface.

Fig. 1. X-ray Tube

The cathode is concaved spherically so that cathode rays are focussed upon the anti-cathode, the rays falling within a spot not more than 0.08 inch in diameter. Owing to the repulsion between the particles constituting the cathode rays, the optical focus point of the cathode should be just in front of the surface of the anti-cathode, so that the actual focus point will fall upon the surface of the anti-cathode. The vacuum tube, made of thin glass to reduce the absorption of the X-rays, is blown in spherical form to withstand the external pressure most effectively.

**Character of X-Rays.** — Numerous attempts made to prove that X-rays are undulatory form, similar to that of light, have been unsuccessful. It has been found that X-rays are neither reflected nor refracted and are not deflected like cathode rays by a magnetic force. Barkla (*Phil. Trans.*, 1905, p. 467) found that such rays may be polarized and his conclusions have been confirmed by other investigators. According to the existing information, it may only be presumed that, when the negatively electrified particles constituting the cathode rays strike any solid substance, they lose their charge and give rise to the extremely high vibrations known as X-rays. It has been shown that such rays do not emanate from the impact spot on the anti-cathode but from a ring surrounding the spot, and travel in all directions from the surface of the anti-cathode, the densest emanation being in a direction normal to the surface.

**Properties of X-Rays.** — All substances, many of which are opaque to ordinary light, transmit X-rays to a greater or less degree. In most cases the transparency of any substance to such rays is (roughly) inversely proportional to its specific gravity. In the accompanying table are given the relative transparencies of various substances and their specific gravities, the transparency of air being taken as unity.

When X-rays are passed through gases, the gases become ionized and their electrical conductivity is accordingly increased. This property has been used as a means of measuring the relative strengths of X-rays.

Certain substances fluoresce under the action of X-rays making the existence of X-rays visible to the eye. The fluorescent screens ordinarily used for anatomical examinations are coated with barium platino-cyanide, potassium platino-cyanide or calcium tungstate.

X-rays are to a considerable degree chemically active and photographs may be made of objects generally opaque to the eye but built up of substances of

different transparencies to the X-rays, so that the internal structure of the object is revealed in the photograph. Such photographs made with highly sensitive plates are called radiographs or skiagraphs.

Considerable use is also made of X-rays in the electro-therapeutic treatment of certain diseases especially those of the skin.

**Manipulation of the Tube.** — It is important that the tube be connected in the proper polarity as a reverse current in the tube will cause it to blacken. The voltage used with the tube depends upon its size and the degree of vacuum attained. The ordinary tube requires a voltage of from 50,000 to 100,000 volts or, as usually stated, a voltage which will puncture a needle gap of from 1 to 10 inches in air. The source of e.m.f. used with the tube is usually an induction coil (q.v.) and in some cases a static generator (q.v.). The voltage required to puncture a tube is materially reduced if a sheet of tinfoil electrically connected to the cathode terminal is wrapped around the outside of the tube at the cathode end and covering about one-third of its surface. The current taken by a tube is extremely small so that the connecting wires need only be strong enough to withstand breakage but must be heavily insulated. Under ordinary use the internal pressure of the gas in the tube decreases due to the oxidation of the gas content by the metals and glass of which the tube is constructed.

the internal pressure in the tube decreases, it may become inoperative and old then be heated in an oven to release the occluded gases and reestablish proper pressure. Certain "regenerative" tubes contain palladium which ludes gas at ordinary temperatures and gives off gas under heat, thereby attaining a constant pressure within the tube.

**"Hard" and "Soft" Tubes; Condition of Tubes.**—The penetrating power of an X-ray tube is proportional, within certain limits, to its vacuum. High-vacuum tube, known as a "hard" tube, will emit a few rays of great penetrating power, whereas a low vacuum tube, known as a "soft" tube will emit a greater number of rays of less penetrability. In most cases better contrast is obtained upon the photographic plate or fluorescent screen when a "soft" tube is used than when a "hard" tube is used, since the rays emitted by a "hard" tube may penetrate all the constituent parts of the object examined with nearly equal strength.

The condition of a tube under operation may be easily detected by observing the color of the vacuous discharge. When running under normal conditions, the tube will glow with a greenish-yellow light; the face of the anode will emit a yellow light, but in the space behind the anode, a violet glow will appear. The question of correct polarity may then be checked by this appearance before the anode. A pinkish light within the tube indicates that the vacuum is low, and the absence of any glow indicates too high a vacuum. A needle connected in parallel with the tube will show when the voltage is too high and protects the tube from excessive voltages.

**Coolidge Tube.**—In the ordinary X-ray tube, shown in Fig. 1, the emission from the cathode is due to the bombardment of the cathode by positive ions. The stability of operation of the tube is therefore dependent upon the maintenance of a constant gas pressure within the tube. In the Coolidge tube (Fig. 2), use is made of the principle of emission of electrons from hot surfaces, the cathode being constituted of an electrically heated spiral of tungsten (c) surrounded by a focussing surface (S) of tungsten or some other refractory material. The anti-cathode or anode (A), which also serves as anode, consists of a piece of wrought tungsten.

Fig. 2.

The pressure within the tube is made as low as possible, usually not more than a few hundredths of a micron. The tungsten spiral is heated by current supplied from a storage battery, while the terminals of the tube are connected to a potential source of direct or alternating current. The operating temperature of the tube is lower with direct than with alternating current.

The principal advantages of the Coolidge tube over the ordinary Röntgen tube are (1) the use of either direct or alternating current, (2) the independent control of the penetrating power and intensity of the X-rays by adjusting the applied voltage or the temperature of the cathode, (3) the continuous stable operation of the tube under any adjustment for several hours, (4) the reduction of the temperature and absence of the fluorescence of the glass and (5) the production of intense X-rays of any desired penetrating power.

## APPENDIX

### STANDARDS OF THE AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS

---

#### CHAPTER I

#### GENERAL PRINCIPLES UPON WHICH THE A. I. E. E. STANDARDS ARE BASED

---

temperatures in this and the following chapters are given in centigrade degrees.)

#### HEATING

**10. General Principles.**—The General Principles by reference to which ratings of electrical machines are fixed, so far as their heating is concerned, is that the life of insulating materials depends upon the temperatures to which these materials are subjected. Taking, as a basis, the results of experiments with machinery in practical service and the results of laboratory tests of insulating materials, limiting "hottest-spot" temperatures have been established for various classes of insulation for purposes of standardization. Limiting "observable" temperatures are deduced from these limiting "hottest-spot" temperatures by subtracting therefrom a specified number of degrees Fahrenheit, for purposes of standardization represents the margin fixed between the limiting hottest spot and the limiting observable temperatures. This margin may be designated as the "conventional allowance."

**11. Methods of Temperature Measurement.**—There are three fundamental methods of temperature measurement, namely:

1. The Thermometer Method.
2. The Resistance Method, and,
3. The Embedded-Detector Method.

The General Principles stated in Section 1000 permit of the use of whichever method is best suited to the class of machine, or part thereof, to be tested, by introducing appropriate values for the limiting observable temperature by each method. All the values of the observable temperatures are based upon the "hottest-spot" limitation adopted for purposes of standardization for the class of insulation employed.

1002. **Methods of Temperature Measurement Defined.**—These are the fundamental methods of making temperature measurements are designated Methods 1, 2 and 3, and are defined as follows:

TABLE 100  
Methods of Temperature Measurement

Method	Description of Method
1.	<p style="text-align: center;"><b>Thermometer Method</b></p> <p>This method consists in the measurement of the temperature by mercury or alcohol thermometers, by resistance thermometers, or by thermocouples, any of these instruments being applied to the hottest accessible part of the completed machine. The method does not include the use of thermocouples or resistance coils embedded in the machine as described under Method No. 3.</p>
2.	<p style="text-align: center;"><b>Resistance Method</b></p> <p>This method consists in the measurement of the temperature of windings by their increase in resistance. In the application of this method, thermometer measurements shall also be made wherever practicable without disassembling the machine,* in order to increase the probability of obtaining the highest observable temperature. The measurement indicating the higher temperature shall be taken as the "observable" temperature.</p>
3.	<p style="text-align: center;"><b>Embedded Temperature-Detector Method</b></p> <p>This method consists in the measurement of the temperature by thermocouple or resistance temperature detectors, located as nearly as possible at the estimated hottest spot. When Method No. 3 is used, it shall, when required, be checked by Method No. 2. The highest observable temperature obtained from the readings of the embedded detectors shall not exceed the values permitted by the Rules for Method 3, and the highest observable temperature obtained by Method 2 shall not exceed the values permitted by the Rules for Method 2.</p>

\* Note. As one of the few instances in which the thermometer check cannot be applied in Method II, the rotor of a turbo alternator may be cited.

1003. **Conventional Allowances for the Three Methods of Temperature Measurement.**—The specified differences by which the "observable" temperatures shall, for purposes of standardization, be assumed to be lower than the "hottest spot" temperatures, (which may be designated the "Conventional Allowances"), are as follows:

Method 1.....	15° C.
" 2.....	10° C.
" 3.....	(See following table)

TABLE 101

## Conventional Allowances for Method 3

Method 3	
windings with two coil-sides per slot with detectors between top and bottom coil-sides (and between coil-sides and core).	5° C.
windings with one coil-side per slot for 500 volts or less, with detectors between coil-side and core and between coil-side and wedge.	10° C.
windings with one coil-side per slot for more than 5000 volts, with detectors between coil-side and core and between coil-side and wedge.	10° C. plus 1° C. for every kv. of terminal pressure of the machine above 5 kv.

**M. Classification of Insulating Materials.** — The insulations employed in Electrical Machinery are subdivided into four main classes, designated O, A, B, and C and defined as follows:

TABLE 102

## Classification of Insulating Materials

	Description of Material
O	Cotton, silk, paper and similar materials when neither impregnated nor immersed in oil.
A	Cotton, silk, paper and similar materials when so treated or impregnated as to increase the thermal limit, or when permanently immersed in oil; also enamelled wire.
B	Mica, asbestos and other materials capable of resisting high temperatures, in which any Class A material or binder is used for structural purposes only, and may be destroyed without impairing the insulation or mechanical qualities of the insulation. (The word "impair" is used in the sense of causing any change which could disqualify the insulation for continuous service.)
C	Materials capable of resisting higher temperatures than Class B, such as pure mica, porcelain, quartz, etc.

**M.\* Limiting "Hottest Spot" Temperatures.** — The limiting "hottest spot" temperatures are, for purposes of standardization, taken at the following:

For Class O material.....	90° C.
For Class A material.....	105° C.
For Class B material.....	125° C. (See Note)
For Class C material.....	no limit yet specified

\*66) The Institute recognizes the ability of manufacturers to employ Class B insulation successfully at maximum temperatures of 150° C. or even higher. However, scientific data covering experience over a period of years at such temperatures is recent unavailable, the Institute adopts 125° C. as a conservative limit for this classification, and any increase above this figure should be the subject of special guarantee by manufacturer.

If different insulating materials are used on various parts of one winding (for instance in the slot and for the end windings) the temperature of each material shall not exceed the limit set for that material.

When insulation consists of layers of materials having different temperature limits (for instance high-temperature limit material adjacent to the copper and lower-temperature limit material adjacent to the iron or to the air) the temperature of each material shall not exceed the limit set for that material.

**1006. Limiting Observable Temperatures.**— The limiting observable temperatures for use with Methods 1, 2 and 3, are arrived at by subtracting the "conventional allowances" from the limiting "hottest-spot" temperatures of insulating materials. They are set forth as follows:

**TABLE 103**  
**Limiting Observable Temperatures**

		Class O Material	Class A Material	Class B Material
Method 1		75° C.	90° C.	110° C.
Method 2		80° C.	95° C.	115° C.
Method 3	For windings with two coil-sides per slot with detectors between top and bottom coil-sides and between coil-sides and core.	85° C.	100° C.	120° C.
	For windings with one coil-side per slot with detectors between coil-side and core and between coil-side and wedge.	80° C. (minus 1 degree for every 1000 volts of terminal pressure of the machine above 5000 volts.)	95° C. (minus 1 degree for every 1000 volts of terminal pressure of the machine above 5000 volts.)	115° C. (minus 1 degree for every 1000 volts of terminal pressure of the machine above 5000 volts.)

\* See also Note, Section 1005.

**1007. Limiting Observable Temperature of Oil.**— The oil in which apparatus is permanently immersed shall, in no part, have a temperature, observable on a thermometer, in excess of 90° C.

**1008. Standard Ambient Temperatures of Reference.**— The following values are adopted for the standard ambient temperatures of reference:

For Air..... 40° C.  
For Water..... 25° C.

These values for the standard ambient temperatures of reference apply to conditions where the actual ambient temperature does not exceed them.

**1009. Limiting Observable Temperature Rise.**— The limiting observable temperature rises in the following Table 104 are obtained by subtracting the standard ambient temperatures of reference given in § 1008 from the limiting observable temperatures given in Table 103. The limiting observable temperature rises to be used in practice are given later in the Rules. They are in some cases greater and in other cases smaller than those given in Table 104. § 1010.

For the purpose of rating, the limiting observable temperature rise must be increased even when the ambient temperature is lower than the standard ambient temperature of reference.

TABLE 104  
Limiting Observable Temperature Rises

Method		Air Cooled		
		Class O	Class A	Class B*
Method 1		35° C.	50° C.	70° C.
Method 2		40° C.	55° C.	75° C.
Method 3	For windings with two coil-sides per slot, with detectors between top and bottom coil-sides and between coil-sides and core.	45° C.	60° C.	80° C.
	For windings with one coil-side per slot with detectors between coil-side and core and between coil-side and wedge.	40° C. (minus 1 degree for every 1000 volts of terminal pressure of the machine above 5000 volts.)	55° C. (minus 1 degree for every 1000 volts of terminal pressure of the machine above 5000 volts.)	75° C. (minus 1 degree for every 1000 volts of terminal pressure of the machine above 5000 volts.)

See also Note, Section 1005.

**10. General Comments on Special and Specific Cases.** — In the foregoing it has been assumed for the purpose of presenting a comprehensive, logical and consistent plan, that the Rules actually used in the industry are exactly in accord with the General Principles. Practical experience indicates the necessity of establishing definite Rules to cover Special as well as Specific Cases. These are set forth in later chapters. Any case not specifically dealt with may be covered under the General Principles.

**11. Comments on the Method of Measurement to be Employed.** — In the absence of definite Rules, the manufacturer may, on the occasion of the acceptance test, use any of the three methods for the temperature measurements. In special cases, however, restrictions on the choice of method are imposed. These are set forth in the Rules.

**12. Comments on Temperature Limits in Special Cases.** — Temperature limits are prescribed in the Rules for special cases where conditions determined by practice, by experience, or by agreements, require departures (often arbitrary) from the limits of temperature rise corresponding to the General Principles.

**13. Hottest Spot Temperature the Primary Point of Reference.** — The hottest spot temperature is the primary point of reference, or the "benchmark" used as the basis for the foregoing scheme or temperature delimitation. It is not employed in commercial transactions or in the ordinary course of testing or operation of electrical machinery.

**14. Observable Temperature Rise the Working Standard.** — The observable temperature rise is the working standard. A summary of working data and explanatory notes, will be found in Table 300.

**15. Duration of Temperature Test and Correction to Time of Shut Down.** — Whatever method of temperature measurement be employed, it is required that (a) operation shall be continued until constant temperatures are determined if the machine has a continuous rating, or for the full period if the machine has a short time rating, and

(b) when measurements cannot be made while the machine is loaded, appropriate corrections to raise the temperature readings to the time of shut down shall be applied. See Chapter II.

**MECHANICAL AND COMMUTATION LIMITATIONS**

These limitations are set forth in subsequent Chapters dealing with special kinds of machines.

**WAVE SHAPE**

1300. The sine wave shall be considered as standard except where the departure therefrom is inherent in the operation of the system of which the machine forms a part.

**DIELECTRIC STRENGTH AND INSULATION RESISTANCE**

(See §§ 2350 to 2380 incl.)

1300. The injury produced by dielectric stress applied to insulation is related to the time during which the stress is applied. A stress up to a certain limit may be applied for an indefinite period without injury to the insulation. A somewhat greater stress will cause heating of the insulation and a progressive deterioration, eventually resulting in breakdown. Higher values of stress cause more rapid deterioration and a quicker breakdown. It is customary to determine whether machinery will withstand the voltage stresses met in practice by a preliminary test for a definite period of time at a voltage considerably higher than the normal voltage to which the machinery is to be subjected. This test is not high enough to produce injury to the insulation during the period of test.

1301. The test voltage which shall be applied to determine the suitability of insulation for commercial operation is dependent upon the kind and size of machine, and its operating voltage, upon the nature of the service in which it is to be used, and upon the severity of the mechanical and electrical stresses which it may be subjected. The voltages and other conditions of test which are recommended have been determined as reasonable and proper for the great majority of cases, and are proposed for general adoption, except when special reasons make a modification desirable.

1400. The insulation resistance of machinery is of doubtful significance compared with the dielectric strength. It is subject to wide variation with temperature, humidity and cleanliness of the parts. When the insulation resistance falls below prescribed values it can, in most cases of good design where no defect exists, be brought up to the required standard by cleaning and drying the machine. The insulation resistance therefore may afford a useful indication as to whether the machine is in suitable condition for application of the dielectric test.

**EFFICIENCY**

(See §§ 2331 to 2333 incl.)

1500. The conditions under which efficiency is determined are those prevailing to the operation of the machine. These include voltage, current, power factor, frequency, wave shape, speed, temperature, or such of them as may apply in any particular case.

1501. The efficiency at all loads of all apparatus shall be corrected to a reference temperature of 75° C.

1502. In the case of machinery, two efficiencies are recognized, conventional efficiency (§ 3524) and directly measured efficiency. Unless otherwise specified the conventional efficiency is to be employed. When the efficiency of a machine is stated without specific reference to the load conditions, rated load is always to be understood, whether the efficiency be the conventional or directly measured efficiency.

**RATING**

(See §§ 2302 to 2331 incl.)

1600. Principle of Machine Rating. — (a) *Rating by Temperature Rise:* The principle upon which machine rating is based, so far as relates to thermal characteristics, has been stated in earlier sections.

(b) *Rating by Limitations Other than Temperature Rise:* In some machines the rating is limited by other than thermal considerations. In such cases, the principle upon which machine rating is based is that the rated load applied continuously or for a stated period, shall not cause the various limitations specified

inter chapters; e.g., §§ 4250-4252 inclusive, to be exceeded. The rating shall be based upon the capacity as limited by heating unless the capacity as limited by other characteristics, is less.

## CHAPTER II

### GENERAL RULES

The expressions "machinery" and "machines" are here employed in a general sense, in order to obviate the constant repetition of the words "machinery" or "induction apparatus."

To ensure satisfactory results, electrical machinery should be specified to conform to the Institute Standards, in order that it shall comply in operation, with approved limitations in the following respects, so far as they are applicable.

Operating temperature	Efficiency
Mechanical strength	Power factor
Commutation	Wave shape
Dielectric strength	Regulation
Insulation resistance	

### OPERATION

#### Temperature Limits

**14. Permissible Temperatures with Insulations of More than One Class.**

(1) If different insulating materials are used on various parts of one winding (instance in the slot and for the end windings) the temperature of each material shall not exceed the limit set for that material.

(2) When insulation consists of layers of materials having different temperature limits (for instance high-temperature limit material adjacent to the copper lower-temperature-limit material adjacent to the iron or to the air) the temperature of each material shall not exceed the limit set for that material.

**15. Temperatures of Metallic Parts of Machines.**—(a) *Parts Adjacent to Insulating Material:* Metallic parts of machines in contact with or adjacent to kind of insulation, shall not attain a temperature in excess of that allowed for adjacent insulation.

*Parts not Adjacent to Insulating Material:* All parts of machines other than those covered by § 2116 (a) may be operated at such temperatures as shall be injurious in any other respect.

**16. Protection against Short Circuit.**—The Institute recognizes the self-protectibility, both mechanical and thermal, of certain sizes and types of machines, when subjected to severe short-circuits, and recommends that ample provision be provided in such cases, external to the machine if necessary.

### RATING

#### General

**1. Expression of Rating.**—Except where otherwise specified the machines shall be rated in terms of their available *output*. For exceptions see §§ 4223, 6204 and 6223.

**2. Institute Rating.**—The Institute Rating of a machine shall be its rating when operating with a cooling medium of the ambient temperature of reference specified in §§ 2211 and 2212 and with barometric conditions within range given in § 2215. See §§ 4300, 4310, 4312, 4110 and 4300.

#### Ambient Temperature of Reference and Altitude Correction

**1. Ambient Temperature of Reference for Air.**—The standard ambient temperature of reference, when the cooling medium is air, shall be 40° C.

**2. Ambient Temperature of Reference for Water-Cooled Machinery.**—For water-cooled machinery, the standard temperature of reference for incom-

**2213. Machines Cooled by Other Means.**—Machines cooled by means other than air or water shall receive special consideration.

**2214. Outdoor Machinery Exposed to Sun's Rays.**—Outdoor machinery not protected from the sun's rays at times of heavy load, shall receive special consideration.

**2215. Altitude.**—Increased altitude has the effect of increasing the temperature rise of some types of machinery. In the absence of information in regard to the height above sea level at which a machine is intended to work in continuous service, this height is assumed not to exceed 1000 meters (3300 feet). Machinery operating at an altitude of 1000 meters or less, a test at any altitude less than 1000 meters is satisfactory, and no correction shall be applied to the observed temperatures. Machines intended for operation at higher altitudes shall be regarded as special. It is recommended that when a machine is intended for service at altitudes above 1000 meters (3300 feet) the permissible temperature rise at sea level, shall be reduced by 1 per cent for each 100 meters (330 feet) by which the altitude exceeds 1000 meters.

#### Kind of Rating

There are various kinds of rating such as:

**2220. Continuous Rating.**—A machine rated for continuous service shall be able to operate continuously at its rated output, without exceeding any limitations established herein.

In the absence of any specification as to the kind of rating, the continuous rating shall be understood.

**2221. Short-Time Rating.**—A machine rated for discontinuous or short-time service (*i. e.*, service including runs alternating with stops of sufficient duration to ensure substantial cooling), shall be capable of operating at its rated output during a limited period, to be specified in each case, without violating any of the limitations established herein. Such a rating is a short-time rating.

**2222. Duty-Cycle Operation.**—Many machines are operated on a duty cycle which repeats itself with more or less regularity. For purposes of test either a continuous or a short-time equivalent load may be selected, which shall simulate as nearly as possible the thermal conditions of the actual duty-cycle.

**2223\*. Standard Short-Time Ratings.**—The following periods shall be used for short-time ratings: 5, 10, 15, 30, 60 and 120 minutes.

**2224. A. I. E. E. and I. E. C. Ratings.**—When the prescribed conditions of test are those of the A. I. E. E. Standards the rating of the machine is the A. I. E. E. Rating. (See § 2401.) When the prescribed conditions of the test are those of the I. E. C. Rules, the rating of the machine is the I. E. C. rating. A machine so rated in either case may bear a distinctive sign upon its rating plate. The I. E. C. stands for "International Electrotechnical Commission."

**2225. Continuous Rating Implied.**—Machines marked "A. I. E. E. Rating" or "I. E. C. Rating" shall be understood to have a continuous rating, unless otherwise marked in accordance with §§ 2223, 5201 or 5202.

#### Rating by Temperature Rise

**2226. Limiting Observable Temperature Rises.**—The following limiting observable temperature rises have been adopted.

(2223) When, for example, a short-time rating of 10 minutes duration is adopted, the thermally equivalent load is 25 kw. for that period, then such a machine shall be understood to have a 10-minute rating of 25 kw.

In every case the equivalent short-time test shall commence only when the windings or other parts of the machine are within 5° C. of the ambient temperature at the time starting the test.

TABLE 200

ing Observable Temperature Rise for Machines for Operation in Locations where the Ambient Temperature will not Exceed 40° C. for Air or 5° C. for Water.

Class A insulation use the values in the table.

Class D insulation use 15° C. lower values.

Class B insulation use 20° C. higher values (or 45° C. higher in the cases as by the Note in § 2005).

Class C insulation no limits yet specified.

Name	Method 1	Method 2	Method 3	
			For windings with two coil-sides per slot with detectors between top and bottom coil-sides and between coil sides and core	For windings with one coil-side per slot with detectors against core and against wedge
1. Insulated windings other than 2.3 Note 1	50° C. Note 1	55° C. Note 1	60° C. Note 1	55° C. minus 1° for every 1000 volts by which the terminal pressure of the machine exceeds 5000 volts. Note 1
2. Single layer field windings with exposed surfaces uninsulated	60° C.	60° C.		
3. Short-circuited insulated windings	60° C.			
4. Field Windings (other than 5)		55° C.		
5. Single layer field windings with exposed surfaces uninsulated	60° C.	60° C.		
6. Windings in slots	50° C.	55° C.		
7. Short-circuited insulated windings	60° C.			
8. Transformers and Induction Regulators		55° C.		

1— (a) The temperature of the windings of transformers and induction regulators is to be ascertained by Method 2.

off immediately at the end of the temperature run and air intake shall be closed to prevent further admission of cooling air. In checking the temperatures ascertained by means of the readings of thermometers well distributed and in good contact with the coils and noted and the maximum temperature indicated by them, if higher than that deduced by resistance, shall be taken as the maximum observable temperature of the windings. With the above procedure, the observable temperature rise for air-blast transformers shall attain a value not in excess of 80° C. as determined by thermometer, although it may not exceed 55° C. as determined by resistance.

(c) Method 3 shall be applied to all stators of machines with cores having a width 25 cm and over; it shall also be applied to all machines of 5000 volts and over and of over 10000 kVA regardless of core width.

(d) Method 2 shall not be used for circuits of low resistance (other than transformer windings), such as interpole windings, where external joints and connections form a considerable part of the total resistance.

(e) For all other cases it is optional to employ either Method 1 or Method 2. This is equivalent to authorizing Method 1 with a 5° C. lower limit of observable temperature than is permitted for Method 2).

Note 2. — For enclosed machines (rotating) the limiting observable temperature shall be taken as 5 degrees higher than the values set forth in the Table for Items 1 and 2.

Note 3. — A further limitation to this Table relates to the restriction of its application to machinery for operation in locations whose altitude is not more than 1000 meters above sea level. Recommendations relating to the limiting temperature rise for machines operating at higher altitudes are given in §§ 2215 and 2231.

Note 4. — If different insulating materials are used on various parts of one winding (for instance in the slot and for the end windings) the temperature of each material shall not exceed the limit set for that material.

When insulation consists of layers of materials having different temperature-limits (for instance high-temperature-limit material adjacent to the copper and lower-temperature-limit material adjacent to the iron or the air) the temperature of each material shall not exceed the limit set for that material.

**2231. Exceptions to Table 200.** — (a) When the thermometers are applied directly to the surfaces of bare windings, such as an edgewise strip conductor or a cast copper winding, the limiting observable temperature rise shall be 15° C. higher than given for Method 1 in the table.

(b) For commutators, collector rings, or bare metallic surfaces not forming part of a winding, the limiting observable temperature rise shall be 15° C. higher than given for Method 1 in the table.

(c) Any machinery destined for use with higher ambient temperatures, cooling mediums, and also any machinery for operation at altitudes for which no provision is made in § 2215, should be the subject of special guarantee by the manufacturer. The methods of test and performance set forth in these Rules will, however, afford guidance in such cases.

**2232. Limiting Observable Temperature of Oil.** — The oil in which apparatus is permanently immersed shall in no part have a temperature, observable by thermometer, in excess of 90° C.

## TESTS

### Ambient Temperature

**2200.\* Measurement of the Ambient Temperature During Tests of Machinery.** — (a) *General:* The ambient temperature is to be measured by means of several thermometers placed at different points around and half-way up the machine at a distance of 1 to 2 meters (3 to 6 feet), and protected from direct and abnormal heat radiation, preferably as in § 2301.

(b) *Mean Temperature:* The value to be adopted for the ambient temperature during a test, is the mean of the readings of the thermometers (placed as above), taken at equal intervals of time during the last quarter of the duration of the test.

(c) *Use of Idle Units:* It is sometimes desirable to avoid errors due to thermal lag in temperature changes, by employing an idle unit of the same size and

(2300) The cooling fluid may either be led to the machine through ducts, or through pipes, or merely surround the machine freely. In the former case the ambient temperature is to be measured at the intake of the machine head.

held to the same conditions of cooling as the unit under test, for obtaining the ambient temperature.

**1301. Oil Cup.**— In order to avoid errors due to the time lag between the temperature of large machines and the variations in the ambient air, all reasonable precautions must be taken to reduce these variations and the errors arising therefrom. Thus, the thermometer for determining the ambient temperature shall be immersed in a suitable liquid, such as oil, in a suitably heavy metal cup. It can be made to respond to various rates of change, by proportioning the amount of oil to the metal in the containing cup. A convenient form for such an oil cup consists of a massive metal cylinder, with a hole drilled partly through

This hole is filled with oil and the thermometer is placed therein with its bulb well immersed. The larger the machine under test, the larger should be the metal cylinder employed as an oil cup in the determination of the ambient temperature. The smallest size of oil cup employed in any case shall consist of a metal cylinder 25 mm. in diameter and 50 mm. high (1 in. in diameter and 2 in. h.).

### Machine Temperatures

**1310. Temperature Rise for Any Ambient Temperature.**— A machine may be tested at any convenient ambient temperature, preferably not below 10° C., but whatever be the value of this ambient temperature, the permissible rises of temperature must not exceed those given in Table 200.

**1311. Correction for the Deviation of the Ambient Temperature of the Cooling Medium, at the Time of the Heat Test, from the Standard Ambient Temperature of Reference.**— Numerous experiments have shown that deviation of the temperature of the cooling medium from that of the standard of reference, at the time of the heat run, has a negligible effect upon the temperature rise of machines; therefore, no correction shall be applied for this deviation.

**1312. Duration of Temperature Test of Machine for Continuous Service.**— A temperature test shall be continued until sufficient evidence is available to show that the maximum temperature and temperature rise would not exceed the requirements of the rules, should the test be prolonged until the attainment of a steady final temperature.

**1313. Duration of Temperature Test of Machine with a Short-Time Rating.**— The duration of the temperature test of a machine with a short-time rating shall be the time required by the rating. In every case the equivalent short-time test shall commence only when the windings and other parts of the machine are within 5° C. of the ambient temperature at the time of starting the test. § 2225.

**1314. Duration of Temperature Test for Machine Having More than One Rating.**— The duration of the temperature test for a machine with more than one rating shall be the time required by that rating which produces the greatest temperature rise. In cases where this cannot be determined beforehand, the machine shall be tested separately under each rating.

**1315. Temperature Measurements During Heat Run.**— When possible, temperature measurements shall be taken during operation, as well as when the machine is stopped. The highest figures thus obtained shall be adopted. In order to abridge the long heating period, in the case of large machines, reasonable overloads of current during the preliminary period are suggested for machines.

**1316. Rules for Correcting to Time of Shut-Down.**— (a) Whenever a sufficient time has elapsed between the instant of shut-down and the time of the ambient temperature measurement to permit the temperature to fall, suitable corrections shall be applied, so as to obtain as nearly as practicable the temperature at the instant of shut-down. This can sometimes be approximately effected by plotting a curve with temperature readings as ordinates and time as abscissas, and extrapolating back to the instant of shut-down. In other instances, accepted correction factors can be applied; e.g., in the case of machines meas-

factured in large quantities, the correction obtained from tests made on representative machines may be used.

(b) Exception. In cases where successive measurements show increasing temperatures after shut-down, the highest value shall be taken.

#### Details of Testing Methods

**2290. Covering of Thermometer.**—Thermometers used for taking temperatures of machinery shall be covered by felt pads 4 cm. X 5 cm. (1½ in. X 2 in.) 3 mm. (¼ in.) thick cemented on; oil putty may be used for stationary and small apparatus.

**2291.\* Temperature Coefficient of Copper.**—The temperature coefficient of copper shall be deduced from the formula  $1/(234.5+\theta)$ . Thus, at an initial temperature  $\theta=40^{\circ}$  C., the temperature coefficient of increase in resistance per degree centigrade rise is  $1/(274.5=0.00364)$ . The following table, deduced from the formula, is given for convenience of reference.

TABLE 201  
Temperature Coefficients of Copper Resistance

Temperature of the winding, in degrees C. at which the initial resistance is measured	Increase in resistance of copper per °C., per ohm of initial resistance
0	0.00427
5	0.00418
10	0.00409
15	0.00401
20	0.00393
25	0.00385
30	0.00378
35	0.00371
40	0.00364

**2292. Temperature Measurement of Low Resistance Circuit.**—In circuits of low resistance, where joints and connections form a considerable part of the total resistance, the measurement of temperature by the resistance method shall not be used. (Except transformers, for which see § 6320.)

**2293.\* Location of Embedded Temperature Detectors.**—Embedded temperature detectors should be placed in at least two sets of locations. One of these should be between a coil-side and the core and one between the top and bottom coil-sides where two coil-sides per slot are used. Where only one coil-side per slot is used, one set of detectors shall be placed between coil-side and core, and one set between coil-side and wedge. A liberal number of detectors shall be employed, and all reasonable efforts, consistent with safety, shall be made to locate them at the various places where the highest temperatures are likely to occur. See § 1002.

(2291) Temperature by Resistance: The temperature by resistance may be calculated by the following formula:

Let  $R_{\theta}$  = resistance at  $\theta^{\circ}$  C.,  $R_{\theta_1}$  = resistance at  $\theta_1^{\circ}$  C. Then

$$\theta_1 = \frac{R_{\theta_1}}{R_{\theta}}(234.5 + \theta) - 234.5.$$

(2293) A coil side is one of the two active sides of the coil in a slot.

## Efficiency

**31.\* Efficiencies Recognized.**—Two efficiencies are recognized, conventional efficiency and directly measured efficiency. Unless otherwise specified, conventional efficiency is to be employed. See §§ 3514 and 3524. Input and output determinations of efficiency may be made directly, measurable output by brake, or equivalent, where applicable. Within the limits of practical application, the circulating power method, sometimes described as the Kinson or "loading-back" method, may be used.

**32.\* Normal Conditions for Efficiency Tests.**—(a) *General:* The efficiency correspond to, or be corrected to, the normal conditions herein set forth, shall be regarded as standard. These conditions include voltage, current, power-factor, frequency, wave-shape, speed, temperature, or such of them as apply in each particular case.

) *Load:* When the efficiency of a machine is stated without specific reference to the load conditions, rated load is always to be understood whether the efficiency be the conventional or directly measured efficiency.

) *Wave Shape:* The sine wave shall be standard, unless a different wave shape is inherent in the operation of the system. See § 2350.

d) *Temperature of Reference:* The efficiency of all apparatus at all loads shall be corrected to a reference temperature of 75° C., but tests may be made at any convenient ambient temperature, preferably not less than 15° C.

) *Power Factor:* The efficiency of alternators and transformers shall be stated at the rated power factor.

**33. Direct Measurement of Efficiency.**—(a) *General:* Electric power shall be measured at the terminals of the apparatus.

) *Polyphase Machines:* In polyphase machines, sufficient measurements shall be made on all phases to avoid errors of unbalance.

) *Mechanical Power:* Mechanical power delivered by machines shall be measured at the pulley, gearing or coupling, on the rotor shaft, thus excluding loss of power in the belt or gear friction. See, however, an exception in 02.

## Wave Shape

**34. Standard Wave Shape.**—The Sine Wave shall be considered as standard, except where departure therefrom is inherent in the operation of the system in which the electrical machine forms a part.

## Tests of Dielectric Strength

**350. Condition of Machine to be Tested.**—Commercial tests shall, in general, be made with the completely assembled machine and not with individual parts. The machine shall be in good condition, and high-voltage tests, unless otherwise specified, shall be applied before the machine is put into commercial service, and shall not be applied when the insulation resistance is low due to dirt or moisture. High-voltage tests to determine whether specifications fulfilled are admissible on new machines only.

**361. Where High-Voltage Tests are to be Made.**—Unless otherwise agreed upon, high-voltage tests of machines shall be made at the factory.

**362. Temperature at which High-voltage Tests are to be Made.**—High-voltage tests shall be made at the temperature assumed under normal operation or at the temperature attained under the conditions of commercial testing.

2331) The need for assigning conventional values to certain losses arises from the fact that some of the losses in electrical machinery are practically indeterminable, and that, in many cases, either be approximated by an approved method of test, or else values recommended by the Institute and designated "conventional" values shall be employed in arriving at the "conventional efficiency."

2332 d) In calculating plant or system efficiency it may be desirable to calculate the losses in each individual machine or part of the system at the actual temperature of that machine or part during the specified interval. These losses may be appreciably different from the losses at 75° C., which latter shall be the standard temperature of reference for all efficiency guarantees.

**2352. Points of Application of Voltage.** — (a) *General:* The test voltage shall be successively applied between each electric circuit and all other electric circuits and metal parts grounded.

(b) *Interconnected Polyphase Windings:* Interconnected polyphase windings shall be considered as one circuit. All windings except that under test shall be connected to ground.

**2353. Frequency and Wave Shape of Test Voltage.** — The frequency of testing voltage shall be not less than the rated frequency of the machine tested. A sine wave shape is recommended (see §§2340 and 4351). The test shall be made with alternating voltage having a crest value equal to  $\sqrt{2}$  times the specified test voltage.

**2354. Duration of Application of Test Voltage.** — (a) *General:* The test voltage for machines shall be applied continuously for a period of 60 seconds, with exception § 4355 (b).

(b) *Standard Machines and Devices produced in large quantities:* Standard machines and devices produced in large quantities for which the standard test pressure is 2500 volts or less, may be tested for one second with a test pressure 50 per cent higher than the one-minute test pressure.

**2355.\* Standard Test Voltage.** — (a) *General:* The standard test voltage for all machines, except as otherwise specified, shall be twice the normal voltage of the circuit to which the machine is connected plus 1000 volts. See exceptions §§ 2357, 4361, 6361, 7323 (b).

**2357. Assembled Apparatus.** — Where a number of pieces of apparatus are assembled together and tested as an electrical unit they shall be tested with a per cent lower voltage than the lowest required on any of the individual pieces of apparatus.

**2358. Measurement of Voltage in Dielectric Strength Tests.** — There are two methods of measuring the voltage used in making dielectric strength tests, namely:

1. The voltmeter method.

a. The spark-gap method, using either the sphere spark-gap or the conical spark-gap.

**2359.\* Use of Voltmeters and Spark-gaps in Dielectric Tests.** — When making high-voltage tests on electrical machinery every precaution must be taken against the occurrence of spark-gap discharges in the circuits from which the machine is being tested. A non-inductive resistance of about one ohm per volt of test pressure shall be inserted in series with one terminal of the spark-gap. If the test is made with one electrode grounded, this resistance shall be inserted directly in series with the non-grounded electrode; if neither terminal is grounded one-half shall be inserted directly in series with each electrode. In either case this resistance shall be as near the measuring gap as possible and not in series with the tested apparatus. A water tube is the most suitable form of resistor.

**2360. Use of Spark-gap with Machines of Low Capacitance.** — When the machine under test does not require sufficient charging current to distort the high-voltage wave shape, or change the ratio of transformation, the spark-gap should be set for the required test voltage and the testing apparatus adjusted to give a voltage at which this spark-gap just breaks down. This adjustment should be made with the machine under test disconnected. The machine should then be connected, and with the spark-gap about 20 per cent longer, the testing apparatus again adjusted to give the voltage of the former breakdown.

(2360) All dielectric strength tests shall be based on the normal voltage of the system, even if apparatus is applied on a part of the system which ordinarily operates somewhat below the normal voltage.

(2359) The resistance will damp high-frequency oscillations at the time of breakdown and limit the resulting current.

Carbon resistors should not be used because their resistance may become very low at high voltages.

is the assumed voltage of test. This voltage shall be maintained for the led interval.

11.° Use of Spark-gap with Machines of High Capacitance.— When the ping current of the machine under test may appreciably distort the voltage or change the effective ratio of the testing transformer, the first adjustment stage with the gap set for the test voltage shall be made with the machine r test connected to the circuit and in parallel with the spark-gap.

12. Measurements with Voltmeter.— In measuring the voltage with a meter, the instrument should preferably derive its voltage from the high-voltage circuit, either directly, or by means of a voltmeter coil placed in the ag transformer, or through an auxiliary ratio transformer. It is permissible measure the voltage at other places such as the transformer primary, provided corrections can be made for the variations in ratio caused by the charging nt of the machine under test, or provided there is no material variation in ratio. In any case when the capacitance of the machine to be tested is such cause wave distortion, the testing voltage must be checked by a spark-gap t forth in §§ 2364 and 2365 or by a crest-voltage meter. If the crest-voltage r is calibrated in crest volts, its readings must be reduced to the correspond- .m.s. sinusoidal value by dividing by  $\sqrt{2}$ .

13. Measurements with Spark-gaps.— (a) General: If proper precautions taken, spark-gaps may be used to advantage in checking the calibration of meters for high-voltage tests of machines.

(b) Range of Voltages: For the calibrating purposes set forth above, the re gap shall be used for voltages above 50 kv., and is preferred down to 30 kv. needle spark-gap may, however, be used for voltages from 10 to 50 kv.

14. Needle Spark-gap.— The needle spark-gap shall be between sewing needles, supported axially at the ends of linear conductors, which are at twice the length of the gap. There must be a clear space around the gap radius at least twice the gap length.

15. Needle-gap Sparking Distances.— The sparking distances in air between No. 60 double long sewing needle points for various root-mean-square tidal voltages shall be assumed to be as shown in Table 202.

TABLE 202

Needle-Gap Spark-Over Voltages  
(At 25° C. and 760 mm. barometer)

M. S. Klovetts	Millimeters	R. M. S. Klovetts	Millimeters
10	11.9	35	51
15	15.4	40	59
20	25.4	45	75
25	33	50	90
30	41		

he values in Table 202 refer to a relative humidity of 60 per cent. Variations in this humidity may involve appreciable variations in the sparking distance.

261) When making arc-over tests of large insulators, leads, etc., partial arc-over of tested apparatus may produce oscillations which will cause the measuring gap to discharge prematurely. The measured voltage will then appear too high. In such tests the equivalent ratio of the testing transformer should be measured by gap to within 20 per cent of the arc-over voltage of the tested apparatus with the tested apparatus in circuit. The measuring gap should then be greatly lengthened out and the voltage increased until the apparatus arcs over. This arc-over voltage should then be determined by multiplying the voltmeter reading by the equivalent ratio found above. Direct measurement of spark-over voltage over one gap by another gap should always be avoided.

**2366.\* Sphere Spark-gap.** — The standard sphere spark-gap shall be between two suitably mounted spheres. No extraneous body, or external part of circuit, shall be nearer the spheres than twice their diameter.

The shanks shall be not greater in diameter than  $\frac{1}{16}$ th the sphere diameter. Metal collars, etc., through which the shanks extend, shall be as small as practicable and shall not, during any measurement, come closer to the spheres than the maximum gap length used in the measurement.

The sphere diameter should not vary more than 0.1 per cent, and the curvature, measured by a spherometer, should not vary more than 1 per cent from that of a true sphere of the required diameter.

**2367.\* Use of Spherometer.** — In using the spherometer to measure curvature, the distance between the points of contact of the spherometer feet shall be within the limits as indicated in Table 203.

TABLE 203

Spherometer Specifications

Diameter of sphere in mm.	Distance between contact points in mm.	
	Maximum	Minimum
62.5	35	25
125	45	35
250	65	45
500	100	65

**2368. Sphere-gap Sparking Distances.** — The sparking distance between spheres for various r.m.s. sinusoidal voltages shall be assumed to be as shown in Table 204.

**2369.\* Correction of Gap Spacing for Air-density.** — The spacing at which it is necessary to set a gap to spark over at some required voltage, is found as follows. Divide the required voltage by the correction factor given in Table 204 and use the new voltage thus obtained, to find the corresponding spacing from Table 204, using a graph of the latter, if more convenient.

**2370.\* Correction of Voltage for Air-density.** — The voltage at which a gap sparks over is derived from the voltage corresponding to the spacing in Table 204 by multiplying by the correction factor.

f (2366) When used as specified, the accuracy obtainable should be approximately 2 per cent.

(2367) In using sphere-gaps constructed as indicated in § 2366 and § 2367, it is assumed that the apparatus will be set up for use in a space comparatively free from external dielectric fields. Care should be taken that conducting bodies forming part of the circuit, or of circuit potential, are not so located with reference to the gap that their dielectric fields are superposed on the gap, e.g., the protecting resistance should not be arranged so as to present large masses or surfaces near the gap, even at a distance of two sphere diameters.

In case the sphere is grounded, the spark point of the grounded sphere should be approximately five diameters above the floor or ground.

(2369 and 2370) Effect of Air-density on Spark-over Voltage. The spark-over voltage, for a given gap, decreases with decreasing barometric pressure and increasing temperature. This variation may be considerable at high altitudes. When the variation from sea level is not great, the relative air density may be used as the correction factor; when the variation is great, or greater accuracy is desired, the correction factor corresponding to the relative air density should be taken from Table 204 in which

$$\text{Relative air-density} = \frac{0.302\delta}{273+t}$$

$\delta$  = barometric pressure in mm.

$t$  = temperature in deg. C.

Corrected curves may be plotted for any given altitude, if desired. It will be noted in Table 210 that for values of relative air density above 0.9 the correction factor does not differ greatly from the relative air density.

A sphere-gap is more sensitive than the needle-gap to momentary rises of  $\pi$  and the voltage required to spark over the gap should be obtained by closing the gap under constant voltage, or by slowly raising the voltage to a fixed setting of the gap. Open arcs should not be permitted in proximity to the gap during its operation, as they may affect its calibration.

TABLE 205  
Air-density Correction Factors for Sphere Gaps

Relative air-density	Diameter of standard spheres in mm.			
	63.5	125	250	500

#### Insulation Resistance

**2300. General.** — The insulation resistance test shall be made with all circuits of equal voltage above ground connected together. Circuits or groups of circuits of different voltage above ground shall be tested separately.

**2301. Voltage for Insulation Resistance Test.** — Insulation resistance test shall, if possible, be made at a d-c. pressure of 500 volts. Since the insulation resistance varies with the pressure, it is necessary that, if a pressure other than 500 volts is to be employed in any case, this other pressure shall be carefully specified.

**2302.\* Minimum Values.** — The insulation resistance of a machine at its operating temperature shall be not less than that given by the following formula:

$$\text{Insulation Resistance in megohms} = \frac{\text{voltage at terminals}}{\text{rating in kv-a.} + 1000}$$

The formula applies only to dry apparatus. Such high values are not attainable in oil-immersed apparatus.

#### Regulation

**2300. Conditions for Tests of Regulation.** — (a) *Speed and Frequency:* The regulation of generators shall be determined at constant speed, and that of alternating-current machines at constant frequency.

(b) *Wave Form:* A sine wave of voltage shall be assumed in determining the regulation of alternating-current machinery receiving electric power, except where expressly specified otherwise. See § 2340.

(2382) The order of magnitude obtained by this rule is shown in the following table:

TABLE 206  
Insulation Resistance of Machines Excluding Oil-immersed Apparatus

Rated voltage of machine	Megohms		
	100 kv-a.	1000 kv-a.	10,000 kv-a.
100	0.091	0.05	
1,000	0.91	0.50	0.091
10,000	9.1	5.0	0.91
100,000	.....	50	9.1

**Temperature:** It is desirable that all parts of the machine affecting the rating be maintained at constant temperature between the two loads and the influence of temperature is of consequence, a reference temperature of C. shall be considered as standard. If change of temperature should occur during the tests the results shall be corrected to the reference temperature of C.

## CONSTRUCTION

### Rating Plates

**81. Marking of Rating Plate.**—(a) *Distinctive Marking:* It is recommended that the rating plate of machines which comply with the Institute shall carry a distinctive special sign, such as "A.I.E.E. 1922 Rating" or "Rating."

*Significance of Marking:* The absence of any statement to the contrary on the rating plate of a machine implies that it is intended for continuous service at the standard altitude and ambient temperature. See §§ 2211, 2212, and 2220.

*Marking for Various Ratings:* The rating plate of a machine intended to be used under various kinds of rating must carry the necessary information in regard to those kinds of ratings.

## CHAPTER III

### GENERAL DEFINITIONS

In this chapter are given definitions which are of general application to electric circuits, machines and systems. Definitions pertaining to a specific class of apparatus are given in the chapter on the class of apparatus in question. The definitions here given are primarily descriptive rather than scientifically precise. The definitions given below for currents are also applicable, in most cases, to electromotive forces, potential differences, magnetic fluxes, etc.

### DEFINITIONS

#### General

**80. Ambient Temperature.**—The ambient temperature is the temperature of the air or water which comes into contact with the heated parts of a machine and carries off its heat. See §§ 2300 and 2301.

**86. Electrical Tension.**—Electrical tension is electromotive force, or difference of potential.

**81. Voltage.**—Voltage is electrical tension expressed in volts.

**89. Resistivity.**—The resistivity of a material is the resistance expressed in ohms between two opposite faces of a centimeter cube of the material, and is usually coupled with a statement of the temperature. See § 9050.

#### Apparatus

**84. Resistor.**—A resistor is a device used primarily because it possesses property of electrical resistance. Resistors are used in electric circuits for purposes of operation, protection, or control. See § 7017.

**87. Inductor.**—An inductor is a device used primarily because it possesses property of inductance.

**88. Reactor.**—A reactor is a device used primarily because it possesses property of reactance. Reactors are used in electric circuits for purposes of operation, protection or control. See § 7018.

#### Kinds of Currents

**104. Direct Current.**—A direct current is a unidirectional current. As ordinarily used, the term designates a practically non-pulsating current.

**106. Pulsating Current.**—A pulsating current is a current which has regularly recurring variations in magnitude. As ordinarily employed the term applies to a unidirectional current.

**112. Continuous Current.**—A continuous current is a practically non-

**3118. Alternating Current.** — An alternating current is a current the direction of which reverses at regularly recurring intervals. Unless distinctly otherwise specified, the term *alternating current* refers to a periodically varying current with successive half waves of the same shape and area. See § 3212.

**3120. Oscillating, or Free Alternating Current.** — An oscillating, or free alternating current is the current following any electro-magnetic disturbance in a circuit having capacity, inductance, and less than the critical resistance. When the critical resistance of a circuit is reached the current becomes aperiodic.

### Alternating Currents

**3204. Cycle.** — A cycle is one complete set of positive and negative values of an alternating current.

**3206. Period.** — The period of an alternating current is the time required for the current to pass through one cycle.

**3208. Frequency.** — The frequency of an alternating current is the number of cycles through which it passes per second, that is, the reciprocal of the period.

**3212. Wave Shape.** — The wave shape, or wave form, of an alternating current is the shape of the curve obtained when the instantaneous values of the current are plotted against time in rectangular coordinates.

Two alternating quantities are said to have the same wave shape when the ordinates of corresponding phase bear a constant ratio to each other. The wave shape, as thus understood, is therefore independent of the frequency of the current and of the scale to which the curve is plotted.

**3214. Sine Wave, or Simple Alternating Current.** — A sine wave, or simple alternating current, is a current whose wave shape is sinusoidal.

**3218.\* Root-Mean-Square or Effective Value.** — The root-mean-square or effective value of an alternating current is the square root of the mean of the squares of the instantaneous values for one complete cycle. It is usually abbreviated *r.m.s.* Unless otherwise specified, the numerical value of an alternating current refers to its *r.m.s.* value. The word "virtual" is sometimes used in place of *r.m.s.*, particularly in Great Britain.

**3222. Phase.** — Phase is the fraction of the period of an alternating current which has elapsed since the current passed through the zero position of reference.

This fraction is usually expressed in angular measure, and the period corresponding to one complete cycle is taken as representing  $2\pi$  radians or 360 degrees. The angles are frequently called electric angles, and the degree electric degrees.

In the usual equation  $i = I_m \sin(\omega t + \phi)$

the quantity  $(\omega t + \phi)$  is the phase and  $\phi$  is the phase angle of the current.

**3224.\* Phase Difference; Lead and Lag.** — The phase difference of two alternating quantities of the same frequency is the difference between their phases at any instant. That quantity whose maximum occurs first in time is said to lead the other, and the latter is said to lag behind the former.

Fig. 3-1.

**3226. Vector Representation and Angular Velocity.** — A sine-wave current or voltage may be represented by a vector of constant length rotating counter-clockwise at a constant angular velocity ( $\omega = 2\pi f$ ); this angular velocity is frequently termed the angular velocity of the current or voltage.

**3230.\* Counter-clockwise Convention.** — It is recommended that in any vector diagram, the leading vector be drawn counter-clockwise with respect to the lagging vector, as in Fig. 3-1 where  $O I$  is

(3218) The *r.m.s.* value of a sine wave (see Section 3214) is equal to its maximum or crest value, divided by  $\sqrt{2}$ .

(3224) When the two alternating quantities do not have the same wave form, the phase difference as here defined may not be identical with equivalent phase difference as defined in Section 3262.

(3230) See Publication 13 of the International Electrotechnical Commission, *Standards of Terms and Definitions*.

sents the vector of a current in a simple alternating-current circuit lagging behind the vector  $OE$  of impressed electromotive force.

**3234. Power.** — Power is the rate of transfer of energy. In the case of an alternating-current circuit the word power is generally used to denote the average value of the power over a cycle. The power in an electric circuit at any instant is equal to the product of the values of the current and voltage at that instant, and is generally called the instantaneous power.

**3235. Apparent Power or Volt-amperes.** — The apparent power, or volt-amperes, in an alternating-current circuit is the product of the r.m.s. value of the voltage across the circuit by the r.m.s. value of the current in the circuit. Apparent power is also expressed in kilovolt-amperes, abbreviated kv-a.

**3241.\* Power Factor.** — Power factor is the ratio of the power to the apparent power.

**3242. Power Factor in Polyphase Circuits.** — The power factor of a polyphase circuit, either balanced or unbalanced, is the ratio of the total active power in watts to the total vector volt-amperes.

The total vector volt-amperes is the square root of the sum of the squares of the total active power and the total reactive power.

The total reactive power is the algebraic sum of the reactive powers corresponding to the separate harmonic components of the system.

**3244. Momentary and Average Power Factors.** — Power factors are either momentary power factors or integrated "average power factors"; i.e., extended over a specific time interval by averaging the active and reactive powers over the interval. Thus, a power factor may be an integrated average five-minute power factor, or an integrated average hour power factor, or an integrated average monthly power factor, etc.

The difference between a polyphase power factor (momentary) and a polyphase power factor (integrated average) lies only in the period of time over which the active and reactive powers are taken.

**3245.\* Reactive Volt-amperes.** — The reactive volt-amperes in a circuit is the square root of the difference between the square of the apparent power and the square of the power.

**3250.\* Reactive Factor.** — The reactive factor is the ratio of the reactive volt-amperes to the total volt-amperes.

**3254.\* Active Component.** — The active component of the current in a circuit is the average power divided by the voltage.

**3256.\* Reactive Component.** — The reactive component of the current in a circuit is the square root of the difference between the square of the current and the square of the active component of the current.

**3260. Equivalent Sine Wave.** — An equivalent sine wave is a sine wave which has the same frequency and the same r.m.s. value as the actual wave.

**3262. Equivalent Phase Difference.** — The equivalent phase difference (applicable to non-sinusoidal currents and voltages) is the phase difference between the equivalent sine waves of current and voltage when so related as to have the same power factor as the non-sinusoidal quantities.

There are cases, however, where this equivalent phase difference is misleading.

(3242) The power factor when both the current and voltage are sinusoidal is equal to the cosine of the angle which expresses their difference in phase (see Section 3224).

(3246) The reactive volt-amperes, when both current and voltage are sinusoidal, is equal to the volt-amperes times the sine of the angle which expresses the phase difference between current and voltage.

(3250) The reactive factor, when both current and voltage are sinusoidal, is equal to the sine of the angle which expresses their phase difference.

(3254) The active, or in-phase component of the current in a circuit corresponds to average power passing in a given direction through the circuit. With sine-wave voltage and current, the active component of the current is in phase with the voltage.

(3256) The reactive, or quadrature, component of the current in a circuit corresponds to power alternating in direction in the circuit so that the average value of the power transferred in a given direction through a cycle is zero. With sine-wave current and voltage the reactive component of the current is in quadrature with the voltage.

since the presence of harmonics in the voltage wave, current wave, or in both may reduce the power factor without producing a corresponding displacement of the two wave forms with respect to each other; e.g., the case of an a-c. In such cases, the components of the equivalent sine waves, the equivalent reactive factor and the equivalent reactive volt-amperes may have no physical significance.

**2266.\* Crest Factor or Peak Factor.** — The crest factor or peak factor of a wave is the ratio of the crest, or maximum, value to the r.m.s. value.

**2270.\* Form Factor of a Wave.** — The form factor of a wave is the ratio of the r.m.s. to the algebraic mean ordinate taken over a half-cycle beginning with the zero value. If the wave passes through zero more than twice during a single cycle, that zero shall be taken which gives the largest algebraic mean for the succeeding half-cycle.

**2274. Deviation Factor of a Wave.** — The deviation factor of a wave is the ratio of the maximum difference between corresponding ordinates of the wave and of the equivalent sine wave to the maximum ordinate of the equivalent sine wave when the waves are superposed in such a way as to make the maximum difference as small as possible.

**2278. Telephone Interference Factor of a Wave.** (See § 4353.) — The telephone interference factor is the ratio of the square root of the sum of the squares of the weighted values of all the sine-wave components (including all alternating waves both fundamental and harmonics) to the r.m.s. value of the wave.

#### Circuits and Phases

**2284. Electric Circuit.** — An electric circuit is a path in which an electric current may flow. Strictly speaking, an electric circuit is a complete circuitous path, but the term circuit is commonly employed to designate a specific part of a complete path. When part of a complete path is referred to, such as a branch circuit, a derived circuit, or a conductor, both the terminals and the conductors which form that path should be specified in order to avoid ambiguity; e.g., circuit *a-b-c*. When the whole circuit is referred to, it may be designated as complete or closed circuit.

**2284.\* Single-phase Circuit.** — A single-phase circuit is a circuit energized by a single alternating electromotive force.

**2286.\* Three-phase Circuit.** — A three-phase circuit is a combination of circuits energized by alternating electromotive forces which differ in phase by one-third of a cycle; i.e., 120 degrees.

**2288.\* Quarter-phase or Two-phase Circuit.** — A quarter-phase or two-phase circuit is a combination of circuits energized by alternating electromotive forces which differ in phase by a quarter of a cycle; i.e., 90 degrees.

**2290.\* Six-phase Circuit.** — A six-phase circuit is a combination of circuits energized by alternating electromotive forces which differ in phase by one-sixth of a cycle, i.e., 60 degrees.

**2292. Polyphase Circuit.** — A polyphase circuit is a circuit of more than a single phase. This term is ordinarily applied to symmetrical systems.

**2294. Symmetrical Voltages and Currents.** — Polyphase voltages or currents are symmetrical when the voltages or currents have the same wave shape and r.m.s. value and differ in phase each from the next by the same angle.

**2296. Symmetrical Polyphase System.** — A symmetrical polyphase system is a polyphase system in which the voltages are symmetrical.

(3266) The crest factor of a sine wave is  $\sqrt{2}$ .

(3270) The form factor of a sine wave is  $\frac{\pi}{2\sqrt{2}}$  or 1.11.

(3284) A single-phase circuit is usually supplied through two wires. The currents in these two wires, counted outwards from the source, differ in phase by 180 degrees at half cycle.

(3286) In practice the phases may vary several degrees from the specified angle.

(3288) In practice the phases may vary several degrees from the specified angle.

(3290) In practice the phases may vary several degrees from the specified angle.

**362.\* Balanced Polyphase System.**—A balanced polyphase system is a polyphase system in which both the currents and voltages are symmetrical.

#### Loads

**364. Reactive Load.**—A reactive load is a load in which the current lags and or leads the voltage across the load.

**365. Non-reactive Load.**—A non-reactive load is a load in which the current is in phase with the voltage across the load. (The term non-inductive load sometimes used for non-reactive load.)

**366. Inductive Load.**—An inductive load is a reactive load in which the current lags behind the voltage across the load.

**367. Capacitive Load.**—A capacitive load is a reactive load in which the current leads the voltage across the load.

**368.\* Balanced Polyphase Load.**—A balanced polyphase load is a load to which symmetrical currents are supplied when it is connected to a system having symmetrical voltages.

**369. Connected Load.**—The connected load on any system, or part of a system, is the combined continuous rating of all the receiving apparatus on consumers' premises which is connected to the system, or part of the system under consideration.

**370. Peak Power.**—The peak power is the average power during a time interval of specified duration occurring within a given period of time, that interval being selected during which the average power is greatest.

**371. Load Factor.**—The load factor is the ratio of the average power to the peak power.

In each case, the interval of maximum load and the period over which the average is taken should be definitely specified, such as a "half-hour monthly" load factor. The proper interval and period are usually dependent upon local conditions and upon the purpose for which the load factor is to be used.

**372. Plant Factor.**—The plant factor is the ratio of the average load to the capacity of the power plant; *i.e.*, to the aggregate ratings of the generators.

**373. Demand of an Installation or System.**—The demand of an installation or system is the load which is drawn from the source of supply at the receiving terminals averaged over a suitable and specified interval of time. Demand is expressed in kilowatts, kilovolt-amperes, amperes, or other suitable units.

**374. Maximum Demand.**—The maximum demand of an installation or system is the greatest of all the demands which have occurred during a given period. It is determined by measurement, according to specifications, over a specified time interval.

**375. Demand Factor.**—The demand factor of any system or part of a system, is the ratio of the maximum demand of the system, or part of a system, to the total connected load of the system, or of the part of the system under consideration.

**376. Diversity Factor.**—The diversity factor of any system, or part of a system, is the ratio of the sum of the maximum power demands of the subdivisions of the system, or part of a system, to the maximum demand of the system, or part of the system under consideration, measured at the point of supply.

(372) The term balanced polyphase system is applied also to a quarter-phase (or two-phase) system in which the voltages have the same wave form and r.m.s. value and in which the currents have the same wave form and r.m.s. value and differ in phase by ninety degrees.

(374) The term balanced polyphase load is applied also to a load to which are supplied currents having the same wave form and r.m.s. value and differing in phase by ninety degrees when it is connected to a quarter-phase (or two-phase) system having voltages of the same wave form and r.m.s. value.

## Machinery and Apparatus

**3504. Capacity (or Properly, Capability).** — The word "capacity" is frequently used in the general sense of "capability." It is also used in an exact sense to denote the load which, when carried by a machine, apparatus or device will, under specified conditions of test, cause it to reach any one of its *physical limitations*, such for example, as operating temperature or ability to maintain required voltage.

Capacity should be distinguished from rating. On account of the different senses in which it has been employed (see § 3508), capacity is less used than formerly was, rating being more useful commercially.

**3508.\* Rating.** — A rating of a machine, apparatus or device is an arbitrary designation of an operating limit. —

(The rating of a machine is the output marked on the rating plate, and is to be based on, but shall not exceed the maximum load which can be taken by the machine under prescribed conditions of test. This is also called the maximum output. *Maximum possible rating obviously corresponds with capability defined in § 3504.*)

**3514. Efficiency.** — The efficiency of an electric machine or apparatus is the ratio of its useful output to its total input. Unless otherwise specified the useful output and input shall mean the power output and the power input respectively.

**3524.\* Conventional Efficiency.** — The conventional efficiency of an electric machine or apparatus is the ratio of the output to the sum of the output and losses, or of the input minus the losses to the input, when, in either case, conventional values are assigned to one or more of these losses.

**3534. Plant, or System, Efficiency.** — Plant, or system, efficiency is the ratio of the energy delivered from the plant or system to the energy received by a specified period of time. In calculating plant, or system, efficiency it is desirable to calculate the losses in each individual machine, or part of the system, at the actual temperature of that machine, or part, during the specified period. These losses may be appreciably different from the losses at 75° C., which shall be the standard temperature of reference for all efficiency measurements. This definition is not applicable to storage batteries. See § 2332.

**3538. Regulation.** — The regulation of a machine in regard to some characteristic quantity (such as terminal voltage or speed) is the change in that quantity occurring between any two loads. Unless otherwise specified, the two loads considered shall be zero load and rated load, and at the temperature attained under normal operation. The regulation may be expressed by the numerical values of the quantity at the two loads, or it may be expressed as the "percentage regulation," which is the percentage ratio of the change in the quantity occurring between the two loads, to the value of the quantity at either one or the other load, taken as the normal value. The normal value may be either the no-load value, as the no-load speed of induction motors; or it may be the rated-load value, as in the voltage of a-c. generators.

It is assumed that all parts of the machine affecting the regulation maintain a constant temperature between the two loads, and where the influence of temperature is of consequence a reference temperature of 75° C. shall be considered as standard.

## Systems

**3560. Normal Voltage.** — In systems employing transformers, the normal voltage of the system or circuit is defined as the highest rated voltage of the secondaries of transformers supplying the system or circuit. This voltage applies to all parts of that particular system or circuit.

(3508) The term maximum load does not refer to loads applied solely for machine commutation, or similar tests.

(3524) The need for assigning conventional values to certain losses arises from the fact that some of the losses in electric machinery are practically indeterminate, and, in many cases, either be approximated by an approved method of test, or else are recommended by the Institute and designated "conventional" values shall be assigned for them in arriving at the "conventional efficiency."

TABLE 201  
SYMBOLS AND ABBREVIATIONS

Name of quantity	Symbol for the quantity	Unit	Abbreviation for the unit
acceleration due to gravity . . .	$g$	centimeter per second per second	cm. per sec. per sec.
capacitance . . . . .	$Y, y$	mho	.....
angular velocity . . . . .	$\omega$	radian per second	.....
capacitance (Electrostatic capacity) . . . . .	$C$	farad	.....
conductance . . . . .	$g$	mho	.....
conductivity . . . . .	$\gamma$	*mho per centimeter	mho per cm
current . . . . .	$I, i$	ampere	.....
electric constant . . . . .	$K$	.....	.....
efficiency . . . . .	$\eta$	per cent	.....
electrical tension . . . . .	$E, e$ or $V, v$	volt	.....
electromotive force, abbreviated e.m.f. . . . .	$E, e$	volt	.....
electrostatic field intensity . . . . .	$F$	.....	.....
electrostatic flux . . . . .	$\Psi$	.....	.....
electrostatic flux density . . . . .	$D$	.....	.....
energy, in general . . . . .	$U$ or $W$	joule, watt-hour	.....
frequency . . . . .	$f$	cycle per second	~
impedance . . . . .	$Z, z$	ohm	.....
inductance (or coefficient of self-induction) . . . . .	$L$	henry	.....
intensity of magnetization . . . . .	$J$	.....	.....
length . . . . .	$l$	centimeter	cm.
magnetic field intensity . . . . .	$H, \mathcal{H}$	gilbert per centimeter	gilbert per cm.
magnetic flux . . . . .	$\Phi, \phi$	maxwell	.....
magnetic flux density . . . . .	$B, \mathcal{B}$	gauss	.....
magnetic reluctance . . . . .	$\mathcal{R}$	oersted	.....
magnetomotive force, abbreviated m.m.f. . . . .	$\mathcal{F}$	gilbert*	.....
mass . . . . .	$m$	gram	g
mutual inductance (or coefficient of mutual induction) . . . . .	$M$	henry	.....
number of conductors or turns . . . . .	$N$	convolution or turn of wire	.....
permeability . . . . .	$\mu = B/H$	.....	.....
phase displacement . . . . .	$\theta, \phi$	degree or radian	°
potential difference, abbreviated p. d. . . . .	$V, v$ or $E, e$	volt	.....
power . . . . .	$P, p$	watt	.....
quantity of electricity . . . . .	$Q, q$	coulomb, ampere-hour	.....
reactance . . . . .	$X, x$	ohm	.....
resistance . . . . .	$R, r$	ohm	.....

864) An additional unit for magnetomotive force is the "ampere-turn," for the "line," for magnetic flux-density "maxwells per sq. in." The numerical values of resistivity and conductivity are *ohms resistance* and *mhos conductivity* between two opposite faces of a cm. cube of the material in question, but the correct names are as given, not ohms and mhos per cm., cube, as commonly stated. The value 980.665 for  $g_0$  has been the accepted standard value for many years and was formerly considered to correspond accurately to 45° latitude and sea-level. Latest measurements, however, have shown that the most reliable value for 45° and sea-level is slightly different; but this does not affect the standard value given above.

TABLE 301—Continued

Name of quantity	Symbol for the quantity	Unit	Abbreviation for the unit
Resistivity.....	$\rho$	*ohm-centimeter	ohm-cm.
Standard acceleration due to gravity (at about 45 deg. latitude and sea level) equals 980.665*.....	$g_0$	{ centimeter per second per second	{ cm. per sec. per sec.
Susceptance.....	$b$	mho	.....
Susceptibility.....	$\kappa = J/H$	.....	.....
Temperature.....	$\theta$	degree centigrade	°C.
Time.....	$t$	second	sec.
Velocity of rotation.....	$n$	revolution per second	rev. per sec.
Voltage.....	$E, e$ or $V, v$	volt	.....

**3608. Symbols for Maximum, Instantaneous and R.M.S. Values.**— $I_m$  and  $P_m$  should be used for maximum cyclic values,  $e$ ,  $i$  and  $p$  for instantaneous values,  $E$  and  $I$  for r.m.s. values (see §3218) and  $P$  for the average value of power, or the active power. These distinctions are not necessary in dealing with direct-current circuits. In print, vector quantities should be represented by bold-face capitals.

## CHAPTER IV

## STANDARDS FOR ROTATING MACHINES (OTHER THAN RAILWAY MOTORS, RAILWAY SUBSTATION MACHINES CARRYING TRACTION LOADS, AND AUTOMOBILE PULSION MACHINES)

The A. I. E. E. Standards for Rotating Machines are the General Standards shown in Chapters II and III and the Standards in other chapters which are applicable to the devices involved, together with the modifications and additions given in this chapter.

## DEFINITIONS

## General

Certain rules applying exclusively to railway machinery have, for convenience, been placed in Chapter V, with cross-references in all cases in this chapter. The rules of Chapter IV apply to railway machinery except as they are modified by the rules of Chapter V.

**4000. Classification of Electric Rotating Machinery.**—Rotating electric machinery may be classified in various ways, these classifications overlapping or interlocking in considerable degree. *First*, Rotating electric machinery may be classified as Direct-Current and Alternating-Current; *Second*, according to the function of the machines; e.g., Motors, Generators, Boosters, Motor-Generators, Dynamotors, Double-Current Generators, Converters and Phase Advancers; *Third*, according to construction or principle of operation; e.g., Commutating, Synchronous, Induction, Unipolar, Rectifying. Obviously, some of these machines could be rationally included in either classification. Motor-Generators and Rectifying Machines.

In the following, self-evident definitions have for the most part been omitted.

## Functional Classification of Rotating Electric Machines

**4001. Generator.**—A generator is a machine which transforms mechanical power into electric power.

**4002. Motor.**—A motor is a machine which transforms electric power into mechanical power.

**803. Booster.**— A booster is a generator inserted in series in a circuit to raise its voltage. A booster may be driven by an electric motor (in which case it is termed a motor-booster) or otherwise.

**804. Motor-generator Set.**— A motor-generator set is a transforming set consisting of one or more motors mechanically coupled to one or more generators.

**805. Dynamotor.**— A dynamotor is a transforming device combining both motor and generator action in one magnetic field, either with two armatures, or with one armature having two separate windings and independent commutators.

**806. Direct-current Compensator or Balancer.**— A direct-current compensator or balancer is a machine which comprises two or more similar direct-current machines (usually with shunt or compound excitation) directly coupled to each other and connected in series across the outer conductors of a multiple-system of distribution, for the purpose of maintaining the potentials of the intermediate wires of the system, which are connected to the junction points between the machines.

**807. Double-current Generator.**— A double-current generator is a machine which supplies both direct and alternating currents from the same armature-winding.

**808. Converter.**— A converter is a machine which employs mechanical action in changing electric energy from one form into another. There are several types of converters, as defined in §§ 4009 to 4013 below.

**809. Direct-current Converter.**— A direct-current converter is a machine which converts from a direct current to a direct current, usually with a change of rate. Such a machine may be either a motor-generator set or a dynamotor.

**810. Synchronous Converter.**— A synchronous converter (sometimes called a rotary converter) is a machine which converts from an alternating to a direct current, or vice-versa. It is a synchronous machine with a single closed-circuit stator winding, a commutator and slip rings.

**811. Cascade Converter.**— A cascade converter (also called a motor converter) is a combination of an induction motor with a synchronous converter, secondary circuit of the former feeding directly into the armature of the latter; *i. e.*, a synchronous converter concatenated with an induction motor.

**812. Frequency Converter.**— A frequency converter is a machine which converts the power of an alternating-current system from one frequency to another, with or without a change in the number of phases, or in the voltage.

**813. Rotary Phase-converter.**— A rotary phase-converter is a machine which converts from an alternating-current system of one or more phases to an alternating-current system of a different number of phases, but of the same frequency.

**814. Phase Advancer.**— A phase advancer is a machine which supplies reactive volt-amperes to the system to which it is connected. Phase advancers may be either synchronous or asynchronous.

**815. Synchronous Condenser or Synchronous Phase Advancer.**— A synchronous condenser or synchronous phase advancer is a synchronous machine, running either idle or with load, the field excitation of which may be varied so as to modify the power factor of the system, or through such modification to influence the load voltage.

#### Constructional Classification of Rotating Electric Machines

**816. Direct-current Commutating Machines.**— A direct-current commutating machine comprises a magnetic field of constant polarity, an armature, a commutator connected therewith. Specific types of direct-current commutating machines are: Direct-Current Generators; Direct-Current Motors; Direct-Current Boosters; Direct-Current Motor-Generator Sets and Dynamos; Direct-Current Compensators or Balancers; and Arc Machines.

**817. Alternating-current Commutating Machine.**— An alternating-current commutating machine comprises a magnetic field of alternating polarity, an armature, and commutator connected therewith. See §§ 4071 to 4074.

4018. **Synchronous Commutating Machine.**—Synchronous commutating machines include synchronous converters, cascade-converters, and dual-current generators.

4019. **Synchronous Machine.**—A synchronous machine comprises a constant magnetic field and an armature receiving or delivering alternating-current in synchronism with the motion of the machine; *i.e.*, having a frequency proportional to the speed of the machine. Specific types of synchronous machines are defined in §§ 4020 to 4023 below.

4020. **Alternator.**—An alternator is a synchronous alternating-current generator, either single-phase or polyphase.

4021. **Polyphase Alternator.**—A polyphase alternator is a polyphase synchronous alternating-current generator, as distinguished from a single-phase alternator.

4022. **Inductor Alternator.**—An inductor alternator is an alternator in which both field and armature windings are stationary, and in which masses of iron inductors, by moving past the coils, alter the magnetic flux through them. It may be either single-phase or polyphase.

4023. **Synchronous Motor.**—A synchronous motor is a machine structurally identical with an alternator, but operated as a motor.

4024. **Induction Machine.**—An induction machine is a machine with primary and secondary windings rotate with respect to each other; *e.g.*, induction motors, induction generators, certain types of frequency converters, and certain types of rotary phase-converters.

4025. **Induction Motor.**—An induction motor is an alternating-current motor, either single-phase or polyphase, comprising independent primary and secondary windings, one of which, usually the secondary, is on the rotor member. The secondary winding receives power from the primary by electromagnetic induction.

4026. **Induction Generator.**—An induction generator is a machine structurally identical with an induction motor, but driven above synchronous speed as an alternating-current generator.

4027. **Engine Type Generator.**—An engine type generator is one coupled to an engine in such a way that it cannot be run independently of the engine.

4028. **Unipolar or Acyclic Machine.**—A unipolar, or acyclic machine, is a direct-current machine, in which the voltage generated in the active conductors maintains the same direction with respect to those conductors.

#### Speed Classification of Motors

4029. **Constant-speed Motor.**—A constant-speed motor is one whose speed is either constant or does not materially vary; such as a synchronous motor, an induction motor with small slip, and an ordinary direct-current shunt motor.

4030. **Multispeed Motor (or Change Speed Motor).**—A multispeed motor is a motor which can be operated at any one of several distinct speeds (these speeds being practically independent of the load), but which cannot be operated at intermediate speeds.

4031. **Adjustable-speed Motor.**—An adjustable-speed motor is one in which the speed can be varied gradually over a considerable range, but when once adjusted remains practically unaffected by the load; such as a shunt motor designed for a considerable range of speed variation.

4032. **Base Speed of an Adjustable-speed Motor.**—The base-speed of an adjustable-speed motor is that speed of the motor obtained with full field at full load with no resistor in the armature circuit.

4033. **Varying-speed Motor.**—A varying speed motor is one whose speed varies with the load, ordinarily decreasing when the load increases; such as a series motor, a compound-wound motor, and a series-shunt motor. As a class of varying-speed motors, may be cited adjustable varying-speed motors or motors in which the speed can be varied over a considerable range at a given load, but when once adjusted, varies with the load; *e.g.*, compound-wound motors arranged for adjustment of speed by varying the strength of the shunt field.

### Classification of Rotating Electric Machines Relative to their Degree of Enclosure

**1041. Open Machine.** — An open machine is of either the pedestal-bearing or bracket type where there is no restriction to ventilation, other than that resisted by good mechanical construction.

**1042. Protected Machine.** — A protected machine is one in which the armature field coils, and other live parts are protected mechanically from accidental careless contact, while free ventilation is not materially obstructed.

**1043. Enclosed Ventilated Machine.** — An enclosed ventilated (or semi-enclosed) machine is one in which the ventilating openings in the frame are fitted with wire screen, expanded metal, or other suitable perforated covers, the apertures not exceeding  $\frac{1}{2}$  square inch (3.2 sq. cm.) in area. See § 4316.

**1044. Totally Enclosed Machine.** — A totally enclosed machine is one so closed as to prevent circulation of air between the inside and the outside of the case, but not sufficiently to be termed air-tight.

**1045. Separately Ventilated Machine.** — A separately ventilated machine is one whose ventilating air supplied by an independent fan or blower external to the machine.

**1046. Self-ventilated Machine.** — A self-ventilated machine differs from a separately ventilated machine only in having its ventilating air circulated by a fan, blower, or centrifugal device integral with the machine.

If the heated air expelled from the machine is conveyed away through a pipe attached to the machine, this should be so stated.

**1047. Water-cooled Machine.** — A water-cooled machine is one which entirely depends on water circulation for the removal of its heat.

**1048. Drip-proof Machine.** — A drip-proof machine is one so protected as to exclude falling moisture or dirt. A drip-proof machine may be either open or semi-enclosed, if it is provided with suitable protection integral with the machine, or enclosed as to exclude effectively falling solid or liquid material.

**1049. Explosion-proof Machine (or Flame-proof Machine).** — An explosion-proof machine is a machine in which the enclosing case can withstand, without injury, any explosion of gas that may occur within it, and will not transmit the explosion to any inflammable gas outside it.

**1050. Machine with Explosion-proof Slip-ring Enclosure.** — A machine in which the slip rings and brushes alone are included within an explosion-proof enclosure should not be described as an explosion-proof machine, but as a machine with an explosion-proof slip-ring enclosure.

### Classification of Alternating-Current Commutator Motors

An alternating-current commutator motor may be classified under more than one of the following groups)

#### Classification by Phases of Energy Supply.

**1051. Single-phase Commutator Motor.** — A single-phase commutator motor is one that receives the whole of its energy from only one phase of an alternating-current supply system, without requiring external phase-converting apparatus.

**1052. Polyphase Commutator Motor.** — A polyphase commutator motor is one that receives its energy from a plurality of phases of an alternating-current supply system, or from a single-phase system through phase-converting apparatus external to the motor.

#### Classification by Speed Characteristics.

**1053. General.** — For convenience, alternating-current commutator motors may be classified with reference to their speed characteristics as (1) constant-speed motors, (2) multi-speed motors, (3) adjustable-speed motors, and (4) variable-speed motors. Definitions of these terms as given in §§ 4035 to 4039 in general, should be adopted for alternating-current commutator motors, in so far as they are applicable.

#### Classification by Excitation.

**1054. Stator-excited Commutator Motor.** — A stator-excited commutator motor is one in which the torque-producing field is due to a current in a winding

located on the stator. By the "torque-producing field" is meant that component of the magnetic field which, with the in-phase component of the current, produces the torque of the motor.

**4063. Rotor-excited Commutator Motor.** — A rotor-excited commutator motor is one in which the torque-producing field is due to a current in a winding located on the rotor. See § 4064.

**4064. Stator- and Rotor-excited Commutator Motor.** — A stator- and rotor-excited commutator motor is one in which the torque-producing field is due to currents in windings located on the stator and on the rotor. See § 4064.

**4067.\* Constant-field Commutator Motor.** — A constant-field commutator motor is one in which the torque-producing field remains practically constant independent of the load. See § 4064.

**4068.\* Varying-field Commutator Motor.** — A varying-field commutator motor is one in which the torque-producing field varies in some proportion to the current in the armature (which latter is generally the rotor). See § 4064.

#### Classification by Neutralization and Compensation.

**4069. Neutralized Commutator Motor.** — A neutralized commutator motor is one in which use is made of a winding for producing a magnetizing force at each instant and at each point in the air-gap under the pole face is practically equal and opposite to the magnetizing force due to the armature current.

**4070. Compensated Commutator Motor.** — A compensated commutator motor is one in which means, other than a neutralizing winding, are provided within the motor for improving the power-factor.

#### Classification by Energy Reception.

**4071. Conduction Commutator Motor.** — A conduction commutator motor is one in which the working energy is supplied to only one of the members, and is conveyed to it by conduction. By "working energy" is meant the energy which is directly converted into mechanical energy, and which includes shaft energy output plus core losses and friction.

**4072. Transformer Commutator Motor.** — A transformer commutator motor is one in which the working energy is transmitted from one member to the other by transformer action.

A motor in which the energy required by its armature (which is generally the rotor) is conveyed to it by electromagnetic induction or transformer action, properly be referred to either as an "induction motor," or as a "transformer motor." Although it is equally applicable to a motor having a commutator, the term "induction motor" is usually applied to a motor without a commutator. The term "transformer commutator motor" is therefore recommended for use with motors of the induction, or transformer type, having commutators.

**4073. Transformer-conduction Commutator Motor.** — A transformer-conduction commutator motor is one in which the energy required by its armature (which is generally the rotor) is conveyed to it by both conduction and electromagnetic induction.

**4074. Repulsion Commutator Motor.** — A repulsion commutator motor is a transformer commutator motor in which use is made of brushes for short-circuiting a number of coils of the commutated winding.

#### Miscellaneous Definitions

**4088. Saturation Factor.** — The saturation factor of a machine is the ratio of a small percentage increase in field excitation to the corresponding percentage increase in voltage thereby produced. Unless otherwise specified, the saturation factor of a machine refers to the no-load excitation required at normal speed.

(4067) Alternating-current commutator motors of this class will in general have load-speed characteristics similar to those of the direct-current shunt motor, but will have load-speed characteristics similar to those of the constant-field machines.

(4068) Such a motor will in general have load-speed characteristics similar to those of the direct-current series motor.

ted and voltage. It is determined from measurements of saturation made on the circuit at rated speed.

**6008. Percentage Saturation.** — The percentage saturation of a machine at any excitation may be found from its saturation curve (generated voltage as ordinate, against excitation as abscissas), by drawing a tangent to the curve at the ordinate corresponding to the assigned excitation, and extending the tangent to intercept the axis of ordinates drawn through the origin. The ratio of the intercept on this axis to the ordinate at the assigned excitation, when expressed per cent, is the percentage saturation, and is independent of the scales selected for excitation and voltage. This ratio as a fraction, is equal to the reciprocal of the saturation-factor at the same excitation, deducted from unity; or, if  $f$  be the saturation factor and  $p$  the percentage saturation,

$$p = 100 \left( 1 - \frac{1}{f} \right).$$

**6009. Variation in Alternators.** — The variation in alternators, or alternating-current circuits in general is the maximum angular displacement, measured in electrical degrees (see § 3222) of corresponding ordinates of the wave and of a wave of absolutely constant frequency equal to the average frequency of the alternator or circuit in question, and may be due to the variation of the prime mover. See §§ 14010 and 14011.

**6010. Per cent Resistance Drop.** — The per cent resistance drop in an electric machine is the ratio of the internal resistance drop at 75° C. to the terminal voltage expressed in per cent.

Unless otherwise specified this per cent drop shall be referred to rated load and rated power factor.

The per cent resistance drop in an induction motor is expressed in terms of internally induced electromotive force.

**6011. Per cent Reactance Drop.** — The per cent reactance drop in an electric machine or apparatus is the ratio of the internal reactance drop to the terminal voltage, expressed in per cent.

Unless otherwise specified this per cent drop shall be referred to rated load and rated power factor.

The per cent reactance drop in an induction motor is expressed in terms of the internally induced electromotive force.

**6012. Per cent Impedance Drop.** — The per cent impedance drop in an electric machine is the ratio of the internal impedance drop at 75° C. to the terminal voltage, expressed in per cent.

Unless otherwise specified this per cent drop shall be referred to rated load and rated power factor.

The per cent impedance drop in an induction motor is expressed in terms of the internally induced electromotive force.

**6013. Magnetic Degree.** — A magnetic degree is the 360th part of the angle subtended, at the axis of a machine, by a pair of its field poles. One *mechanical degree* is thus equal to as many magnetic degrees as there are pairs of poles in the machine.

**6014. Regulation of D-C. Generators.** — The regulation of a d-c. generator is usually stated by giving the numerical values of the voltage at no load and at full load, and in some cases it is advisable to state regulation at intermediate loads. The regulation of d-c. generators refers to changes in voltage corresponding to gradual changes in load, and does not relate to the comparatively large momentary fluctuations in voltage that frequently accompany instantaneous changes in load.

**6015. Regulation of Constant-potential A-C. Generators.** — In constant-potential a-c. generators, the regulation is the rise in voltage (when the specified load at specified power factor is reduced to zero) expressed in per cent of normal full-load voltage.

**6016.** If  $p$  is the number of pairs of poles, the variation of an alternator is  $p$  times the variation of its prime mover, if direct-connected, and  $p\pi$  times the variation of the prime mover if rigidly connected thereto in such a manner that the angular speed of the alternator is times that of the prime mover.

**4006. Regulation of Constant-current Machines.**— In constant-current machines the regulation is the ratio of the maximum difference of current between the rated-load value (occurring in the range from rated-load to short-circuit minimum limit of operation), to the rated-load current.

**4007. Regulation of Constant-speed Motors.**— In constant-speed current motors and induction motors, the regulation is the ratio of the difference between full-load and no-load speeds to the no-load speed.

**4008. Regulation of Converters, Dynamotors, Motor-Generators and Frequency Converters.**— In converters, dynamotors, motor-generators, and frequency converters, the regulation is the change in the terminal voltage at the output side between the two specified loads. This may be expressed by giving the numerical values, or as the percentage of the terminal voltage at rated load.

## OPERATION

### Temperature Limits

**4106. Exceptions to General Temperature Limits Given in Chapter II.**

(a) Railway Motors: See §§ 5203 and 5101.

(b) Automobile Propulsion Machines: See § 5305.

(c) Railway Substation Machines: See §§ 5201 and 5102.

(d) Squirrel Cage and Amortisseur Windings. The temperature may attain any value such as will not occasion mechanical injury to the machine.

(e) Field Control Railway Motors: See § 5204.

**4106. Collector Rings.**— The observable temperature of collector rings shall not be permitted to exceed the values set forth in § 2231 (b) for the insulation employed either in the collector rings themselves or in adjacent insulation whose life would be affected by the heat from the collector rings.

**4107. Commutators.**— The observable temperature shall in no case be permitted to exceed the values given in § 2231 (b) for the insulation employed either in the commutator or in an insulation whose life would be affected by the heat of the commutator. These temperature limits are intended only to protect the insulation of the commutator and of the adjacent parts and are not intended as a criterion of successful commutation.

**4108. Cores.**— The observable temperature of those parts of the iron core in contact with insulating materials shall in no case be permitted to exceed the values given in §§ 2231 (b) for the insulation employed.

**4109. Other Parts (Such as Brush-holders, Brushes, Bearings, Pole-cores, etc.).**— All parts of electrical machinery other than those whose temperature affects the temperature of the insulating material may be operated at such temperatures as shall not be injurious in any other respect.

**4110. Maximum Temperature Rise in Service.**— Whatever may be the ambient temperature when the machine is in service, the limits of the maximum observable temperature or of temperature rise specified in the rules should not be exceeded in service; for, if the maximum temperature be exceeded, the insulation may be endangered, and if the rise be exceeded, the excess load may lead to injury, by exceeding limits other than those of temperature; such as commutation, stalling load and mechanical strength. For similar reasons, loads in excess of the rating should not be taken from a machine.

## RATING

### Units in Which Rating Shall be Expressed

**4220. Rating of D-C. Generators.**— The rating of direct-current generators shall be expressed in kilowatts (kw.) available at the terminals at a specified voltage.

**4221. Rating of Alternators.**— The rating of alternators shall be expressed in kilovolt-amperes (kv-a.) available at the output terminals, at a specified voltage and power factor.

**4222.\* Rating of Motors.**— It is strongly recommended that the rating

(4222) Since the input of machinery of this class is measured in electrical units and since the output has a definite relation to the input, it is logical and desirable to measure the delivered power in the same units as are employed for the received power. Therefore, the output of motors should be expressed in kilowatts instead of in horsepower.

motors shall be expressed in kilowatts (kw.) available at the shaft. (An exception to this rule is made in the case of railway motors, which, for some purposes, are also rated by their *input*.) See § 5203.

**4229. Rating of Auxiliary Machinery.**—Auxiliary machinery, such as regulators, balancer sets, synchronous-condensers, etc., shall have their ratings appropriately expressed. It is also essential to specify the voltage (and frequency, a-c.), of the circuits on which the machinery may appropriately be used.

#### Limitations Other than Temperature Rise

**4230.\* Mechanical Limitations.**—\*(a) *General:* All types of rotating machines shall be so constructed that they will safely withstand an over-speed 25 per cent, except in the case of steam turbines, which, when equipped with emergency governors, shall be constructed to withstand 20 per cent over-speed. (b) *Generators:* Water-wheel generators shall be constructed for the maximum runaway speed which can be attained by the combined unit.

(c) *Motors:* Motors for continuous service shall, except when otherwise excised, be required to develop running torque at least 175 per cent of that corresponding to the running torque at their rated load, without stalling. Obviously, duty-cycle machines must carry their peak loads without stalling.

**4231. Commutation Limitations.**—(a) *Continuously Rated Machines:* Continuously rated machines shall be required to commute successfully momentary loads of 150 per cent of the amperes corresponding to the continuous rating, keeping the rheostat set for rated-load excitation. Successful commutation is such that the brushes nor commutator are injured by the test. See §§ 2220 and 5203.

(b) *Machines for Duty-cycle Operation:* Machines for duty-cycle operation with widely fluctuating loads shall commute successfully under their specified rating conditions. See §§ 2222 and 2223.

**4232. Limitations of Stability.**—Continuously rated machines shall be required to carry momentary loads of 150 per cent of the amperes corresponding to the continuous rating, keeping the rheostat set for rated-load excitation. In the case of direct-connected generators, this clause is not to be interpreted requiring the prime mover to drive the generator at this overload.

### TESTS

#### Ambient Temperature

**4233. Measurement of the Ambient Temperature During Tests of Machines.** (See § 2300) (a) *Machines Cooled by Forced Draught:* In the testing of rotating machines, cooled by forced draught, a conventional weighted mean shall be employed, a weight of four being given to the temperature of the circulating air applied through ducts and a weight of one to the surrounding room air. See 300 Note.

(b) *Machines Below Floor Line:* Where machines are partly below the floor level in pits, the temperature of the rotor shall be referred to a weighted mean of pit and room temperatures, the weight of each being based on the relative portions of the rotor in and above the pit. Parts of the stator constantly in the pit shall be referred to the ambient temperature in the pit.

#### Machine Temperatures

**4234. Machines with Small Ventilating Apertures.**—Machines having ventilating openings smaller than 0.03 sq. in. (0.13 sq. cm.) in area, when intended to be operated in locations or under conditions where the openings are liable to become clogged, should be considered as totally enclosed machines and tested as

such, on account of the hitherto prevailing practise of expressing mechanical output in horsepower, it is recommended that for machinery of this class the rating should, for the present, be expressed both in kilowatts and in horsepower; as follows:

Kw. ————— Approx. equiv. h.p. —————

For the purposes of these rules the horsepower shall be taken as 746.0 watts.

In order to lay stress upon the preferred future basis, it is desirable that on rating tests, the rating in kilowatts shall be shown in larger and more prominent characters than the rating in horsepower.

One kilowatt is equal to 102 kilogrammeters per second.

(250 a) In the case of series motors, it is impracticable to specify percentage values for the momentary overload, on account of the varying service conditions.

such with openings closed, and in all cases the rating on this basis should be indicated on the rating plate.

4319. Exception to Temperature Limits Used in Method 1. — In the case of enclosed motors and generators, the limits of the observable temperature rise shall be 5° C. higher than allowed by the general rule. This rule does not apply to those types of machines defined in §§ 4043, 4045 and 4046.

4320. Exception to Temperature Limits Used in Method 2. — In the case of enclosed motors and generators, the limits of the observable temperature rise shall be 5° C. higher than allowed by the general rule. This rule does not apply to those types of machines defined in §§ 4043, 4045 and 4046.

4321. Method of Temperature Measurement Used in Determining Temperature of Stators of Machines. — Method 3 should be applied to all stators of machines with cores having a width of 30 cm. (30 in.) or over. It should also be applied to all machines of 5000 volts or more, if rated over 500 kv-a., regard less of core width.

#### Efficiency

4334.\* Classification of Losses. — Losses are classified as shown in Table 401.

4335.\* Losses to be Considered in Machines. — Conventional efficiency shall be based upon the losses listed in Table 402, and these losses shall be measured as specified in §§ 4336-4342 inclusive.

TABLE 401

Classification of Losses in Machinery

Accurately Measurable	Approximately Measurable or Determinable	Indeterminable
No-load core losses including eddy-current losses in conductors at no-load	Brush Friction loss	Iron loss due to distortion
Load $I^2R$ losses in windings No-load $I^2R$ losses in windings	Brush-contact loss	Eddy-current losses in conductors due to transverse fluxes occasioned by the currents
	Losses due to windage and to bearing friction	Eddy-current losses in conductors due to tooth saturation resulting from distortion of the main flux
		Tooth-frequency losses due to flux distortion under load
	Dielectric losses	Short-circuit loss commutation

(4334) The losses in constant-potential machinery, either of the stationary type or the constant-speed rotary type, are of two classes; namely, those which remain essentially constant at all loads, and those which vary with the load. The former include losses, windage and friction, also  $I^2R$  losses in any shunt windings. The latter are losses in series windings. The constant losses may be determined by measuring the power required to operate the machine at no load, deducting any series  $I^2R$  losses. The loss at any load may be computed from the measured resistance of the series windings at the given load current.

6336. *I<sup>2</sup>R Loss.* — (a) *General:* The *I<sup>2</sup>R* loss shall be based upon the current and the measured resistance.

(b) *Polyphase Induction-motor Rotor:* The *I<sup>2</sup>R* loss in the rotors of polyphase induction motors should be determined from the slip, whenever the latter is carefully determinable, using the following equation:

$$\text{Rotor } I^2R \text{ loss} = \frac{\text{output} \times \text{slip}}{1 - \text{slip}}$$

TABLE 402  
Losses in Rotating Electric Machines  
(References are to Sections)

induction machines	4336(b)	4337(a)	4338	4339(a) 4339(c)	4341 Note 2	4342(b)	4343(b)

Notes: (1) Except railway motors.

(2) When there are collector rings.

(3) Brush friction and brush contact losses are negligible except in the case of revolving-armature machines.

(4) For the booster type of synchronous converter, where the booster forms an integral part of the unit, its losses shall be included in the total converter losses in estimating the efficiency.

(5) These losses, while usually of low magnitude, are erratic, and the Institute is not at this time prepared to make recommendations for approximating them.

(6) In large slip-ring motors, in which the slip cannot be directly measured by a slip ring, the rotor *I<sup>2</sup>R* loss shall be determined by direct resistance measurement; the rotor full-load current to be calculated by the following equation:

$$\text{Current per ring} = \frac{\text{watts output}}{\text{rotor voltage at stand-still} \times \sqrt{3} \times K}$$

(335) This simple method of determining the losses and hence the efficiency is only approximate, since the losses which are assumed to be constant do actually vary to some extent with the load, and also because the actual loss in the copper windings is sometimes appreciably greater than the calculated *I<sup>2</sup>R* loss. The difference between the approximate  $\eta$ , as above determined, and the actual losses, is termed "stray-load losses." These losses are due to distortions in electric or magnetic fluxes from their no-load distributions and are brought about by the load current. They are usually only approximately calculable, or may be indeterminable, but certain of them reach values in various kinds of machinery, which require that they should be taken into account.

Electric losses are usually negligible.

The stray-load losses include the items in the column of Table 401 headed "Indeterminable" but do not include the increased core losses due to increased excitation for operating in normal deep under load.

This equation applies to three-phase rotors. For rotors wound for two-phase use 2 instead of the  $\sqrt{3}$ .  $K$  may be taken as 0.95 for motors of 150 kw. or less. The factor  $K$  usually decreases as the size of motor is reduced, but no special value can be stated for smaller sizes.

(c) *Synchronous Converters*: The  $I^2R$  losses in the armature winding shall be derived from those corresponding to its use as a direct-current generator, by all suitable factors.

**4337. Bearing Friction and Windage.**—(a) *General*: Drive the machine by an independent motor, the output of which shall be suitably determined. The machine under test shall have its brushes removed and shall not be excited. This output represents the bearing friction and windage of the machine under test.

(b) *Induction Motors*: The bearing friction and windage of induction motors may be measured by running motors free at the lowest voltage at which they will rotate continuously at approximately rated speed; the watts input, less  $I^2R$  loss, under these conditions being taken as the friction and windage.

(c) *Engine-type Generators*: In the case of engine-type generators (see § 4307) the windage and bearing friction loss is ordinarily very small, amounting to a fraction of one per cent of the output. This loss shall be neglected owing to its small value and the difficulty of measuring it.

(d) *D. C. Railway Motors*: See § 5337.

**4338. Brush Friction of Commutator and Collector Rings.**—(a) *General*: Drive the machine from an independent motor, the output of which shall be suitably determined. The brushes shall be in contact with the commutator or collector rings, but the machine shall not be excited. The difference between the output obtained in the test in § 4337 and this output shall be taken as the brush friction. The surfaces of the commutator and brushes should be smooth and glazed from running when this test is made.

(b) *D. C. Railway Motors*: See § 5338.

**4339. Core Losses.**—(a) *General*: Drive the machine from an independent motor, the output of which shall be suitably determined. The brushes shall be in contact, and the machine shall be excited, so as to produce at the terminal voltage corresponding to the calculated internal voltage for the load under consideration. The difference between the output obtained by this test and that obtained by test under § 4338 (a) shall be taken as the core loss.

(b) *Synchronous Machines*: The internal voltage of synchronous machines shall be determined by correcting the terminal voltage for the resistance drop only.

(c) *Induction Motors*: The core loss of an induction motor may be determined by measuring the watts input to the motor when running free at rated voltage and frequency and subtracting therefrom the no-load copper loss, bearing friction and windage.

(d) *D. C. Railway Motors*: See § 5339.

**4341.\* Brush-contact  $I^2R$  Loss.**—(a) *General*: One volt drop per brush shall be considered as the Institute standard drop corresponding to the  $I^2R$  brush-contact loss, for carbon and graphite brushes with pigtailed attachments.

(4341) The brush-contact  $I^2R$  loss depends largely upon the material of which the brush is composed.

As indicating the range of variation the following table will be of interest:

TABLE 463  
Brush-contact Drop

Grade of brush	Volts drop across one brush-contact (Average of positive and negative brushes)
Hard carbon.....	1.1
Soft carbon.....	0.9
Graphite.....	0.5 to 0.8
Metal-graphite types....	0.15 to 0.5 (The former for largest proportion of metal)

and one-half volts per brush shall be allowed where pigtails are not attached. al-graphite brushes shall be considered as special.

) *Automobile Motors*: See § 5347.

1042.\* *Stray Load-losses*.—(a) *Synchronous Machines*: These include iron  $w$ , and eddy-current losses in the copper, due to fluxes varying with load also to saturation.

Stray load-losses shall be determined by operating the machine on short circuit and at rated-load current. This, after deducting the windage and iron and  $I^2R$  loss, gives the stray load-loss for polyphase generators and motors. These losses in single-phase machines are large; but the Institute is yet prepared to specify a method for measuring them.

) *Induction Machines*: These include eddy-current losses in the stator core, and other eddy-current losses due to fluxes varying with the load. In designs consisting of relatively small conductors, these eddy-current losses are usually negligible.

With rotor removed, measure the power input to the stator with different values of current at the rated frequency. The curve plotted with these values shows the combined  $I^2R$  and stray load-losses due to eddy-currents in the stator core. Deduct the  $I^2R$  loss determined from the resistance, and the difference will represent the stray load-losses corresponding to the various currents. While this method is not accurate for some types of motors it usually represents a sufficiently good approximation.

1043. *Miscellaneous Losses*.—(a) *Field-rheostat Losses*: Field-rheostat losses shall be included in the generator losses where there is a field rheostat in series with the field magnets of the generator, even when the machine is separately excited.

) *Ventilating Blower*: When a blower is supplied as part of a machine set, the power required to drive it shall be charged against the complete unit, but not against the machine alone.

) *Other Auxiliary Apparatus*: Auxiliary apparatus, such as a separate motor for a generator or motor, shall have its losses charged against the plant in which the generator and exciter are a part, and not against the generator. An exception should be noted in the case of turbo-generator sets with direct-connected exciters, in which case the losses in the exciter shall be charged against the generator. The actual energy of excitation and the field-rheostat losses, if any, shall be charged against the generator. See § 4343 (a).

#### Wave Shape

1044. *Deviation Factor of a Wave*.—The deviation factor of the open circuit terminal voltage wave of synchronous machines shall not exceed ten per cent unless otherwise specified. See § 3274.

1045. *Telephone Interference Factor of a Wave*.—(For trial only.) (See § 178.)—(a) *Conditions of Test*. The weighting of the sine-wave components at different frequencies shall be as given in Fig. 4-1.

The telephone interference factor of a voltage wave, corresponding to this weighting, may be measured by the use of the network shown in Fig. 4-2.

With this network the telephone interference factor of a voltage wave is the ratio of the current  $I$  in micro-amperes in the meter branch of the network to the voltage  $E$  applied to the external terminals of the network. The measurement may be made on the low-tension side of a potential transformer. A sensitive vacuum thermo-couple provided with a shunt, and a direct-current millivoltmeter have been found convenient for measuring the current.

b) The appropriate limiting value of the telephone interference factor of a wave (see § 3278), either for machines or for circuits, has not yet been determined, and cannot now be specified. The whole matter of interference, including suitable arrangements for both power and communication systems, is under

Fig. 4-2

#### Tests of Dielectric Strength

**4388. Frequency of Test Voltage.** — In d-c. machines, and in general commercial application of a-c. machines, the testing frequency of 60 cycles per second is recommended.

**4381.\* Exceptions to Standard Test Voltage Given in Section 4386.**

(a) *Field Windings of Alternating-current Generators:* Field windings of alternating-current generators shall be tested with 10 times the exciter voltage, but in no case with less than 1500 volts nor more than 3500 volts.

(b) *Field Windings of Synchronous Machines:* Field windings of synchronous machines including motors and converters which are to be started with alternating current are to be tested as follows:

When machines are to be started with field short-circuited, the field windings shall be tested as specified in § 4361 (a).

When machines are to be started with fields open-circuited and sectionalized at starting, the field windings shall be tested with 5000 volts.

When machines are to be started with fields open-circuited and connected all series while starting, the windings shall be tested with 5000 volts for less than 275 volts excitation and 8000 volts for excitation of 275 volts to 750 volts.

(c) *Phase-wound Rotors of Induction Motor:* The secondary windings of induction rotors of induction motors shall be tested with twice their normal induced voltage, plus 1000 volts. When induction motors with phase-wound rotors are to be reversed, while running at approximately normal speed, by reversing the primary connections, the test shall be four times the normal induced voltage plus 1000 volts.

d) *Small Motors and Generators:* Small machines taking not over 660 watts having an output not exceeding  $\frac{1}{2}$  h. p. (373 watts), such as fractional horsepower motors, and intended solely for operation on supply circuits not exceeding 120 volts, shall be tested with 900 volts.

e) *Alternating-current Machines Connected to Permanently Grounded Single-phase Systems:* Alternating-current machines connected to permanently grounded single-phase systems, for use on permanently grounded circuits operating at more than 300 volts shall be tested with 2.73 times the voltage of the circuit to ground, plus 1000 volts. This does not refer to three-phase machines with grounded star neutral.

(f) *Machines for Use on Circuits of 25 Volts or Lower:* Machines for use on circuits of 25 volts or lower, such as bell-ringing apparatus, electric machines used in automobiles, machines used on low-voltage battery circuits, etc., shall be tested with 500 volts.

### Regulation

390. *Conditions for Tests of Regulation (see § 2390).—*(a) *Power Factor:* For alternating-current generators the power factor of the load to which the regulation refers should be specified. Unless otherwise specified, it shall be understood as referring to non-inductive load, that is, to a load in which the current is in phase with the e.m.f. at the terminals of the machine.

b) *Excitation:* In commutating machines, rectifying machines and synchronous machines, the regulation shall be determined under such conditions as to maintain the field adjustment constant at a value which gives rated-load voltage at rated-load current. These conditions are as follows:

1. the case of separately excited fields: constant excitation.

2. the case of shunt machines: constant resistance in the shunt-field circuit.

3. the case of series or compound machines: constant resistance shunting the series field windings.

390.\* *Tests and Computation of Regulation of A-C. Generators.—*(a) *Methods Available:* The regulation of alternating-current generators may be determined by any one of the three following methods, which are given in the order of preference:

b) *Method I. By Loading:* The regulation can be measured directly, by loading the generator at the specified output and power factor, then reducing the load to zero, and measuring the terminal voltage, with speed and excitation adjusted to the same values as before the change. This method is not generally applicable for shop tests, particularly on large generators and it becomes necessary to determine the regulation from such other tests as can be readily made.

(c) *Method II. From Test Curves:* This method consists in computing the

361 b) Series-field windings should be regarded as part of the armature circuit and tested as such.

361 c) By normal induced voltage is here meant the voltage between slip rings on the rotor circuit at standstill with normal voltage impressed on the primary.

361 f) The present National Electrical Code limit for a single outlet is 660 watts.

390 a) Method II for deducing the load-saturation curve, at any assigned power

regulation from experimental data of the open-circuit saturation curves and the zero-power-factor saturation curve. The latter curve, or one approximating very closely to it, can be obtained by over-exciting the generator while carrying a load of idle-running under-excited synchronous motors. The power loss under these conditions is very low and the load-saturation curve approximates very closely the zero-power-factor saturation curve. From this curve and the open-circuit curve, points for the load-saturation curve for any specified power factor can be obtained by means of vector diagrams.

regarded as empirical. Its value depends upon the fact that experience has demonstrated the reasonable correctness of the results obtained by it.

Fig. 4-3

Fig. 4-4

Fig. 4-5

Fig. 4-6

To apply Method II, it is necessary to obtain from test the open-circuit saturation curve Fig. 4-3, and the load-saturation curve  $BC$  at zero power factor and rated-load current. At any given excitation  $Oc$ , the voltage that would be induced on open circuit is  $a$ . The terminal voltage at zero power factor is  $cb$  and the apparent internal drop is  $ak$ . The terminal voltage  $cd$  at any other power factor can then be found by drawing an equivalent diagram as in Fig. 4-4, where  $\phi$  is an angle such that  $\cos \phi$  is the power factor of the load.  $b$  is the resistance drop ( $IR$ ) in the stator winding,  $ba$  the total internal drop and  $ca$  the total induced voltage;  $bd$  and  $ac$  being laid off to correspond with the values obtained from Fig. 4-3. The terminal voltage at power factor  $\cos \phi$  is then  $cd$  Fig. 4-4, which when laid off in Fig. 4-3 gives point  $d$ . By finding a number of such points, the curve  $Bdd'$  for power factor  $\cos \phi$  is obtained and the regulation at this power factor expressed in per cent) is  $\frac{100 \times a'd'}{c'd'}$  since  $a'd'$  is the rise in voltage when the load at power factor  $\cos \phi$  is thrown off at normal voltage  $c'd'$ .

Generally, the ohmic drop can be neglected as it has little influence on the regulation.

(d) *Method III. From Estimated Zero-power-factor Curve.* Where it is not possible to obtain by test a zero-power-factor curve as in Method II this curve may be estimated closely from open-circuit and short-circuit curves, by reference tests at zero power factor on other machines of similar magnetic circuit. Having obtained the estimated zero-power-factor curve, the load saturation for any other power factor is obtained as in Method II, § 4394 (c).

1395. *Compound Wound D-C. Generator.*—In determining the regulation of a compound-wound d-c. generator, two tests shall be made, one bringing the load down and the other bringing the load up, between no-load and rated load. The results may differ somewhat, owing to residual magnetism. The mean of the two results shall be used.

where regulation at unity power factor is being estimated. For low power factors the effect is negligible in practically all cases. If resistance is neglected, the simpler Form Fig. 4-5, may be used.

(394 d) Method III is the same as Method II except that the zero-power-factor curve may be estimated. This may be done as follows. In Fig. 4-6,  $OA$  is the open-circuit saturation curve and  $OB$  the short-circuit line as obtained from test. The zero-power-factor curve corresponding to any current  $BF$  will start from point  $B$ , and for machines designed with low saturation and low reactance, will follow parallel to  $OA$  as shown by dotted curve  $BD$ , which is  $OA$  shifted horizontally parallel to itself by the distance  $BF$ .

In high-speed machines, or in others having low reactance, and a low degree of saturation in the magnetic circuit, the zero-power-factor curve will be quite close to  $BD$  particularly in those parts that are used for determining the regulation. This is the case in many turbo-generators and high-speed water-wheel generators.

In many cases, however, the zero-power-factor curve will deviate from  $BD$ , as shown by  $BC$ , and the deviation will be most pronounced in machines of high reactance, high saturation and large magnetic leakage. The position of curve  $BC$  with relation to  $BD$  can be approximated with sufficient exactness by investigating the corresponding relation as obtained by test at zero power factor on machines of similar characteristics and magnetic circuit. Curve  $BC$  can also be calculated by methods based on the results of test at any power factor. After curve  $BC$  has been obtained, the load-saturation curve and regulation for any other power factor can be derived as in Method II, § 4394 (c).

## CHAPTER V

STANDARDS FOR ELECTRIC RAILWAYS AND FOR  
AUTOMOBILE PROPULSION MACHINES

The A. I. E. E. Standards for Electric Railways and for Automobile Propulsion Machines are the General Standards shown in Chapters II and III, and the Standards in other Chapters which are applicable to the devices involved together with the modifications and extensions given in this Chapter.

## DEFINITIONS

## General

**7000. Contact Conductors.** — A contact conductor is that part of the distribution system other than the traffic rails, which is in immediate electrical contact with the circuits of the cars or locomotives.

## Contact Rails

**5003.\* Contact Rail.** — (a) *General:* A contact rail is a rigid contact conductor

(b) *Overhead Contact Rail:* An overhead contact rail is a contact rail which is above the elevation of the maximum equipment line.

(c) *Third Rail:* A third rail is a contact conductor placed at either side of the track, the contact surface of which is a few inches above the level of the top of the track rails.

(c) *Center Contact Rail:* A center contact rail is a contact conductor placed between the track rails, having its contact surface above the ground level.

(e) *Underground Contact Rail:* An underground contact rail is a contact conductor placed beneath the ground level.

(f) *Gage of Third Rail:* The gage of a third rail is the distance, measured parallel to the plane of running rails, between the gage line of the nearest track rail and the inside gage line of the contact surface of the third rail.

(g) *Elevation of Third Rail:* The elevation of a third rail is the elevation of the contact-surface of the third rail, with respect to the plane of the top of running rails.

(h) *Third Rail Protection:* A third rail protection is a guard for the purpose of preventing accidental contact with the third rail.

## Trolley Wires

**5004. Trolley Wire.** — A trolley wire is a flexible contact conductor, customarily supported above the cars.

**5005. Messenger Wire or Cable.** — A messenger wire or cable is a wire or cable running along with and supporting other wires, cables or contact conductors.

A primary messenger is directly attached to the supporting system. A secondary messenger is intermediate between a primary messenger and the wires, cables or contact conductors.

**5006. Classes of Construction.** — (a) *General:* Overhead trolley constructions are classed as *Direct Suspension* and *Messenger or Catenary Suspension*.

(b) *Direct Suspension:* A direct suspension is the form of overhead wiring construction in which the trolley wires are attached, by insulating devices, directly to the main supporting system.

(c) *Messenger or Catenary Suspension:* A messenger or catenary suspension is the form of overhead trolley construction in which the trolley wires are attached, by suitable devices, to one or more messenger cables, which in turn may be carried either in *Simple Catenary*, i. e., by primary messengers, or in *Compound Catenary*, i. e., by secondary messengers.

(5003 b) The maximum equipment line is the contour which embraces cross-section of all rolling stock under all normal operating conditions.

**5007. Supporting Systems.**—(a) *General:* Supporting systems for trolley cars shall be classed as follows:

(b) *Simple Cross-Span Systems:* Simple cross-span systems are those having at each support a single flexible span across the track or tracks.

(c) *Messenger Cross-span Systems:* Messenger cross-span systems are those having at each support two or more flexible spans across the track or tracks, the upper span carrying part or all of the vertical load of the lower span.

(d) *Bracket Systems:* Bracket systems are those having at each support an arm or similar rigid member, supported at only one side of the track or tracks.

(e) *Bridge Systems:* Bridge systems are those having at each support a rigid member, supported at both sides of the track or tracks.

**5000.\* Transmission System.**—When the current generated for an electric railway is changed in kind or voltage, between the generator and the cars or locomotives, that portion of the conductor system carrying current of a kind or stage substantially different from that received by the cars or locomotives, constitutes the *transmission system*.

**5031.\* Distribution System.**—That portion of the conductor system of an electric railway which carries current of the kind and voltage received by the cars or locomotives, constitutes the *distribution system*.

**5032. Substation.**—A substation is a group of apparatus or machinery which receives current from a transmission system, changes its kind or voltage, and delivers it to a distribution system.

## OPERATION

### Temperature Limits

**5101.\* Railway Motors in Continuous Service.**—The following maximum permissible temperatures are permissible in the windings of railway motors, when in continuous service.

TABLE 501

Temperatures of Railway Motors in Continuous Service

Class of material See § 1004	Temperature	
	By Thermometer See § 1002	By Resistance See § 1002
A	85° C.	110° C.
B	100° C.	130° C.

**5120. Railway Substation Machines and Transformers.**—Under conditions specified in § 5201, the windings of railway substation machines and transformers carrying traction loads may have observable temperature rises 5° C. in excess of the limiting observable temperature rises specified in Table 500.

**5130.\* Automobile Propulsion Machines.**—On stand test, the observable temperature rises shall not exceed the limits specified in § 5205.

## RATING

### Ratings of Railway Substation Machinery and Transformers

**5201.\* Nominal Rating of Railway Substation Machines and Transformers.**—The nominal rating of a substation machine or transformer carrying traction

(5030 and 5031) These definitions are identical in sense, although not in words, with those of the Interstate Commerce Commission, as given in their Classification of

loads shall be the kv-a. output at a stated power factor input, which, having produced a constant temperature in the machine or transformer, may be increased 50 per cent for two hours, without producing temperature rises exceeding by more than 5° C. the limiting values given in Table 200. These machines or transformers should be capable of carrying a load of twice their normal rating for a period of one minute, without disqualifying them for continuous service. The name plate should be marked "nominal rating."

#### Ratings of Railway Motors

**5202.\* Nominal Rating of Railway Motors.** — The nominal rating of a railway motor shall be the mechanical output at the car or locomotive axle, measured in kilowatts, which causes a rise of temperature above the surrounding air, by thermometer, not exceeding 90° C. at the commutator, and 75° C. at any other normally accessible part after one hour's continuous run at rated voltage (and frequency in the case of an alternating-current motor) on a stand with the motor covers arranged to secure maximum ventilation without external blower. The rise in temperature as measured by resistance shall not exceed 100° C. The statement of the nominal rating shall include the corresponding voltage and armature speed.

**5203.\* Continuous Ratings of Railway Motors.** — The continuous ratings of a railway motor shall be the *inputs* in amperes at which it may be operated continuously at  $\frac{1}{2}$ ,  $\frac{3}{4}$  and full voltage respectively, without exceeding the observable temperature rises specified in Table 502, when operated on stand test with motor covers and cooling system, if any, arranged as in service. Inasmuch as the same motor may be operated under different conditions as regards ventilation, it will be necessary in each case to define the system of ventilation which is used. In case motors are cooled by external blowers, the flow of air on which the rating is based shall be given.

TABLE 502

Stand-test Temperature Rises of Railway Motors

Class of material See § 1004	Temperature rises of windings	
	By Thermometer See § 1002	By Resistance See § 1002
A	65° C.	85° C.
B	80° C.	105° C.

**5204. Field-control Railway Motors.** — The nominal and continuous ratings of field-control motors shall relate to their performance with the operating field which gives the maximum motor rating. Each section of the field windings shall be adequate to perform the service required of it, without exceeding the specified temperature rises.

#### Ratings of Automobile Propulsion Machines

**5205. Automobile Propulsion Machines.** — The rating of automobile motors and generators shall be based upon temperature rise, on a stand test and with motor covers arranged as in service, fifteen degrees by thermometer or twenty-five degrees by resistance, above those of Table 200.

(5201 and 5202) In the absence of any specification as to the kind of rating the "nominal" rating shall be understood.

(5203) The temperature rise in service may be very different from that on stand-test. See § 5402 for the relation between stand-test and service temperatures as affected by ventilation.

## Ratings of Electric Locomotives

**§210. Rating.** — Locomotives shall be rated in terms of the weight on drivers, nominal one-hour tractive effort, continuous tractive effort and corresponding speeds.

**§211. Weight on Drivers.** — The weight on drivers, expressed in pounds, shall be the sum of the weights carried by the drivers and of the drivers themselves.

**§212. Nominal Tractive Effort.** — The nominal tractive effort, expressed in pounds, shall be that exerted at the rims of the drivers when the motors are operating at their nominal (one-hour) rating.

**§213. Continuous Tractive Effort.** — The continuous tractive effort, expressed in pounds, shall be that exerted at the rims of the drivers when the motors are operating at their full-voltage continuous rating, as indicated in § 5203.

In the case of locomotives operating on intermittent service, the continuous tractive effort may be given for  $\frac{1}{2}$  or  $\frac{3}{4}$  voltage, but in such cases the voltage shall be clearly specified.

**§214. Speed.** — The rated speed, expressed in miles per hour, shall be that at which the continuous tractive effort is exerted.

## TESTS

## Efficiency

## Losses in D-C. Railway Motors

**§337. Losses in Gearing and Axle Bearings.** — The losses in gearing and axle bearings for single-reduction single-g geared motors, varies with the type, mechanical finish, age and lubrication. The following values, based upon accumulated tests, shall be used in the comparison of single-reduction single-g geared motors § 5339.

TABLE 803

## Losses in Axle Bearings and Single-reduction Gearing of Railway Motors

Per cent of input at nominal rating	Losses as per cent of input
200	3.5
150	3.0
125	2.7
100	2.5
75	2.5
60	2.7
50	3.2
40	4.4
30	6.7
25	8.5

Note. — Further investigation may indicate the desirability of giving separate values of the losses for full and tapped fields, or low- and high-speed motors.

**§338. Brush Friction, Armature-bearing Friction and Windage.** — The brush friction, armature-bearing friction and windage shall be determined as a total under the following conditions:

In making the test, the motor shall be run without gears. The kind of brushes and the brush pressure shall be the same as in commercial service. Drive the machine idle as a series motor on low voltage. The product of armature counter-

electromotive-force and amperes at any speed shall be the sum of the above losses at that speed. See § 5339.

**5339.\* No-load Core Loss, Brush Friction, Armature-bearing Friction and Windage.** — The no-load core loss, brush friction, armature-bearing friction and windage shall be determined as a total under the following conditions:

In making the test, the motor shall be run without gears. The kind of brushes and the brush pressure shall be the same as in commercial service. With the field separately excited, such a voltage shall be applied to the armature terminals as will give the same speed for any given field current as is obtained with that field current when operating at normal voltage under load. The sum of the losses above-mentioned, is equal to the product of the counter-electromotive force and the armature current.

The no-load core loss is obtained by deducting from the total losses thus obtained the power required to drive the motor at corresponding speeds determined under § 5338.

The core loss under load shall be assumed to have the values given in Table 504.

TABLE 504

Core Loss in D-C. Railway Motors at Various Loads

Per cent of input at nominal rating	Loss as per cent of no-load core loss
200	165
150	145
100	130
75	125
50	123
25 and under	122

**Note.** — With motors designed for field control the core losses shall be assumed to be the same for both full and permanent field. It shall be the mean between the no-load losses at full and permanent field, increased by the percentages given in the above table.

**5341. Automobile Motors.** — When automobile motors are of low voltage, the great influence of brush-contact losses on the efficiency requires that these losses be determined experimentally for the type of brush used.

(5339) In comparing projected railway motors, and in case it is not possible or desirable to make tests to determine mechanical losses, the following values of these losses determined from the averages of many tests over a wide range of sizes of single-reduction single-gear motors, will be found useful, as approximations. They include axle-bearing, gear, armature-bearing, brush-friction, windage, and stray-load losses.

TABLE 505

Approximate Losses in D-C. Railway Motors

Input in per cent of that at nominal rating	Losses as per cent of input
100 or over	5.0
75	5.0
60	5.3
50	6.1
40	8.8
30	13.3
25	17.0

The core loss of railway motors may also be determined as specified for other motors.

## CHARACTERISTIC CURVES OF RAILWAY MOTORS

**8401. General.**—The Characteristic Curves of railway motors shall be plotted with the current as abscissas and the tractive effort, speed and efficiency ordinates. In the case of a-c. motors, the power factor shall also be plotted ordinates.

**8402. Voltage.**—Characteristic curves of direct-current motors shall be based on full voltage, which shall be taken as 600 volts, or a multiple thereof.

**8403. Field-Control Motors.**—In the case of field-control motors, characteristic curves shall be given for all operating field connections.

## SELECTION OF RAILWAY MOTOR FOR SPECIFIED SERVICE

**8404. Data Required in Selecting Motor.**—The following information, relative to the service to be performed, is required, in order that an appropriate motor may be selected.

- (a) Weight of total number of cars in train (in tons of 2000 lb.) exclusive of electrical equipment and load.
- (b) Average weight of load and durations of same, and maximum weight of load and durations of same.
- (c) Number of motor cars or locomotives in train, and number of trailer cars in train.
- (d) Diameter of driving wheels.
- (e) Weight on driving wheels, exclusive of electrical equipment.
- (f) Number of motors per motor car.
- (g) Voltage at train with power on the motors—average, maximum and minimum.
- (h) Rate of acceleration in miles per hour per second.
- (i) Rate of braking (in miles per hour per second).
- (j) Speed limitations, if any (including slowdowns).
- (k) Distances between stopping points.
- (l) Average duration of stops.
- (m) Schedule speed, including stops, in miles per hour.
- (n) Train resistance in pounds per ton of 2000 pounds at stated speeds.
- (o) Moment of inertia of revolving parts, exclusive of electrical equipment.
- (p) Profile and alignment of track.
- (q) Distance coasted as a percentage of the distance between stopping points.
- (r) Duration of layover at end of run, if any.

**8405. Method of Comparing Motor Capacity with Service Requirements.** When it is not convenient to test motors under actual specific service conditions, recourse may be had to the following method of determining temperature from the stand-tests.

The essential motor losses affecting temperatures in service are those in the armatures and windings, core and commutator. The mean service conditions may be assessed, as a close approximation, in terms of that continuous current and core loss which will produce the same losses and distribution of losses as the average service.

**8406. Calculation for comparing motor capacity with service requirements.** The rating of a motor should be determined, wherever possible, by testing it in service, or an equivalent duty-cycle. When the service or equivalent duty-cycle tests are not available, the ratings of the motor may be utilized as follows to determine its temperature.

The motor losses which affect the heating of the windings are as stated above, those in the armatures and in the core. The former are proportional to the square of the current, but they vary with the voltage and current, according to curves which can be supplied by the manufacturers. The procedure is therefore as follows:

Plot a time-current curve, a time-voltage curve, and a time-core loss curve for the duty-cycle which the motor is to perform, and calculate from these the root-mean-square current and the average core loss.

If the calculated r.m.s. service current exceeds the continuous rating, when run with the service core loss and speed, the motor is not sufficiently powerful for the duty-contemplated.

A stand-test with the current and voltage which will give losses equal to those in service, will determine whether the motor has sufficient capacity to meet the service requirements. In service, the temperature rise of an enclosed motor (§ 4044), well exposed to the draught of air incident to a moving car or locomotive, will be from 75 to 90 per cent (depending upon the character of the service) of the temperature rise obtained on a stand-test with the motor completely enclosed and with the same losses. With a ventilated motor (§ 4045 and § 4046) the temperature rise in service will be 90 to 100 per cent of the temperature rise obtained on a stand-test with the same losses.

In making a stand-test to determine the temperature rise in a specific service it is essential in the case of a self-ventilated motor (§ 4046) to run the armature at a speed which corresponds to the schedule speed in service. In order to obtain this speed it may be necessary, while maintaining the same total armature losses, to change somewhat the ratio between the  $I^2R$  and core-loss components.

### CONSTRUCTION

**§ 4001.\* Standard Height of Trolley Wire on Street and Interurban Railways.**— It is recommended that supporting structures shall be of such height that the lowest point of the trolley wire shall be at a height of 18 feet (5.5 m.) above the top of rail under conditions of maximum sag, unless local conditions prevail. On trackage operating electric and steam road equipment and at crossings over steam roads, it is recommended that the trolley wire shall be not less than 21 feet (6.4 m.) above the top of rail, under conditions of maximum sag.

**§ 4002. Standard Gage of Third Rails.**— The gage of third rails shall be not less than 26 inches (66 cm.) and not more than 27 inches (68.6 cm.).

**§ 4003. Standard Elevation of Third Rails.**— The elevation of third rails shall not be less than 2½ inches (7 cm.) and not more than 3¼ inches (8.9 cm.).

### BIBLIOGRAPHY

#### United States

American Electric Railway (Engineering) Association: Engineering Manual.  
Association of Railway Electrical Engineers: Standards.

(c) If the calculated r.m.s. service current does not exceed the continuous rating, the motor run with average service core loss and speed, the motor is ordinarily suitable for service.

In some cases, however, it may not have sufficient thermal capacity to avoid excessive temperature rises during the periods of heavy load. In such cases a further calculation is required, the first step of which is to compute the equivalent voltage which, with the r.m.s. current, will produce the average core loss. Having obtained this, determine as follows, the temperature rise due to the r.m.s. service current and equivalent voltage:

Let $\theta_0$ = temperature rise	} with r.m.s. service current, and equivalent service voltage
$P_0$ = $I^2R$ loss, kw.	
$P_c$ = core loss, kw.	
$\theta_1$ = temperature rise	
$P_1$ = $I^2R$ loss, kw.	
$P_c$ = core loss, kw.	} with continuous load current corresponding to the equivalent service voltage.

Then

$$\theta = \theta_1 \frac{P_0 + P_c}{P_1 + P_c}, \text{ approximately.}$$

(d) The thermal capacity of a motor is approximately measured by the ratio of electrical loss in kw. at its nominal (one-hour) capacity, to the corresponding maximum observable temperature rise during a one-hour test starting at ambient temperature.

(e) Consider any period of peak load and determine the electrical losses in kilowatt-hours during that period from the electrical efficiency curve. Find the excess of the electrical losses over the losses with r.m.s. service current and equivalent voltage. The excess is divided by the coefficient of thermal capacity, will equal the extra temperature rise due to the peak load. This temperature rise added to that due to the r.m.s. service current and equivalent voltage, gives the total temperature rise. If the total temperature rise in such period exceeds the safe limit, the motor is not sufficiently powerful for the service.

(f) If the temperature reached, due to the peak loads, does not exceed the safe limit, the motor may yet be unsuitable for the service, as the peak loads may cause excessive sparking and dangerous mechanical stresses. It is, therefore, necessary to compare the peak loads with the short-period overload capacity. If the peaks are also within the capacity of the motor, it may be considered suitable for the given duty-cycle.

## CHAPTER VI

STANDARDS FOR TRANSFORMERS AND OTHER  
STATIONARY INDUCTION APPARATUS

Wherever the General Standards in Chapters II and III apply to transformers they are referred to in the following Chapter by cross references. Certain rules applying exclusively to railway machinery have, for convenience, been placed in Chapter V with cross references in all case to this Chapter. Rules in Chapter VI apply to railway machinery except as they are modified by the rules in Chapter V.  
 Note: The word "Transformer" will be used throughout this Chapter as abbreviation of "Transformer or other stationary induction apparatus."

## DEFINITIONS

## Apparatus

**100. Stationary Induction Apparatus.** — For the purpose of these Standards, stationary induction apparatus is defined as electric apparatus which changes mechanical energy to electric energy through the medium of magnetic energy, without mechanical motion. It comprises several forms, as defined in §§ 6001 and 6015 to 6018.

**101. Transformer.** — A transformer is a form of stationary induction apparatus in which the primary and secondary windings are ordinarily insulated one from another.

**110. Auto-transformer.** — An auto-transformer is one which has a part of its turns common to both primary and secondary circuits.

**111. Voltage-regulator.** — A voltage-regulator is a form of stationary induction apparatus which has turns in shunt and turns in series with the circuit, so arranged that the voltage ratio of the transformation, or the phase relation between the circuit-voltages, is variable at will.

**112. Contact Voltage-regulator.** — A contact voltage-regulator is a voltage regulator in which the number of turns in one or both of the coils is adjustable.

**113. Induction Voltage-regulator.** — An induction voltage-regulator is one in which the relative position of the primary and secondary coils is adjustable.

**114. Magneto Voltage-regulator.** — A magneto voltage-regulator is one in which the direction of the magnetic flux with respect to the coils is adjustable.

**115. Reactor.** — A reactor is a device used primarily because it possesses the property of reactance. Reactors are used in electric circuits for purposes of regulation, protection or control.

## Parts of Apparatus

**120. High-voltage and Low-voltage Winding.** — The terms "high voltage" and "low voltage" are used to distinguish the winding having the greater from that having the lesser number of turns.

**6021. Primary and Secondary Windings.**—The terms "primary" and "secondary" serve to distinguish the windings in regard to energy flow, the primary being that which receives the energy from the supply circuit, and the secondary that which receives the energy by induction from the primary.

**6022. Full Capacity Tap.**—A full capacity tap is a tap from a transformer winding on which the unit may be operated at rated kv-a. capacity with exceeding the specified temperature rise.

**6023. Reduced Capacity Tap.**—A reduced capacity tap is one on which the unit may not be operated at full capacity without exceeding the specified temperature rise.

#### Properties of Apparatus

**6031. Rated Current of a Constant-potential Transformer.**—The rated current of a constant-potential transformer is that secondary current which, multiplied by the rated-load secondary voltage, gives the kv-a. rated output. It is, a transformer of given kv-a. rating must be capable of delivering the rated output at rated secondary voltage, while the primary impressed voltage increased to whatever value is necessary to give rated secondary voltage.

**6032. Full or Reduced Capacity Taps.**—Where transformers are provided with taps from either the high-voltage or low-voltage windings, a definite statement shall be made as to whether such are full capacity or reduced capacity.

**6033. Rated Primary Voltage of a Constant-potential Transformer.**—The rated primary voltage of a constant-potential transformer is the rated secondary voltage multiplied by the turn ratio.

**6034. Ratio of a Transformer.**—The ratio of a transformer, unless otherwise specified, shall be the ratio of the number of turns in the high-voltage winding to that in the low-voltage winding; *i.e.*, the "turn-ratio."

**6035. Voltage Ratio of a Transformer.**—The voltage ratio of a transformer is the ratio of the r.m.s. primary terminal voltage to the r.m.s. secondary terminal voltage, under specified conditions of load.

**6036. Current Ratio of a Transformer.**—The current ratio of a transformer is the ratio of the r.m.s. primary current to the r.m.s. secondary current, under specified conditions of load.

**6037. Volt-ampere Ratio of Transformer.**—The volt-ampere ratio of a transformer should not be confused with real efficiency, is the ratio of the volt-ampere output to the volt-ampere input of a transformer at any given power factor.

**6050.\* Per Cent Resistance Drop.**—The per cent resistance drop in a transformer is the ratio of the internal resistance drop at 75° C. to the secondary terminal voltage expressed in per cent.

**6051.\* Per Cent Reactance Drop.**—The per cent reactance drop in a transformer is the ratio of the internal reactance drop to the secondary terminal voltage expressed in per cent.

**6052.\* Per Cent Impedance Drop.**—The per cent impedance drop in a transformer is the ratio of the internal impedance drop at 75° C. to the secondary terminal voltage expressed in per cent.

**6053. Regulation of Constant-Potential Transformer.**—In constant-potential transformers, the regulation is the difference between the no-load and full-load values of the secondary terminal voltage at the specified power factor (with constant primary impressed terminal voltage) expressed in per cent of the rated-load secondary voltage, the primary voltage being adjusted to any value that the apparatus delivers rated output at rated secondary voltage. See § 6390.

**Ambient Temperature.**—See § 3000.

(6050-6051-6052) The internal drop in a transformer is the sum of the primary (reduced to secondary terms) and the secondary drop.

## RATING

## General

6201

TABLE 601

Limiting Observable Temperatures and Temperature Rises for Transformers Using Class A<sup>o</sup> Insulation

	† Air cooled and air blast	Oil cooled	Water cooled
Limiting observable temperature . . . . .	95° C.	95° C.	80° C.
Standard ambient temperature . . . . .	40° C.	40° C.	25° C.
Limiting observable temperature rise . . . . .	55° C.	55° C.	55° C.

\* For cotton, silk, paper and similar materials when neither treated, impregnated nor immersed in oil, the limits of the observable temperature rise shall be 15° C. below the limits fixed for these materials when impregnated.

† For exceptions in the case of Airblast Transformers, see § 6320 (b).

The temperature of the windings of transformers is always to be ascertained by Method 2.

6202. Limiting Observable Temperature of Oil (From § 2232). — The oil in which apparatus is permanently immersed shall, in no part, have a temperature, observable by thermometer, in excess of 90° C.

Permissible Temperatures of Insulations of More than One Class. — See 2104.

Temperatures of Metallic Parts of Transformers. — See § 2116.

Protection Against Short Circuit. — See § 2120.

Nominal Rating of Railway Substation Transformers. — See § 5201.

Expression of Rating. — See § 2202.

Institute Rating. — See § 2204.

6204.\* Rating of Protective Reactors. — Protective reactors shall be rated on the following characteristics:

(a) Kilovolt-amperes absorbed by normal current.

(b) Normal current, frequency and line (delta) voltage.

(c) Current which the device is required to stand under short-circuit conditions.

## Ambient Temperature of Reference

Ambient Temperature of Reference for Air. — See § 2216.

Ambient Temperature of Reference for Water-cooled Transformers. — See 2212.

Transformers Cooled by Other Means. — See § 2213.

Outdoor Transformers Exposed to Sun's Rays. — See § 2214.

## Altitude Correction

Altitude. — See § 2215.

6215. Exception to "Altitude." — See § 2215. — Water-cooled oil-immersed transformers are exempt from this reduction.

## Units in Which Rating Shall be Expressed

6221. Rating of Transformers. — The rating of transformers shall be expressed in kilovolt-amperes (kv-a.) available at the output terminals, at a specified frequency and voltage.

6225. Rating of Other Stationary Induction Apparatus. — Other stationary induction apparatus, such as auto-transformers, regulators, reactors, etc., shall have their ratings appropriately expressed. It is also essential to specify the voltage and frequency of the circuits on which the apparatus may be used.

(6204) Reactors shall be so designed as to be capable of withstanding the sudden application, without mechanical injury, of rated current at normal frequency.

## Kinds of Rating

Continuous Rating. — See § 2220.

Short-time Rating. — See § 2221.

Duty-cycle Operation. — See § 2222.

Standard Short-time Ratings. — See § 2223.

A. I. E. E. and I. E. C. Ratings. — See § 2224.

Continuous Rating Implied. — See § 2225.

6226. Nominal Ratings. — Nominal ratings are ratings which do not conform with §§ 2220 and 2221. They are sometimes used for railway substation transformers carrying traction loads. Transformers with nominal rating shall be capable of operating under the conditions enumerated in § 5301.

## Rating by Temperature Rise

Permissible Temperature Rises for Various Ambient Temperatures above Standard. — See § 2331 (c).

## TESTS

## Ambient Temperature

Measurement of Ambient Temperatures during Tests of Transformers. — See § 2300.

6300. Measurement of the Ambient Temperature During Tests of Water-cooled Transformers. — The temperature rise of water-cooled transformers shall be based entirely upon the temperature of the cooling water and it is not necessary to take into account the heat carried off by the air, unless it exceeds the amount specified below. If, under assumed standard conditions of water at 25° C., and air at 40° C., the amount of heat which would be carried off by the air is 15 per cent or more of the total, the temperature of the cooling water during test, should be maintained within 5° C. of that of the surrounding air. Where this is impracticable the ambient temperature should be determined from the change in the resistance of the windings, using a disconnected transformer, supplied with the normal amount of cooling water, until the temperature of the windings has become constant.

Oil Cup. — See § 2301.

## Transformer Temperatures

Temperature Rise for Any Ambient Temperature. — See § 2310.

Correction for the Duration of the Ambient Temperature of the Cooling Medium, at the Time of the Heat Test, from the Standard Ambient Temperature of Reference. — See § 2311.

6311.\* Correction for the Deviation of the Ambient Temperature of the Cooling Medium, at the Time of the Heat Test of Air-blast Transformers from the Standard Ambient Temperature of Reference. — A correction shall be applied to the observed temperature rise of the windings of air-blast transformers due to difference in resistance, when the temperature of the ingoing cooling air differs from that of the standard of reference. This correction shall be the ratio of the inferred absolute ambient temperature of reference to the inferred absolute temperature of the ingoing cooling air, *i.e.*, the ratio  $274.5 / (234.5 + \theta)$ ; where  $\theta$  is the ingoing cooling-air temperature.

Duration of Temperature Test of Transformers for Continuous Service. — See § 2312.

Duration of Temperature Test of Transformer with a Short-time Rating. — See § 2313.

Duration of Temperature Test for Transformer Having More than One Rating. — See § 2314.

Temperature Measurements During Heat Run. — See § 2315.

(6311) Thus, a cooling-air room temperature of 30° C. would correspond to an inferred absolute temperature of 264.5° on the scale of copper resistivity, and the correction to 40° C. ( $274.5^\circ$  inferred absolute temperature) would be  $274.5 / 264.5 = 1.04$ , making the correction factor 1.04; so that an observed temperature rise of say 50° C. at the ingoing ambient temperature of 30° C. would be corrected to  $50 \times 1.04 = 52^\circ$  C., this being the temperature rise which would have occurred had the test been made with the standard ingoing cooling-air temperature of 40° C.

**6317. Methods of Loading Transformers for Temperature Tests.**—(a) *General:* Whenever practicable, transformers should be tested under conditions that will give losses approximating as nearly as possible to those obtained under normal or specified load conditions, maintained for the required time. The maximum temperature rises measured during this test should be considered as the observable temperature rises for the given load. See §§ 2312 to 2314.

An approved method of making these tests is the *loading-back* method. The principal variations of this method are given in § 6317 (b), (c) and (d).

(b) *Loading-back with duplicate single-phase transformers:* Duplicate single-phase transformers may be tested in banks of two, with both primary and secondary windings connected in parallel. Normal magnetizing voltage should be applied and the required current circulated from an auxiliary source. One transformer can be held under normal voltage and current conditions while the other may be operating under slightly abnormal conditions.

(c) *Loading-back with one three-phase transformer:* One three-phase transformer may be tested in a manner similar to § 6317 (b) provided the primary and secondary windings are each connected in delta for the test. Normal three-phase magnetizing voltage should be applied and the required current circulated from an auxiliary single-phase source.

(d) *Loading-back with three single-phase transformers:* Duplicate single-phase transformers may be tested in banks of three in a manner similar to that described in § 6317 (c), by connecting both primary and secondary windings in delta, applying normal three-phase magnetizing voltage and circulating the required current from an auxiliary single-phase source.

(e) *Other Methods:* Among other methods that have a limited application and can be used only under special conditions may be mentioned:

Applying dead load by means of some form of rheostat.

Running alternately for certain short intervals of time on open circuit and then on short-circuit, alternating in this way until the transformer reaches a steady temperature. In this test, the voltage for the open-circuit interval and the current for the short-circuit interval shall be such as to give the same integrated core loss, and the same integrated copper loss as in normal operation.

**6320. Method of Temperature Measurement.**—(a) *Description:* The temperature of transformer windings shall be measured by their increase in resistance, corrected to the instant of shut-down when necessary, and by thermometers. Whichever measurement yields the higher temperature, that temperature shall be taken as the highest observable temperature by Method 2.

(b) In the case of air-blast transformers, it is important to have the thermometers well distributed and in good contact with the coils, and it is especially important to note the temperature near the air outlet. In measuring the temperature of air-blast transformers, the air supply shall be shut off immediately at the end of the temperature run and the air intake closed to prevent further admission of cooling air. With the above procedure, the observable temperature rise for air-blast transformers may attain a value not in excess of  $50^{\circ}$  C. as determined by thermometer, although it must not exceed  $55^{\circ}$  C. as determined by resistance.

(c) *Temperature Correction for Cooling of Transformer Windings after Shut-down:* Since a drop in temperature occurs in a winding between the instant of shut-down and the time of measuring the hot resistance, a correction shall be applied to the temperature determined from this measurement so as to obtain, as nearly as practicable, the temperature at the instant of shut-down. This correction may be determined approximately by plotting a time-temperature curve with temperatures as ordinates and times as abscissas and extrapolating back to the instant of shut-down.

In cases where successive measurements show increasing temperatures after shut-down the highest value shall be taken.

In certain cases, however, other correction factors may be applied as follows:

*Oil-Immersed Transformers:* For the purpose of simplifying the application of the rule to transformers when the weight of copper in each winding is known and the copper loss as determined by wattmeter measurement does not exceed 10 watts per pound, the extrapolation method has been reduced to the following

under ordinary conditions of testing. The correction in degrees C. shall be the product of the watts loss per pound of copper for each winding multiplied by a factor depending upon the time elapsed between shut-down and the time of the temperature reading as given in the following table:

Time in minutes	Factor
1	0.19
2	0.33
3	0.43
4	0.50

For intermediate times, the value of the factor can be obtained by interpolation.

When the copper loss, measured by wattmeter, does not exceed 7 watts per pound an arbitrary correction of one degree per minute may be used provided the time elapsed between the instant of shut-down and the measurement of the hot resistance does not exceed four minutes.

For determining the copper loss in watts per pound, the total loss in both windings as measured by the wattmeter should be apportioned between the high- and low-voltage windings in the same ratio as their respective  $I^2R$  losses.

**Air-blast Transformers:** An arbitrary correction of one degree per minute may be used provided the time elapsed between the instant of shut-down and the measurement of the hot resistance does not exceed four minutes.

(d) *Covering of Thermometers:* Thermometers used for taking the temperature of air-cooled or air-blast transformers shall have their bulbs covered in protection from air currents. This shall be done by felt pads, approximately 4 cm. X 5 cm. (1½ in. X 2 in.) and 3 mm. (¼ in) thick, except that where pads are inconvenient, as in ventilating ducts between coils, grooved wooden staves may be used.

**Temperature Coefficient of Copper.** — See § 2331.

#### Efficiency

**Efficiencies Recognized.** — See § 2331.

**Normal Conditions for Efficiency Tests.** — See § 2332.

**Direct Measurement of Efficiency.** — See § 2333.

**6334. Classification of Losses.** — (a) *General:* Losses are classified as shown below.

(b) *No-load Losses:* No-load losses include the core loss, the  $I^2R$  loss due to the exciting current and the dielectric loss in the insulation.

(c) *Load Losses:* Load losses include  $I^2R$  losses, and stray load losses due to eddy-currents caused by fluxes varying with load.

**6335. Losses to be Considered in Transformers.** — Conventional efficiency shall be based upon the losses listed in § 6334 and these losses shall be measured as specified in §§ 6336 and 6337.

**6336. No-load Losses.** — The no-load losses shall be measured with open secondary circuit at the rated frequency, and with an applied primary voltage giving the rated secondary voltage plus the  $IR$  drop which occurs in the secondary under rated-load conditions.

**6337. Load Losses.** — The load losses include  $I^2R$  and stray load losses. They shall be measured by applying a primary voltage, at rated frequency, sufficient to produce rated load current in the windings, with the secondary windings short-circuited.

#### Wave Shape

**Standard Wave Shape.** — See § 2340.

#### Tests of Dielectric Strength

**Condition of Transformers to be Tested.** — See § 2350.

**Where High-voltage Tests are to be Made.** — See § 2351.

**Temperatures at which High-voltage Tests are to be Made.** — See § 2352.

**Points of Application of Voltage.** — See § 2353.

**Frequency and Wave Form of Test Voltage.** — See § 2354.

**Duration of Application of Test Voltage.** — See § 2355.

**336. Standard Test Voltage.**—(From § 2356.) *General:* The standard test voltage for all machines, except as otherwise specified, shall be twice the normal voltage of the circuit to which the machine is connected plus 1000 volts, exception § 6361.

**339. Transformers for Star Connection.**—Transformers which may be used in star connection on three-phase circuits shall be tested on the basis of the line voltage for which they are rated. See § 6361(f).

**361.\* Exceptions to Standard Test Voltage Given in Section 3336.**—(a) *Distributing Transformers:* Transformers for primary pressures from 550 to 6000 volts, the secondaries of which are directly connected to consumer's circuits and commonly known as distributing transformers, shall be tested with 500 volts from primary to core and secondary combined. The secondary windings shall be tested with twice their normal voltage plus 1000 volts.

(b) *Auto-transformers:* Auto-transformers used for starting purposes, shall be tested with the same voltage as the test voltage of the apparatus to which they are connected.

(c) *Household Devices:* Transformers taking not over 560 watts and intended for operation on supply circuits not exceeding 275 volts, shall be tested with 1900 volts.

(d) *Transformers for Use on Circuits of 25 Volts or Lower:* Transformers for use on circuits of 25 volts or lower, such as bell-ringing apparatus, shall be tested with 500 volts.

(e) *Alternating-current Transformers Connected to Permanently Grounded Single-phase Systems, for use on Permanently Grounded Circuits of more than 300 Volts:* Transformers used under these conditions shall be tested with 2.73 times the voltage of the circuit to ground plus 1000 volts. This does not refer to three-phase transformers operating with grounded neutral.

(f) *Transformers to be used on Star-connected Three-phase Circuits:* Transformers which may be used in star connection on three-phase circuits shall have line to line (as distinguished from line to neutral) voltage of the circuits on which they may be used indicated on the rating plate and the test shall be based on line to line voltage. See § 6360.

(g) *Testing Transformers:* Rules do not apply to testing transformers, for which no definite rule has yet been established.

(h) *Protective Reactors:* Protective reactors shall be tested from conductors to ground with 2000 volts plus  $2\frac{1}{4}$  times the line voltage.

**362.\* Testing Transformers by Induced Voltage.**—Under certain conditions it is permissible to test transformers by inducing the required voltage in the windings in place of using a separate testing transformer. By "required voltage" is meant a voltage such that the line end of the winding shall receive a voltage to ground equal to that required by the general rules.

**363. Transformers with Graded Insulation.**—Where transformers have been graded insulation they shall be so marked. They shall be tested by inducing the required test voltage in the transformer and connecting the successive line to ground.

Transformer windings permanently grounded within the transformer shall be tested by inducing the required test voltage in such windings. See § 6361.

Use of Voltmeter and Spark-gaps in Dielectric Tests. — See § 2359.

Use of Spark-gap with Transformers of Low Capacitance. — See § 2360.

Use of Spark-gap with Transformers of High Capacitance. — See § 2361.

Measurements with Voltmeter. — See § 2362.

Measurements with Spark-gap. — See § 2363.

361 d) This rule does not include bell-ringing transformers of ratio 125 to 6 volts.

362) This test can be made by connecting the windings of two or more transformers in series, with one end of the series grounded and a voltage impressed such as will give the line from the free end to ground required by the above rule.

361 a) This method is not generally applicable for shop tests, particularly on large transformers.

## Regulation

Conditions for Tests of Regulation. — See § 2390.

§2390. Conditions for Test of Regulation. — (a) *Frequency*: The regulation of transformers is to be determined at constant frequency.

(b) *Power Factor*: In transformers, the power factor of the load to which the regulation refers should be specified. Unless otherwise specified, it shall be understood as referring to non-inductive load, that is, to a load in which the current is in phase with the e.m.f. at the output side of the transformer. See § 2390.

§2391.\* Tests and Computation of Regulation. — (a) *Method I. By Loading*: The regulation of a constant potential transformer can be determined by loading the transformer and measuring the change in voltage with change in load, at the specified power factor.

(b) *Method II. From Impedance Watts and Volts*: The regulation of a constant potential transformer for any specified load and power factor can be computed from the measured impedance watts and impedance volts as follows:

Let  $P$  = impedance watts, as measured in the short-circuit test,

$E_s$  = impedance volts, as measured in the short-circuit test,

$P_{75}$  = impedance watts, as measured in the short-circuit test, and corrected to 75° C.,

$IX$  = Reactance Drop in Volts,

$I$  = Rated Primary Current,

$E$  = Rated Primary Voltage,

$q\%$  = per cent drop in phase with current,

$qz\%$  = per cent drop in quadrature with current,

$$IX = \sqrt{E_s^2 - \left(\frac{P}{I}\right)^2}$$

$$q\% = 100 \frac{P_{75}}{EI}$$

$$qz\% = 100 \frac{IX}{E}$$

Then:

For unity power factor, we have approximately,

$$\text{Per cent regulation} = q\% + \frac{qz^2}{200}$$

For inductive loads of power-factor  $w$  and reactive-factor  $z$ ,

$$\text{Per cent regulation} = wq\% + wqz\% + \frac{(wqz - wq\%z)^2}{200}$$

## CONSTRUCTION

## Rating Plates

Marking of Rating Plates. — See § 2401.

## Transformer Connections

(These rules do not apply to auto-transformers)

General:

§402.\* Scope. — These rules specify the markings of leads brought out of the case but not the markings of winding terminals inside of the case, except that these terminals shall be marked with numbers in any manner that will permit of convenient reference and that cannot be confused with the markings of the leads brought out of the case.

(§402) It is recognized that special cases will arise from time to time that these rules will not cover and that it would be very difficult to cover by any set of general rules.

## TRANSFORMER LEAD MARKINGS SINGLE-PHASE TRANSFORMERS

SUBTRACTIVE POLARITY

Note. — The above figures illustrate the application of the rules on lead markings to transformers having subtractive and additive polarity.

402.\* **Markings of Leads.** — \*(a) *General:* The leads shall be distinguished from one another by marking each lead with a capital letter followed by a number. The letters to be used are: *H* for high-voltage leads, *X* (or low-voltage leads) and *Y* for tertiary winding leads. The numbers to be used are 1, 2, 3.

403 a) By "tertiary winding" is meant a third winding that, compared with both of other two windings, has smaller kv-a. rating than either or, if the kv-a. rating is the same as one or both of the other two, has lower voltage. *E.g.*, if a transformer has three rate windings, one for 1000 kv-a., 33,000 volts, one for 600 kv-a., 550 volts and one for kv-a. 6,600 volts, the 400 kv-a. winding is the tertiary winding; or, if a transformer has three separate windings each with a capacity of 1,000 kv-a., and with voltages of 20, 6,600 and 550 volts respectively, the 550-volt winding is the tertiary winding. According to this definition neither one of two similar windings arranged for series-parallel connection is to be classed as a tertiary winding.

(b) *Neutral Lead*: A neutral lead shall be marked with the proper letter followed by *O*, e.g., *HO*, *XO*.

6404. *Diagrammatic Sketch of Connections*. — The manufacturer shall furnish with each transformer a complete diagrammatic sketch showing the leads and internal connections and their markings and the voltages obtainable at the various connections.

This sketch should preferably be on a metal plate attached to the transformer case.

#### Single-phase Transformers:

6405. *Order of Numbering Leads in any Winding*. — The leads of any winding (high-voltage, low-voltage or tertiary) brought out of case shall be numbered 1, 2, 3, 4, 5, etc., the lowest and highest numbers marking the full winding and the intermediate numbers marking fractions of winding or taps. All numbers shall be so applied that the potential difference from any lead having a lower number toward any lead having a higher number shall have the same sign at any instant.

### TRANSFORMER LEAD MARKINGS AND VOLTAGE VECTOR DIAGRAMS FOR THE USUAL THREE-PHASE TRANSFORMER CONNECTIONS

THREE PHASE TRANSFORMERS WITHOUT TAPS

	FIG. 8-9	FIG. 8-10
GROUP - 3 ANGULAR DISPLACEMENT 30°		
	FIG. 8-11	FIG. 8-12
ANGULAR DISPLACEMENT 30°		
	FIG. 8-13	FIG. 8-14
THREE PHASE TRANSFORMERS WITH TAPS		
GROUP - 3 ANGULAR DISPLACEMENT 30°		
	FIG. 8-15	

Note. — The above figures are included to illustrate the method of marking transformer leads that are brought out of the case and are not intended to standardize sections, vector diagrams or polarity.

(6403 b) A lead brought out from the middle of a winding for some other use, that of neutral lead, e.g., a corner cent starting tap, shall be marked as a tap lead.

a winding is divided into two or more parts for series-parallel connections, the leads of these parts are brought out of case, the above rule shall apply to series connection with the addition that the leads of each portion of winding shall be given consecutive numbers. See Figs. 6-5 and 6-6.

66. Relation of Order of Numbering Leads of Different Windings. — The numbering of the high-voltage and low-voltage leads shall be so applied that  $H_1$  and  $X_1$  are connected together and voltage applied to the transformer, voltage between the highest numbered  $H$  lead and the highest numbered  $X$  lead shall be less than the voltage of the full high-voltage winding.

The same relation shall apply between high-voltage and tertiary and low-voltage and tertiary winding.

67. Polarity. — When leads are marked in accordance with the above rules, polarity of a transformer is:

Positive when  $H_1$  and  $X_1$  are adjacent. See Figs. 6-7, 6-8 and 6-9.

Negative when  $H_1$  is diagonally located with respect to  $X_1$ . See Figs. 6-2, and 6-6.

68. Location of  $H_1$  Lead. — To simplify the work of connecting transformers in parallel it is recommended that the  $H_1$  lead shall be brought out on right-hand side of the case, facing high-voltage side of the case.

#### TRANSFORMER LEAD MARKINGS AND VOLTAGE VECTOR DIAGRAMS FOR THE USUAL SIX-PHASE TRANSFORMER CONNECTIONS

		SIX PHASE TRANSFORMERS WITHOUT TAPS			
GROUP - 4	ANGULAR REPLACEMENT 0°				
		FIG. 6-10	FIG. 6-17		
GROUP - 5	ANGULAR REPLACEMENT 30°				
		FIG. 6-18	FIG. 6-19		
		SIX PHASE TRANSFORMERS WITH TAPS			
GROUP - 5	ANGULAR REPLACEMENT 30°				
		FIG. 6-20	FIG. 6-21		

2. — The above figures are included to illustrate the method of marking transformer leads that are brought out of the case and are not intended to standardize connection, vector diagrams or polarity.

69. Parallel Operation. — Transformers having leads marked in accordance with these rules may be operated in parallel by connecting similarly marked together, provided their ratio, voltages, resistances and reactances are such permit parallel operation.

70. In some cases design may be such as to permit parallel operation, although the difference in the number of tap leads, the leads to be connected together may not be the same number.

**Three-phase Transformers:**

**6410. Marking of Full Winding Leads.**— The three high-voltage leads and the three low-voltage leads which connect to the full-phase windings shall be marked  $H_1, H_2, H_3$  and  $X_1, X_2, X_3$ . The full-phase winding of a tap winding shall be marked  $Y_1, Y_2, Y_3$ .

**6411.\* Relation between High-voltage and Low-voltage Windings.**— *General:* The markings shall be so applied that if the phase sequence of volt on the high-voltage side is in the time order  $H_1, H_2, H_3$  it is in the time order of  $X_1, X_2, X_3$  on the low-voltage side and  $Y_1, Y_2, Y_3$  for a tertiary winding.

*(b) Angular Displacement:* In order that the markings of lead connect between phases shall indicate definite phase relations, they shall be made accordance with one of the three three-phase groups as shown. The angular displacement between the high-voltage and low-voltage windings is the same in each of the voltage vector diagrams (Figs. 6-7 to 6-14 inclusive) between lines passing from its neutral point through  $H_1$  and  $X_1$  respectively.

**6412. Tap Leads.**— (a) *General:* Where tap leads are brought out of case (neutral lead excepted) they shall be marked with the proper letter followed by the numbers, 4, 7, etc., for one phase, 5, 8, etc., for another phase and 6, 9 for the third phase. See Fig. 6-15.

(b) *Delta Connection:* The order of numbering tap leads shall be as follows: 4, 7, etc., from lead 1 toward lead 2; 5, 8, etc., from lead 2 toward lead 3; 6, 9, etc., from lead 3 toward lead 1. See Fig. 6-15.

(c) *Star Connection:* The order of numbering tap leads shall be as follows: 4, 7, etc., from lead 1 towards neutral; 5, 8, etc., from lead 2 towards neutral and 6, 9, etc., from lead 3 towards neutral. See Fig. 6-15.

**6413. Interphase Connection Made Outside of Case.**— Where the interphase connections are made outside of case, the leads shall be marked with the proper letter followed by the numbers 1, 4, 7, 10, etc., for one phase; 2, 5, 8, 11, etc., for the second phase; and 3, 6, 9, 12, etc., for the third phase.

The markings shall be so applied that when a star connection is made joining together the highest numbered leads of each phase, all rules hereof excepting § 6403 (b) apply.

**6414.\* Parallel Operation.**— Transformers having leads marked in accordance with these rules may be operated in parallel by connecting similarly marked leads together provided their angular displacements are the same and also their ratios, voltages, resistances, and reactances are such as to permit parallel operation.

**6415. Location of H1 Lead.**— To simplify the work of connecting transformers in parallel it is recommended that the  $H_1$  lead shall be brought out of the right-hand side of the case, facing the high-voltage side of the case.

**Three-Phase to Six-phase Transformers:**

**6416. Rules that are Applicable for Three-Phase Transformers.**— Sections 6411 (b) and 6413 shall apply to three-phase to six-phase transformers. Sections 6410 and 6412 shall apply to three-phase windings but not to six-phase windings.

**6417. Markings of Six-phase Leads.**— The six leads which connect to full-phase windings shall be marked  $X_1, X_2, X_3, X_4, X_5, X_6$ . See Figs. 6-16 to 6-19 inclusive.

**6418. Relation between Three-phase and Six-phase Windings.**— *General:* The markings shall be so applied that if the phase sequence of volt

(6411 b) Any three-phase transformer having a delta-Y connection may be represented by voltage vector diagram in accordance with Fig. 6-11 or Fig. 6-12. A three-phase transformer having Y-delta connection may be represented by voltage vector diagram either in accordance with Fig. 6-12 or Fig. 6-14. Since these voltage vector diagrams are equivalent, it is recommended that the terminal markings for three-phase transformers having delta-Y connection be always made in accordance with Fig. 6-11; that the terminal markings for three-phase transformers having Y-delta connection always be made in accordance with Fig. 6-12.

(6414) In some cases designs may be such as to permit parallel operation although due to a difference in the number of tap leads, the leads to be connected together are not similarly marked.

the three-phase side is in the time order  $H_1, H_2, H_3$ , it is in the time order  $X_1, X_2, X_3, X_4, X_5, X_6$  on the six-phase side.

b) *Angular Displacement*: In order that the markings of lead connections between phases shall indicate definite phase relations, they shall be made in accordance with one of the four six-phase groups shown in Figs. 6-16 to 6-19 inclusive. The angular displacement between the high-voltage and low-voltage windings is the angle in each of the voltage vector diagrams from its trail through  $H_1$  and  $X_1$  respectively.

619.\* *Tap Leads*. — (a) *General*: Where tap leads from low-voltage windings are brought out of the case (neutral lead excepted), they shall be marked as follows:

§ *Diametrical Connection*: Diametrical connection tap leads shall be led from the two ends of each phase winding towards the middle or neutral point in the following order:  $X_7, X_{13}$ , etc., from  $X_1$  towards neutral;  $X_8, X_{14}$ , etc., from  $X_2$  towards neutral;  $X_9, X_{15}$ , etc., from  $X_3$  towards neutral;  $X_{10}, X_{16}$ , etc., from  $X_4$  towards neutral;  $X_{11}, X_{17}$ , etc., from  $X_5$  towards neutral;  $X_{12}, X_{18}$ , etc., from  $X_6$  towards neutral. See Fig. 6-20.

§ *Tap from the middle point of any phase winding, not intended as a neutral*, shall be given a number determined by counting from  $X_1, X_2$  or  $X_3$  and not from  $X_4, X_5$ , or  $X_6$ ; e.g., if the only taps brought out are 50 per cent starting from the middle point, they shall be numbered  $X_7, X_8$ , and  $X_9$ .

§ *Double Delta Connection*: Tap leads shall be marked in the following order:  $X_7, X_{13}$ , etc., from  $X_1$  towards  $X_3$ ;  $X_8, X_{14}$ , etc., from  $X_2$  towards  $X_4$ ;  $X_9, X_{15}$ , etc., from  $X_3$  towards  $X_5$ ;  $X_{10}, X_{16}$ , etc., from  $X_4$  towards  $X_6$ ;  $X_{11}, X_{17}$ , etc., from  $X_5$  towards  $X_1$ ;  $X_{12}, X_{18}$ , etc., from  $X_6$  towards  $X_2$ . See Fig. 6-21.

## CHAPTER VII

### STANDARDS FOR SWITCHING, CONTROL AND PROTECTIVE APPARATUS

The A. I. E. E. Standards for Switching Control and Protective Apparatus are the General Standards shown in Chapters II and III and the Standards in Chapters IV and V which are applicable to the devices involved, together with the modifications and extensions given in this Chapter.

419 c) For starting purposes it is generally customary to bring out only two taps from one delta and start three-phase.

## DEFINITIONS

## Devices—General

**7000.\* Switching and Control Apparatus.** — For the purpose of these Standardization Rules switching and control apparatus is defined as electric apparatus whose function is primarily to control or protect in some predetermined manner an electric apparatus to which it is connected.

**7001. Switch.** — A switch is a device for making, breaking or changing connections in an electric circuit.

**7002. Master-switch.** — A master-switch is a switch which serves to govern the operation of contactors and auxiliary devices of an electric controller.

**7003. Control Switch.** — A control switch is a switch for controlling electrically-operated switches and circuit breakers.

**7004. Auxiliary Switch.** — An auxiliary switch is a switch actuated by the main device, for signalling, interlocking, etc.

**7005. Circuit Breaker.** — A circuit breaker is a device (other than a fuse) constructed primarily for the interruption of a circuit under *irregular* conditions.

**7006. Contactor.** — A contactor is a device for repeatedly establishing and interrupting an electric circuit under normal conditions.

**7007.\* Electric Controller.** — An electric controller is a device, or group of devices, which is designed to control in some predetermined manner the operation of the apparatus to which it is connected.

**7008.\* Motor-starter.** — A motor-starter is an electric controller designed for accelerating a motor to normal speed in one direction of rotation.

**7009. Automatic Motor-starter.** — An automatic motor-starter is a motor-starter designed to automatically control the acceleration of a motor.

**7010. Auto-transformer Motor-starter.** — An auto-transformer motor-starter is a motor-starter having an auto-transformer to furnish a reduced voltage for starting. The device includes the necessary switching mechanism, and is frequently called a Compensator or Auto-starter.

**7015.\* Fuse.** — A fuse is an element designed to melt or dissipate at a predetermined current value, and intended to protect against abnormal conditions of current.

**7016. Electric Protective Relay.** — An intermediate device, equipped with contacts to open or close an auxiliary circuit, by means of which one circuit is indirectly controlled by a change in conditions in the same or other circuit.

**7017. Rheostat.** — A rheostat is a resistor which is provided with means for readily varying its resistance. See § 3064.

**7018. Protective Reactor.** — A protective reactor (See § 3078) is a device for protecting circuits by limiting the current flow and localizing the damage under short-circuit conditions.

(7000) The "National Electrical Code" of the National Fire Protection Association deals with certain circuit breakers up to 550 volts rating and switches and fuses up to 600 volts rating fuses.

(7007) A switch (see § 7001) should not be called a controller.

(7008) A device designed for starting a motor in either direction of rotation is called a controller (see § 7007).

(7015) Any terminals, tubes, etc., integral with this element are included as part of the fuse.

Fuses may be divided into two classes:

(a) Those designed to protect the circuit and apparatus both against short-circuits and against definite amounts of overload (e.g. fuses of the National Electric Code which blow on overload in excess of 10 per cent).

(b) Those designed to protect the system only against short-circuits; (e.g. expulsion fuses, which blow at several times the current which they are designed to carry continuously). The line separating these two classes is not definitely fixed.

**7019.\* Lightning Arrester.**—A lightning arrester is a device for protecting circuits and apparatus against lightning or other abnormal potential rises of short duration.

**7020. Under-voltage or Low-voltage Release Switching and Control Apparatus.**—Under-voltage or low-voltage release switching and control apparatus is apparatus which, on the reduction or failure of voltage, operates to cause the interruption of power to the main circuit, but which does not prevent the re-establishment of the main circuit on return of voltage.

**7021. Under-voltage or Low-voltage Protection Switching and Control Apparatus.**—Under-voltage or low-voltage protection switching and control apparatus is apparatus which, on the reduction or failure of voltage, operates to cause and maintain the interruption of power to the main circuit.

**7022. Phase-failure Protection Switching and Control Apparatus.**—Phase-failure protection switching and control apparatus is apparatus which, on the occurrence of power in one wire of a polyphase circuit, operates to cause and maintain the interruption of power on the circuit.

**7023. Phase-reversal Protection Switching and Control Apparatus.**—Phase-reversal protection switching and control apparatus is apparatus which, on the reversal of the phase relations in a polyphase circuit, operates to cause and maintain the interruption of power on the circuit.

#### Electric Protective Relays—Classified According to Functions

**7024. Directional Relay.**—Any relay which functions in conformance with the direction of power or voltage or current or phase rotation, etc.

**7027. Power-Directional Relay.**—Any relay which functions in conformance with the direction of power.

**7028.**—This includes both unidirectional relays with single-throw contacts and bidirectional relays with double-throw contacts. The reason this name is given to "reverse power" is that the device is frequently used to function in either normal direction of power. Furthermore, in some cases, the normal direction of the system may permit power to flow in either direction. Relays used in either alternating or direct-current circuits are to be classed as power-directional relays.

**7029. Polarity-directional Relay.**—Any relay which functions by reason of the sense of the direction of polarity.

**7029. Phase-rotation Relay.**—Any relay which functions by reason of the sense of the direction of phase rotation.

**7030. Current Relay.**—Any relay which functions at a predetermined value of the current. These may be either over-current relays or under-current relays.

**7031. Voltage Relays.**—Any relay which functions at a predetermined value of the voltage. These may be either over-voltage relays or under-voltage relays.

**7032. Power Relay.**—Any relay which functions at a predetermined value of the power. These may be either over-power relays or under-power relays.

**7033. Frequency Relay.**—Any relay which functions at a predetermined value of the frequency. These may be either over-frequency relays or under-frequency relays.

**7034. Temperature Relay.**—Any relay which functions at a predetermined temperature in the apparatus protected.

**7035. Open-phase Relay.**—Any relay which functions by reason of the opening of one phase of a polyphase circuit.

7019) Lightning arresters may be divided into two classes:

a) Those intended to discharge for a very short time.

b) Those intended to discharge for a period of several minutes.

**7000. Differential Relay.** — Any relay which functions by reason of the difference between two quantities, such as current or voltage, etc.

**NOTE.**—This term includes relays heretofore known as "ratio balance relays," "biased," and "percentage differential relays."

#### Electric Protective Relays—Classified According to Applications

**7040. Locking Relay.** — Any relay which renders some other relay or other device inoperative under predetermined values of current or voltage, etc.

**7041. Trip-free Relay.** — Any relay which prevents holding in an electrically operated device, such as a circuit breaker, while an abnormal condition exists in the circuit.

**7042. Auxiliary Relay.** — Any relay which assists another relay in the performance of its function and which operates in response to the opening or closing of its operating circuit.

**7043. Signal Relay.** — An auxiliary relay which operates an audible or visible signal.

#### Electric Protective Relays—General Qualifying Terms

**7000. Notching.** — A qualifying term applied to any relay, indicating that number of separate impulses are required to complete operation.

**7051. Inverse Time.** — A qualifying term applied to any relay indicating that there is purposely introduced a delayed action, which delay decreases as the operating force increases.

**7052. Definite Time.** — A qualifying term applied to any relay indicating that there is purposely introduced a delayed action, which delay remains substantially constant regardless of the magnitude of the operating force. If forces slightly above the minimum operating value, the delay may be inversely proportional to the force.

**7053. Instantaneous.** — A qualifying term applied to any relay indicating that no delayed action is purposely introduced.

**7054. Use of Terms.** — Where relays operate in response to changes in more than one condition, all functions should be mentioned.

#### Characteristics of Devices—General

**7000. "Air" as a Prefix.** — The prefix "air" applied to a device which interrupts an electric circuit indicates that the interruption occurs in air.

**7001. "Oil" as a Prefix.** — The prefix "oil" applied to a device which interrupts an electric circuit indicates that the interruption occurs in oil.

**7002. Fume-resisting.** — Fume-resisting switching and control apparatus is apparatus so constructed that it will not be readily injured by the specified fumes.

**7003.\* Drip-proof.** — Drip-proof switching and control apparatus is apparatus so protected as to exclude falling moisture or dirt.

**7004. Dust-proof.** — Dust-proof switching and control apparatus is apparatus so constructed or protected that the accumulation of dust within or without the device will not interfere with its successful operation.

**7005. Dust-tight.** — Dust-tight switching and control apparatus is apparatus so constructed that the dust will not enter the enclosing case.

**7006. Explosion-proof.** — Explosion-proof switching and control apparatus is apparatus so constructed that explosions of gas within the casing will not injure it or ignite inflammable gas outside it.

**7007. Gas-proof.** — Gas-proof switching and control apparatus is apparatus so constructed or protected that the specified gas will not interfere with successful operation.

(7003) Drip-proof apparatus may be either open or semi-enclosed, if it is provided with suitable protection integral with the apparatus, or so enclosed as to exclude effectively falling solid or liquid material.

**808. Gas-tight.**—Gas-tight switching and control apparatus is apparatus constructed that the specified gas will not enter the enclosing case.

**809. Moisture-resistant.**—Moisture-resistant switching and control apparatus is apparatus so constructed or treated that it will not be readily injured by moisture. (Such apparatus shall be capable of operating in a very humid atmosphere, such as found in mines, evaporating rooms, etc.).

**810. Splash-proof.**—Splash-proof switching and control apparatus is apparatus so constructed or protected that external splashing will not interfere with its successful operation.

**811. Submersible.**—Submersible switching and control apparatus is apparatus so constructed that it will operate successfully when submerged in water under specified conditions of pressure and time.

**812. Sleet-proof.**—Sleet-proof switching and control apparatus is apparatus so constructed or protected that the accumulation of sleet will not interfere with its successful operation.

#### Parts of Devices—General

**800. Conducting Parts.**—Conducting parts of switching and control apparatus are those designed to carry current or which are conductively connected therewith.

**801. Contact.**—A contact is a surface common to two conducting parts, held by pressure, for the purpose of carrying current.

**802. Magnet Brake.**—A magnet brake is a friction brake controlled by electromagnetic means.

**803. Grounded Parts.**—Grounded parts are those parts which may be connected to have the same potential as the earth.

#### Properties of Devices—General

**804. Interrupting Rating.**—Interrupting (breaking or rupturing) rating is rating based upon the r.m.s. current at normal voltage which the device can interrupt under prescribed conditions at stated intervals a specified number of times.

### OPERATION

#### Temperature Limits

**7101.\* Circuit Breakers, Relays and Switches.**—The maximum observable temperature rises of the various parts of circuit breakers, relays and switches shall not exceed the following limits for ambient temperatures up to and including, but not greater than 40° C. See § 7301.

Contacts in air when clean and bright.....	30° C.
Contacts in oil.....	30° C.
Motors.....	40° C.
Potential Coils, Class O insulation.....	35° C.
Series Coil, Class O insulation.....	50° C.
Series and Potential Coils, Class A insulation.....	50° C.
Series and Potential Coils, bare or Class B insulation.....	70° C.
All other parts.....	70° C.

**7102. Magnetic Contactors.**—The maximum observable temperature rises of the various parts of magnetic contactors shall not exceed the following limits

7101) The Institute calls attention to the inherent decrease in current which can be carried by switch and circuit-breaker contacts in air, due to oxidation of the contact faces. The rating of air switches and circuit breakers is, therefore, based on sufficient maintenance to keep the temperature rise within the specified limits. Relays which form part of controllers are to have the temperature limits specified in § 7102.

for ambient temperatures up to and including but not greater than 40° C. § 7302.

Laminated contacts.....	65° C.
Operating oils.....	70° C.
Solid contacts.....	100° C.
Current-carrying parts insulated with asbestos or other fireproof material.....	150° C.

**7105.\* Fuses.** — The maximum observable temperature rise of coils or windings, measured by thermometer, shall not exceed the following limits for ambient temperatures up to and including but not greater than 40° C.

If insulation is of unimpregnated fibrous material.....	35° C.
If insulation is of fibrous material treated to withstand heat.....	50° C.
If insulation is of asbestos, mica or similar heat-resisting material with a cotton binder.....	70° C.

**7106. Cast Grid Resistors.** — The maximum observable temperature rise of cast grids used as resistors shall not exceed 350° C. for ambient temperatures up to and including but not greater than 40° C.

## RATING

### Expression of Rating

**7201. Rating of Circuit Breakers and Switches.** — The rating of a circuit breaker or switch shall include the following items:

- the normal r.m.s. current which it is designed to carry.
- the normal r.m.s. voltage of the circuit on which it is intended to operate.
- the normal frequency of the current.
- the interrupting rating of the device. See § 7060.

**7202. Continuous Current-carrying Capacity of Fuses.** — Fuses shall be constructed that they will carry continuously 110 per cent of their rated current.

**7203. Rating of Lightning Arresters.** — The rating of a lightning arrester shall be the voltage of the circuit on which it is to be used.

## TESTS

### Heat Tests

**7301. Circuit Breakers, Relays and Switches.** — The rated current of circuit breakers, relays and switches at rated frequency shall be applied continuously until the temperature becomes constant. The temperature rises measured by thermometer or thermocouple (Method No. 1) placed on the surface of the parts to be measured shall not exceed the limits specified in § 7103.

The ambient temperature shall be determined by taking the average of readings of three thermometers placed as follows:

- One 12 inches above;
- One 12 inches below;
- One midway but 12 inches from the breaker as installed.

**7302. Magnetic Contactors.** — The rated current of magnetic contactors at rated frequencies shall be applied continuously or until the temperature becomes constant when continuous duty is specified. It shall be applied for the specified length of time when given a short time rating. The temperature rises measured by thermometer shall not exceed the limits specified in § 7103.

### Tests of Dielectric Strength

**7303.\* Standard Test Voltage.** — (a) *Apparatus rated at 600 volts or less.* The standard test voltage for all switching and control apparatus rated at 600 volts or less shall be twice the normal voltage of the circuit to which the apparatus is to be connected plus 1000 volts.

(7105) Coils or windings such as accompany fuses of the magnetic blow-out type.  
 (7303) This assumes a precipitation of 1/10th inch (2.54 mm.) per minute at an angle of 45° from the perpendicular with water having a resistivity as low as 7000 ohm-cm.

- 3) *Apparatus rated above 600 volts:* Apparatus rated above 600 volts shall be tested at  $2\frac{1}{2}$  times rated voltage, plus 2000 volts, at a specified altitude. As a supplementary test, devices for outdoor use should be capable of withstanding for 10 seconds a dielectric wet test at twice rated voltage plus 1000 volts.
- 4) *Auto-Transformers for Motor-starters:* Auto-transformers for motor-starters shall be tested with the same voltage as the test voltage of the apparatus to which they are to be connected.

#### Tests of Lightning Arresters.

71. *Resistance.* — The resistance of the arrester at double potential and at normal potential, shall be determined by observing the discharge currents through the arrester.
72. *Arrester with Gap.* — In the case of any arrester using a gap, a test shall be made of the spark potential on either direct-current or 60 cycle a-c. excitation.
73. *Equivalent Sphere Gap.* — The equivalent sphere gap under disruptive charge shall be measured, using a considerable quantity of electricity.
74. *Continuous Surges.* — The endurance of the arrester to continuous surges shall be tested.
75. *Dielectric Strength.* — See §§ 2355 and 7373.

## CHAPTER VIII

### STANDARDS FOR METERS, INSTRUMENTS AND INSTRUMENT TRANSFORMERS

The A.I.E.E. Standards for Meters, Instruments and Instrument Transformers are the General Standards shown in Chapters II and III, and the Standards in other Chapters which are applicable to the devices involved, together with modifications and extensions given in this Chapter.

#### DEFINITIONS

- 100.<sup>a</sup> *Meter.* — A meter is a device which registers through a totalizing mechanism, the integral, with respect to time, of the electrical quantity to which it responds. (This definition does not preclude the general use of "meter" as a prefix or in compound words, to mean a "measuring device.")
- 101.<sup>b</sup> *Instrument.* — An instrument is a device which indicates or records the present value of the quantity under observation.
102. *General Nomenclature.* — In general, the names of meters and instruments are self-defining. The following names are preferred to others some-

100 and 1001) While the word "instrument" is a general term which may properly include indicating, integrating and recording devices, there is a tendency to restrict its use to indicating devices and to recording (graphic or curve drawing) devices. Integrating devices are then denoted by the word "meter." This distinction gives rise to the above definitions.

times used for the same devices: Reactive-factor Meter, Power-factor Meter, Watthour Meter, Reactive Volt-Ammeter (or Reactive Volt-ampere Indicator) etc.

**8003. Recording Instruments.**—Recording ammeters, voltmeters, wattmeters, etc., are instruments which record graphically, upon time charts, the values of the quantities they measure.

**8004.\* Crest Voltmeter.**—A crest voltmeter is a voltmeter depending for its indications upon the crest, or maximum value of the voltage of the system to which it is connected. Crest voltmeters shall be marked in true crest volts as also in the r.m.s. value of the sinusoidal wave having the same crest rate (See § 2362.)

**8005. Synchronoscope (also called a Synchroscope or Synchronization Indicator).**—A synchronoscope is a device which indicates synchronism between two machines, and in addition shows whether the incoming machine is fast or slow.

**8006. Line-drop Voltmeter Compensator.**—A line-drop voltmeter compensator is a device used in connection with a voltmeter which causes the needle to indicate the voltage at some distant point of the circuit.

**8007. Demand-meter.**—(a) *General:* A demand-meter is a device which indicates or records the demand or maximum demand. In practice, two types are recognized. See §§ 3454, 3458, 3460 and 3464.

(b) *Integrated-Demand-Meter:* An integrated-demand-meter is a demand meter which indicates or records the maximum demand obtained through integration.

(c) *Logged-Demand-Meter:* A logged-demand-meter is a demand-meter in which the indication of maximum demand is subject to a characteristic time lag.

**8009.\* Period of an Instrument.**—The period of an instrument, sometimes called the "periodic time," is the time taken for the pointer to make one complete oscillation (two consecutive swings). A swing is a complete movement in either direction.

**8010. Instrument Transformer.**—An instrument transformer is a transformer suitable for use with measuring instruments; that is, one in which the conditions of phase and of current or potential in the primary circuit, are represented with acceptable accuracy in the secondary circuit. An instrument transformer may be either an instrument current transformer or an instrument potential (voltage) transformer.

**8011.\* Secondary Burden.**—The secondary burden of a current transformer is an expression in ohms and henrys of the resistance and inductance of the external circuit connected to the secondary of that transformer.

**8012. Voltage Ratio of Instrument Transformer.**—The voltage ratio of an instrument potential transformer is the ratio of the r.m.s. primary terminal voltage to the r.m.s. secondary terminal voltage, under specified secondary burden.

**8013. Current Ratio of Instrument Transformer.**—The current ratio of an instrument current transformer is the ratio of r.m.s. primary current to r.m.s. secondary current, under specified secondary burden.

**8014. Marked Ratio of Instrument Transformer.**—The marked ratio of an instrument transformer is the ratio which the apparatus is designed to give under average conditions of use. When a precise ratio is required, it is necessary to specify the voltage or current, frequency, load and secondary burden.

(8004) Corona voltmeter (see Transactions of the A. I. E. E., Volume XXXIX, page 1057) is recognized as a satisfactory form of crest voltmeter.

(8020) In strongly damped instruments, the period is influenced by the amplitude of the movement.

(8031) Considerable uncertainty of meaning has been occasioned by the use of the terms, load, secondary load, and secondary connected load for this quantity, and such use is discouraged.

## OPERATION

**§101. Permissible Temperature in Shunts.**—(a) *General:* The limiting observable temperature of shunts measured by Method 1 shall not exceed  $120^{\circ}\text{C}$ .

(b) *Exceptions:* The above rule shall not apply to shunts having no soldered joint and made of material which is not permanently changed in resistance if continuously subjected to a higher temperature.

**§110. Grounding of Meters and Instruments.**—The covers of meters and instruments, which are used with current and potential transformers, shall be connected to the grounded sides of the secondary circuits of such transformers in all cases where the indications of the instrument are liable to be influenced by electrostatic action.

**§111. Instrument Current Transformers on Open Secondary Circuit.**—Under conditions of open secondary circuit, current transformers shall be capable of carrying continuously rated primary current without damage to the primary insulation and without interruption of service.

**§112. Instrument Current Transformers on Closed Secondary Circuit.**—Under conditions of closed secondary circuit, current transformers shall withstand 40 times rated current applied for 1 second, without injury.

## RATING

**§200. General.**—The rating of a meter is a designation assigned by the manufacturer to indicate its operating limitations. The full scale marking of an instrument does not necessarily correspond to its rating, but if the rating differs from the full scale marking, the rating shall be marked on the instrument.

**§201. Standard Ambient Temperature.**—For purposes of rating meters and instruments, the standard ambient temperature shall be  $40^{\circ}\text{C}$ . See §§ 8301 and 2211.

**§202. Rating Limitation of the Circuits of Meters and Instruments.**—No part of a meter or instrument shall be given a rating higher than that corresponding to the maximum current or voltage to which it may be continuously subjected.

**§203. Temperature Rise of Meter and Instrument Windings.**—The permissible temperature rises in meters and instruments shall be based upon the temperatures specified in § 1005 and the standard ambient temperature of  $40^{\circ}\text{C}$ .

**§204. Temperature Rise in Shunts.**—Shunts shall be rated in accordance with their observable temperature rise by Method 1, assuming the ultimate temperatures specified in § 8101 and an ambient temperature specified in § 8201.

## TESTS

**§200. Measurement of Temperature Rise of Shunts.**—Observable temperature shall be measured in such a manner as not to cause local change of temperature.

**§201. Standard Temperature of Reference for Meter and Instrument Characteristics.**—The standard temperature of reference for meter and instrument characteristics shall be  $20^{\circ}\text{C}$ . See §§ 8201, 2211.

**§202. Damping.**—The pointer being at zero before any load is applied, damping shall be measured by suddenly applying and maintaining a load which will give a steady deflection of one-half full angular scale, and observing the following quantities:

(a) The number of swings taken by the pointer in coming to rest.

(§203) Heating is frequently an immaterial consideration in determining the rating of meters and instruments. Losses, impairment of accuracy and other factors often determine the rating.

(b) The time, in seconds, required for the pointer to come to rest.

(c) The overshooting, in per cent of the angular displacement due to the disturbance.

#### Dielectric Strength of Instrument Transformers.

**8310. Test Voltage Instrument Potential Transformers.** — The test voltage for instrument potential transformers shall be twice the normal voltage of the circuit to which it is connected plus 1000 volts.

**8311. Test Voltage of Instrument Current Transformer.** — The test voltage of instrument current transformers shall be  $2\frac{1}{2}$  times the rated voltage plus 500 volts.

**8312. Test Voltage for Meters and Instruments.** — Meters and instruments which have a potential circuit shall withstand a test of twice potential of the circuit plus 1000 volts. Instruments without a potential circuit shall withstand a test of 1000 volts.

### SPECIFICATION OF CHARACTERISTICS

**8300. Errors of Indicating Instruments.** — In specifying the accuracy of an indicating instrument, the error at any point on the scale shall be expressed as a percentage of the full scale reading.

**8301. Torque.** — The torque of meters and instruments shall be expressed in millimeter-grams.

**8302. Damping.** — The damping of an instrument shall be expressed in two of the quantities enumerated in § 8302, all three of which are essential to a complete description.

**8303.\* Marking of Switchboard Shunts.** — The marking of switchboard shunts shall include the rating in amperes, the drop in volts at that rating and the serial number of any instrument in connection with which the shunt may be calibrated. When shunts are designed to be used with devices taking sufficient current to be an appreciable proportion of the whole, this fact shall be indicated.

### BIBLIOGRAPHY

British Engineering Standards Association: Standard Specifications for Indicating Ammeters, Voltmeters and Wattmeters; Standard Specifications for Recording (Graphic) Ammeters, Voltmeters, and Wattmeters, Standard Specifications for Instrument Transformers; Standard Specifications for Electrodynamometer Meters.

(8503) For example, if with 100 amperes rated load in the main circuit, a measuring device takes 10 amperes, leaving 100 less 10 amperes in the shunt with a drop of 0.09 volts, the shunt shall be marked: Volts 0.090. Amperes 100 less 10.

## CHAPTER IX

### STANDARDS FOR WIRES AND CABLES

#### DEFINITIONS

- 9000.\* Wire.** — A wire is a slender rod or filament of drawn metal.
- 9001.\* Conductor.** — A conductor is a wire or combination of wires not insulated from one another, suitable for carrying a single electric current.
- 9002.\* Stranded Conductor.** — A stranded conductor is a conductor composed of a group of wires, or of any combination of groups of wires.
- 9003. Strand.** — A strand is one of the wires, or groups of wires, of any stranded conductor.
- 9004.\* Cable.** — A cable is either a stranded conductor (single-conductor cable), or a combination of conductors insulated from one another (multiple-conductor cable).
- 9005.\* Stranded Wire.** — A stranded wire is a group of small wires, used as single wire.
- 9006.\* Cord.** — A cord is a small, flexible, insulated cable.
- 9007. Concentric Strand.** — A concentric strand is a strand composed of a central core surrounded by one or more layers of helically-laid wires or groups of wires.
- 9008. Concentric-lay Cable.** — A concentric-lay cable is a single-conductor cable composed of a central core surrounded by one or more layers of helically-laid wires.
- 9009.\* Rope-lay Cable.** — A rope-lay cable is a single-conductor cable composed of a central core surrounded by one or more layers of helically-laid groups of wires.

(9000) The definition restricts the term to what would ordinarily be understood by the term "solid wire." In the definition, the word "slender" is used in the sense that the length is great in comparison with the diameter. If a wire is covered with insulation, it is properly called an insulated wire; while primarily the term "wire" refers to the metal, nevertheless when the context shows that the wire is insulated, the term "wire" will be understood to include the insulation.

(9001) The term "conductor" is not to include a combination of conductors insulated from one another, which would be suitable for carrying several different electric currents. Bus conductors (such as bus-bars) are, of course, conductors, but are not considered for the terminology here given.

(9002) The wires in a stranded conductor are usually twisted or braided together.

(9004) The first kind of cable is a single conductor, while the second kind is a group of several conductors. The component conductors of the second kind of cable may be either solid or stranded, and this kind of cable may or may not have a common insulating covering. The term "cable" is applied by some manufacturers to a solid wire heavily coated and lead-covered; this usage arises from the manner of the insulation, but such a conductor is not included under this definition of "cable." The term "cable" is a general one, and in practice, it is usually applied only to the larger sizes. A small cable is called a "stranded wire" or a "cord," both of which are defined below. Cables may be bare or insulated, and the latter may be armored with lead, or with steel wires or bands.

(9005) A wire has been defined as a slender rod or filament of drawn metal. If such a filament is subdivided into several smaller filaments or strands, and is used as a single wire, it is called a "stranded wire." There is no sharp dividing line of size between a "stranded wire" and a "cable." If used as a wire, for example in winding inductances or magnets, it is called a stranded wire and not a cable. If it is substantially insulated, it is called a "cord," defined below.

(9006) There is no sharp dividing line in respect to size between a "cord" and a "cable," and likewise no sharp dividing line in respect to the character of insulation between a "cord" and a "stranded wire." Rubber is used as the insulating material in many classes of cords.

(9009) This kind of cable differs from the preceding in that the main strands are themselves stranded.

**9010.\* N-conductor Cable.**— An N-conductor cable is a combination of N conductors insulated from one another.

**9011.\* N-conductor Concentric Cable.**— An N-conductor concentric cable is a cable composed of an insulated central conductor with (N-1) tubular stranded conductors laid over it concentrically and separated by layers of insulation.

**9012.\* Duplex Cable.**— A duplex cable is a cable composed of two insulated stranded conductors twisted together.

**9013. Twin Cable.**— A twin cable is a cable composed of two insulated stranded conductors laid parallel, having a common covering.

**9014. Twin Wire.**— A twin wire is a cable composed of two small insulated conductors laid parallel, having a common covering.

**9015.\* Triplex Cable.**— A triplex cable is a cable composed of three insulated single-conductor cables twisted together.

**9016.\* Twisted Pair.**— A twisted pair is a cable composed of two insulated conductors, twisted together, without a common covering.

**9017.\* Sector Cable.**— A sector cable is a multiple-conductor cable in which the cross-section of each conductor is substantially a sector, an ellipse, or a figure intermediate between them.

**9018. Round Conductor.**— A round conductor is either a solid or stranded conductor of which the cross-section is substantially circular.

**9019.\* Split Conductor.**— A split conductor is a conductor which is divided into two or more parts, separated from one another by insulation which is compared with the insulation around the conductor.

**9020. Factor of Assurance.**— The factor of assurance of wire or cable insulation is the ratio of the voltage at which it is tested to that at which it is used.

**9021. Insulation Resistance.**— The insulation resistance of an insulated conductor is the electrical resistance offered by its insulation, to an impressed voltage tending to produce a leakage of current through the same.

**9022.\* Circular Mil.**— A circular mil is a unit of area equal to  $\frac{\pi}{4}$  ( $\approx 0.7854$ ) of a square mil. The cross-sectional area of a circle in circular mils is therefore equal to the square of its diameter in mils. A circular inch is equal to a million circular mils.

**9023.\* Lay.**— The lay of any helical element of a cable is the axial length of a turn of the helix of that element.

**9024. Direction of Lay.**— The direction of lay is the lateral direction in which the strands of a cable run over the top of the cable as they recede from an observer looking along the axis of the cable.

(9010) It is not intended that the name as here given be actually used. One would instead speak of a "3-conductor cable," a "12-conductor cable" etc. In referring to the general case, one may speak of a "multiple-conductor cable" (as in § 9004 above).

(9011) This kind of cable usually has only two or three conductors. Such cables are used particularly for alternating currents. The remark on the expression "N-conductor" given for the preceding definition also applies here.

(9012) They may or may not have a common insulating covering.

(9015) They may or may not have a common insulating covering.

(9016) The two conductors of a "twisted pair" are usually substantially insulated, but that the combination is a special case of a "cord."

(9017) Sector cables are used in order to obtain decreased overall diameter and to permit the use of larger conductors in a cable of given diameter.

(9019) The term split conductor usually designates a conductor in two parts or splits which may be either concentric or external to one another.

(9022) A mil is the one-thousandth part of an inch. There are 1974 circular mils in a square millimeter.

(9023) Among the helical elements of a cable may be each strand in a concentric-cable, or each insulated conductor in a multiple-conductor cable.

## ANNEALED COPPER STANDARD

10.\* **Standard Annealed Copper.** (a) *General:* The following shall be taken normal values for standard annealed copper.

*Resistance:* At a temperature of 20° C., the resistance of a wire of standard annealed copper one meter in length and of a uniform section of 1 square meter is  $1/58 \text{ ohm} = 0.017241 \dots \text{ohm}$ .

*Density:* At a temperature of 20° C., the density of standard annealed  $\pi$  is 8.89 grams per cubic centimeter.

*Temperature Coefficient of Resistance:* At a temperature of 20° C., the "stant mass" temperature coefficient of resistance of standard annealed  $\pi$ , measured between two potential points rigidly fixed to the wire, is  $93 = 1/254.45 \dots$  per degree centigrade.

*Resistance of Standard Annealed Copper at 20° C.:* As a consequence, it results from (b) and (c) that, at a temperature of 20° C., the resistance of a standard annealed copper of uniform section, one meter in length and weighing one gram, is  $(1/58) \times 8.89 = 0.15328 \dots \text{ohm}$ .

## OPERATION

## Temperature Limits

60.\* **Maximum Temperatures.**—The temperature of the insulation of a wire or cable at the surface of the conductor shall not be allowed to exceed the following values.

$t$  = maximum safe temperature.

$E$  = r.m.s. operating electromotive force in kilovolts between conductors,

Impregnated paper,  $t = 85 - E$

Varnished cambric,  $t = 75 - E$

Rubber insulation,  $t = 60 - \frac{E}{4}$ .

## DESIGNATION

100. **Designation of Wires by Diameter or Gage Number.**—The sizes of wires shall be stated by their diameters in mils, the American Wire Gage (Brown & Sharpe) sizes being taken as standard. For brevity, in cases where the careful specification is not required, the sizes of wires may be stated by the number in the American Wire Gage.

101. **Designation of Cables by Cross-sectional Area.**—The sizes of round conductors shall be stated by their cross-sectional area in circular mils or circular inches, except in the case of flexible stranded conductors, for

1050) See I. E. C. Publication No. 28, "International Standard of Resistance for per." March, 1914.

Paragraphs (b) and (c) define what are sometimes called "Volume Resistivity" and "Mass Resistivity," respectively. This may be expressed in other units as follows:

Volume Resistivity = 1.7241 microhms-cm. (microhms in a centimeter cube) at 20° C.

Mass Resistivity = 875.20 ohms (mile, pound) at 20° C.

For detailed specifications of commercial copper see the Standard Specifications of the American Society for Testing Materials.

1100) For example: At a working pressure of 3.3 kv., the maximum safe limiting temperature at the surface of the conductor, or conductors, in a cable would be as follows:

For impregnated paper 81.7° C.

For varnished cambric 71.7° C.

For rubber insulation 59.2° C.

The life of the insulation of a cable depends in a great measure upon the actual temperature attained by the insulation. The result of operating at temperatures in excess of the safe limit is to shorten the life of the insulating material. When the safe limits are exceeded, deterioration is rapid and permanent, the damage increasing with the length of time that the excessive temperature is maintained and with the amount of excess temperature until finally the insulation breaks down.

Some of the older types of cable for voltages above 7500 have a dielectric loss that is so high that it may add considerably to the heating that would otherwise result. In such cases the dielectric loss is a material factor in determining the safe load to be carried by the cable, and the safe operating temperature will be determined by the temperature at which cumulative heating occurs under the conditions of service, if this occurs at a lower temperature than that at which the insulation deteriorates.

which see § 9402. The cross-sectional area of a cable shall be considered to be the sum of the cross-sectional areas of its component wires, when measured perpendicular to their axes. The sizes of stranded conductors smaller than 250,000 circular mils (*i.e.*, No. 0000 A. W. G. or smaller) may be stated by means of the gage number of a solid wire having the same cross-sectional area.

9308.\* **Conductivity.**—The conductivity of the metal of wires shall be expressed in terms of the conductivity of the Annealed Copper Standard, as defined in § 9050.

9309.\* **Copper-wire Tables.**—The copper-wire tables published by the Bureau of Standards in Circular No. 31 are adopted. Table VI therein gives the values of diameters and cross-sections of A. W. G. sizes to four significant figures. These tables are based upon the Annealed Copper Standard described in § 9050.

## TESTS

### General

9300. **Cable Lengths Tested.**—Electrical tests of insulation on wires and cables shall be made on the entire lengths to be shipped.

9301. **Immersion in Water.**—(a) *General:* The outer surface of the insulation of complete insulated wires and cables shall be grounded while being electrically tested. If the insulation is not provided with a conducting covering, and if the covering is not liable to injury by water, the ground shall be obtained by immersing the insulated wire or cable in water for at least twelve hours and testing at the end of that period while immersed. If the outer covering is susceptible to injury by immersion, the insulated conductor shall be tested before the application of such covering.

Dry core paper insulated lead covered cables, such as telephone and telegraph cables, for use in water, shall be tested after at least twelve hours immersion.

(b) *Multiple-conductor Cable:* In the case of multiple-conductor cables without waterproof overall jacket of insulation, no immersion test shall be made on finished cables, but only on the individual conductors before assembly.

### Tests of Dielectric Strength

9310. **Object of Tests.**—High-voltage tests are intended to detect weak spots in the insulation and to determine whether its dielectric strength is sufficient for enabling it to withstand the voltage to which it is likely to be subjected in service, with a suitable factor of assurance.

9311. **Nature of Tests.**—High-voltage tests shall be made at the factory by subjecting the insulation to an alternating voltage. The initially applied voltage must not be greater than the working voltage, and the rate of increase shall be approximately uniform and not over 100 per cent in 10 seconds, and not less than 100 per cent in 60 seconds.

9312.\* **Magnitude and Duration of the Test Voltage.**—(a) *General:* Wires and cables shall be tested at the place of manufacture for five consecutive minutes, except as provided in § 9312 (b) and (f).

(b) *Rubber Insulation, National Electrical Code:* Rubber covered wires and cables for working pressures up to 600 volts alternating, insulated in accordance with the requirements of the National Electrical Code, shall be tested in accordance with that Code.

(9202) For any given wire, let

- $k$  = conductivity, in per cent of Annealed Copper Standard;
- $l$  = length, meters;
- $R$  = resistance, ohms;
- $W$  = weight, grams;
- $\theta$  = temperature, degrees centigrade.

Then the conductivity may be derived from the following formula:

$$k = \frac{15.528}{\frac{WR}{l} + 0.000597(20 - \theta)}$$

(9203) For detailed specifications of commercial copper, see the Standard Specifications of the American Society for Testing Materials.

c) *Thirty per cent to 40 per cent Hevea Rubber Insulation for Pressures up to 600 Volts, a-c.*: Wires and cables for working pressures up to 600 volts alternating insulated with 30 per cent to 40 per cent Hevea rubber compound, unless insulation thickness is less than specified in § 9405, shall be tested in accordance with Table 901.

TABLE 901

## High-voltage Tests for Rubber Insulated Wires and Cables

per cent to 40 per cent Hevea Rubber Insulation for working pressures up to 600 Volts a-c.)

A. W.G. or Cir. Mils.	Size Sq. mm.	Test-pressure kilovolts
14-8	2.081- 8.366	3.0
7-0000	10.55 -107.3	3.5
150,000 and larger	127 and larger	4.0

d) *Thirty per cent to 40 per cent Hevea Rubber Insulation for Pressures over 600 Volts, a-c.*: Wires and cables insulated with 30 per cent Hevea rubber compound for working pressures over 600 volts alternating, shall be tested with one volt per 64th inch of thickness (2.53 kv. per mm.) up to 10/64th inch (6 mm.). Above 10/64ths inch, (3.96 mm.), the test pressure shall be 10 volts plus 1.5 kilovolts per 64th inch (3.79 kv. per mm.) additional up to 1/4th inch (11.89 mm.). Where the insulation thickness is 16/64ths inch (2 mm.) or over, this rule shall apply only to conductors over 26,000 cir. mils (27. mm.) area.

e) *Varnished Cambric and Impregnated Paper Insulation*: Varnished cambric impregnated paper insulated wires or cables shall be tested in accordance with Table 902.

TABLE 902

## High-voltage Tests for Varnished Cambric or Impregnated Paper Insulated Cables

(Minimum Values)

Operating kv.	Test kv.	Operating kv.	Test kv.
Below 0.5	2.5*	5	14
0.5	3	7.5	19.5
1	4	10	25
2	6.5	over 10	2½ times operating pressure
3	9		
4	11.5		

\* The minimum thickness of insulation shall be 1/16 in. (1.6 mm.).

or intermediate working voltages, the test voltage shall be interpolated.

f) *Telephone, Telegraph and Annunciator Wires and Cables*: Section 9312 does not apply to wires and cables for telephone, telegraph, annunciator and bar devices.

113. *Frequency of Test Voltage.* — The frequency of the test voltage shall exceed 100 cycles per second, and should approximate as closely as possible sine wave. The source of energy should be of ample capacity.

114. *Dielectric Strength Tests.* — Ultimate dielectric strength tests, when used, shall be made on samples not more than 6 meters (20 ft.) long. The

912 c) Hevea rubber is rubber from the Hevea Brasiliensis tree. Compounds containing 30 to 40 per cent of Hevea rubber have electrical and mechanical properties similar to compounds insulated in accordance with the requirements of the National Electrical Code.

912 e) Different engineers specify different thickness of insulation for the same working voltages. Therefore, at the present time the test kv. corresponding to working voltages given in Table 902, are based on the minimum thickness of insulation specified by users and operating companies.

maximum allowable temperature, at which the test is made, for the particular type of insulation and the particular working pressure, shall be not greater than the temperature limits given in § 9100.

**9315. Multiple-conductor Cables.** — If a multiple-conductor cable is designed for the same operating voltage between conductors and sheath or water as between conductors, each conductor shall be tested against the other conductors connected together and to the sheath or water. If the cable is designed for an operating voltage between conductors and ground different from that between conductors, the test between conductors and the sheath or water shall be made separately and shall be based on the normal operating voltage between conductors and sheath or water as prescribed in § 9312.

#### Insulation Resistance

**9320.\* Expression of Insulation Resistance.** — Insulation resistance shall be expressed in megohms. Linear insulation resistance, or the insulation resistance of unit length, shall be expressed in terms of the megohm-kilometer, or the megohm-mile, or the megohm-thousand-feet, and shall be corrected to a temperature of 15.5° C., using a temperature coefficient determined experimentally for the insulation under consideration.

**9321. Megohms Constant.** — The megohms constant of an insulated conductor shall be the factor  $K$  in the following equation:

$$R = K \log_{10} \frac{D}{d}$$

where  $R$  = insulation resistance, in megohms, for a specified unit length,  
 $D$  = outside diameter of insulation,  
 $d$  = diameter of conductor.

Unless otherwise stated,  $K$  will be assumed to correspond to the mile unit of length.

**9322. Measurement of Insulation Resistance.** — The apparent insulation resistance should be measured after the high-voltage test, measuring the leakage current after a one-minute electrification, with a continuous e.m.f. of from 50 to 500 volts, the conductor being maintained negative to the sheath or water.

**9323. Insulation Resistance of Multiple-conductor Cables.** — The insulation resistance of each conductor of a multiple-conductor cable shall be the insulation resistance measured from each conductor to all the other conductors in multiple with the sheath or water.

#### Capacitance or Electrostatic Capacity

**9330.\* Expression of Capacitance.** — Capacitance shall be expressed in microfarads. Linear capacitance, or the capacitance of unit length, shall be expressed in microfarads per unit length (kilometer, or mile, or one thousand feet), and shall be corrected to a temperature of 15.5° C., using a temperature coefficient determined experimentally for the insulation under consideration.

**9331. Microfarads Constant.** — The microfarads constant of an insulated conductor shall be the factor  $K$  in the following equation:

$$C = \frac{K}{\log_{10} \frac{D}{d}}$$

where  $C$  = capacitance in microfarads per unit length,  
 $D$  = outside diameter of insulation,  
 $d$  = diameter of conductor.

Unless otherwise stated,  $K$  will be assumed to refer to the mile unit of length.

(9330) In the case of dry-core paper-insulated cables, the temperature coefficient of insulation resistance cannot be closely determined on account of variations in design and manufacture. Therefore no temperature corrections shall be applied to insulation resistance tests. Tests should be made at a temperature of 15.5° C. or higher.

(9330) In the case of dry-core paper-insulated cables, the temperature coefficient of capacitance cannot be determined closely on account of variations in design and manufacture. Therefore no temperature corrections shall be applied to capacitance tests. Tests should be made at a temperature of 15.5° C. or higher.

TABLE 908

## Proposed Standard Cables

This table is offered for consideration but will not be recommended for fixation until ratified by other societies interested.)

Note 1. — Nominal diameters and circular mils of the individual wires are taken from Table VI, circular No. 31 of the Bureau of Standards.

Note 2. — The variation of the mean diameter of any wires shall not exceed 1 per cent or below the nominal diameter.

Note 3. — The variation of the total cross-section of the cable shall not exceed 1 per cent above or below the nominal cross-section.

Note 4. — Sizes are expressed as A. W. G. numbers except where diameters are given in mils.

822. Measurement of Capacitance. — The capacitance of cable shall be measured with alternating current by comparison with a standard condenser. It is preferable that the measurement be made either at a frequency approximating that of operation or at a frequency giving results approximating the corresponding to the operating frequency or frequencies.

823. Capacitance of Paired Cables. — The capacitance of paired cables shall be measured between the two conductors of any pair, the other wires being connected to the sheath or ground.

**9404. Capacitance of Multiple-conductor Cables (not paired).** — The capacitance of multiple-conductor (not paired) cables shall be measured between conductors, and also between each conductor and the other conductors connected to the sheath or ground.

### CONSTRUCTION

#### Stranding

**9400.\* Proposed Standard Cables.** — Insulated cables not requiring special flexibility shall be made of the number and size strands specified in Table 904.

**9401. Cables not Requiring Special Flexibility.** — Cables not requiring special flexibility and not made in accordance with § 9400 shall be stranded in accordance with Table 904.

TABLE 904

Standard Stranding of Concentric-Lay Cables

Size (see Note 1)	Square mm.	Number of Wires (See note 3)	
		A Bare, insulated or weatherproof cables for aerial use	B Insulated cables for other than aerial use

00 "	67.4	7	19
2 "	33.6	7	7
7 and smaller	10.5	..	7

Note 1. — For intermediate sizes, use stranding for next larger size.

Note 2. — Conductors of 0000 A. W. G. and smaller are often made solid and this table of stranding should not be interpreted as excluding this practice.

Note 3. — Class A cable, sizes 0000 and 000 A. W. G., is usually made of 7 strands when bare and 19 strands when insulated or weatherproof.

**9402.\* Flexible Cables.** — Conductors of special flexibility should ordinarily be made with wires of regular A. W. G. sizes, and rated by the number and size of wires. The stranding of flexible cables is given in Table 905.

(9400) The basis of this rule is the use of strands of American Wire Gage sizes. To meet existing operating conditions, four sizes of strands other than American Wire Gage sizes have been deemed necessary and their diameters are shown in mils.

(9402) Where necessary to closely approximate a regular size cable, the strands may be made of half-size wires from No. 15 to No. 30 A. W. G.

TABLE 905  
Stranding of Flexible Cables

aller	.....	.....	To equal Required Size	30.0	.....	Bunched

1. — The A.W.G. cross-sectional areas except for 61 strands, are approximated per cent. In the case of 61 strand cables the approximation is 6 per cent.

2. — Circular mils are based on theoretical diameters of A. W. G. sizes, which are or below values given in table by less than 0.1 mil.

3. — "61×7" in the rating of a rope-lay cable signifies 61 strands of 7 wires each.

\* Correction for Lay. — Two per cent shall be taken as the standard increment of resistance and of mass, due to stranding. In cases where the lay is not known, the increment should be calculated and not assumed.

) The resistance and mass of a stranded conductor are greater than in a solid wire of the same cross-sectional area, depending on the lay (i.e., the pitch of the wires).

## Thickness of Insulation

**9406. Thickness of Insulation for Rubber Insulated Wires and Cables.**— Unless special conditions warrant departures from this rule, the thickness of insulation for rubber compounds containing from 30 to 40 per cent of Hevea rubber, shall be in accordance with Table 906.

**TABLE 906**  
Thickness of Insulation  
30 to 40 per cent Hevea Rubber Compound  
Recommended Walls of Insulation, 64ths. Inch

Size A. W. G. or Cir. Mils	Square mm.	Working pressure, volts alternating										
		600 or less	1500	2500	3500	5000	6000	7000	8000	9000	10000	11000
14-8	2.08-8.37	3	6	8	10	12	14	16	18	20	22	24
7-2	10.6-33.6	4	7	9	10	12	14	16	18	20	22	24
1-0000	42.4-107	5	8	10	10	12	14	16	18	20	22	24
250,000- 500,000	127-253	6	9	10	11	12	14	16	18	20	22	24
550,000- 1,000,000	279-507	7	10	10	12	12	14	16	18	20	22	24
1,250,000- 2,000,000	633-1013	8	10	10	12	14	16	18	18	20	22	24

Notes. — In multiple-conductor cables, the thickness of insulation on each conductor shall be based on the highest r.m.s. voltage between the conductor and the outside of this insulation. The above table is based upon alternating voltages of commercial frequencies. For voltages over 600, the insulation thickness for direct-current cables has not been established. For intermediate sizes the insulation thickness should be the same as for the next larger sizes.

## CHAPTER X

## STANDARDS FOR STORAGE BATTERIES

## DEFINITIONS

- 10001. Battery.** — A group of cells electrically connected. Storage batteries are conveniently divided in two groups: stationary batteries and portable batteries. Stationary batteries include line batteries, load-regulating batteries, all-load batteries, oil switch and exciter-reserve batteries, stand-by batteries, phone exchange batteries and farm light batteries. Portable batteries include starting and lighting batteries, vehicle batteries, car lighting batteries, electric locomotive batteries, mine-lamp batteries, and ignition batteries.
- 10002. Cell.** — A single element with electrolyte and container.
- 10003. Element.** — The positive and negative groups with separators assembled.
- 10004. Group.** — Assembly of a set of positive or a set of negative plates for a cell.
- 10005. Jar or Tank.** — The container for a cell.  
Note. — The term tank is generally confined to lead containers supported by wood.
- 10006. Separator.** — A device for preventing metallic contact between the plates of opposite polarity within the cell.
- 10007. Electrolyte.** — A solution of sulphuric acid for lead batteries and of caustic hydroxides for nickel-iron batteries.
- 10008. Positive Plate.** — The grid and active material from which the current flows to the external circuit when the battery is discharging.
- 10009. Negative Plate.** — The grid and active material to which the current flows from the external circuit when the battery is discharging.
- 10010. Grid.** — A metallic framework for conducting current and holding active material or active material units of the plate.
- 10011. Active Materials.** — Substances reacting chemically to produce electrical energy during discharge of the cell, but subject to oxidation or reduction when on charge in the reverse direction, transforming electrical energy into chemical energy. In the charged condition, these are lead peroxide on the positive plates and sponge lead on the negative plates of lead-acid cells, but for nickel-iron cells they are nickel peroxide in the positive tubes and iron in the active pockets.
- 10012. Couple.** — One positive and one negative plate connected together as a unit for adjacent cells.
- 10013. Counter Cells.** — Cells of practically no capacity used to oppose the voltage.
- 10014. End Cells.** — Those cells of a battery which may be cut in or out of the circuit for adjusting the voltage.
- 10015. Terminals.** — Fittings to provide electrical connections to storage cells or batteries.
- 10016. Pilot Cell.** — A selected cell whose temperature, voltage and gravity are assumed to indicate the state of charge of the entire battery.

## MISCELLANEOUS

- 10020. Ampere-hour Capacity.** — The number of ampere-hours which can be delivered by a cell or battery under specified conditions as to temperature, rate of discharge and final voltage.
- 10021. Ampere-hour Efficiency.** — The ratio of the ampere-hours output of a cell or battery under specified conditions of temperature, rate of discharge and final voltage, to the ampere-hours of input required for complete charge. See efficiency.

- 10032. Average Voltage.**—The average value of the voltage during the period of charge or discharge. It is conveniently obtained from the area integral of the voltage curve.
- 10033. Boost Charge.**—A partial charge, usually at a high rate for a short period.
- 10034. Charge.**—The restoration of the active materials in a battery by passing a direct current through it in the opposite direction to that of the discharge.
- 10035. Charging Rate.**—The current, expressed in amperes, at which a battery is charged.
- 10036. Closed Circuit Voltage.**—The voltage at a cell or terminals of the battery when current is flowing.
- 10037. Constant-current Charge.**—A charge in which the current is maintained at constant value. For portable lead batteries this usually involves two rates called the starting and the finishing rates.
- 10038. Constant-potential Charge.**—A charge in which the voltage at the terminals of the battery is held at a constant value. A modified constant-potential system is one in which a fixed resistance is inserted in the charging circuit to limit the initial current.
- 10039. Discharge.**—The conversion of the chemical energy of the battery into electrical energy.
- 10040. Efficiency.**—The ratio of the useful output to the required input. The efficiency from an electro-chemical standpoint is the ampere-hour efficiency. It represents the ratio of the quantity of electricity delivered by the battery to the quantity required for a complete recharge, expressed in ampere-hours. The energy efficiency is the watt-hour efficiency. It represents the ratio of the energy delivered by the battery to the energy expended in charging it, expressed as watt-hours measured at the terminals of the battery. If the measurements are made at the buses, the watt-hour efficiency of the installation may be obtained. The so-called volt efficiency is the ratio of the average voltage on discharge to the average voltage on charge. The watt-hour efficiency of the battery is customarily taken as the product of the ampere-hour efficiency and the volt efficiency.
- 10041. Final Voltage.**—The prescribed voltage upon reaching which the discharge is considered complete. The final voltage is usually chosen so that the useful capacity of the cell is realized. Final voltages vary with the kind of battery and the rate of the discharge.
- 10042. Equalizing Charge.**—A charge given to a lead battery to insure complete reduction of the lead sulphate. The equalizing charge is ordinarily at the finishing rate or less.
- 10043. Finishing Rate.**—The rate of charge expressed in amperes to which the charging current for lead batteries is reduced near the end of charge to prevent excessive gassing.
- 10044. Gassing.**—The evolution of oxygen or hydrogen, or both.
- 10045. Polarity.**—An electrical condition determining the direction in which current tends to flow. By common usage the discharge current is said to flow from the peroxide plate or position through the external circuit. In a nickel-iron battery the positive plate is that containing nickel peroxide.
- 10047. Reversal.**—Change in normal polarity of a storage cell.
- 10048. Specific Gravity.**—The ratio of the weight of a given volume of the liquid electrolyte to the weight of the same volume of water at a specified temperature. It is usually measured in storage battery work by a hydrometer.
- 10049. Trickle Charge.**—A continuous charge at low rate for batteries in wet storage. It is approximately 1 per cent of the finishing rate.
- 10050. Volt Efficiency.**—The ratio of the average voltage of the cell or battery on discharging to the average voltage on charge. See "efficiency."
- 10051. Watt-hour Capacity.**—The ampere-hour capacity multiplied by the average voltage during discharge. It may, however, be measured directly.

2. **Watt-hour Efficiency.**— The ratio of the watt-hours of useful output watt-hours of input expended in charging. See "efficiency."

### TEMPERATURE

1. The capacity obtained from a storage battery on discharge varies with temperature of the electrolyte. In order to compare various batteries, standard reference temperatures are necessary; the following standard reference temperatures are established:

1. The temperature of electrolyte at beginning of discharge shall be 25° C. (77° F.).

2. The ambient temperature on discharge shall be from 5° C. to 35° C. higher than the temperature of the electrolyte, on the beginning of discharge. The ambient temperature shall be kept constant throughout the discharge.

(a) No limit is placed on the temperatures obtained by the electrolyte on discharge.

For lead acid batteries, the limit of temperature of electrolyte permitted on discharge depends upon the specific gravity of the electrolyte, higher temperatures permitted on low gravity electrolyte. In general, it is desirable that the temperature of the electrolyte on charge shall not exceed 45° C. (113° F.).

### RATINGS

#### General

1. The capacities of storage batteries for different classes of service are directly comparable. The capacity depends upon the discharge rate, the temperature of electrolyte (which has been standardized as 25° C.), the specific gravity of electrolyte, and final voltage allowed.

2. Storage batteries shall be rated in accordance with the following standard capacity specifications:

a) Ampere-hour capacity.

b) Discharge rate.

c) Reference temperature of discharge—25° C.

d) Specific gravity of electrolyte at 25° C.

e) Final voltage limit per cell on discharge.

3. The tabulated data required by the capacity specifications shall either be shown on a name-plate attached to battery, or, where this is not practicable, furnished separately.

### TESTS

#### General

1. Batteries shall be tested as required, to determine if the rated capacity is obtained under the conditions as given in capacity specifications.

### BATTERIES FOR SPECIAL SERVICE

2. In certain definite classes of service, some or all of the variables given in capacity specifications (No. 10202) can be definitely stated and standardized.

## CHAPTER XI

### STANDARDS FOR ILLUMINATION

This chapter consists of extracts from the Report of the Committee on Illumination and Standards of the Illuminating Engineering Society. It is included by permission.

#### General

0. **Radiant flux,  $\phi$ ,** is the rate of flow of radiation evaluated with reference to energy, and is expressed in ergs per second or in watts.

1. **Luminous flux** is the rate of flow of radiant energy evaluated with

(1), (11006), (11007), (11008), (11010), (11011) These are the International Standards as agreed on at the Paris meeting of the International Commission on Illumination in 1921.

reference to visual sensation. Although luminous flux must strictly be defined, as above, it may be regarded for practical photometric purposes as an entity, since the rate of flow is for such purposes invariable.

**11002.** Visibility,  $K_\lambda$ , of radiation of a particular wave-length is the ratio of the luminous flux at that wave-length to the corresponding radiant flux.

Defining equation: 
$$K_\lambda = \frac{F_\lambda}{\Phi_\lambda}$$

**11003.\*** The mechanical equivalent of light is the ratio of radiant flux to luminous flux for the wave-length of maximum visibility, and is expressed in ergs per second per lumen, or in watts per lumen. It is the reciprocal of the maximum visibility.

**11004.** Luminosity of a particular wave-length is the product of the visibility of that wave-length and the corresponding ordinate of the spectral curve of radiant flux, and is represented by the ordinate of the spectral curve of luminous flux. This curve is called the spectral luminosity curve and is different with different sources.

**11005.** The Luminous efficiency of any source is the ratio of the luminous flux to the radiant flux from the source and is expressed in lumens per watt.

**11006.\*** Luminous intensity of a point source in any direction is the flux per unit solid angle (one steradian) emitted by the source in that direction. (The flux from any source of dimensions which are negligibly small by comparison with the distance at which it is observed, may be treated as if it was emitted from a point.)

**11007.\*** Illumination at any point of a surface is the luminous flux density at that point, or when the illumination is uniform, the flux per unit of intercepted area.

**11008.\* International Candle.** — The unit of luminous intensity is the International Candle, such as has resulted from international agreement between the three national standardizing laboratories of France, Great Britain and the U. S. A. in 1909.

This unit has been conserved since then by means of incandescent lamps in the laboratories which continue (or remain) charged with conservation.

**11009.** Candlepower, *cp.*, is luminous intensity expressed in candles.

**11010.\* Lumen.** — The unit of luminous flux is the lumen. It is equal to the flux emitted in a unit solid angle by a uniform point source of one International candle.

**11011.\* Lux, Phot, Foot-candle.** — The practical unit of illumination is the lux. It is equal to one lumen per square meter, or it is the illumination of the surface of a sphere of one meter radius due to a uniform point source of one International candle placed at its center.

As a consequence of certain recognized usages, the illumination can also be expressed by means of the following units:

Using the centimeter as the unit of length, the unit of illumination is one lumen per square centimeter, and is called the phot. Using the foot as the unit of length, the unit of illumination is one lumen per square foot, and is called the foot-candle.

**11012.** Brightness of an element of a luminous surface may be expressed in either of two ways: (a) in terms of intensity,  $I$ , (b) in terms of flux,  $F$ .

(a) Brightness in terms of the luminous intensity  $I$  (or candle-power) per unit of projected area of the surface (candlepower brightness) corresponds to

$$\text{defining equation, } bI = \frac{dI}{dS \cos \theta}$$

where  $\theta$  is the angle between the normal to the surface and the line of sight.

(b) Brightness in terms of the flux,  $F$ , proceeding from a unit area of the surface

(11003) This term has been used in a variety of senses. As here defined it refers only to the minimum mechanical equivalent of light. The reciprocal of this quantity is sometimes called the luminous equivalent of radiation.

(11010) A uniform source of one candlepower emits  $4\pi$  lumens.

, on the assumption that the surface is a perfect diffuser; *i.e.*, that it obeys cosine law of emission or reflection, (lumen brightness) corresponds to the

$$\text{defining equation, } bF = \frac{dF}{dS}$$

fect diffusion assumed).

he units in which brightness is measured according to (a) and (b) differ only numerical value. See § 11013.

**1012. Lambert, L.** is the unit of brightness in the lumen system. The bert is the brightness of a perfectly diffusing surface emitting or reflecting lumen per square centimeter. For most purposes the millilambert, 0.001 bert, is the preferable practical unit.

o say that the brightness of a surface as viewed from a given point is  $n$  berts, signifies that its brightness is the same as that of a perfectly diffusing ace emitting or reflecting  $n$  lumens per square centimeter.

a practice no surface obeys exactly the cosine law of emission or reflection; ce the brightness of a surface generally is not uniform but varies somewhat i the angle at which it is viewed.

erfectly diffusing surface emitting one lumen per square foot will have a tness of 1.076 millilamberts.

rightness expressed in candles per square centimeter may be reduced to berts by multiplying by  $\pi = 3.14$ .

rightness expressed in candles per square inch may be reduced to lamberts multiplying by  $\pi/6.45 = 0.487$ .

#### Surfaces and Media Modifying Luminous Flux

**1020. Diffusing surfaces and media** are those which break up the incident and distribute it more or less in accordance with the cosine law, as for mple, white plaster and opal glass.

**1021. Redirecting surfaces and media** are those which change the direction he luminous flux in a definite manner; as for example, a mirror or a lens.

**1022. Scattering surfaces and media** are those which redirect the luminous ; and break it up into a multiplicity of separate pencils; as for example, le glass, reflecting or transmitting.

**1023.\* Reflection factor, of a body  $\rho$ ,** is the ratio of the flux reflected by the y to the flux incident upon it. The reflection from a body may be regular, use or mixed. In regular reflection the flux is reflected at an angle of reflec- equal to the angle of incidence. In diffuse reflection the flux is reflected in directions. In perfectly diffuse reflection, the distribution of the reflected is in accordance with Lambert's cosine law. In most practical cases, there superposition of regular and diffuse reflection.

**1024.\* Absorption factor, of a body  $a$ ,** is the ratio of the flux absorbed by the y to the flux incident upon it.

**1025.\* Transmission factor, of a body  $\tau$ ,** is the ratio of the flux transmitted the body to the flux incident upon it.

$$\rho + a + \tau = 1.$$

#### Illumination

**1030. Unidirectional illumination** on a surface is that produced by a single it source of relatively small dimensions. It is characterized by the fact that mall opaque object placed near the illuminated surface casts a sharp shadow.

**1031. Multidirectional illumination** on a surface is that produced by several arated light sources of relatively small area. It is characterized by the fact t a small opaque object placed near the illuminated surface casts several dows.

11023) (11024) (11025) These terms are introduced to replace the more commonly d terms, Coefficient of reflection, Coefficient of absorption, Coefficient of transmission, ch latter terms refer to the specific properties of materials rather than to the behavior bodies under specified conditions, such as angle of incidence, etc.

**11032.** Diffused illumination is that produced either by primary or secondary light sources having dimensions relatively large with respect to the distance from the point illuminated, and scattering light in all directions. It is characterized by relative lack of shadow. Diffused illumination may be derived principally from a single direction as in the light from a skylit window or from all directions as in the open air. Perfectly diffused illumination on a surface is shadowless.

In any practical case of illumination on a surface there is usually a mixture of the above types.

**11033.** Coefficient of utilization of an illumination installation on a given plane is the total flux received by that plane divided by the total flux from all lamps illuminating it. When not otherwise specified, the plane of reference is assumed to be a horizontal plane 30 inches (76 cm.) from the floor.

**11034.** Variation factor of an illumination installation is the ratio of the maximum or minimum illumination on a given plane to the average illumination on that plane.

**11035.** Variation range of illumination on a given plane is the ratio of the maximum illumination to the minimum illumination on that plane.

**11036.** Hemispherical ratio for a given lighting unit is the ratio of the luminous flux in the upper hemisphere to that in the lower hemisphere.

**11037.** Brightness ratio is the ratio of the brightness of any two surfaces. When the two surfaces are opposed, the brightness ratio is commonly called "brightness contrast."

#### Illuminants

**11040.** The output of all illuminants should be expressed in lumens.

**11041.** Illuminants should be rated upon a lumen basis rather than a candle power basis.

**11042.** Lamp efficiency is the ratio of the luminous flux output to the power input.

**11043.** The lamp efficiency or specific output of electric lamps should be stated in terms of lumens per watt and that of illuminants depending upon combustion should be stated in lumens per British thermal unit per hour.

**11044.** The power consumption of auxiliary devices which are necessarily employed in circuit with a lamp should be included in the input of the lamp. For example, the watts lost in the ballast resistance of an arc lamp are properly chargeable to the lamp.

**11045.** The specific consumption of an electric lamp is its watt consumption per lumen. "Watts per candle" is a term used commercially in connection with electric incandescent lamps, and denotes watts per mean horizontal candle.

**11046.** Life Tests.—Electric incandescent lamps of a given type may be assumed to operate under comparable conditions only when their lumens per watt consumed are the same. Life test results, in order to be compared, must be either conducted under, or reduced to, comparable conditions of operation.

**11047.** In comparing different luminous sources not only should their candle power be compared, but also their relative form, brightness, distribution of illumination and character of light.

#### Lamp Accessories

**11048.** A reflector is an appliance the chief use of which is to reflect the luminous flux of a lamp in a desired direction or directions.

**11049.** A shade is an appliance the chief use of which is to diminish or to interrupt the flux of a lamp in certain directions where such flux is not desirable. The function of a shade is commonly combined with that of a reflector.

**11050.** A globe is an enclosing appliance of clear or diffusing material the chief use of which is either to protect the lamp or to diffuse its light.

## Photometry

1040. Performance curve is a curve representing the behavior of a lamp in particular (candlepower, consumption, etc.) at different periods during its

1041. Characteristic curve is a curve expressing a relation between two basic properties of a luminous source, as candlepower and volts, candlepower rate of fuel consumption, etc.

1042. Mean horizontal candlepower of a lamp is the average candlepower in a horizontal plane passing through the luminous center of the lamp.

It is here assumed that the lamp (or other light source) is mounted in the same manner, or, as in the case of an incandescent lamp, with its axis of symmetry vertical.

1043. Mean spherical candlepower of a lamp is the average candlepower of a lamp in all directions in space. It is equal to the total luminous flux of the lamp measured in all directions divided by  $4\pi$ .

1044. Mean hemispherical candlepower of a lamp (upper or lower) is the average candlepower of a lamp in the hemisphere considered. It is equal to the total luminous flux emitted by the lamp in that hemisphere divided by  $2\pi$ .

1045. Mean zonal candlepower of a lamp is the average candlepower of a lamp over the given zone. It is equal to the total luminous flux emitted by the lamp in that zone divided by the solid angle of the zone.

1046. Spherical reduction factor of a lamp is the ratio of the mean spherical candlepower to the mean horizontal candlepower of the lamp.

TABLE 1100

## Photometric Units and Abbreviations

Photometric quantity	Name of unit	Symbols and defining equations	Abbreviation for name of unit
Luminous flux . . . . .	Lumen . . . . .	$F, \psi$	l.
Luminous intensity . . . . .	Candle . . . . .	$I = \frac{dF}{d\omega}, \quad \Gamma = \frac{d\psi}{d\omega}$	cp.
Illumination . . . . .	Phot, foot-candle, lux . . . . .	$E = \frac{dF}{dS} = \frac{I}{r^2} \cos \theta$	pb. fc.
Exposure . . . . .	{ Phot-second . . . . . Micro phot-second . . . . .	$E t$	phs. & phs.
Brightness . . . . .	{ Apparent candle per sq. cm. Apparent candle per sq. in. Lambert . . . . .	$b_l = \frac{dI}{dS \cos \theta}$ $b_l = \frac{dF}{dS}$	L. m.l.
Reflection factor . . . . .		$\rho$	
Absorption factor . . . . .		$\alpha$	
Transmission factor . . . . .			$\tau$
Mean spherical candlepower . . . . .			scp.
Mean lower hemispherical candlepower . . . . .			lcp.
Mean upper hemispherical candlepower . . . . .			ucp.
Mean zonal candlepower . . . . .			zcp.
Mean horizontal candlepower . . . . .			mhc.

1040) In the case of a uniform point-source, this factor would be unity, and for a thin cylindrical filament obeying the cosine law it would be  $\pi/4$ , perfect diffusion assumed.

14. 1 lumen is emitted by 0.07958 spherical candlepower.  
 15. 1 spherical candlepower emits 12.57 lumens.  
 16. 1 lux = 1 lumen incident per square meter = 0.0001 phot = 0.1 milliphot.  
 17. 1 phot = 1 lumen incident per square centimeter = 10,000 lux = 1,000 sq  
 photos = 1,000,000 microphots.  
 18. 1 milliphot = 0.001 phot = 0.929 foot-candle.  
 19. 1 foot-candle = 1 lumen incident per square foot = 1.076 milliphots = 10.76  
 20. 1 lambert = 1 lumen emitted per square centimeter of a perfectly diffu  
 surface.  
 21. 1 millilambert = 0.001 lambert.  
 22.\*1 lumen, emitted, per square foot = 1.076 millilamberts.  
 23.\*1 millilambert = 0.929 lumen, emitted, per square foot.  
 24. 1 lambert = 0.3183 candle per square centimeter = 2.054 candles per sq  
 inch.  
 25. 1 candle per square centimeter = 3.1416 lamberts.  
 26. 1 candle per square inch = 0.487 lambert = 487 millilamberts.

## CHAPTER XII

## STANDARDS FOR TELEPHONY AND TELEGRAPHY

Many of the following definitions are tentative and not yet fully established. Criticisms and suggestions, addressed to the Secretary of the Standards Committee, will be welcomed. Some of the definitions are specific to telephony and differ in detail from similar definitions appearing in other parts of the

## DEFINITIONS

## Line Circuits

**12000. Ground-return Circuit.** — A ground-return circuit is a circuit consisting of one or more metallic conductors in parallel, with the circuit completed through the earth.

**12001. Metallic Circuit.** — A metallic circuit is a circuit of which the conductors forms no part.

**12002. Two-wire Circuit.** — A two-wire circuit is a metallic circuit consisting of two parallel conductors insulated from each other.

**12003. Superposed Circuit.** — A superposed circuit is an additional circuit obtained from a circuit normally required for another service, and in such a manner that the two services can be given simultaneously without mutual interference.

**12004. Phantom Circuit.** — A phantom circuit is a superposed circuit consisting of one side of which consists of the two conductors of a two-wire circuit in parallel.

**12005. Side Circuit.** — A side circuit is a two-wire circuit forming one side of a phantom circuit.

**12006. Non-phantomed Circuit.** — A non-phantomed circuit is a metallic circuit, which is not arranged for use as the side of a phantom circuit.

**12007. Simplex Circuit.** — A simplex circuit is a two-wire metallic circuit, arranged for the superposition of a single ground-return signaling circuit operating over the wires in parallel.

**12008. Compositing Circuit.** — A compositing circuit is a two-wire metallic circuit, arranged for the superposition on each of its component metallic conductors of a single independent ground-return signaling circuit.

**12009. Quadded or Phantom Cable.** — A quadded or phantom cable is a cable adapted for the use of phantom circuits.

**12010. Simplex Circuit.** — A simplex circuit in telegraphy is one arranged for operation in one direction at one time.

**12011. Duplex Circuit.** — A duplex circuit in telegraphy is one arranged for simultaneous operation in opposite directions.

- 012. Diplex Circuit.** — A diplex circuit in telegraphy is one arranged for simultaneous transmission of two messages in the same direction.
- 013. Quadruplex Circuit.** — A quadruplex circuit in telegraphy is one used for the simultaneous transmission of two messages in each direction.
- 014. Multiplex Circuit.** — A multiplex circuit in telegraphy is one arranged for simultaneous transmission of one or more messages in both directions. Diplex and quadruplex are examples of multiplex whereas diplex is not.
- 015. Linear Electrical Constants.** — The linear electrical constants of a line are the electrical constants per unit length of the line, e.g., linear resistance, linear inductance, etc.
- 016. Smooth Line.** — A smooth line is a line whose electrical elements are continuously and uniformly distributed throughout its length.
- 017.\* Periodic Line.** — A periodic line is a line consisting of successive sections in each of which one or more electric elements are not distributed uniformly. As examples of periodic lines are (1) loaded lines and (2) artificial lines consisting of successive similar sections of lumped constants.
- 018. Equivalent Smooth Line.** — An equivalent smooth line of a periodic line is a smooth line having the same electrical behavior as the periodic line, at a single frequency, when measured at terminals or at corresponding section junctions.
- 019. Equivalent Periodic Line.** — An equivalent periodic line of a smooth line is a periodic line having the same electrical behavior, for an assumed single frequency, as the smooth line, when measured at terminals or at corresponding section junctions. The terms conjugate smooth line and conjugate periodic line are also sometimes used.
- 020. Composite Line.** — A composite line is a line consisting of a plurality of successive sections having different linear electrical constants, as in the case where an underground cable section is joined to an overhead open-wire section.
- 021. Loaded Line.** — A loaded line is one in which the normal reactance of the circuit has been altered for the purpose of increasing its transmission efficiency.
- 022. Series Loaded Line.** — A series loaded line is one in which the normal reactance has been altered by reactance serially applied.
- 023. Shunt Loaded Line.** — A shunt loaded line is one in which the normal reactance of the circuit has been altered by reactance applied in shunt across the circuit.
- 024. Continuous Loading.** — A continuous loading is a series loading in which the added inductance is uniformly distributed along the conductors.
- 025.\* Coil Loading.** — A coil loading is one in which the normal inductance of the circuit is altered by the insertion of lumped inductance in the circuit at intervals.

#### Circuit Constants and Characteristics

- 026. Damping of a Circuit.** — The damping at a given point in a circuit in which the source of energy has been withdrawn, is the progressive diminution in the effective value of electromotive force and current at that point during the withdrawal of electrical energy.
- 027.\* Damping Constant.** — The damping constant of a circuit is a measure of the rate at which the energy is dissipated in the circuit.
- 027<sup>a</sup>** The term periodic in this definition refers to the line constants and not to time constants.
- 028.** This lumped inductance may be applied either in series or in shunt. Commonly understood, coil loading is a series loading, in which the lumped inductance is applied at uniformly spaced recurring intervals.
- 029.** Applied to the admittance of a condenser or other simple circuit having capacity, the damping constant for a harmonic electromotive force of given frequency is the ratio of the conductance  $G$ , of the condenser or simple circuit at that frequency to the capacitance  $C$ , of the condenser at the same frequency. ( $G/2C$ ).

of the ratio of the dissipative to the reactive component of its admittance impedance.

**12002.\* Mutual Impedance.** — The mutual impedance for single frequency alternating currents, between a pair of terminals and a second pair of terminals of a network, under any given condition, is the negative ratio of the electromotive force produced between either pair of terminals on open circuit to the current flowing between the other pair of terminals.

**12003.\* Self-impedance.** — The self-impedance between a pair of terminals of a network, under any given condition, is the ratio of the electromotive force applied across the terminals to the entering current.

**12004.\* Characteristic Impedance.** — The characteristic impedance of a line is the ratio of the applied electromotive force to the resulting steady-state current upon a line of infinite length and uniform structure, or of periodic recurrent structure.

**12005.\* Sending-end Impedance.** — The sending-end impedance of a line is the ratio of the applied electromotive force to the resulting steady-state current at the point where the electromotive force is applied.

**12006.\* Propagation Constant.** — The propagation constant of a line or section of a line of periodic recurrent structure, is the natural logarithm of the ratio of the steady-state currents at various points separated by unit length in a uniform line of infinite length, or at successive corresponding points of recurrent structure of infinite length. The ratio is determined by the value of the current at the point nearer the transmitting end by the ratio of the current at the point more remote.

**12007.\* Attenuation Constant.** — The attenuation constant for a line at a given frequency is the real part of the propagation constant taken at that frequency.

**12008.\* Wave-length Constant.** — The wave-length constant is the imaginary part of the propagation constant.

**12009.\* Standard Cable.** — A standard cable is an ideal uniform line in which the attenuation of a line or network may be specified. It is characterized by the following constants: Linear resistance, 88 ohms per loop mile (54.7 ohms per loop km.). Linear capacitance between wires 0.054 microfarad per loop mile (0.03355 microfarad per loop km.). Linear inductance and leakage, 0.

### Equivalent Circuits

**12102.\* Equivalent Circuit.** — An equivalent circuit is a simple network of series and shunt impedances, which, at a given frequency, is the approximate electrical equivalent of a complex network.

**12103.\* "T" Equivalent Circuit.** — A "T" equivalent circuit is a star or "Y" connection of three impedances externally equivalent to a complex network. See Fig. 12-1 for symbol.

(12052) A receiving-end impedance is an example of a mutual impedance.

Single-frequency voltages and currents are here supposed to be represented by complex numbers. Their ratio is therefore a complex number.

(12053) Single-frequency voltages and currents are here supposed to be represented by complex numbers. Their ratio is therefore a complex number.

(12054) In practice, the terms (1) line impedance, (2) surge impedance, (3) natural impedance, (4) sending-end impedance, (5) initial sending-end impedance, (6) final sending-end impedance, (7) natural impedance and (8) free impedance, have apparently been more or less indefinitely and indiscriminately used as synonyms with what is here called "characteristic impedance."

Single-frequency voltages and currents are here supposed to be represented by complex numbers. Their ratio is therefore a complex number.

(12055) See note under "Characteristic Impedance." In case the line is of infinite length of uniform structure or of periodic recurrent structure, the sending-end impedance and the characteristic impedance are the same.

Single-frequency voltages and currents are here supposed to be represented by complex numbers. Their ratio is therefore a complex number.

(12056) Single-frequency voltages and currents are here supposed to be represented by complex numbers. Their ratio is therefore a complex number.

(12102 to 12106 Incl.) As ordinarily considered, the simple networks, as defined on p. 2172

4. **"T" Equivalent Circuit.** — An "T" equivalent circuit is a connection of three impedances in the form shown in Fig. 12-2, which is externally equivalent to a complex network. It differs from the "Π" equivalent circuit in that the impedances are arranged symmetrically on the two sides of the circuit, which is often desirable in connection with practical problems, as indicating that the circuit is balanced with respect to ground.

5. **"Π" Equivalent Circuit.** — A "Π" equivalent circuit is a connection of three impedances externally equivalent to a complex network, so called a "U" equivalent circuit. See Fig. 12-3 for symbol.

Fig. 12-1

Fig. 12-2

6. **"O" Equivalent Circuit.** — An "O" equivalent circuit is a connection of four impedances in the form shown in Fig. 12-4, externally equivalent to a complex network. It differs from the Π equivalent circuit in that the impedances are arranged symmetrically on the two sides of the circuit, which is often desirable in connection with practical problems, as indicating that the circuit is balanced with respect to ground.

Fig. 12-3

Fig. 12-4

### Telephony

1. **Manual Telephone System.** — A manual telephone system is one in which the calling party gives his order to an operator who completes the call by hand, either with or without the assistance of one or more additional operators.

2. **Automatic or Full Mechanical Telephone System.** — An automatic or full mechanical telephone system is one in which the calling party is enabled to make a call by remote-control switches without the aid of an operator.

3. **Semi-automatic or Semi-mechanical Telephone System.** — A semi-automatic or semi-mechanical telephone system is one in which the calling party gives order to an operator who completes the call through remote-control switches.

4. **Telephone Exchange.** — A telephone exchange consists of one or more offices with associated plant, by means of which telephone service is provided in a specified local community.

5. **Telephone Exchange Area or District.** — A telephone exchange area or district is the area or district served by a telephone exchange.

6. **Central Office (British "Exchange").** — A central office is a switching or inter-connecting lines terminating therein.

7. **Toll Central Office.** — A toll central office is one in which toll and long distance lines terminate.

8. **Local Central Office.** — A local central office is one in which subscriber's lines terminate.

**12208. Private Branch Exchange (Generally Abbreviated "P. B. E").**— A private branch exchange is a telephone system generally installed on the premises of a subscriber, including a switchboard and extension sets, and connected to a central office, affording intercommunication between the extension sets and also between these sets and the central office.

**12209. Private Exchange.**— A private exchange is one which serves a business organization or individual, and is not connected to a central office.

**12210. Private Automatic Exchange.**— A private automatic exchange is an automatic exchange which serves one business organization or individual, and is not connected to a central office.

**12211. Subscriber Set (Often Abbreviated to "Subset").**— A subscriber set is an assembly of apparatus for sending and receiving telephone calls.

**12212. Subscriber Station (Often Abbreviated to "Substation").**— A subscriber station is an installed subscriber set connected to a central office for the purpose of sending and receiving telephone calls.

**12213. Pay Station (British "Public Call Office").**— A pay station is a subscriber station available for the use of the public on the payment of a fee. The fee may be either deposited in a coin box or paid to an attendant.

**12214. Toll Station.**— A toll station is a pay station located outside of a service area and affording toll and long distance service only.

**12215. Subscriber Line or Subscriber Loop.**— A subscriber line or subscriber loop is the wire connection between a subscriber station and the central office.

**12216. Subscriber Line Circuit.**— A subscriber line circuit is a subscriber line with its associated individual central office apparatus.

**12217. Individual Line (British "Direct Line").**— An individual line is a subscriber line which connects one subscriber station to a central office, though it may have one or more extension sets.

**12218. Party Line.**— A party line is a subscriber line which connects two or more subscriber stations to a central office.

**12219. Tip Side or Tip Wire, Ring Side or Ring Wire.**— The tip side or ring side or wire, is that conductor of a circuit which is associated with the corresponding member of a jack.

**12220. Negative Side or Negative Wire, Positive Side or Positive Wire.**— The negative side or wire, or the positive side or wire, is that conductor of a circuit which is normally connected to the corresponding pole of a battery.

**12221. Main Distributing Frame.**— A main distributing frame is a structure for terminating the permanent inside and outside wires of a central office and for effecting flexible junctions between them. It generally carries certain protective devices and functions as a test point between line and office.

**12222. Intermediate Distributing Frame.**— An intermediate distributing frame is a structure for terminating permanent inside wires of a central office and for effecting flexible junctions between them.

**12223. Switchboard.**— A switchboard is an assemblage of apparatus which provides a coordinate structure for switching talking and signaling circuits.

**12224. Switchboard Section.**— A switchboard section is an element or part, one or more of which constitutes a complete manual switchboard.

**12225. Operating Room.**— An operating room is a room which contains a manual switchboard and associated apparatus.

**12226. Combination Current.**— A combination current consists of two or more currents of different characteristics in the same circuit. As ordinarily used the term refers to currents whose characteristics are steadily maintained, as for example, a combination of direct current and an alternating current.

**12227. Manual Ringing.**— Manual ringing is ringing which is affected and continues with the operation of a key.

**12228. Machine Ringing.**— Machine ringing is intermittent and is caused to act periodically by the apparatus itself.

- 12329. Superimposed Ringing Current.** — A superimposed ringing current is a combination current for ringing, consisting of a direct and an alternating current.
- 12330. Pulsating Ringing Current.** — A pulsating ringing current is a current for ringing in which the succeeding impulses are separated by intervals approximately equal to those of the impulses themselves.
- 12331. Harmonic Selective Signaling.** — Harmonic selective signaling employs devices tuned mechanically or electrically to the frequency of the ringing current, so that each device will not operate when receiving current intended to operate other device.
- 12332. Multiple Harmonic Signaling.** — Multiple harmonic signaling employs frequencies which are integral multiples of the lowest frequency.
- 12333. Non-multiple Harmonic Signaling.** — Non-multiple harmonic signaling employs frequencies which are not integral multiples of the lowest frequency.
- 12334. "To Call."** — "To call" is to originate a telephone call.
- 12335. "To Dial."** — "To dial" a number is to use a dial type of calling device in order to control automatic switches.
- 12336. "To Set Up."** — "To set up" a number is to use a key type or multiple type of calling device in order to control automatic switches.
- 12337. Calling Device.** — A calling device is an apparatus by means of which automatic switches are controlled for the purpose of establishing a connection.
- 12338. Calling Party.** — A calling party is a person who originates a telephone call.
- 12339. Called Party.** — A called party is the person who answers when a call is called.
- 12340. Reverting Call.** — A reverting call is one between two stations on the same subscriber line.
- 12341. Telephone Traffic.** — Telephone traffic is the aggregate volume of communication handled in a given time.
- 12342. "Busy."** — "Busy" is the condition of a line or an apparatus when it is in use.
- 12343. Free.** — Free is the condition of a line or an apparatus when it is not busy. Free is the opposite of busy.
- 12344. "To Make Busy."** — "To make busy" is to cause a line or an apparatus to appear to be busy.
- 12345. "To Release" or to "Disconnect."** — "To release" or "to disconnect" is to terminate a telephone connection by disengaging the apparatus.
- 12346. "To Clear."** — "To clear" is to restore a line or an apparatus to the normal condition.
- 12347. Trunk.** — A trunk is the wire connection between switching devices in central offices.
- 12348. Trunk Circuit.** — A trunk circuit is a trunk with its associated individual apparatus.
- 12349. Trunked Call.** — A trunked call is one which employs an inter-office trunk or a trunk between two switchboard positions.
- 12350. Relay.** — A relay is a device by means of which contacts in one circuit are operated by a change in conditions in the same circuit or in one or more associated circuits. (See Rule 7016.)
- 12351. Polar Relay.** — A polar relay is a relay which operates in response to a change in the direction of the current in the controlling circuit.
- 12352. Quick Operating Relay.** — A quick operating relay is one which operates its contacts within a specified brief time limit.
- 12353. Quick Release Relay.** — A quick release relay is one which releases its contacts within a specified brief time limit.
- 12354. Quick Acting Relay.** — A quick acting relay is one which has the properties of both a quick operating and a quick release relay.

**12255. Slow Operating Relay.** — A slow operating relay is one which does not operate until after a specified delay.

**12256. Slow Release Relay.** — A slow release relay is one which when operated will not release until after a specified delay.

**12257. Slow Acting Relay.** — A slow acting relay is one which has the properties of both a slow operating and a slow release relay.

**12258. Line Relay.** — A line relay is one whose coil is normally in the circuit.

**12259. Cut-off Relay.** — A cut-off relay is one which when operated disconnects from a line apparatus normally connected to it.

**12260. Relay Coil Section.** — A relay coil section is one of two or more windings of a coil on one and the same core. The several sections may be carried or placed side by side on the core.

**12261. Tension Spring.** — A tension spring is one which functions to exert mechanical pressure but does not carry an electrical current.

**12262. Contact Spring.** — A contact spring is one which takes an active part in switching a circuit.

**12263. Main Contact Spring.** — A main contact spring is one which switches a circuit between two or more other contact springs.

**12264. Armature Spring.** — An armature spring is the first of a group of springs moved by the armature. It may or may not be a main contact spring.

**12265. Plunger Spring.** — A plunger spring is the first of a group to be moved by the plunger.

**12266. Impulse Springs.** — Impulse springs are those which act to make or break a circuit for the purpose of sending impulses.

**12267. Make-Before-Break Contact Springs** (Abbreviation "M. B. B.") — Make-before-break contact springs are those in which the main spring makes the front contact before it breaks away from the back contact. Also called continuity preserving contact.

**12268. Back Contact Spring.** — A back contact spring is one against which the main contact spring rests when in the normal position.

**12269. Front Contact Spring.** — A front contact spring is one against which the main contact spring rests when in the operated position.

**12270. Automatic Signaling.** — Automatic signaling is effected without aid of an operator.

**12271. Automatic Switch.** — An automatic switch is a remote control device for controlling talking or signaling circuits.

**12272. Finder Switch.** — A finder switch is a switch connected to one or a smaller number of circuits and which finds automatically a circuit out of a larger number of circuits from whence the signal comes.

**12273. Line Switch.** — A line switch is a switch connected to one or a larger number of circuits from which a signal comes and which finds automatically a circuit out of a smaller number of circuits.

**12274. Selector Switch.** — A selector switch is a switch whose duty is to select a particular group of trunks and one trunk of the group selected in particular cases, one of these functions may be omitted.

**12275. Connector Switch or Final Selector.** — A connector switch or final selector is a switch whose duty is to establish a connection with the called party. It is usually operated by the last digit or digits of the call number.

**12276. Switch Frame.** — A switch frame is a structure for mounting an assembly of switching apparatus which may be integral therewith.

**12277. Section of Switches.** — A section of switches, considered from a wiring standpoint, is a group of adjacent switches whose banks are connected together.

**12278. Switchroom.** — A switchroom is a room which contains an assembly of automatic switches and associated apparatus.

**1. Bank Wires.** — Bank wires are those wires which multiple adjacent banks to each other.

**1. Bank Cable.** — A bank cable is one which connects a switch bank to a track.

**. Multiple Cable.** — A multiple cable is one which multiples together more sections of switch banks by connecting together their terminals.

**. Impulse.** — An impulse is any sudden change of brief duration of the current of a circuit.

**. Make Impulse.** — A make impulse is an impulse due to a temporary current.

**. Break Impulse.** — A break impulse is an impulse due to a temporary stop of current.

**. Impulse Frequency.** — The impulse frequency is the number of impulses occurring per second. The reciprocal of this is the impulse period.

**. Impulse Period.** — The impulse period is the period of time included between the corresponding points in periodically recurring impulses. It thus adds to the period of alternating current.

**. Impulse Ratio.** — Impulse ratio is the ratio of duration of an impulse to the impulse period.

**. Impulse Circuit.** — An impulse circuit is one through which impulses are transmitted.

**. Telephone Impulse Repeater.** — A telephone impulse repeater is a device for repeating impulses from one line circuit into another and for performing other duties.

**. Supervisory Signal.** — A supervisory signal is a device for attracting the attention of an attendant to a duty in connection with switching apparatus or series. This includes cord supervisory lamps on a manual switchboard and supervisory lamps in an automatic exchange which indicates that a line has been occupied but has not completed its function.

**. Tell-tale Signal.** — A tell-tale signal is a device for locating the fault in some apparatus; for example, the blowing of a fuse, the continued flow of heavy current by apparatus intended to receive only momentary current, etc.

**. Alarm Signal.** — An alarm signal is a sound-producing device for drawing attention to either a supervisory or a tell-tale signal.

**. Amplifier.** — See § 13040.

**Telephone Repeater.** — A telephone repeater is a device for amplifying voice current from one line circuit into another line circuit.

**Telephone Receiver.** — A telephone receiver is an electrically operated device designed to produce sound waves or vibrations which correspond to electromagnetic waves or vibrations actuating it.

**Microphone.** — A contact device designed to have its electrical resistance and materially altered by slight differences in mechanical pressure.

**Telephone Transmitter.** — A telephone transmitter is a sound-wave- or vibration-operated device designed to produce electromagnetic vibrations which correspond to the sound waves or vibrations actuating it.

**\* Coefficient of Coupling of a Transformer.** — The coefficient of coupling of a transformer at a given frequency is the ratio of the mutual impedance to the square root of the product of the self-impedances of the primary and of the secondary.

**Repeating Coil.** — A term used in telephone practice meaning the transformer, and ordinarily a transformer of unity ratio.

**1. Single-frequency voltages and currents are here supposed to be represented by complex numbers. Their ratio is therefore a complex number.**

**12305.\* Retardation Coil.** — A retardation coil is a reactor (reactance) used in a circuit for the purpose of selectively reacting on currents which vary at different rates.

**12306. Manual Switchboard.** — A manual switchboard is one in which switching operations are performed by hand.

**12307. Multi Office Exchange (British "Multi Exchange System").** — A multi office exchange is one which is composed of more than one office.

**12308. Trunk Hunting.** — Trunk hunting is the operation of an automatic switch in moving its wipers or brushes to an idle set of terminals or contacts of a chosen group of terminals or contacts.

**12309. Wiper.** — A wiper is that portion of the moving member of a selector which engages with a bank contact.

**12310. Bank.** — A bank is an assembly of fixed contacts with which the moving members of a selector engage. Banks are usually multiplied.

### Telegraphy

**12300. Relay.** — A relay is a device by means of which contacts in one circuit are operated by a change in conditions in the same circuit or in one of a number of associated circuits.

**12301. Polar Relay.** — A polar relay is a relay which operates in response to a change in the direction of the current in the controlling circuit.

**12302. Non-polar Relay, or Neutral Relay.** — A non-polar relay is a relay which operates in response to a change in the strength of the current in the controlling circuit, irrespective of the direction of the current.

**12303. Neutral Relay.** — See non-polar relay.

**12304. Selector.** — A selector is a device which performs certain functions such as causing an electric lamp to light, or an electric bell to sound, in response to a definite signal or group of successive signals received over a communication circuit.

**12305. Direct-point Repeater.** — A direct-point repeater is a repeating apparatus in which the receiving relay controlled by the signals received over a line repeats these signals into another line or lines without the interposition of any other repeating or transmitting apparatus.

**12306. Concentrator.** — A concentrator is a traffic distributing device by means of which a number of telegraph or telephone lines, and connecting operating instruments are brought together at one point to facilitate their connection at such times as signals or messages are to be transmitted from one line to the other.

**12307. Transmitter.** — A transmitter is a device for effecting electrical changes in a controlled circuit. The term transmitter is commonly applied to devices which in response to a controlling means effects in a main telegraph circuit electrical changes necessary to send signals over the line.

**12308. Synchronous System.** — A synchronous system of telegraphy is one in which the proper transmission and reception of signals is dependent upon the synchronous operation of similar commutators or other devices located at the sending and receiving stations of a circuit.

**12309. Differential Duplex.** — A differential duplex is a duplex system in which at each station one of two portions of the receiving instrument is connected in series with the line wire and the other in series with an artificial line having such electrical characteristics that the effects upon the receiver of currents induced through the main and artificial lines, as a result of outgoing signals, are neutralized.

**12310. Bridge Duplex.** — A bridge duplex is a duplex system in which the receiving instruments at each station are connected across two impedances

(12305) In telephone and telegraph usage, the terms "impedance coil," "inductance coil," "choke coil" and "reactance coil" are sometimes used in place of the term "retardation coil."

ies with the line wire and the other in series with the artificial line in each case, so that no electrical change in the receiver circuit is affected by outgoing signals.

11. **Half-set Repeater.** — A half-set repeater is a repeater used for connecting together a simplex circuit and a duplexed circuit converting them into equivalent of a single simplex circuit.

12. **Intermediate Current Supply.** — An intermediate current supply is an ungrounded source of current connected in series with a line wire at a station and a terminal on a ground return telegraph circuit.

13. **Phantoplex Circuit.** — A phantoplex circuit is a superposed circuit induced by alternating current over a simplex, duplex or quadruplex circuit fed from direct-current sources.

14. **Spark Condenser.** — A spark condenser is a condenser, with or without added non-inductive resistance, connected with a pair of instrument contact points for the purpose of diminishing sparking at these points.

15. **Current Margin.** — In a non-polar simplex system, the difference between the current flowing through a receiving instrument when operated, to that flowing when not operated.

16. **Margin Ratio.** — In a non-polar simplex system, the ratio of the current flowing through a receiving instrument when operated, to that flowing when not operated.

17. **Percentage Margin.** — In a non-polar simplex, the current margin expressed as a percentage of the current flowing through the relay when operated.

18. **Main Circuit.** — A main circuit is a major electrical circuit of a telegraph system and includes both transmitting and receiving devices.

19. **Local Circuit.** — A local circuit is a circuit, within the limits of the main circuit, usually controlled by a receiving instrument in a main circuit or connected with a transmitter effecting changes in a main line circuit.

## CHAPTER XIII

### STANDARDS FOR RADIO COMMUNICATION

#### General

This chapter has been mainly abstracted from the report of the Standardization Committee of the Institute of Radio Engineers, and is here included for information, until further revised. For full particulars, see the I. R. E. Standardization Committee report.

1. **Acoustic Resonance Device.** — One which utilizes, in its operation, resonance at the audio frequency of the received signals.

2. **Antenna.** — A system of conductors designed for radiating or absorbing energy of electromagnetic waves.

3. **Atmospheric Absorption.** — That portion of the total loss of radiated energy due to atmospheric conductivity.

4. **Audio Frequencies.** — Frequencies corresponding to the normally audible vibrations. These are assumed to lie below 10,000 cycles per second.

5. **Capacitive Coupler.** — An apparatus which, by electric fields, joins together two radio-frequency circuits, and which is used to transfer electrical energy between these circuits through the action of electric forces.

6. **Coefficient of Coupling (Inductive).** — The ratio of the effective mutual inductance of two circuits to the square root of the product of the self-inductances of each of these circuits.

7. **Direct Coupler.** — A coupler which magnetically joins two circuits through a common conductive portion.

**19007. Counterpoise.** — A system of electrical conductors forming a portion of a radiating oscillator, the other portion of which is the antenna. In land stations a counterpoise forms a capacitive connection to ground.

**19008. Damped Alternating Current.** — A damped alternating current is an alternating current whose amplitude progressively diminishes.

**19009. Damping Factor.** — The damping factor of an exponentially damped alternating current is the product of the logarithmic decrement and the frequency.

Let  $I_0$  = initial amplitude,

$I_t$  = amplitude at the time  $t$ ,

$e$  = base of Napierian logarithms,

$a$  = damping factor.

Then  $I_t = I_0 e^{-at}$ .

**19010. Detector.** — That portion of the receiving apparatus which, connected to a circuit carrying currents of radio frequency, and in conjunction with a diode contained or separate indicator, translates the radio-frequency energy into a form suitable for operation of the indicator. This translation may be done either by the conversion of the radio-frequency energy, or by means of the control of local energy by the energy received.

**19011. Electromagnetic Wave.** — A periodic electromagnetic disturbance progressing through space.

**19012. Forced Alternating Current.** — A current, the frequency and damping of which are equal to the frequency and damping of the exciting electromagnetic force.

**19013. Free Alternating Current.** — The current following any electromagnetic disturbance in a circuit having capacitance, inductance, and less than the critical resistance.

**19014. Critical Resistance of a Circuit.** — That resistance which determines the limiting condition at which the oscillatory discharge of a circuit passes into an aperiodic discharge.

**19015. Group Frequency.** — The number per second of periodic change of amplitude or frequency of an alternating current.

Note 1. Where there is more than one periodically recurrent change of amplitude or frequency, there is more than one group frequency present.

Note 2. The term "group frequency" replaces the term "spark frequency."

**19016. Inductive Coupler.** — An apparatus which, by magnetic forces, couples two portions of two radio-frequency circuits and is used to transfer electrical energy between these circuits, through the action of these magnetic forces.

**19017. Logarithmic Decrement.** — The logarithmic decrement of an exponentially damped alternating current is the logarithm of the ratio of successive current amplitudes in the same direction.

Note: Logarithmic decrements are standard for a complete period or cycle.

Let:  $I_n$  and  $I_{n+1}$  be successive current amplitudes in the same direction.

$d$  = logarithmic decrement.

Then: 
$$d = \log_e \frac{I_n}{I_{n+1}}$$

**19018. Radio Frequencies.** — The frequencies higher than those corresponding to the normally audible vibrations, which are generally taken as 10,000 cycles per second. See also Audio Frequencies.

Note: It is not implied that radiation cannot be secured at lower frequencies and the distinction from audio frequencies is merely one of definition based on convenience.

**19019. Resonance.** — Resonance of a circuit to a given exciting alternating e.m.f. is that condition due to variation of the inductance or capacity in which the resulting effective current (or voltage) in that circuit is a maximum.

**3021. Standard Resonance Curve.** — A standard resonance curve is a curve ordinates of which are the ratios of the square of the current at any frequency to the square of the resonant current, and the abscissas are the ratios of the corresponding wave length to the resonant wave length; the abscissas and ordinates having the same scale.

**3022. Sustained Radiation.** — Sustained radiation consists of waves radiated by a conductor in which an alternating current flows.

**3023. Tuning.** — The process of securing the maximum indication by adjusting the time period of a driven element. (See Resonance.)

**3024. Wave-Meter.** — A wave-meter is a radio-frequency measuring instrument, calibrated to read wave lengths.

**3025. Decrometer.** — An instrument for measuring the logarithmic decrement of a circuit or of a train of electromagnetic waves.

**3027. Attenuation, Radio.** — The decrease with distance from the radiating source, of the amplitude of the electric and magnetic forces accompanying (and constituting) an electromagnetic wave.

**3028. Attenuation, Coefficient of (Radio).** — The coefficient which, when multiplied by the distance of transmission through a uniform medium, gives the natural logarithm of the ratio of the amplitude of the electric or magnetic forces at that distance, to the initial value of the corresponding quantities.

**3029. Coupler.** — An apparatus which is used to transfer radio-frequency energy from one circuit to another by associating portions of these circuits.

**3030. Amplifier.** — An amplifier is an instrument which modifies the effect of a local source of energy in substantial accordance with the wave-form of the induced energy, and gives out a wave of greater amplitude than that which it receives.

**3042. Phase Angle Defect.** — The phase angle defect of a condenser is the departure from quadrature of the phase difference between potential and current terminals. This is sometimes called the phase angle of a condenser: although strictly speaking the phase angle of a condenser is  $90^\circ$  less the phase angle defect, it is therefore exactly  $90^\circ$  when the phase angle defect is zero.

**3043. Impulse E.m.f.** — An e.m.f. the effective value of which becomes small compared with its maximum value in a time which is short compared with the duration of the current which it causes.

**3044. Directive Coefficient.** — The directive coefficient of a transmitting antenna at a given distance therefrom on the surface of the earth or sea, for a given wave length, is the ratio of average field intensity within an angle of stated degrees centered about the direction of maximum radiation, to the average field intensity in all directions.

**3045. Directional Selectivity.** — The directional selectivity of a receiving antenna at a given wave length is the ratio of the average e.m.f. induced in that antenna for waves of equal intensity coming from directions comprised within an angle of stated degrees centered about the direction of best reception, to the average e.m.f. induced in the antenna for waves of equal intensity coming from all directions.

**3046. Radiation Efficiency.** — The radiation efficiency of an antenna at a given wave length is the ratio of radiation resistance to the antenna resistance.

**3047. Selectivity.** — The (overall) selectivity of a receiving system is the product of the several selectivities of that system.

**3048. Average Selectivity.** — The average selectivity of a receiving system is the  $n$ th root of the product of the  $n$  selectivities of that system.

**3049.\* Radio-Frequency Selectivity.** — The radio-frequency selectivity of a receiving element \* of a receiving system is the ratio of resonant response (in terms of selective voltage or current measured at the indicator) to the non-resonant

## CHAPTER XIV

## STANDARDS FOR PRIME MOVERS AND GENERATOR UNITS

## General

14000. Regulation of Steam Engines, Steam Turbines and Internal Combustion Engines. — In steam engines, steam turbines and internal combustion engines, the percentage speed regulation is usually expressed as the percentage ratio of the maximum variation of speed, to the rated-load speed in passing slowly from rated-load to no-load (with constant conditions at the supply).

14001. Fluctuation of Steam Engines, Steam Turbines and Internal Combustion Engines. — The percentage fluctuation of a steam engine, steam turbine or internal combustion engine, is the immediate percentage speed regulation corresponding to a sudden change from rated-load to no-load.

14002. Regulation of Hydraulic Turbines. — In a hydraulic turbine or water motor, the percentage speed regulation is expressed as the percentage ratio of the maximum variation in speed in passing slowly from rated-load to no-load (at constant head of water), to the rated-load speed.

14003. Regulation of Generator Units. — In a generator unit, consisting of generator combined with a prime mover, the speed or voltage regulation shall be based upon constant conditions of the prime mover; *i.e.*, constant steam-pressure head, etc. It includes the inherent speed variations of the prime mover. For this reason, the regulation of a generator unit is to be distinguished from the regulation of either the prime mover, or of the generator combined with it, when taken separately.

14010.\* Variation in Prime Movers. — The variation in prime mover shall do not give an absolutely uniform rate of rotation or speed, as in reciprocating steam engines, is the maximum angular displacement in position of the revolving member expressed in degrees, from the position it would occupy with uniform rotation, and with one revolution taken as 360 degrees. See § 4088.

14011. Pulsation in a Prime Mover, or in the Alternator Connected Thereto. — The pulsation in a prime mover, or in the alternator connected thereto, is the ratio of the difference between the maximum and minimum velocities in one engine-cycle to the average velocity.

## BIBLIOGRAPHY

## United States

American Society of Mechanical Engineers: Boiler Code.

## Foreign

British Engineering Standards Association: Standard Electrical Practice for New Systems and Installations (Low and Medium Pressures); Steam Turbines for Electrical Plants; Report on Reciprocating Steam Engines for Electrical Purposes.

(14010) If  $p$  is the number of pairs of poles, the variation of an alternator is  $p$  times the variation of its prime mover, if direct connected, and  $p$  is times the variation of the prime mover if rigidly connected thereto in such a manner that the angular speed of the alternator is  $n$  times that of the prime mover.

## CHAPTER XV

STANDARDS FOR TRANSMISSION LINES AND  
DISTRIBUTION LINES

Note: For flash-over tests of insulators, see foot-note to § 2361.

## General

2360. Regulation of Transmission Lines, Feeders, etc. — The regulation of transmission lines, feeders, etc., is the change in the voltage at the receiving end when rated non-inductive load and no-load, with constant impressed voltage at the sending end. The percentage regulation is the percentage change in voltage to the normal rated voltage at the receiving end.

## CHAPTER XVI

## MISCELLANEOUS STANDARDS

## HEATING DEVICES

2360. Value of A-C. Test Voltage for Household Devices. — Heating devices taking not over 660 watts, intended solely for operation on supply circuits not exceeding 275 volts, shall be tested with 500 volts at operating temperature.

# INTERNATIONAL ELECTROTECHNICAL COMMISSION

## I. E. C. RULES FOR ELECTRICAL MACHINERY

### VOLUME I

(Adopted at the Plenary Meeting, held in London, October, 1919)

These rules apply to rotating machines of which the terminal pressure does not exceed 5000 volts or of which the rated output does not exceed 750 kv.-a. or of which the stator cores do not exceed 50 cm. in length axially, and to transformers which are not water-cooled.

### PART I. GENERAL

#### I. Scope of Rules

1. *Rotating Machines.* — The rules of the I. E. C. contained in this publication apply to rotating machines, of which the terminal pressure does not exceed 5000 volts or of which the rated output does not exceed 750 kv.-a., or of which the stator cores do not exceed 50 cm. in length axially.

2. *Transformers.* — These rules also apply to all transformers which are not water-cooled. (For water-cooled transformers, see Appendix II.)

3. *Altitude.* — In the absence of any information in regard to the height above sea level at which the machine is intended to work in ordinary service this height is assumed not to exceed 1000 meters. If the machine is intended to work at an altitude above 1000 meters a correction to the temperature should be applied. The value for this correction has not yet been fixed by the I. E. C.

4. *Temperature.* — In the absence of any information to the contrary, it is assumed that the temperature of the cooling air shall not exceed 40° C.

#### II. Definitions

5. *Rating.* — (See Appendix IV.)

6. *Use of the Term "Machine."* — The term "machine" is used in the rules in its most general sense, so as to avoid the constant repetition of the words "machines, transformers and other electromagnetic induction apparatus."

7. *Use of the Term "Power."* — It is usual to speak of a machine in terms of power. It is necessary to note that the term "power" should be used in the following way:

(a) For direct-current generators, the electric power at the terminals expressed in watts (w.) or kilowatts (kw.).

(b) For alternators, the apparent power at the terminals, expressed in volt-amperes (v.-a.) or kilovolt-amperes (kv.-a.).

(c) For motors, the mechanical power available at the shaft, expressed in watts (w.) or kilowatts (kw.).

(d) For transformers, apparent output at the secondary terminals, expressed in volt-amperes (v.-a.) or kilovolt-amperes (kv.-a.).

#### III. I. E. C. Rating

8. *Test Rating.* — The I. E. C. rating has been established as a test rating which will enable an exact comparison to be made between machines of different makes.

9. *Classes of Rating.* — There are two classes of I. E. C. rating:

(a) The I. E. C. continuous rating (see Clause 10).

(b) The I. E. C. short-time rating or limited-time rating (see Clause 11).

o. *Continuous Rating.*—The I. E. C. continuous rating is the load which may be carried on test, under the conditions of that rating, for an unlimited period without the limits of the I. E. C. rules, as regards temperature rise, being exceeded.

1. *Service Thermally Equivalent to the Continuous Rating.*—Any machine intended for continuous service on fluctuating load may be given for test purposes a thermally equivalent I. E. C. continuous rating, provided that the service for which it is intended shall not cause, in any of its parts, temperatures or temperature rises in excess of those allowed by the I. E. C. rules when the machine is tested under the conditions of its continuous rating.

*General Note re Classes of Fluctuating Load Service, inserted by the Editing Committee.*—It is desirable to distinguish between two kinds of fluctuating load service:

(i) *That in which the overload peaks can be sustained by a machine of ordinary construction, without modification, and without exceeding the limits of temperature rise allowed by these rules for the machine when tested under its I. E. C. continuous rating.*

(ii) *That in which the overload peaks involve special provisions in design or construction either for mechanical or for electrical reasons.*

To designate this second class of service it is customary in Great Britain and the United States of America to employ the term "duty cycle rating," and the word "cycle" in this case signifies a period of time sufficiently long to include all the variations of load which might influence either the electrical construction or the mechanical construction of the machine.

12. *Short-time Rating.*—The I. E. C. short-time rating is the load which can be carried on test for the time specified in the rating, the test being started with the machine cold and carried out under all the conditions of the rating, without the limits fixed by these I. E. C. rules, as regards temperature rise, being exceeded.

13. *Service Thermally Equivalent to the Short-time Rating.*—Any machine intended for service on loads which vary considerably may be given for test purposes a thermally equivalent I. E. C. short-time rating, provided that the service for which it is intended shall not occasion, in any of its parts, temperatures or temperature rises in excess of those allowed by these rules when the machine is tested under the conditions of its short-time rating.

## PART II. INFORMATION TO BE GIVEN WITH ENQUIRIES AND ORDERS FOR ELECTRICAL MACHINES

### IV. General Information

*Note.*—The term *machine* is used in these rules in its most general sense so as to avoid the constant repetition of the words *machines*, *transformers* and other *electromagnetic induction apparatus*.

14. *General Information.*—The enquiry or order for an electrical machine should give the following general information:

- (a) The service output.
- (b) The class of service required.

In the absence of any indication to the contrary, continuous service is understood.

(c) The maximum temperature of the cooling air in which the machine is intended to work when it exceeds 40° C.

In the absence of any definite information, it is understood that the temperature of the cooling air will not exceed 40° C.

(d) The altitude of the place where the machine is intended to work, if it exceeds 1000 meters. In regard to altitude, see Clause 3.

(e) Any special requirements, if necessary, with regard to windings, methods of connection, neutral points and special tapping points, etc.

(f) When the apparatus is intended to operate in parallel with other apparatus, the fact should be stated.

(g) Any special requirements in regard to electrical and mechanical details such as protective devices, cooling arrangements, etc.

(Specific recommendations regarding these details will be made at a later date by the I. E. C.)

#### V. Supplementary Information

15. *Supplementary Information.* — The above general information should be completed by the following supplementary information in regard to the particular machine forming the subject of the order:

16. *Direct-current Generator.*

Output at the terminals, in watts (w.) or kilowatts (kw.).

Pressure between terminals, in volts.

Current, in amperes.

Speed, in revolutions per minute.

Method of excitation.

17. *Direct-current Motor.*

Output at the shaft, in watts (w.) or in kilowatts (kw.).

Pressure between terminals, in volts.

Current, approximate, in amperes.

Speed at rated output, approximate, in revolutions per minute.

Method of excitation.

18. *Alternating-current Transformer.*

Frequency, in periods per second.

Number of phases.

Output, in voltamperes (v.-a.), or in kilovoltamperes (kv.-a.).

Primary pressure between terminals, in volts.

Secondary pressure between terminals, in volts, at no-load and at rated output with statement as to the power factor of the load fed by the secondary. If the power factor is not specified it shall be taken as 0.8.

Secondary current, in amperes.

For transformers intended to work in parallel, the primary pressure, current, and power factor on short-circuit test, shall also be stated.

For three-phase transformers the method of connection shall also be indicated in accordance with the vector diagrams (see Appendix).

Any special requirements as to the accessibility of neutral points or special tapping points shall be indicated.

Note. — Whatever may be the nature of the transformers (step-up or step-down) the primary terminals are those which are connected to the source of electrical energy and the secondary terminals those which receive the electrical energy.

19. *Synchronous Alternator for Alternating Currents, Single or Polyphase.*

Frequency, in periods per second.

Number of phases.

Output between terminals, in volt-amperes (v.-a.) or kilovolt-amperes (kv.-a.).

Pressure between terminals, in volts, corresponding to the rated output. Power factor of the system to be supplied. If this is not specified it shall be taken as 0.8.

Current, in amperes.

Speed, in revolutions per minute.

Excitation pressure, in volts (if the alternator is not provided with special exciter).

Maximum exciting current available, in amperes (if the alternator is not provided with a special exciter).

**20. Synchronous Motor for Alternating Currents, Single or Polyphase.**

Frequency, in periods per second.

Number of phases.

Mechanical output at the shaft, in watts (w.) or in kilowatts (kw.).

Current, approximate, in amperes.

Pressure, in volts, of supply available.

Speed, in revolutions per minute.

Unless otherwise specified, the motor must be capable of giving its rated mechanical output at unity power factor.

If the motor is required to act as a device for improving the power factor, the value of the reactive power required shall be stated.

Excitation pressure, in volts (if the motor is not provided with a special exciter).

Method of starting to be employed and source of power available for this purpose.

Maximum exciting current available, if limited.

**21. Non-synchronous Motor for Alternating Currents, Single or Polyphase.**

Frequency, in periods per second.

Number of phases.

Mechanical power at the shaft, in watts (w.) or in kilowatts (kw.).

Pressure between terminals, in volts.

Current, approximate, in amperes.

Speed, in revolutions per minute, approximate, at the rated output.

Rotor, whether wound or squirrel cage.

Method of starting.

Unless otherwise specified it is assumed that the stator receives the supply current.

Starting torque in kilograms at one meter.

Ratio of the starting current to the current corresponding to the rated output.

Ratio of the starting torque to the torque corresponding to the rated output.

The last three items are to be stated for the motor with its starting accessories.

**PART III. CONDITIONS TO BE FULFILLED BY ELECTRICAL MACHINERY**

**VI. General Remarks**

**22. General.** — This section deals with the conditions to be fulfilled by a machine purporting to comply with the I. E. C. Rules.

**VII. Limits of Temperature and Temperature Rise**

**TEMPERATURE LIMITS**

**23. Table of Temperature Limits.** — The following table gives the limits for observable temperatures and temperature rises of windings and of certain parts of machines.

The permissible temperature limits are indicated in Column 1 of the table. The permissible limits of temperature rise are given in Column 2. The temperature rises measured on any machine which has worked for the specified time at the output corresponding with its I. E. C. rating shall not exceed in any of its parts the limiting values given in Column 2 of the table. The highest permissible temperature given in Column 1 and the temperature rises given in Column 2 of the table should never be exceeded by a machine operating in service. (For exception see Clause 27.)

## Temperature Limits

Item No.	Nature of the insulation of the winding or name of part.	Column 1	Column 2
		Highest permissible observable temperature	Highest permissible observable temperature rise for the purpose of fixing the international rating
		Degrees C.	Degrees C.
1	Cotton, paper or silk, non-impregnated.....	80	40
2	Cotton, paper or silk, impregnated (see Clause 24).....	95	55
3	Cotton, paper or silk, immersed in oil.....	95	55
4	Enamelled wire (see Clause 25).....	95	55
5	Mica, asbestos, glass, porcelain, micaite and similar compositions..	115	75
6	Insulated windings permanently short-circuited.....	100	60
7	Non-insulated windings permanently short-circuited.....	110	70
8	Oil (for temperature limits, see Appendix II).	..	..
9	Commutators, slip rings (see Cl. 27)	90	50
10	Bearings.....	80	40
11	Iron core immersed in oil.....	95	55
12	Iron core in contact with windings..	Same as the windings	
13	Iron core not in contact with windings nor immersed in oil. The temperature and temperature rise shall not exceed that allowed for the windings themselves, and in no case shall the temperature and temperature rise exceed 110° C. and 70° C. respectively.		
14	Single layer windings: An increase of 5° C. above the temperatures given for items 1, 2 and 4 shall be permitted in the case of coils, revolving or stationary, with single layer windings when not immersed in oil.		

24. *Impregnated Cotton, Paper or Silk.*—An insulation is considered to be "impregnated" when a suitable substance replaces the air between its fibers, even if this substance does not completely fill the spaces between the insulated conductors. The impregnating substance, in order to be considered suitable, must have good insulating properties; must entirely cover the fibers and render them adherent to each other and to the conductor; must not produce interstices within itself as a consequence of evaporation of the solvent or through any other cause; must not flow during the operation of the machine at full working load at the temperature limit specified; must not deteriorate under prolonged action of heat.

25. *Enamelled Wire.*—When employing the temperature limits in the table for enamelled wire the maker must satisfy himself that the enamel employed is of good quality.

26. *Compound Insulations Made Up of Different Materials.*—When the insulation consists of layers of several different materials, the lowest of the temperatures permitted for the different insulating materials employed (see Clause 23) is to be adopted as the limiting temperature. The insulating material, even when forming the support, shall always be assumed as forming part of the winding.

27. *Commutators and Slip Rings.*—The observable temperature and temperature rise of commutators and slip rings may exceed the values given in Item 9 of the table provided that the temperature of the commutator or slip ring

- a) The temperatures of the insulating materials in the commutator and the adjoining windings shall not exceed those allowed in the table for the slating materials of those parts.
- b) The manufacturer shall give a special guarantee that the high temperature attained shall not impair the commutation.
- c) The temperature shall not be so high as to affect the quality of the soldered parts and the connections.

#### REFERENCE TEMPERATURE OF COOLING MEDIUM

8. *Reference Temperature of Cooling Medium.* — (a) *Temperate Climates.* — In the absence of any indication to the contrary the maximum temperature of air in which the machine is intended to operate in service shall be deemed to be  $40^{\circ}\text{C}$ .
- b) *Cold Climates.* — In cold climates, when the actual temperature of the air in which this machine is intended to operate in service is not much different from  $40^{\circ}\text{C}$ , it is recommended that this conventional reference temperature of  $40^{\circ}\text{C}$  should be adopted.
- c) *Tropical Climates.* — The question of a reference temperature for cooling for machines intended to operate in service in tropical climates will be dealt with by the I. E. C. at a later date.
- 1) *Water Cooling* (see Appendix II).

#### PERMISSIBLE LIMITS FOR TEMPERATURE RISE

9. *Permissible Limits for Temperature Rise.* — The limits permitted for temperature rise are deduced from the values allowed for the highest permissible allowable temperature (see Clauses 23-27) by subtracting therefrom  $40^{\circ}\text{C}$ , the value assumed as that of the maximum cooling air temperature of the air in which the machine may be required to work in service (see Clause 28).

#### TEMPERATURE MEASUREMENTS

1. *Value of Temperature of Cooling Medium.* — A machine may be tested in any convenient cooling air temperature less than  $40^{\circ}\text{C}$ , but whatever be the value of this cooling air temperature the permissible rises of temperature shall not exceed those given in Column 2 of the table (see Clause 23). Corrections for variations in the cooling air temperature are not considered necessary within the limits of cooling air temperature obtaining in general practice.
2. In the case of cooling by means of forced ventilation, the temperature of the air measured where it enters the machine, shall be considered as the cooling air temperature.
3. For all machines cooled by other means, special rules will be necessary. (For further cooling, see Appendix II).

1. *Measurement of Cooling Air Temperature During Tests.* — The cooling air temperature shall be measured by means of several thermometers placed at different points around and half-way up the machine at a distance of one to two meters, and protected from all heat radiation and draughts. The value to be adopted for the temperature of the cooling air during a test shall be the mean of the readings of the thermometers (placed as mentioned above), taken at equal intervals of time during the last quarter of the duration of the test.
2. In order to avoid errors due to the time lag between the temperature of the machines and the variations in the cooling air, all reasonable precautions shall be taken to reduce these variations and the errors arising therefrom.

#### METHODS OF MEASUREMENT OF THE TEMPERATURES OF MACHINES

1. *Measurement of the Temperatures of Machines.* — Two methods of determining the temperature of windings and other parts of machines are recognized;

(a) Thermometer method.

(b) Resistance method.\*

33. *Thermometer Method.* — In this method the temperature is determined by thermometers applied to the accessible surfaces of the completed machine. The term "thermometer" also includes thermocouples and resistance-thermometers.

34. *Resistance Method.* — In this method the temperature rise of the winding is determined by the increase in the resistance of the windings themselves as checked by thermometers applied to the accessible surfaces of the windings to ascertain whether there is any higher local temperature. The highest of the temperatures thus found shall be taken as the observable temperature.

35. *Temperature of Windings.* — The temperature of windings, as a rule shall be measured by the resistance method. The thermometer method alone is permitted in the following cases:

(a) When it is not practicable to determine the temperature rise by the resistance method, as for example with low resistance commutating coil and compensating windings, and in general in the case of low resistance windings, especially when the resistance of joints and connections forms a considerable portion of the total resistance. In this case the temperature limits given in the table apply without correction.

(b) Single layer windings, revolving or stationary, when not immersed in oil. In this case an increase of 5° C. above the limits of temperature and of temperature rise given in the table is permitted.

(c) When, for reasons of manufacturing in quantity, the thermometer method is used alone, although the resistance method would be possible. In this case the value of the highest permissible observable temperature and temperature rise given in the table shall be reduced by five degrees except in the case of stationary field coils, when the values given in the table shall be reduced by the difference between resistance and thermometer measurements as determined on similar machines, but in no case shall such reduction be less than 5° C.

36. *Corrections of Measurements Taken after the Machine Has Shut Down.* — If the temperature is measured only after shut-down, the highest temperature attained while running shall be deduced by extrapolation on the time-temperature curve.

37. *Measuring Temperature of Direct-current Generators and Motors.* — The temperature of field windings shall be measured in the manner described in Clauses 35 and 36.

The temperature of the armature shall be determined as a rule by thermometers placed on the windings at the hottest accessible parts, and when this method is employed the value of the highest permissible observable temperature and temperature rise shown in the table shall be reduced by 5° C.

38. *Measuring Temperature of Transformers.* — The temperature of transformer windings shall always be ascertained by resistance.

39. *Measuring Temperature of Synchronous Alternators and Motors.* — The temperature of the field windings shall always be ascertained by resistance. The temperature of stator windings shall be ascertained either by resistance or by thermometer in the manner described in the preceding clauses.

40. *Measuring Temperature of Non-synchronous Motors without Commutators.* — The temperatures of the stator and rotor shall be ascertained in the same manner as those of the stator of a synchronous alternator (see Clause 39), except in the case of a permanently short-circuited winding, when the thermometer method shall be employed.

41. *Coefficients of Variation of Resistance of Copper with Temperature.* — In the case of resistance measurements, the temperature coefficient of copper shall be taken from the values stated in the accompanying table, which have been

\* Note. — With a view to brevity, the expression "method of variation of resistance of the winding" is replaced by the term "resistance method," or simply "by resistance."

deduced from the formula  $1/(234.5 + t)$ . Thus, at an initial temperature  $t = 30^\circ \text{C}$ . the temperature coefficient or increase in resistance per degree Centigrade rise  $1/(264.5) = 0.00378$ .

Temperature of the windings in degrees C., at which the initial resistance is measured.	Copper—Increase in resistance per ohm per degree C.
0	0.00427
5	0.00418
10	0.00409
15	0.00401
20	0.00393
25	0.00385
30	0.00378
35	0.00371
40	0.00364

42. When the temperature of a winding is to be determined by resistance, the temperature of the winding before the test measured by thermometer shall not differ much from that of the cooling air.

43. *Duration of Temperature Test for Continuous Rating.*—For machines with I. E. C. continuous rating, the temperature test shall be continued until it is evident that the maximum temperature rise attained would not exceed the limits given in the table (see Clause 23), if the test were to be prolonged until the final steady temperature were attained. If possible, the temperature shall be measured both while running and after shut-down.

44. *Duration of Temperature Test for Short-time Rating.*—For machines with I. E. C. short-time rating the duration of the temperature test shall be that corresponding to the short-time test rating as indicated upon the rating plate.

At the commencement of the test the temperature of the machine must be practically that of the cooling air.

#### X. Commutation

(Not yet prepared.)

### PART IV. MARKINGS

#### II. Rating Plates

45. *Rating Plate.*—Every machine shall bear the information necessary to define the limitations of the service for which it is intended.

For this purpose it shall have, in all cases, a rating plate and also such diagrams and terminal markings as may be necessary.

46. *Information on Rating Plate.*—The rating plate of a machine complying with the I. E. C. rules shall have a distinctive special sign and give the following information:

- (a) The name of the maker.
- (b) The maker's machine number.

(a) The class of rating or the necessary information if the machine is intended to operate under more than one class of rating.

(d) The altitude at which the machine is intended to work if such altitude exceeds 1000 meters.

(e) The following technical information, according to the character of the machine:

In the absence of any indication in regard to the class of rating it is understood that the machine is intended for continuous service.

47. *Direct-current Generator.*

Generator — Direct-current.

Output, in watts (w.) or in kilowatts (kw.), with statement as to the class of rating.

Pressure between terminals, in volts.

Current, in amperes.

Speed, in revolutions per minute.

48. *Direct-current Motor.*

Motor — Direct-current.

Output, in watts (w.) or in kilowatts (kw.), with statement as to the class of rating.

Pressure between terminals, in volts.

Current, approximate, in amperes.

Speed, in revolutions per minute.

49. *Transformer.*

Frequency, in periods per second.

Number of phases.

Apparent output at the secondary, in volt-amperes (v.-a.) or in kilovolt-amperes (kv.-a.), with statement as to the class of rating.

Primary pressure between terminals, in volts.

Secondary pressure, in volts, at no load and at rated load, with statement as to the power factor.

Short-circuit pressure, in volts.

Secondary current, in amperes.

In addition, for three-phase transformers, a vector diagram indicating the method of connection of the windings in accordance with the figures. (See Appendix I.)

50. *Alternator.*

Frequency, in periods per second.

Number of phases.

Apparent output, in volt-amperes (v.-a.) or kilovolt-amperes (kv.-a.), with statement as to the class of rating.

Pressure between terminals, in volts, corresponding to the rated output.

Current, in amperes.

Power factor corresponding to the rated output.

Speed, in revolutions per minute.

Excitation pressure, in volts.

Maximum exciting current, in amperes.

51. *Synchronous Motor.*

Frequency, in periods per second.

Number of phases.

Mechanical output, in watts (w.) or in kilowatts (kw.), with statement as to the class of rating.

Pressure between terminals, in volts, corresponding to the rated output.

Current, approximate, in amperes.

If the motor is intended to work with a power factor different from unity, the necessary information to be given.

Speed, in revolutions per minute.

Excitation pressure, in volts.

Maximum exciting current, in amperes.

2. *Non-synchronous Motor.*

Frequency, in periods per second.

Number of phases.

Mechanical output, in watts (w.) or in kilowatts (kw.), with statement as to the class of rating.

Pressure between terminals, in volts.

Current, approximate, in amperes.

Speed, in revolutions per minute, at rated output.

Maximum pressure between slip rings, in volts.

## APPENDIX I

At the meeting of the Advisory Committee on Rating held in September, 1914, the question of terminal marking and vector diagrams was referred to Messrs. Everest and La Cour. The following rules were forwarded to the Technical Office, but as they have not been submitted to the National Committees, the Editing Committee decided to include them as an Appendix only. They are therefore, hereby submitted to the next Plenary Meeting for ratification.

## Terminal Markings for Transformers

*Single-phase Transformers.*—The terminals of all single-phase transformers shall be marked with the letter T for the high-pressure side and t for the low-pressure side.

The neutral terminal, if provided, shall be marked by N or n.

The letters T and t should be accompanied by subscripts 0, 1, 2, etc., arranged in order of progression in the same direction as the electromotive force in each circuit at the same instant, as shown in the diagram.

If the transformer has two or more windings intended to be coupled in series or in parallel, the subscripts shall be single numbers for the first of such windings (1, 2, etc.), double numbers for the second windings (11, 22, etc.), and so on.

*Polyphase Transformers.*—The terminals of all polyphase transformers shall be marked as follows:

1 *Phase Identification.* The terminals of the high-pressure and low-pressure windings of any one phase shall be marked with the same letter, using capital letters on the high-pressure terminals and small type letters on the low-pressure terminals.

The letters A, B, C, a, b, c shall be used.

The neutral terminal, if provided, shall be marked N or n.

2 *Polarity Identification.* The relative polarity of the corresponding high-pressure and low-pressure windings in each phase shall be indicated by the use of subscripts (0) and (1) after the phase letters, so placed that at the instant when (in, for instance, phase A) the high-pressure terminal marked  $A_1$  is positive to terminal  $A_0$ , the low-pressure terminal  $a_1$  shall be simultaneously positive to that marked  $a_0$ .

## Vector Diagrams for Polyphase Transformers

*Polyphase Transformers Connected Together.*—When two or more polyphase transformers are to be grouped together with their windings connected to the primary and secondary systems, it is essential that the transformers shall correspond, not only as regards the pressures for which they are intended, but also as regards the exact phase relation of the secondary winding to the primary winding.

*Scope of Vector Diagrams.*—All polyphase transformers shall bear a vector diagram which shows accurately the phase relation between primary and secondary terminals. To secure the correctness of such a diagram the following requirements shall be complied with:

The identification of each phase of the secondary winding with the corresponding phase of the primary winding shall be clearly indicated by the same terminal marks (see Paragraph 2 above).

(b) To avoid error arising from differences in methods of winding, the relative instantaneous polarity of primary and secondary windings in each phase shall be indicated at the terminals of the various phase windings (see Paragraph 3 above).

5. *Vector Diagrams.*—The vector diagram of connections shall show the phase letter and the polarity marking for each phase of the windings and shall show correctly how the various phases are connected together. To avoid the complexity of marking both phase letter and polarity mark at each end of every winding vector, it shall be sufficient to show the phase letter connected together with an arrow head to indicate polarity, the arrow head in every case pointing away from that end of the phase which has the polarity mark at its terminal.

6. The following are some typical vector diagrams which embody the principles laid down in these rules:

## APPENDIX II

This Appendix contains proposals prepared by the Advisory Committee on Rating for submission to the National Committee, but not yet presented to the Plenary Meeting for ratification.

### 1. *Temperature Limits for Oil.*

- Temperature limit for oil (measured by thermometer)... 90° C.  
 Temperature limit for the windings (measured by the increase of resistance) and other parts immersed in oil... 95° C.

Notes.—The adoption of these temperatures implies the employment of a grade of oil of which the quality may be verified by ascertaining the flash point and measuring the deposit produced by heating.

The I. E. C. has not yet sufficient data to fix limiting values for the flash point or to prescribe the methods of measurement of the deposit.

2. *Reference Temperature of Cooling Water.*—For water-cooled apparatus in the absence of any indication to the contrary, the maximum temperature of the cooling water in service shall be deemed to be 25° C. at the point of entry.

3. *Temperature Limits for Water-cooled Transformers.*—In the case of oil-immersed water-cooled transformers, the limits of highest permissible observed temperature given in the table are to be reduced by 10° C.; therefore the corresponding limits of temperature rise shown in the table may be increased 10° C.

## APPENDIX III

### Dielectric Tests

This Appendix contains proposals in regard to Dielectric Tests prepared by the Advisory Committee on Rating, for submission to the National Committee, but not yet presented to the Plenary Meeting for ratification.

*Dielectric Tests.*—The high-pressure test shall be applied between the winding and the frame, with the core connected to the frame and to the winding not under test, and shall be applied only to a new and completed machine with all its parts in place under conditions equivalent to normal working conditions, and, unless otherwise specified, the test shall be carried out at the maker's works at the conclusion of the temperature test of the machine.

The test pressure shall be alternating, preferably of sine wave form.

The test shall be commenced at a pressure of less than one-third the test pressure and shall be increased to the full test pressure as rapidly as is consistent with its value being correctly indicated by the measuring instrument. The full test pressure shall then be maintained for one minute in accordance with the values as indicated in the following table:

Machine or part	Test pressure (R. M. S.)
Rotating machines of size less than 1 kw.....	500 volts + twice the rated pressure.
Rotating machines of size 1 kw. to 3 kw.....	1000 volts + twice the rated pressure.
Rotating machines of size above 3 kw.....	1000 volts + twice the rated pressure with minimum, 2000 volts.
Field windings for synchronous generators when the excitation pressure does not exceed 750 volts.	10 times the excitation pressure. Minimum, 2000 volts. Maximum, 3500 volts.
Field windings for synchronous motors:	
(a) When intended to be started up with the field windings short-circuited.	10 times the excitation pressure. Minimum, 2000 volts. Maximum, 3500 volts.
(b) When intended to be started up with the field windings separated by a break-up switch.	5000 volts.
(c) When intended to be started up with the fields on open circuit and without a break-up switch.	5000 volts when the excitation pressure is less than 275 volts. 8000 volts when the excitation pressure is equal to or exceeds 275 volts.
Exciter.....	Not yet decided.
Transformers in general.....	1000 volts + twice the rated pressure.
Transformers for primary pressures over 550 volts, the secondaries of which are for direct connection to public or private distribution systems or public or private consumers (i.e., secondary pressures less than 550 volts).	Primary windings: 1000 volts + twice the rated primary pressure with minimum, 10,000 volts (adopted as a protection to human life). Secondary windings: 1000 volts + twice the rated secondary pressure.
Secondary (rotor) windings of induction motors not permanently short-circuited.	For non-reversing motors: 1000 volts + twice the maximum pressure which could be induced between the slip rings. For reversing motors: 1000 volts + 4 times the pressure between the slip rings at standstill on open circuit with full primary pressure applied to stator windings.
Alternating-current apparatus connected to a single-phase system of more than 300 volts pressure permanently earthed.	Not yet decided.
Assembled apparatus.....	When the test is made on an assembled group of several pieces of new apparatus each one of which has previously passed its high pressure test, the test on such assembled group shall not exceed 85 per cent. of the lowest test pressure appropriate for any part of the group.

## APPENDIX IV

Definitions dealing with the subject of "Rating":

*Great Britain.* — The rating of an electrical machine is the output assigned to it by the maker, together with the associated conditions, all of which are marked on the Rating Plate.

*Note.* — A machine may have a test rating or a service rating, or both assigned to it, and marked on the rating plate.

*United States of America.* — The rating of a machine is the output mark on the Rating Plate and shall be based on, but shall not exceed the maximum load which can be taken from the machine under prescribed conditions of test. This is also called the Rated Output.

(The term "maximum load" does not refer to loads applied solely for mechanical, commutation, or similar tests.)

*France.* — The rating of a machine is determined by the conditions of working such as speed, pressure, current, power factor, etc., as indicated on the Rating Plate.

*Italy.* — The output of a machine is the normal or average output, that is, say, the load at which the machine can work under normal conditions.
